A single choke balun at the antenna feed point may not be sufficient to reduce common-mode current everywhere along a long feed line. If common-mode current on the line far from the antenna feed point is a problem, additional choke baluns can be placed at approximately  $\frac{1}{4}\lambda$  intervals along the line. This breaks up the line electrically into segments too short to act as effective antennas. The chokes in this case function similarly to insulators used to divide tower guy wires into non-resonant lengths.

## DETERMINING BALUN POLARITY

Many baluns, impedance transformers, line isolators, and other similar items are manufactured as sealed units and markings for output polarity with respect to the input connector are not often clear. For designs in which one or more continuous coaxial cables are connected between the input and output terminals, a resistance measurement will suffice to determine polarity. In flux-coupled designs there is no continuity between the input and output terminals at dc so a resistance measurement cannot be used. Similarly, for autotransformer designs there may be a low resistance across the input or output terminals. In these cases, it is necessary to test the units at RF.

The first method is to test the unit using a dual-trace oscilloscope. Analog scopes should be in "Chop" mode so that both traces show display waveforms synchronized in time. Digital scopes must also sample both waveforms at the same time. Do not use "Alt" or an alternating waveform display. Drive the input to the unit with a signal generator's output in the unit's specified operating frequency range. Connect one scope channel to the unit's input and the other channel to the output. If the waveforms are displayed in-phase, the connections to the scope have the same polarity.

The following procedure requires only a signal generator and RF voltmeter (see the

**Test Equipment and Measurements** chapter) and is used to check two identical units. If the units are substantially different, the test may not be conclusive or reliable. The procedure assumes a  $50\Omega$  system impedance. If the units operate at an impedance very different from  $50\Omega$ , such as for 300, 450, or  $600\Omega$  open-wire line, use a 6 to 10 dB attenuator in the generator output to isolate the generator from the mismatch.

Connect the signal generator output to the input of both units using a T connector and identical lengths of feed line. Connect one output terminal of unit "A" to an output terminal of unit "B" and measure the RF voltage across the combined balun outputs. Swap the output terminal connections on one of the units and measure the RF voltage again. One arrangement of connections should show a substantially higher output voltage — this is the arrangement with the same polarity for both units.

## 20.5.1 Quarter-Wave Baluns

**Figure 20.18B** shows a balun arrangement known as a *bazooka*, which uses a sleeve over the transmission line. The sleeve, together with the outside portion of the outer coax conductor, forms a shorted  $\frac{1}{4}\lambda$  section of transmission line. The impedance looking into the open end of such a section is very high, so the end of the outer conductor of the coaxial line is effectively isolated from the part of the line below the sleeve. The length is an electrical  $\frac{1}{4}\lambda$ , and because of the velocity factor may be physically shorter if the insulation between the sleeve and the line is not air. The bazooka has no effect on antenna impedance at the frequency where the  $\frac{1}{4}\lambda$  sleeve is resonant. However, the sleeve adds inductive shunt reactance at frequencies lower, and capacitive shunt reactance at frequencies higher than the  $\frac{1}{4}\lambda$  resonant frequency. The bazooka is mostly used at VHF, where its physical size does not present a major problem.

Another method that gives an equivalent effect is shown at **Figure 20.18C**. Since the voltages at the antenna terminals are equal and opposite (with reference to ground), equal and opposite currents flow on the surfaces of the line and second conductor. Beyond the shorting point, in the direction of the transmitter, these currents combine to cancel out each other. The balancing section acts like an open circuit to the antenna, since it is a  $\frac{1}{4}\lambda$  parallel-conductor line shorted at the far end, and thus has no effect on normal antenna operation. This is not essential to the line-balancing function of the device, however, and baluns of this type are sometimes made shorter than  $\frac{1}{4}\lambda$  to provide a shunt inductive reactance required in certain matching systems (such as the hairpin match described in

**Figure 20.20 — The Quarter/Three-Quarter Wavelength (Q3Q) balun uses the current-forcing function of feed lines odd numbers of  $\lambda/4$  long and the  $\lambda/2$  delay of the longer line to cause equal and opposite currents to flow in the antenna terminals.**

the Antennas chapter).

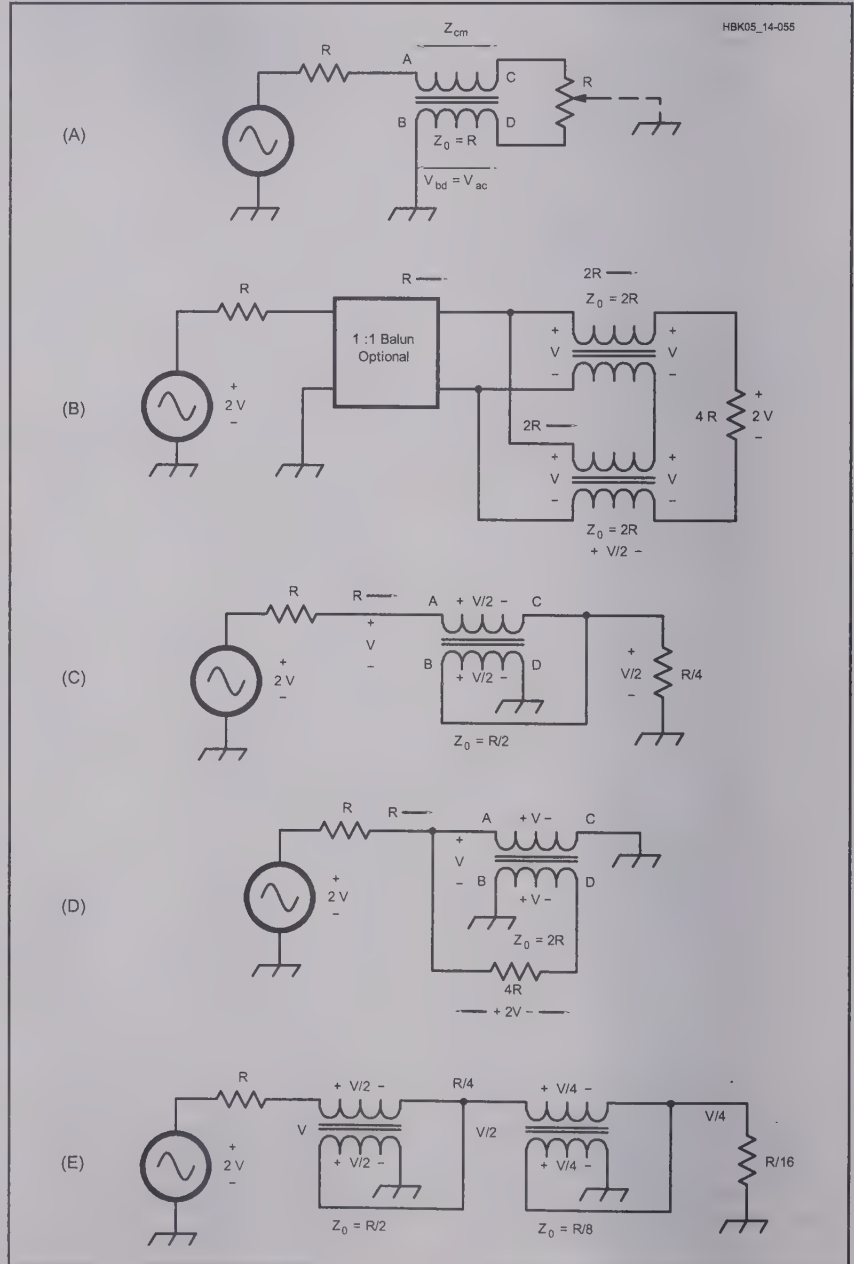

Figure 20.18D shows a balun in which equal and opposite voltages, balanced to ground, are taken from the inner conductors of the main transmission line and a  $\frac{1}{2}\lambda$  phasing section. Since the voltages at the balanced end are in series while the voltages at the unbalanced end are in parallel, there is a 4:1 step-down in impedance from the balanced to the unbalanced side. This arrangement is useful for coupling between a 300 Ω balanced line and a 75 Ω unbalanced coaxial line.

Figure 20.20 shows a variation on the quarter-wave balun called the Quarter/Three-Quarter-Wave, or Q3Q, balun. It is a 1:1 decoupling balun made from two pieces of coaxial cable. One leg is  $\frac{1}{4}\lambda$  long and the other is  $\frac{3}{4}\lambda$  long. The two cables and the feed line are joined together with a T connector. At the antenna, the shields of the cables are connected together and the center conductors connected to the terminals of the antenna feed point. The balun has very little loss and is reported to have a bandwidth of more than 10%.

The balun works because of the current-forcing function of a transmission line is an odd number of  $\lambda/4$  long. The current at the output of such a transmission line is  $V_{IN}/Z_0$  regardless of the load impedance (less line losses — see the references for *QST* articles about this balun), similar to the behavior of a current source. Because both lines are fed with the same voltage, being connected in parallel, the output currents will also be equal.

The current out of the  $\frac{3}{4}\lambda$  line is delayed by  $180^\circ$  from the current out of the  $\frac{1}{4}\lambda$  line and so is out of phase. The result is that equal and opposite currents are forced into the terminals of the load.

## 20.5.2 Transmission Line Transformers

The basic transmission line transformer, from which other transformers are derived, is the 1:1 *choke balun* or *current balun*, shown in Figure 20.21A. To construct this type of balun, a length of coaxial cable or a pair of close-spaced, parallel wires forming a transmission line are wrapped around a ferrite rod or toroid or inserted through a number of beads. (The coiled feed line choke balun is discussed in the next section.) For the HF bands, use type 75 or type 31 material. Type 43 is used on the VHF bands. The  $Z_0$  of the line should equal the load resistance,  $R$ .

Because of the ferrite, a high impedance exists between points A and C and a virtually identical impedance between B and D. This is true for parallel wire lines and it is also true for coax. The ferrite affects the A to C impedance of the coax inner conductor and the B to D impedance of the outer braid equally.

The conductors (two wires or coax braid and center-wire) are tightly coupled by electromagnetic fields and therefore constitute a good conventional transformer with a turns ratio of 1:1. The voltage from A to C is equal to and in-phase with that from B to D. These are called the *common-mode voltages* ( $CM$ ).

A common-mode ( $CM$ ) current is one that has the same value and direction in both wires (or on the shield and center conductor). Because of the ferrite, the  $CM$  current encounters a high impedance that acts to reduce (choke) the current. The normal *differential-mode* ( $DM$ ) signal does not encounter this  $CM$  impedance because the electromagnetic fields due to equal and opposite currents in the two conductors cancel each other at the ferrite, so the magnetic flux in the ferrite is virtually zero. (See the section on Transmitting Ferrite Choke Baluns.)

The main idea of the transmission line transformer is that although the  $CM$  impedance may be very large, the  $DM$  signal is virtually unopposed, especially if the line length is a small fraction of a wavelength. But it is very important to keep in mind that the common-mode voltage across the ferrite winding that is due to this current is efficiently coupled to the center wire by conventional transformer action, as mentioned before and easily verified. This equality of  $CM$  voltages, and also  $CM$  impedances, reduces the *conversion* of a  $CM$  signal to an *undesired*  $DM$  signal that can interfere with the *desired*  $DM$  signal in both transmitters and receivers.

The  $CM$  current, multiplied by the  $CM$  impedance due to the ferrite, produces a  $CM$  voltage. The  $CM$  impedance has  $L$  and  $C$  reactance and also  $R$ . So  $L$ ,  $C$  and  $R$  cause a broad parallel self-resonance at some frequency. The  $R$  component also produces some dissipation (heat) in the ferrite. This dissipation is an excellent way to dispose of a small amount of unwanted  $CM$  power.

Because of the high  $CM$  impedance, the two output wires of the balun in Figure 20.21A have a high impedance with respect to, and are therefore “isolated” from, the generator. This feature is very useful because now any point of  $R$  at the output can be grounded. In a well-designed balun circuit almost all of the current in one conductor returns to the

### Baluns, Chokes, and Transformers

The term “balun” applies to any device that transfers differential-mode signals between a balanced (*bal-*) system and an unbalanced (*un-*) system while maintaining symmetrical energy distribution at the terminals of the balanced system. The term only applies to the function of energy transfer, not to how the device is constructed. It doesn’t matter whether the balanced-unbalanced transition is made through transmission line structures, flux-coupled transformers, or simply by blocking unbalanced current flow. A common-mode *choke balun*, for example, performs the balun function by putting impedance in the path of common-mode currents and is therefore a balun.

A *current balun* forces symmetrical current at the balanced terminals. This is of particular importance in feeding antennas, since antenna currents determine the antenna’s radiation pattern. A *voltage balun* forces symmetrical voltages at the balanced terminals. Voltage baluns are less effective in causing equal currents at their balanced terminals, such as at an antenna’s feed point.

An *impedance transformer* may or may not perform the balun function. Impedance transformation (changing the ratio of voltage and current) is not required of a balun nor is it prohibited. There are balanced-to-balanced impedance transformers (transformers with isolated primary and secondary windings, for example) just as there are unbalanced-to-unbalanced impedance transformers (autotransformer and transmission-line designs). A *transmission-line transformer* is a device that performs the function of power transfer (with or without impedance transformation) by utilizing the characteristics of transmission lines.

Multiple devices are often combined in a single package called a “balun.” For example, a “4:1 current balun” is a 1:1 current balun in series with a 4:1 impedance transformer or voltage balun. Other names for baluns are common, such as “line isolator” for a choke balun. Baluns are often referred to by their construction — “bead balun,” “coiled-coax balun,” “sleeve balun,” and so forth. What is important is to separate the function (power transfer between balanced and unbalanced systems) from the construction.

generator through the other conductor, despite this ground connection. Note also that the ground connection introduces some  $CM$  voltage across the balun cores and this has to be taken into account. This  $CM$  voltage is a maximum if point C is grounded. If point D is grounded and if all “ground” connections are at the same potential, which they often are not, the  $CM$  voltage is zero and the balun may no longer be needed. In a coax balun the return current flows on the inside surface of the braid.

We now look briefly at a transmission line transformer that is based on the choke balun. Figure 20.21B shows two identical choke baluns whose inputs are in parallel and whose outputs are in series. The output voltage amplitude of each balun is identical to the common input, so the two outputs add in-phase (equal time delay) to produce twice the input voltage. It is the high  $CM$  impedance that makes this voltage addition possible. If the power remains constant the load current must be one-half the generator current, and the load resistor is  $2V/0.5I = 4V/I = 4R$ .

### THE GUANELLA TRANSFORMER

The  $CM$  voltage in each balun is  $V/2$ , so there is some flux in the cores. The right side floats. This is named the *Guanella* transformer. If  $Z_0$  of the lines equals  $2R$  and if the load is a pure resistance of  $4R$  then the input resistance  $R$  is independent of line length. If the lines are exactly one-quarter wavelength, then  $Z_{IN} = (2R)^2 / Z_L$ , an impedance inverter, where  $Z_{IN}$  and  $Z_L$  are complex. The quality of balance can often be improved by inserting a 1:1 balun (Figure 20.21A) at the left end so that both ends of the 1:4 transformer are floating and a ground is at the far left side as shown. The Guanella transformer can also be operated from a grounded right end to a floating left end. The 1:1 balun at the left then allows a grounded far left end.

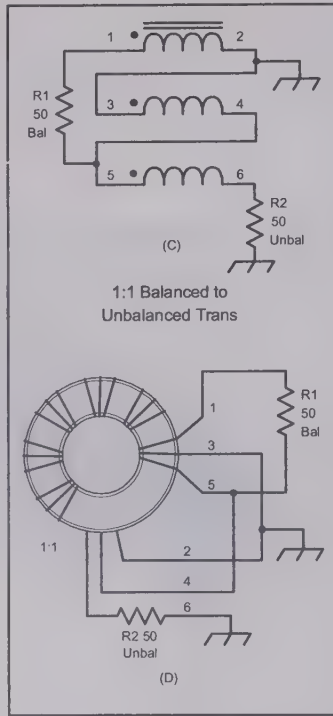

### THE RUTHROFF TRANSFORMER

Figure 20.21C is the *Ruthroff* transformer in which the input voltage  $V$  is divided into two equal in-phase voltages AC and BD (they are tightly coupled), so the output is  $V/2$ . And because power is constant,  $I_{OUT} = 2I_{IN}$  and the load is  $R/4$ . There is a  $CM$  voltage  $V/2$  between A and C and between B and D, so in normal operation the core is not free of magnetic flux. The input and output both return to ground so it can also be operated from right to left for a 1:4 impedance step-up.

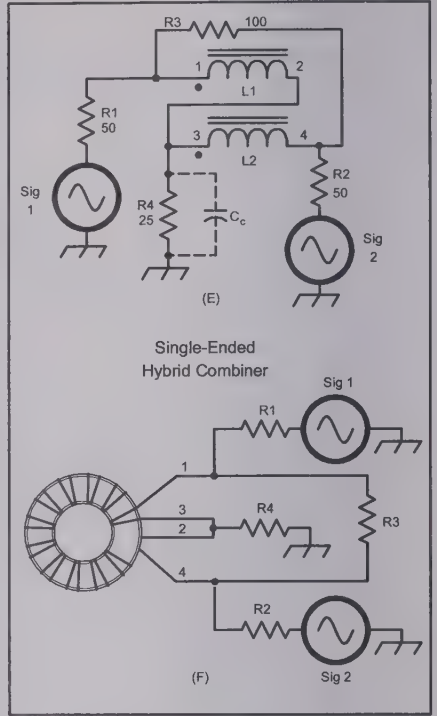

The Ruthroff transformer is often used as an amplifier interstage transformer, for example between 200  $\Omega$  and 50  $\Omega$ . To maintain low attenuation the line length should be much less than one-fourth wavelength at the highest frequency of operation, and its  $Z_0$  should be  $R/2$ . A balanced version is shown in Figure 20.21D, where the  $CM$  voltage is  $V$ , not  $V/2$ , and transmission is from left-to-right only. Because of the greater flux in the cores,

no different than a conventional transformer, this is not a preferred approach, although it could be used with air wound coils (for example in antenna tuner circuits) to couple 75  $\Omega$  unbalanced to 300  $\Omega$  balanced. The tuner circuit could then transform 75  $\Omega$  to 50  $\Omega$ .

### APPLICATIONS OF TRANSMISSION-LINE TRANSFORMERS

There are many transformer schemes that use the basic ideas of Figure 20.21. Several of them, with their toroid winding instructions, are shown in Figure 20.22. Two of the most commonly used devices are the 1:1 current balun and 4:1 impedance transformer wound on toroid cores as shown in Figure 20.23.

Because of space limitations, for a comprehensive treatment we suggest *Transmission*

(see Figure 20.24), creating an inductor from the shield's outer surface. This type of choke balun is simple, cheap and reduces common-mode current. Currents on the outside of the shield encounter the coil's impedance, while currents on the inside are unaffected.

A scramble-wound flat coil (like a coil of rope) shows a broad resonance that easily covers three octaves, making it reasonably effective over the entire HF range. If particular problems are encountered on a single band, a coil that is resonant on that band may be added. The choke baluns described in Table 20.6 were constructed to have a high impedance at the indicated frequencies as measured with an impedance meter. This construction technique is not effective with open-wire or twin-lead line because of coupling between adjacent turns.

The inductor formed by the coaxial cable's shield is self-resonant due to the distributed capacitance between the turns of the coil. The self-resonant frequency can be found by using a dip meter. Leave the ends of the choke open, couple the coil to the dip meter, and tune for a dip. This is the parallel resonant frequency and the impedance will be very high.

The distributed capacitance of a flat-coil choke balun can be reduced (or at least controlled) by winding the cable as a single-layer solenoid around a section of plastic pipe, an empty bottle or other suitable cylinder. Figure 20.25 shows how to make this type of choke balun. A coil diameter of about 5 inches is reasonable. This type of construction reduces the stray capacitance between the ends of the coil.

For both types of coiled-coaxial chokes, use cable with solid insulation, not foamed, to minimize migration of the center conductor through the insulation toward the shield. The diameter of the coil should be at least 10 times the cable diameter to avoid mechanically stressing the cable.

### 20.5.3 Coiled-Coax Choke Baluns

The simplest construction method for a 1:1 choke balun made from coaxial feed line is simply to wind a portion of the cable into a coil

## 20.5.4 Transmitting Ferrite Choke Baluns

A ferrite choke is simply a very low-Q parallel-resonant circuit tuned to the frequency where the choke should be effective. Passing a conductor through most ferrite cores (that is, one turn) produces a resonance around 150 MHz. By choosing a suitable core material, size and shape, and by adding multiple turns and varying their spacing, the choke can be “tuned” (optimized) for the required frequency range. The supplemental article “Measuring Ferrite Choke Impedance” by Jim Brown, K9YC is included with the downloadable supplemental content.

Transmitting chokes differ from other common-mode chokes because they must be designed to work well when the line they are choking carries high power. They must also be physically larger so that the bend radius of the coax is large enough that the line is not deformed. Excellent common-mode chokes having very high power handling capability can be formed simply by winding multiple turns of coax through a sufficiently large ferrite core or multiple cores. (Chokes made by winding coaxial cable on ferrite cores will be referred to as “wound-coax chokes” to distinguish them from the coiled-coax chokes of the preceding section.)

In the June 2015 *QST* article, “Don’t Blow Up Your Balun,” Dean Straw, N6BV noted the additional differential-mode losses (and increased potential for destructive overheating) in chokes when the feed line is severely mismatched. This is in addition to the dissipation due to common-mode current. This situation is more serious in off-center-fed or asymmetrical antennas because the common-mode voltages and currents are greater. The choke must have very high choking impedance to avoid the heating caused by high common-mode voltage. The article is included in the downloadable supplemental information package for this book.

### CHOKES ON TRANSMISSION LINES

A transmission line can be wound around a ferrite core to form a common-mode choke. If the line is coax, all of the magnetic flux associated with differential mode current is confined to the dielectric (the insulating material between the center conductor and the shield). The external ferrite core carries only flux associated with common-mode current.

If the line is made up of parallel wires (a bifilar winding), a significant fraction of the flux associated with differential current will leak outside the line to the ferrite core. Leakage flux can exceed 30% of the total flux for even the most tightly-spaced bifilar winding. In addition to this leakage flux, the core will also carry the flux associated with common-mode current.

When a transformer (as opposed to a choke)

is wound on a magnetic core, all of the field associated with current in the windings is carried by the core. Similarly, all forms of voltage baluns require all of the transmitted power to couple to the ferrite core. Depending on the characteristics of the core, this can result in considerable heating and power loss. Only a few ferrite core materials have loss characteristics suitable for use as the cores of high power RF transformers. Type 61 material has reasonably low dissipation below about 10 MHz, but its loss tangent rises rapidly above that frequency. The loss tangent of type 67 material makes it useful in high power

transformers to around 30 MHz.

Leakage flux, corresponding to 30 to 40% of the transmitter power, causes heating in the ferrite core and attenuates the transmitted signal by a dB or so. At high power levels, temperature rise in the core also changes its magnetic properties, and in the extreme case, can result in the core temporarily losing its magnetic properties. A flux level high enough to make the core hot is also likely to saturate the core, producing distortion (harmonics, splatter, clicks).

Flux produced by common-mode current can also heat the core — if there is enough

## Feed Line Chokes — How Much Impedance is Needed?

Recommended designs for feed line chokes have changed due to a better understanding of their function. Chokes in the path of common-mode current at an antenna’s feed point can be used to perform several functions:

- Isolate the coax shield’s outer surface from the feed point terminals — the usual balun function
- Prevent noise picked up on the shield from entering the feed line to improve the received signal-to-noise ratio
- Reduce power dissipation and core overheating from common-mode current created by imbalance and coupling
- Reduce re-radiation from common-mode current that distorts the antenna pattern and fills in pattern nulls

Chokes can also be placed at the transmitter end of a feed line to reduce common-mode current that would otherwise flow to station equipment. A choke installed along the line can “break up” the coax shield outer surface to reduce interaction with other antennas.

With all of these requirements in mind, the traditional rule of thumb for choking impedance to be ten times the feed point impedance is just barely adequate and often completely inadequate. If all you need to accomplish is modest decoupling at a 50-Ω feed point or for a receive antenna, one of the 500 to 1000 Ω chokes will suffice. For better performance and at higher impedance feed points, such as for an off-center fed dipole (OFCD), higher choke impedances are necessary. At high power, if low-impedance chokes overheat, a high-impedance design will reduce common-mode current and power dissipation. (Before adding a choke, be sure the coaxial feed line’s outer surface is not intended to be part of the antenna!)

Antenna modeling can be used to estimate the effect of chokes on antenna systems. The *ARRL Antenna Book* discusses transmitting choke dissipation or see this chapter’s references for Zack Lau, W1VT’s articles. The time-honored “try it and see!” method works, as well - measure, install, re-measure, and compare the results.

common-mode current. Dissipated power is equal to  $I^2R$ , so it can be made very small by making the common-mode impedance so large that the common-mode current is very small.

## DESIGN CRITERIA

It can be shown mathematically, and experience confirms, that wound-coax chokes having a resistive impedance at the transmit frequency of at least 5000  $\Omega$  and wound with RG-8 or RG-11 size cable on five toroids are conservatively rated for 1500 W under high duty-cycle conditions, such as contesting or digital mode operation. While chokes wound with smaller coax (RG-6, RG-8X, RG-59, RG-58 size) are conservatively rated for dissipation in the ferrite core, the voltage and current ratings of those smaller cables suggests a somewhat lower limit on their power handling. Since the chokes see only the common-mode voltage, the only effect of high SWR on power handling of wound-coax chokes is the peaks of differential current and voltage along the line established by the mismatch.

Experience shows that 5000  $\Omega$  is also a good design goal to prevent RFI, noise coupling and pattern distortion. While 500-1000  $\Omega$  has long been accepted as sufficient to prevent pattern distortion, W1HIS has correctly observed that radiation and noise coupling from the feed line should be viewed as a form of pattern distortion that fills in the nulls of a directional antenna, reducing its ability to reject noise and interference.

Chokes used to break up a feed line into segments too short to interact with another antenna should have a choking impedance on the order of 1000  $\Omega$  to prevent interaction with simple antennas. A value closer to 5000  $\Omega$  may be needed if the effects of common-mode current on the feed line are filling the null of directional antennas.

## BUILDING WOUND-COAX FERRITE CHOKES

Coaxial chokes should be wound with a bend radius sufficiently large that the coax is not deformed (as shown in **Figure 20.26**). When a line is deformed, the spacing between the center conductor and the shield varies, so voltage breakdown and heating are more likely to occur. Deformation also causes a discontinuity in the impedance; the resulting reflections may cause some waveform distortion and increased loss at VHF and UHF. (Coaxial cable has a specified "minimum bend radius".)

Chokes wound with any large diameter cable have more stray capacitance than those wound with small diameter wire. There are two sources of stray capacitance in a ferrite choke: the capacitance from end-to-end and from turn-to-turn via the core; and the capacitance from turn-to-turn via the air dielectric. Both sources of capacitance are increased by increased conductor size, so stray capacitance

will be greater with larger coax. Turn-to-turn capacitance is also increased by larger diameter turns.

At low frequencies, most of the inductance in a ferrite choke results from coupling to the core, but some is the result of flux outside the core. At higher frequencies, the core has less permeability, and the flux outside the core makes a greater contribution.

The most useful cores for wound-coax chokes are the 2.4 inch OD, 1.4 inch ID toroid of type 31 or 43 material, and the 1 inch ID  $\times$  1.125 inch long clamp-on of type 31 material. Seven turns of RG-8 or RG-11 size cable eas-

ily fit through these toroids with no connector attached, and four turns fit with a PL-259 attached. Four turns of most RG-8 or RG-11 size cable fit within the 1 inch ID clamp-on. The toroids will accept at least 14 turns of most RG-6, RG-8X or RG-59 size cables.

Notes:

Chokes for 1.8, 3.5 and 7 MHz should have closely spaced turns.

Chokes for 14 - 28 MHz should have widely spaced turns.

The transmission characteristics were also measured at MF and HF. The data pre-

sented here is a summary of that information and the reader is encouraged to download their entire paper. (See the Bibliography entry for Brown.)

Information on the legacy designs based on RG-213 wound on multiple toroid cores is included in this book's downloadable supplemental information as "Legacy Wound-Coax Ferrite Chokes." Additional discussion of

these designs is available in the *ARRL Antenna Book*, 24th edition.

Figures 20.27, 20.28, and 20.29 are graphs of impedance magnitude for various numbers of turns, types of line, and types of core. Table 20.7 summarizes designs for the 160 through 6 meter ham bands and several practical transmitting choke designs that are "tuned" or optimized for ranges of frequencies. The tables include designs meeting the 5000-Ω minimum impedance requirement and a higher-impedance design if available. Number of turns are limited on the smaller 2.4-inch OD cores.

An additional compilation of recommended air-core and ferrite-core designs is available from Steve Hunt, G3TXQ, at [www.karinya.net/g3txq/chokes](http://www.karinya.net/g3txq/chokes). The guidelines correspond roughly with measurements taken by others but should not be taken as guaranteed or representative of all methods of construction or materials. Note that a 500-Ω impedance may be quite inadequate for applications in which the load impedance is high or if high isolation of the load is required. In such cases, a higher-impedance choke is necessary.

Chokes wound with higher  $Z_0$  line (pairs of #12 THHN, NM, Teflon) work quite well at the feed point of dipoles, but may not at the feed point of a complex array. (See the K9YC paper's discussion of 75-Ω chokes for transmitting arrays.) Chokes wound with the #12 Teflon wire pair were found to have the lowest loss and the least dissipation for each band. The wire is expensive and best purchased from surplus vendors or in a quantity group purchase. Remember that for paired-wire lines,  $Z_0$  will vary with insulation thickness and the dielectric properties of the insulation. See the *ARRL Antenna Book*, 24th edition or the online K9YC paper for a table of  $Z_0$  for lines made with wire pairs.

The other recommended choices, especially for antennas with feed point  $Z_0$  near 50 Ω, is RG-400, followed by a pair made from the white and black conductors removed from Romex (NM) cable.

Enameled copper pairs were found to have much greater loss than other paired lines. This is because of the *proximity effect* that forces current to be concentrated in the side of the conductors closest to each other, raising resistive losses similarly to skin effect. It's also possible for the enamel to be scraped by the ferrite core during winding, shorting to the core at multiple points and significantly degrading choke performance. For both reasons, using enameled wire pairs for ferrite-core chokes is not recommended.

## PRACTICAL CHOKES — CONSTRUCTION NOTES

Start with the information in Building Wound-Coax Chokes at the beginning of this section.

Figure 20.29 — Impedance versus frequency for currently recommended HF coax-wound ferrite transmitting chokes THHN wire wound on a single 2.4-inch toroid core of #31 material.

While the turn diameter on the ferrite toroid cores is smaller than the minimum specified bend radius for RG-400 coax, failures caused by center conductor migration have not been commonly reported. The consensus among

experienced builders and manufacturers is that solid TFE-insulated cable will work as intended as long as it is not operated at its full power rating and repeatedly flexed.

**Starting the Winding:** Wind a cable tie around the cross section of the toroid where you want to start the winding and pull it not quite tight. Feed the cable through the toroid from below, and use another cable tie to secure it to the first one, leaving enough free cable to connect the choke when it is complete. Leave enough cable tie for final tightening later. The choke in Figure 20.30A starts at 3 o'clock and is wound counterclockwise around the core.

**Wind in Sequence:** Take care that turns are wound in order around the core — out

of sequence turns can cancel. Turns can be continued on a second layer when the first layer is filled by overlaying the starting turns of the winding. In Figure 20.30B, the winding starts at the upper left, completely fills the first layer around the core, and continues with five more turns overlaying the start of the winding.

**Turn Spacing:** Measured data are for windings tight to the core, with adjacent windings touching on the inside of the core.

**Paired Lines:** Take care that pairs are not twisted as they are wound. Twisting can reduce choking impedance. Using different colors for the two conductors makes it easier to see twisting, and also to count turns. Keep the wires parallel and flat against the core. Solid conductors are preferred over stranded because turns tend to stay in place. Stranded wire is much less disciplined. (The choke in the figure has short leads for measurement purposes.)

**Maintain polarity** between the two ends of the choke — that is, make sure that the same conductor of a parallel pair is connected to the coax shield at both ends of the choke. This is especially important with arrays, and can be an issue with lightning protection for a choke added to the line not at the feed point. If the polarity is reversed, the choke will still work but the array won't work as designed and static buildup on a coax shield may not be as well discharged.

**Pairing the wire:** Loss, VF, and  $Z_0$  data are for the paired conductors touching, held in place every 3-6 inches with Scotch 33 or 35 (thinner than Scotch 88, it can help squeeze an extra turn on 2.4-inch chokes for 160 meters). Wider spacing will increase  $Z_0$  and decrease attenuation, especially with enameled pairs (because proximity effect is reduced).

**Solid PE-insulated Coax:** These legacy designs have been superseded by the RG-400 and paired-wire designs. These chokes are

heavier, more expensive, and have greater loss (because they use more cores and more coax). These designs are repeatable only if turns pass through the core(s) sequentially, and if they have the same radius and spacing. Space turns evenly around the toroid to minimize inter-turn capacitance. See the online paper for some suggestions for constructing these chokes.

**Supporting the Choke:** Ferrite-core chokes can be heavy, even if wound with the lightest line on a single

core. This can lead to mechanical failure from wind or other flexing of the antenna and feed line. The referenced paper contains several photos of suggested construction techniques. Figure 20.30C shows a center insulator assembly of GPO3 fiberglass supporting two chokes in series (see the K9YC paper for series performance tables), an SO-239 receptacle for convenient feed line attachment, and sturdy attachment points for the dipole legs and a support rope or cable. The photo was taken before a waterproofing coating was applied to seal the electrical connections and provide UV resistance. Silicone adhesive was used to waterproof the SO-239. Lexan or some other UV-resistant plastic will also work for the body of the assembly.

### USING FERRITE BEADS

The early “current baluns” developed by Walt Maxwell, W2DU, formed by stringing multiple beads in series on a length of coax to obtain the desired choking impedance, are really common-mode chokes. Maxwell’s designs utilized 50 very small beads of type 73 material as shown in Figure 20.31. Product data sheets show that a single type 73 bead has a very low-Q resonance around 20 MHz, and has a predominantly resistive impedance of 10-20 Ω on all HF ham bands. Stringing 50 beads in series simply multiplies the impedance of one bead by 50, so the W2DU “current balun” has a choking impedance of 500-1000 Ω, and because it is strongly resistive, any resonance with the feed line is minimal.

This is a fairly good design for moderate power levels, but suitable beads are too small to fit most coax. A specialty coaxial cable such as RG-303 must be used for high-power applications. Even with high-power coax, the choking impedance is often insufficient to limit current to a low enough value to prevent overheating. Equally important — the lower choking impedance is much less effective at rejecting noise and preventing the filling of nulls in a radiation pattern.

Figure 20.31 — W2DU bead balun consisting of 50 FB-73-2401 ferrite beads over a length of RG-303 coax. See text for details.

Newer “bead balun” designs use type 31 and 43 beads, which are resonant around 150 MHz, are inductive below resonance, and have only a few tens of ohms of strongly inductive impedance on the HF bands. Even with 20 of the type 31 or 43 beads in the string, the choke is still resonant around 150 MHz, is much less effective than a wound coaxial ferrite choke, and is still inductive on the HF bands (so it will be ineffective at frequencies where it resonates with the line).

Adding ferrite cores to a coiled-coax balun is a way to increase their effectiveness. The resistive component of the ferrite impedance damps the resonance of the coil and increases its useful bandwidth. The combinations of ferrite and coil baluns shown in Table 20.8 demonstrate this very effectively. Eight feet of RG-8X in a 5 turn coil is a great balun for 21 MHz, but it is not particularly effective on other bands. If one type 43 core (Fair-Rite 2643167851) is inserted in the same coil of

coax, the balun can be used from 3.5 to 21 MHz. If two of these cores are spaced a few inches apart on the coil as in Figure 20.32, the balun is more effective from 1.8 to 7 MHz and usable to 21 MHz. If type 31 material was used (the Fair-Rite 2631101902 is a similar core), low-frequency performance would be even better. The 20-turn, multiple-band, 1.8-3.5 MHz coiled-coax balun in Table 20.6 weighs 1 pound, 7 ounces. The single ferrite core combination balun weighs 6.5 ounces and the two-core version weighs 9.5 ounces.

### 20.5.5 Chokes for Receiving Applications

Common-mode current on feed line shields can cause pattern distortion, ordinary cases of RFI, and noise coupling from other sources. To reduce these effects, a choke impedance of 500-1000 Ω is sufficient.

Chuck Counselman, W1HIS, correctly observes that radiation and noise coupling from the feed line should be viewed as a form of pattern distortion that fills in the nulls of a directional antenna, reducing its ability to reject noise and interference. This is particularly important for receiving antennas that are designed to have deep nulls.

Designing feed line chokes and isolation transformers for noise reduction and receiving antennas is discussed in detail by W1HIS in his referenced online article. Jim Brown K9YC, addresses the issue in a National Contest Journal article (see References and the downloadable supplemental information for this chapter) and in his online paper [k9yc.com/RXChokesTransformers.pdf](http://k9yc.com/RXChokesTransformers.pdf).

## 20.6 PC Transmission Lines

PC board material can be used to create a transmission line. There are several variations in which the PC trace forms one of the conductors and ground plane layers form the other. These are summarized in **Figure 20.33**, where  $\epsilon_r$  is the dielectric constant of the PC board material. (FR4 is the most common material at and above VHF.)

*Microstrip* (Figure 20.33A) is the most common of the PC transmission lines, consisting of an isolated trace above a ground plane.

*Stripline* (Figure 20.33B) is also common in multilayer boards with the PC trace embedded in the PC board material and centered between two ground plane layers.

*Offset stripline* (not shown) is a variation of stripline in which the PC trace is not centered between the ground plane layers.

*Coplanar waveguide* (Figure 20.33C) is feasible at microwave frequencies.

In microstrip and stripline the RF energy is mostly (but not completely) confined to the region between the large surface of the PC trace and the ground plane. Current is spread across the surface of the PC trace at a depth determined by the skin effect (see the **RF Techniques** chapter).

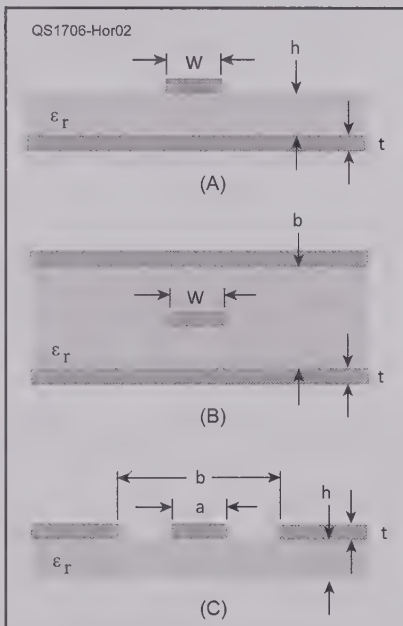

In contrast, the RF energy in coplanar waveguide is contained between the edges of the PC trace and the edges of the adjacent ground plane. The middle surfaces of the PC trace carry little, if any, current. This increases resistive losses because the current is concentrated in a smaller region but the waves travel mostly in air and so have lower losses. This becomes an important tradeoff at microwave frequencies.

Since most designs work with 50- $\Omega$  impedances, combinations of common copper foil thicknesses, trace widths, and board layer thicknesses have been calculated to produce 50  $\Omega$ . Several are shown in **Table 20.9**. For the interested reader, see Wadell's book in the Reference section of this chapter. The free program *AppCAD* ([www.hp.woodshot.com](http://www.hp.woodshot.com)) can handle many PC transmission line design calculations, along with S parameters and balun calculations.

With high-volume commercial and consumer electronics operating at microwave frequencies, connectors for PC transmission lines have become widely available. See the **Component Data and References** chapter's table of connector styles for possible candidates. These small connectors cannot handle a lot of power but are adequate for receiving and low-power transmitting applications. Adapters and adapter cables are available to convert these connectors to the more common SMA, UHF, BNC, N, and other styles used by amateurs.

# 20.7 Waveguides

Above 2 GHz, coaxial cable is a losing proposition for communications operation. Fortunately, at this frequency the wavelength is short enough to allow practical, efficient energy transfer by an entirely different means. A *waveguide* is a conducting tube through which energy is transmitted in the form of electromagnetic waves. The tube is not considered as carrying a current in the same sense that the wires of a two-conductor line do, but rather as a *boundary* that confines the waves in the enclosed space. Skin effect prevents any electromagnetic effects from being evident outside the guide. The energy is injected at one end, either through capacitive or inductive coupling or by radiation, and is removed from the other end in a like manner. Waveguide merely confines the energy of the fields, which are propagated through it to the receiving end by means of reflections against its inner walls.

## 20.7.1 Evolution of Waveguide

Suppose an open-wire line is used to carry UHF or microwave energy from a generator to a load. Imagine the transmission line is supported with quarter-wave stubs, shorted at the far end. The open end of such a stub presents an infinite impedance to the transmission line, provided that the shorted stub is non-reactive.

Thus, the stub acts as an insulating support. Since the stubs act as an open-circuit, an infinite number of them may be connected in parallel without affecting the open-wire line.

Because the shorting link has finite length it also has some inductance. This inductance can be minimized by making the RF current flow on the surface of a plate rather than through a thin wire. If the plate is large enough, it will prevent the magnetic lines of force from encircling the RF current.

The transmission line may be supported from the top as well as the bottom and when infinitely many supports are added, they form the walls of a waveguide at its *cutoff frequency*. Figure 20.34 illustrates how a rectangular waveguide evolves from a two-wire parallel transmission line.

## 20.7.2 Waveguide Operation

As a signal propagates along a waveguide, the metal walls contain the electric and magnetic fields. We'll concentrate on the electric field here, because the dominant mode of propagation for waveguide is called TE or *Transverse Electric*. Figure 20.35 shows how the electric and magnetic fields are oriented for the TE<sub>10</sub> mode. (See the discussion on waveguide modes below.) The electric field intensity in the rectangular waveguide, which is oriented parallel to the shorter side walls. The electric field is strongest in the center and must be zero at the side walls, since the walls are short circuits. This is the reason for the E-plane and H-plane terminology in Figure 20.35D.

The field strength distribution is half of a sine wave at the operating frequency, and propagates down the waveguide as if it were bouncing off the side walls. For this to work, the width of the waveguide must be at least one-half the wavelength of the propagating signal. At lower frequencies with longer

wavelengths, the field cannot be zero at both walls so these signals will not propagate in the waveguide.

## 20.7.3 Waveguide Dimensions CUTOFF AND UPPER FREQUENCIES

The minimum frequency of operation for a waveguide is that at which the waveguide width is a half-wavelength. This is called the waveguide's *cutoff frequency*,  $f_c$ .

$$f_c = c/\lambda_c$$

where  $c$  = the speed of light in free space,  $2.9979 \times 10^8$  meters per second.

A wavelength in the waveguide,  $\lambda_g$ , is longer than a wavelength in free space,  $\lambda_0$ . This implies a velocity faster than the speed of light. But only the *phase velocity* exceeds the speed of light — energy cannot travel faster. The waveguide wavelength varies with frequency as a function of the cutoff frequency:

$$\lambda_g = \frac{\lambda_0}{\sqrt{1 - \left(\frac{\lambda_0}{\lambda_c}\right)^2}}$$

Near the cutoff frequency,  $\lambda_g$  is much longer than the free-space wavelength  $\lambda_0$ , becoming closer to  $\lambda_0$  as frequency increases.

Waveguide operating frequencies are usually well above the cutoff frequency — near (and below) the cutoff frequency, losses increase and the guide wavelength changes rapidly with frequency causing dispersion of the transmitted waveform. This is why a waveguide makes an excellent high-pass filter.

The height of a rectangular waveguide, between top and bottom walls, determines

## RF Safety for Waveguides, Horns and Dishes

Never look into the open end of a waveguide when power is applied, or stand directly in front of a dish while transmitting. Tests and adjustments in these areas should be done while receiving or at extremely low levels of transmitter power (less than 0.1 watt). The FCC has set a limit of 10 mW/cm<sup>2</sup> averaged over a 6-minute period as the safe maximum. Other authorities believe even lower levels should be used. Destructive thermal heating of body tissue results from excessive exposure. This heating effect is especially dangerous to the eyes. The accepted safe level of 10 mW/cm<sup>2</sup> is reached in the near field of a parabolic antenna if the level at  $2D^2/\lambda$  is 0.242 mW/cm<sup>2</sup>. The equation for power density at the far-field boundary is

$$\text{Power Density} = \frac{137.8P}{D^2} \text{ mW/cm}^2$$

where

$P$  = average power in kilowatts

$D$  = antenna diameter in feet

$\lambda$  = wavelength in feet

Figure 20.34 — At its cutoff frequency a rectangular waveguide can be thought of as a parallel two-conductor transmission line supported from top and bottom by an infinite number of 1/4-wavelength stubs.

Figure 20.35 — Field distribution in a rectangular waveguide. The  $TE_{10}$  mode of propagation is depicted.

both the upper frequency limit and the characteristic impedance. The upper limit is the frequency at which the waveguide height is  $\frac{1}{2}\lambda$  — above this frequency, the electric field may change orientation and other modes may propagate.

### WAVEGUIDE DIMENSIONS

In a rectangular guide the critical dimension is  $X$  in Figure 20.35. This dimension must be more than  $\frac{1}{2}\lambda$  at the lowest frequency to be transmitted. In practice, the  $Y$  dimension usually is made about equal to  $\frac{1}{2}X$  to avoid the possibility of operation in other than the dominant mode.

Cross-sectional shapes other than a rectangle can be used, the most important being the circular pipe. Much the same considerations apply as in the rectangular case.

Wavelength dimensions for rectangular and circular guides are given in Table 20.10, where  $X$  is the width of a rectangular guide and  $r$  is the radius of a circular guide. All figures apply to the dominant mode.

### CHARACTERISTIC IMPEDANCE

The characteristic impedance is usually much higher than 50 ohms and is calculated for TE modes using this formula:

$$Z_0 = 377 \left( \frac{\lambda_g}{\lambda_0} \right) \left( \frac{2b}{a} \right)$$

where  $a$  and  $b$  are the large and small

dimensions, respectively, of the rectangular waveguide.  $377 \Omega$  is the approximate impedance of free space.

For example, at 10 GHz, WR90 waveguide is often used. The width is 0.9 inches, or 22.86 mm, and the height is 0.4 inches, or 10.16 mm. The cutoff frequency is 6.56 GHz, but the recommended operating frequency range is 8 to 12.4 GHz. At 10.368 GHz, the free space wavelength is  $\lambda_0 = 28.915$  mm, the guide wavelength is  $\lambda_g = 37.33$  mm and the characteristic impedance is  $Z_0 = 433$  ohms. Several common waveguides are pictured in cross-section in Figure 20.36.

For circular waveguide, the cutoff wavelength is  $\lambda_c = 1.706 \times$  diameter and the characteristic impedance is

$$Z_0 = 377 \left( \frac{\lambda_g}{\lambda_0} \right)$$

### 20.7.4 Waveguide Modes

The operating mode described above is for the dominant mode,  $TE_{10}$  (or  $TE_{11}$  in circular waveguide). This is the lowest frequency mode at which a given waveguide will operate, and is the preferred mode for waveguide transmission.

If there is no upper limit to the frequency to be transmitted, there are an infinite number of ways exist in which the fields can arrange themselves in a guide. Each field configuration is a mode. All modes may be separated into two general groups. One group, designated TM (*Transverse Magnetic*), has the magnetic field entirely crosswise to the direction of propagation, but has a component of electric field in the propagation direction. The other group, designated TE (*Transverse Electric*) has the electric field entirely crosswise to the direction of propagation, but has a component of magnetic field in the direction of

Table 20.10

propagation. TM waves are sometimes called E-waves in older references and TE waves are sometimes called H-waves. The TM and TE designations are preferred, however. The particular mode of transmission is identified by the group letters followed by subscript numbers; for example  $TE_{11}$ ,  $TM_{11}$  and so on. The number of possible modes increases with frequency for a given size of guide.

Higher-order modes are useful in certain applications, for instance, in multi-mode feed horns, where the additional modes can shape the radiation pattern, special high-power waveguides, and in certain cavity filters.

### WAVEGUIDE COUPLING

Energy may be introduced into or extracted from a waveguide or resonator by means of either the electric or magnetic field. One type of adapter, shown in **Figure 20.37**, is a probe like a monopole antenna in the center of a wide wall of the waveguide. The probe in **Figure 20.37A** is simply a short extension of the inner conductor of the coaxial line, oriented so that it is parallel to the electric lines of force. If the probe were very thin and had no capacitance or inductance, it would be  $\frac{1}{4} \lambda$  long and spaced  $\frac{1}{4} \lambda$  from a short-circuit — the closed end of the waveguide. Actual dimensions compensate for the probe inductance and capacitance.

The loop shown in **Figure 20.37B** is arranged so that it encloses some of the magnetic lines of force. The point at which maximum coupling is obtained depends upon the mode of propagation in the guide or cavity. Coupling is maximum when the coupling device is in the most intense field.

Coupling can be varied by turning the probe or loop through a  $90^\circ$  angle. When the probe is perpendicular to the electric lines the coupling is minimum. Similarly, when the plane of the loop is parallel to the magnetic lines the coupling is minimum.

### 20.7.5 Waveguide Termination

If a waveguide is not terminated in its characteristic impedance, there will be an elevated SWR on the line like any other transmission line. A typical termination is a horn antenna, which flares out from the end of the waveguide to match the waveguide's characteristic impedance to the impedance of free space,  $377 \Omega$ .

Waveguide connections are made by bolting their flanges together firmly. Several flanges are shown in **Figure 20.38**. There are two types of flanges, *flat flanges* and *choke flanges*, which have a groove around the waveguide. The groove acts like a shorted stub that presents a high impedance to the RF energy to prevent leakage. Choke flanges should be mated with flat flanges, but two flat flanges may be mated together.

Waveguides of two different sizes may be mated, but there should be a transition between them since different waveguide sizes have different  $Z_0$ . Just as in coaxial lines, impedance discontinuities such as at a transition will cause reflections.

### 20.7.6 Practical Waveguides

Standard waveguide sizes dating to World War II are still in use today. The standard designator is WR $xx$ , where  $xx$  is the wide dimension in hundredths of an inch; for instance, WR90, often used at 10 GHz, has a wide dimension of 90 hundredths of an inch, or 0.9 inches. There are no standards for circular waveguide, so common copper plumbing is often used — 3/4 inch tubing works well at 10 GHz. Practical dimensions for standard waveguides at amateur microwave calling frequencies are shown in **Table 20.11**.

Table 20.11 includes dimensions for the waveguide sizes likely to be encountered in microwave work; while a waveguide would work very well at lower frequencies, it would be very large — one meter wide for the 2-meter band! The recommended frequency range for each type is also shown in the table. For narrowband amateur work, we can stretch the frequency range a bit to take advantage of available waveguide — some of the wave-

**Figure 20.39** — Special sections called bends make right- and 45° angles to avoid introducing impedance discontinuities where the waveguide has to change direction.

guide sizes are usable on more than one band. Many smaller size guides are used at mm-wave frequencies.

Losses in waveguide are very low, much less than coaxial transmission line, but not negligible at the higher frequencies. For example, WR90 loss is approximately 10 dB per 100 feet at 10 GHz. Power handling is not a problem; even the smallest waveguide is rated at far more than the amateur power limit.

Where the waveguide has to change direction, special fittings called *bends* are used,

shown in **Figure 20.39**. These are constructed so that impedance discontinuities from the change in direction are minimized.

Waveguide transmission lines used outdoors will suffer from internal water condensation, like any closed metal container with temperature variations. Even a short length used in a portable station can collect condensation. Commercial installations often pressurize the waveguide with dry air. Otherwise, a drain hole should be provided at the bottom of a run.

## 20.8 Glossary of Transmission Line Terms

**Antenna tuner** — A device that matches the antenna system input impedance to the transmitter, receiver or transceiver output impedance. Also called an *antenna-matching network*, *impedance matcher*, *transmatch*, *ATU*, *matchbox*.

**Balanced line** — A symmetrical two-conductor feed line that has uniform voltage and current distribution along its length.

**Balun** — Contraction of “balanced to unbalanced.” A device to couple a balanced load to an unbalanced feed line or device, or vice versa. May be in the form of a choke balun, or a transformer that provides a specific impedance transformation (including 1:1). Often used in antenna systems to interface a coaxial transmission line to the feed point of a balanced antenna, such as a dipole.

**Characteristic impedance** — The ratio of voltage to current in a matched feed line, it is determined by the physical geometry and materials used to construct the feed line. Also known as *surge impedance* since it represents the impedance electromagnetic energy encounters when entering a feed line.

**Choke balun** — A balun that prevents current from flowing on the outside of a coaxial cable shield when connected to a balanced load, such as an antenna.

**Coax** — See **coaxial cable**.

**Coaxial cable** — Transmission lines that have the outer shield (solid or braided) concentric with the same axis as the inner or center conductor. The insulating material can be a gas (air or nitrogen) or a solid or foam insulating material.

**Common-mode current** — Current that flows equally and in phase on all conductors of a feed line or multiconductor cable.

**Conductor** — A metal body such as tubing, rod or wire that permits current to travel continuously along its length.

**Conjugate match** — Creating a purely resistive impedance by connecting an impedance with an equal-and-opposite reactive component.

**Current balun** — see **Choke balun**.

**Decibel** — A logarithmic power ratio, abbreviated dB. May also represent a voltage or current ratio if the voltages or currents are measured across (or through) identical impedances. Suffixes to the abbreviation indicate references: dBi, isotropic radiator; dBm, milliwatt; dBW, watt.

**Dielectrics** — Various insulating materials used in antenna systems, such as found in insulators and transmission lines.

**Dielectric constant (k)** — Relative figure of merit for an insulating material used as a dielectric. This property determines how much electric energy can be stored in

a unit volume of the material per volt of applied potential.

**Electric field** — An electric field exists in a region of space if an electrically charged object placed in the region is subjected to an electrical force.

**Electromagnetic wave** — A wave of energy composed of an electric and magnetic field.

**Feed line** — See **transmission line**.

**Feed point** — The point at which a feed line is electrically connected to an antenna.

**Feed point impedance** — The ratio of RF voltage to current at the feed point of an antenna.

**Ferrite** — A ceramic material with magnetic properties.

**Hardline** — Coaxial cable with a solid metal outer conductor to reduce losses compared to flexible cables. Hardline may or may not be flexible.

**Impedance match** — To adjust impedances to be equal or the case in which two impedances are equal. Usually refers to the point at which a feed line is connected to an antenna or to transmitting equipment. If the impedances are different, that is a **mismatch**.

**Impedance matcher** — See **Antenna tuner**.

**Impedance matching (circuit)** — A circuit that transforms impedance from one value to another. Adjustable impedance matching circuits are used at the output of transmitters and amplifiers to allow maximum power output over a wide range of load impedances.

**Impedance transformer** — A transformer designed specifically for transforming impedances in RF equipment.

**L network** — A combination of two reactive components used to transform or match impedances. One component is connected in series between the source and load and the other shunted across either the source or the load. Most L networks have one inductor and one capacitor, but two-inductor and two-capacitor configurations are also used.

**Ladder line** — see **Open-wire line**.

**Lambda ( $\lambda$ )** — Greek symbol used to represent wavelength.

**Line loss** — The power dissipated by a transmission line as heat, usually expressed in decibels.

**Load** — (noun) The component, antenna, or circuit to which power is delivered; (verb) To apply a load to a circuit or a transmission line.

**Loading** — The process of a transferring power from its source to a load. The effect a load has on a power source.

**Magnetic field** — A region through which a magnetic force will act on a magnetic object.

**Matched-line loss** — The line loss in a feed line terminated by a load equal to its characteristic impedance.

**Matching** — The process of effecting an impedance match between two electrical circuits of unlike impedance. One example is matching a transmission line to the feed point of an antenna. Maximum power transfer to the load (antenna system) will occur when a matched condition exists.

**Microstrip** — A transmission line made from a strip of printed-circuit board conductor above a ground plane, used primarily at UHF and microwave frequencies.

**Open-wire line** — Parallel-conductor feed line with parallel insulators at regular intervals to maintain the line spacing. The dielectric is principally air, making it a low-loss type of line. Also known as *ladder line* or *window line*.

**Output impedance** — The equivalent impedance of a signal source.

**Parallel-conductor line** — A type of transmission line that uses two parallel wires spaced from each other by insulating material. Also known as *open-wire*, *ladder* or *window line*.

**Phasing lines** — Sections of transmission line that are used to ensure the correct phase relationship between the elements of a driven array, or between bays of an array of antennas. Also used to effect impedance transformations while maintaining the desired phase.

**Q section** — Term used in reference to transmission-line matching transformers and phasing lines.

**Reflection coefficient ( $\rho$ )** — The ratio of the reflected voltage at a given point on a transmission line to the incident voltage at the same point. The reflection coefficient is also equal to the ratio of reflected and incident currents. The Greek letter rho ( $\rho$ ) is used to represent reflection coefficient.

**Reflectometer** — see **SWR bridge**

**Resonance** — (1) The condition in which a system's natural response and the frequency of an applied or emitted signal are the same. (2) The frequency at which a circuit's capacitive and inductive reactances are equal and cancel.

**Resonant frequency** — The frequency at which the maximum response of a circuit occurs. In an antenna, the resonant frequency is one at which the feed point impedance is purely resistive.

**Return loss** — The absolute value of the ratio in dB of the power reflected from a load to the power delivered to the load.

**Rise time** — The time it takes for a waveform to reach a maximum value.

**Series-input network** — A network such as

a filter or impedance matching circuit in which the input current flows through a component in series with the input.

**hunt-input network** — A network such as a filter or impedance matching circuit with a component connected directly across the input.

**skin effect** — The phenomenon in which ac current at high frequencies flows in a thin layer near the surface of a conductor.

**smith chart** — A coordinate system developed by Phillip Smith to represent complex impedances graphically. This chart makes it easy to perform calculations involving antenna and transmission-line impedances and SWR.

**standing-wave ratio (SWR)** — Sometimes called voltage standing-wave ratio (VSWR). A measure of the impedance match between a feed line's characteristic impedance and the attached load (usually an antenna). VSWR is the ratio of maximum voltage to minimum voltage along the feed line, or of antenna impedance to feed line impedance.

**tacking** — The technique of placing similar directive antennas atop or beside

one another, forming a "stacked array." Stacking provides more gain or directivity than a single antenna.

**Stub** — A section of transmission line used to perform impedance matching or filtering.

**Surge impedance** — see **Characteristic impedance**.

**SWR** — see **Standing-wave ratio**.

**SWR bridge** — Device for measuring SWR in a transmission line. Also known as an SWR meter or reflectometer.

**TE mode** — Transverse electric field mode. Condition in a waveguide in which the E-field component of the traveling electromagnetic energy is oriented perpendicular to (transverse) the direction the energy is traveling in the waveguide.

**TM mode** — Transverse magnetic field mode. Condition in a waveguide in which the H-field (magnetic field) component of the traveling electromagnetic energy is oriented perpendicular to (transverse) the direction the energy is traveling in the waveguide.

**Transmatch** — See **Antenna tuner**.

**Transmission line** — The wires or cable

used to connect a transmitter or receiver to an antenna. Also called **feed line**.

**Twin-lead** — Parallel-conductor transmission line in which both conductors are completely embedded in continuous strip of insulating material.

**Unbalanced line** — Feed line with one conductor at dc ground potential, such as coaxial cable.

**Universal stub system** — A matching network consisting of a pair of transmission line stubs that can transform any impedance to any other impedance.

**Velocity factor (VF)** — The speed at which an electromagnetic wave will travel through a material or feed line stated as a fraction of the speed of the wave in free space (where the wave would have its maximum velocity).

**VSWR** — Voltage standing-wave ratio. See **SWR**.

**Waveguide** — A hollow conductor through which electromagnetic energy flows. Usually used at UHF and microwave frequencies instead of coaxial cable.

**Window line** — see **Open-wire line**.

# Antennas

In the world of radio, the antenna is “where the rubber meets the road!” With antennas so fundamental to communication, it is important that the amateur have a basic understanding of their function. That understanding enables effective selection and application of basic designs to whatever communications task is at hand. In addition, the amateur is then equipped to engage in one of the most active areas of amateur experimentation, antenna design. The goal of this chapter is to define and illustrate the fundamentals of antennas and provide a selection of basic designs; simple verticals and dipoles, quads and Yagi beams, and

other antennas, plus a section on rotator use and selection. The reader will find additional in-depth coverage of these and other topics in the *ARRL Antenna Book* and other references provided. This chapter was originally written by Chuck Hutchinson, K8CH, and has been updated by Ward Silver, NØAX. Steve Stearns, K6OIK, contributed a section that updates the discussion of K factor, the effect of antenna diameter on half-wave resonant length. Alan Applegate, KØBG, maintains the material on mobile antennas. The section on Radio Direction Finding Antennas was written by Joe Moell, KØOV.

## 21.1 Antenna Basics

This section covers a range of topics that are fundamental to understanding how antennas work and defines several key terms. (A glossary is included at the end of the chapter.) While the discussion in this section uses the dipole as the primary example, the concepts apply to all antennas.

### 21.1.1 Directivity and Gain

All antennas, even the simplest types, exhibit directive effects in that the intensity of radiation is not the same in all directions from the antenna. This property of radiating more strongly in some directions than in others is called the *directivity* of the antenna. Directivity is the

same for receiving as transmitting.

The directive pattern of an antenna at a given frequency is determined by the size and shape of the antenna, and on its position and orientation relative to the Earth and any other reflecting or absorbing surfaces.

The more an antenna's directivity is enhanced in a particular direction, the greater the *gain* of the antenna. This is a result of the radiated energy being concentrated in some directions at the expense of others. Similarly, gain describes the ability of the antenna to receive signals preferentially from certain directions. Gain does not create additional power beyond that delivered by the feed line — it only focuses that energy.

Gain is usually expressed in decibels, and is always stated with reference to a *standard* antenna — usually a dipole or an *isotropic radiator*. An isotropic radiator is a theoretical antenna that would, if placed in the center of an imaginary sphere, evenly illuminate that sphere with radiation. The isotropic radiator is an unambiguous standard, and for that reason frequently used as the comparison for gain measurements.

When the reference for gain is the isotropic radiator in *free space*, gain is expressed in dBi. When the standard is a dipole, also located in free space, gain is expressed in dBd. Because the dipole has some gain (2.15 dB with respect to the isotropic antenna as explained in the section on dipoles) in its favored direction, the dipole's gain can be expressed as 2.15 dBi. Gain in dBi can be converted to dBd by subtracting 2.15 dB and from dBd to dBi by adding 2.15 dB.

Gain also takes losses in the antenna or surrounding environment into account. For example, if a practical dipole antenna's wire element dissipated 0.5 dB of the transmitter power as heat, that specific dipole's gain with respect to an isotropic antenna would be  $2.15 - 0.5 = 1.65$  dBi.

### 21.1.2 Antenna Polarization

An electromagnetic wave has two components: an electric field and a magnetic field at right angles to each other. For most antennas, the field of primary interest is the electric, or *E-field*. The magnetic field is called the *H-field*. (The abbreviations E- and H- come from Maxwell's equations that describe electromagnetic waves.) By convention, the orientation of the E-field is the reference for determining the electromagnetic wave's *polarization*. The E-field of an electromagnetic wave can be oriented in any direction, so orientation with respect to the Earth's surface is the usual frame of reference. The wave's polarization can be vertical, horizontal, or some intermediate angle. If the E- and H-field orientations rotate as the wave travels, that is elliptical or circular polarization.

Antennas are considered to have polarization, too, determined by the orientation of the E-field of the electromagnetic field radiated by the antenna. Because the E-field of the radiated wave is parallel to the direction of current flow in the antenna's elements, the polarization of the wave and the orientation of the antenna elements is usually the same. For example, the E-field radiated by an antenna with linear elements is parallel to those elements, so that the polarization of the radiated wave is the same as the orientation of the elements. (This is somewhat over-simplified and additional considerations apply for elements that are not linear.) Thus a radiator that is parallel to the earth radiates a horizontally polarized wave, while a vertical antenna radiates a vertically polarized wave. If a wire antenna is slanted, it radiates waves with an E-field that has both vertical and horizontal components.

Antennas function symmetrically — a received signal will create the strongest antenna current when the antenna's elements are parallel to the E-field of the incoming wave just as the radiated wave's E-field will be strongest parallel to current in the antenna's radiating elements. This also means that for the strongest received signal, the antenna elements should have the same polarization as that of the incoming wave. Misalignment of the receiving antenna's elements with the passing wave's E-field reduces the amount of signal received. This is called *cross-polarization*. When the polarizations of antenna and wave are at right angles, very little antenna current is created by the incoming signal.

For best results in line-of-sight communications, antennas at both ends of the circuit should have the same polarization. However, it is not essential for both stations to use the same antenna polarity for ionospheric propagation or sky wave (see the **Propagation** chapter). This is because the radiated wave is bent and rotated considerably during its travel through the ionosphere. At the far end of the communications path the wave may be horizontal, vertical or somewhere in between at any given instant. For that reason, the main consideration for a good DX antenna is a low angle of radiation rather than the polarization.

Most HF-band antennas are either vertically or horizontally polarized. Although circular polarization is possible, just as it is at VHF and UHF, it is seldom used at HF. While most amateur antenna installations use the Earth's surface as their frame of reference, in cases such as satellite communication or EME the terms "vertical" and "horizontal" have no meaning with respect to polarization.

### 21.1.3 Current and Voltage Distribution

Using the dipole as an example, when power is fed to an antenna, the current and voltage vary along its length. The current is minimum at the ends, regardless of the antenna's length. The current does not actually reach zero at the current minima, because of capacitance at the antenna ends. Insulators, loops at the antenna ends, and support wires all contribute to this capacitance, which is also called the *end effect*. The opposite is true

Figure 21.1 — The current and voltage distribution along a half-wave dipole (A) and for an antenna made from a series of half-wave dipoles (B). Both antennas are shown operating at a resonant frequency. Non-resonant antennas will exhibit a different pattern of voltage and current.

of the RF voltage. That is, there is a voltage maximum at each end.

In the case of a half-wave dipole at its resonant frequency there is a current maximum at the center and a voltage minimum at the center as illustrated in Figure 21.1. The graphs of current and voltage distribution along the wire represent the magnitude of the current and voltage waveforms similarly to the envelope of a modulated signal. The magnitude of the voltage and current distributions are 90° out of phase although the actual current and voltage waveforms are in phase, resulting in a purely resistive feed point impedance.

The pattern of alternating current and voltage maxima a quarter-wavelength apart repeats every half-wavelength along a resonant linear antenna as shown in Figure 21.1B. The phase of the current and voltage are inverted in each successive half-wavelength section. (If the antenna is non-resonant, there will still be a current minimum at an open end but the voltage and current patterns on the antenna will be different than shown here.)

Power is dissipated as heat or as signals by the resistance of the antenna, which consists of both the RF resistance of the wire (ohmic loss resistance) and the *radiation resistance*. The radiation resistance is the equivalent resistance that would dissipate the power the antenna radiates, with a current flowing in it equal to the antenna current at a current maximum. Radiation resistance represents the work done by creating current in the antenna that transfers the energy from the signal source to the radiated electromagnetic wave. The loss resistance of a half-wave antenna is ordinarily small, compared with the radiation resistance, and can usually be neglected for practical purposes except in electrically small antennas, such as mobile HF antennas.

### 21.1.4 Impedance

The *impedance* at a given point in the antenna is determined by the ratio of the voltage to the current at that point. For example, if there were 100 V and 1.4 A of RF current at a specified point in an antenna and if they were in phase, the impedance would be approximately 71 Ω. The antenna's *feed point impedance* is the impedance at the point where the feed line is attached. If the feed point location changes, so does the feed point impedance.

Antenna impedance may be either resistive or complex (that is, containing resistance and reactance). The impedance of a *resonant* antenna is purely resistive anywhere on the antenna, no matter what value that impedance may be. For example, the impedance of a resonant half-wave dipole may be low at the center of the antenna and high at the ends, but it is purely resistive in all cases, even though its magnitude changes.

The feed point impedance is important in determining the appropriate method of matching the impedance of the antenna and the transmission line. The effects of mismatched antenna and feed line impedances are described in detail in the **Transmission Lines** chapter of this book. Some mistakenly believe that a mismatch, however small, is a serious matter. This is not true. The significance of a perfect match becomes more pronounced only at VHF and higher, where feed line losses are a major factor. Minor mismatches at HF are rarely significant.

### 21.1.5 Impedance and Height Above Ground

The feed point impedance of an antenna varies with height above ground because of the effects of energy reflected from and absorbed by the ground. For example, a ½ λ (or half-wave) center-fed dipole will have a feed point impedance of approximately 75 Ω in free space far from ground, but Figure 21.2 shows that only at certain electrical heights above ground will the feed point impedance be 75 Ω. The feed point impedance will vary from very low when the antenna is close to the ground to a maximum of nearly 100 Ω at 0.34 λ above ground, varying between ±5 Ω as the antenna is raised farther. The 75 Ω feed point impedance is most likely to be realized in a practical installation when the horizontal dipole is approximately ½, ¾ or 1 wavelength above ground. This is why few amateur λ/2 dipoles exhibit a center-fed feed point impedance of 75 Ω, even though they may be resonant.

Figure 21.2 compares the effects of perfect ground and typical soil at low antenna heights. The effect of height on the radiation resistance of a horizontal half-wave antenna is

not drastic so long as the height of the antenna is greater than 0.2 λ. Below this height, while decreasing rapidly to zero over perfectly conducting ground, the resistance decreases less rapidly with height over actual lossy ground. At lower heights the resistance stops decreasing at around 0.15 λ, and thereafter increases as height decreases further. The reason for the increasing resistance is that more and more energy from the antenna is absorbed by the earth as the height drops below ¼ λ, seen as an increase in feed point impedance.

### 21.1.6 Antenna Bandwidth

The *bandwidth* of an antenna refers generally to the range of frequencies over which the antenna exhibits a specified level of performance. The bandwidth can be specified in units of frequency (MHz or kHz) or as a percentage of the antenna's design frequency.

Popular amateur usage of the term antenna bandwidth most often refers to the 2:1 SWR bandwidth, such as, "The 2:1 SWR bandwidth is 3.5 to 3.8 MHz" or "The antenna has a 10% SWR bandwidth" or "On 20 meters, the antenna has an SWR bandwidth of 200 kHz." Other specific bandwidth terms are also used, such as the *gain bandwidth* (the bandwidth over which gain is greater than a specified level) and the *front-to-back ratio bandwidth* (the bandwidth over which front-to-back ratio is greater than a specified level).

As operating frequency is lowered, an equivalent bandwidth in percentage becomes narrower in terms of frequency range in kHz or MHz. For example, a 5% bandwidth at 21 MHz is 1.05 MHz (more than wide enough to cover the whole band) but at 3.75 MHz only 187.5 kHz! Because of the wide percentage bandwidth of the lower frequency bands 160 meters is 10.5% wide, 80 meters is 3.4% wide) it is difficult to design an antenna with a bandwidth sufficient to include the whole band.

It is important to recognize that SWR bandwidth does not always relate directly to gain bandwidth. Depending on the amount of feed line loss, an 80 meter dipole with a relatively narrow 2:1 SWR bandwidth can still radiate a good signal at each end of the band, provided that an antenna tuner is used to allow the transmitter to load properly and feed line loss is not excessive. Broadbanding techniques, such as fanning the far ends of a dipole to simulate a conical type of dipole, can help broaden the SWR bandwidth.

### 21.1.7 Effects of Conductor Diameter

The impedance and resonant frequency of an antenna also depend on the diameter of the conductors that make up its elements in relation to the wavelength. As diameter

Figure 21.2 — Curves showing the radiation resistance of vertical and horizontal half-wavelength dipoles at various heights above ground. The broken-line portion of the curve for a horizontal dipole shows the resistance over average real earth, the solid line for perfectly conducting ground.

**Figure 21.3 — Effect of antenna diameter on length for half-wavelength resonance in free-space, shown as a multiplying factor,  $K$ . The thicker the conductor relative to the wavelength, the shorter the physical length of the antenna at resonance. For antennas over ground, additional factors affect the antenna's electrical length.**

of a conductor increases, its capacitance per unit length increases and inductance per unit length decreases. This has the net effect of lowering the frequency at which the antenna element is resonant, as illustrated in **Figure 21.3**. The larger the conductor diameter in terms of wavelength, the smaller its *length-to-diameter ratio* ( $l/d$ ) and the lower the frequency at which a specific length of that conductor is  $\frac{1}{2}$  wavelength long electrically, in free space.

### K FACTOR

Based on the standard value for the speed of light, the wavelength  $\lambda$  of an electromagnetic wave in free-space at frequency  $f$  is given by:

$$\lambda(\text{in feet}) = \frac{983.571}{f(\text{in MHz})} \quad (1A)$$

and for one-half wavelength:

$$\frac{\lambda}{2}(\text{in feet}) = \frac{491.786}{f(\text{in MHz})} \quad (1B)$$

A dipole with a length of exactly one-half of a free-space wavelength  $\lambda/2$  has an impedance of  $73.079 + j42.515 \Omega$ , essentially independent of wire diameter. The dipole must be shortened to achieve resonance where reactance is equal to zero. As the diameter of a conductor increases, its capacitance per unit length increases and inductance per unit length decreases. This increases the ratio of stored electric field energy to magnetic field energy, with the result of lowering the frequency at which the antenna element is resonant. Stated another way: For a given frequency, the larger a conductor's diameter,

the lower the frequency at which a dipole made of that conductor is resonant.

A dipole's resonant length is given by the product of the free-space half-wavelength and a constant,

$$L_{\text{Resonant}}(\text{in feet}) = K \times \frac{491.786}{f(\text{in MHz})} \quad \text{or} \quad (2)$$

$$L_{\text{Resonant}}(\text{in inches}) = K \times \frac{5901.43}{f(\text{in MHz})}$$

where  $K$  is a constant between zero and one,  $0 < K < 1$ , that depends on the dipole's "fatness" or "thickness." There are several ways to express dipole thickness. Antenna builders prefer to specify dipole thickness in terms of the half-wavelength-to-diameter ratio  $(\lambda/2)/d$  because a builder generally knows  $d$  and wants to calculate  $L$ . The graph in **Figure 21.3** satisfies this need and allows dipole resonant length to be determined for a given physical thickness and frequency. Most half-wavelength dipoles at HF typically have  $(\lambda/2)/d$  ratios in the range of 2500 to 25,000 with values of  $K$  from 0.97 to 0.98.

The graph shown in **Figure 21.3** and Eq 3A below were determined by Steve Stearns, K6OIK, who evaluated and compared theoretical and numerical methods for calculating dipole and monopole impedance. (See the Bibliography entries for Stearns, Tai and Long, Elliott, and Schelkunoff). If better accuracy than the graph is needed, the formula in Eq 3A should be used. (A more complete discussion of the  $K$  factor and related topics is provided in the *ARRL Antenna Book's* 24th edition.)

$$K = 1 - \frac{0.225706}{\ln\left(\frac{\lambda/2}{d}\right) - 0.429451} \quad (3A)$$

**Example 1:** A half-wavelength dipole for 7.2 MHz has an uncorrected length of  $491.786 / 7.2 = 68.3$  feet. If it is made from #12 AWG wire (0.081 inch diameter), it has a  $(\lambda/2)/d$  ratio of:

$$\frac{491.786}{7.2}(\text{ft}) \times \frac{12 \text{ in/ft}}{0.081 \text{ in}} = 10,119$$

From **Figure 21.3** or Eq 3A, a  $(\lambda/2)/d$  ratio of 10,119 gives  $K = 0.974$ . Thus, by Eq 2, the resonant length of the half-wavelength dipole is  $0.974 \times 68.3 = 66$  feet 7 inches.

It should be understood that  $K$  is not a velocity factor because it is unrelated to waves or the speed of wave travel. Rather,  $K$  arises because if a dipole is exactly one-half wavelength long, the stored energies in the electric and magnetic fields are not exactly equal. A dipole must be shortened to obtain equality and resonance.

### 21.1.8 Radiation Patterns

*Radiation patterns* are graphic representations of an antenna's directivity. Two examples are given in **Figures 21.4** and **21.5**. Shown in polar coordinates (see the **Radio**

**Figure 21.4 — Azimuthal pattern of a typical three-element Yagi beam antenna in free space. The Yagi's boom is along the  $0^\circ$  to  $180^\circ$  axis.**

**Figure 21.5 — Elevation pattern of a 3 element Yagi beam antenna placed  $\frac{1}{2} \lambda$  above perfect ground.**

**Figure 21.6 — Rectangular azimuthal pattern of an 8 element 2 meter Yagi beam antenna by itself and with another identical antenna stacked two feet above it. This example shows how a rectangular plot allows easier comparison of antenna patterns away from the main lobe.**

**Figure 21.7 — Elevation patterns for two 40 meter dipoles over average ground (conductivity of 5 mS/m and dielectric constant of 13) at  $\frac{1}{4}\lambda$  (33 foot) and  $\frac{1}{2}\lambda$  (66 foot) heights. The higher dipole has a peak gain of 7.1 dBi at an elevation angle of about 26°, while the lower dipole has more response at high elevation angles.**

**Mathematics** downloadable supplemental content for information about polar coordinates), the angular scale shows direction and the scale from the center of the plot to the outer ring, calibrated in dB, shows the relative strength of the antenna’s radiated signal (gain) at each angle. A line is plotted showing the antenna’s relative gain (transmitting and receiving) at each angle. The antenna is located at the exact center of the plot with its orientation specified separately.

The pattern is composed of *nulls* (angles at which a gain minimum occurs) and *lobes* (a range of angles in which a gain maximum occurs). The *main lobe* is the lobe with the highest amplitude unless noted otherwise and unless several plots are being compared, the peak amplitude of the main lobe is placed at the outer ring as a 0 dB reference point. The peak of the main lobe can be located at any angle. All other lobes are *side lobes* which can be at any angle, including to the rear of the antenna.

Figure 21.4 is an *azimuthal* or *azimuth pattern* that shows the antenna’s gain in all horizontal directions (azimuths) around the antenna. As with a map, 0° is at the top and bearing angle increases clockwise. (This is different from polar plots generated for mathematical functions in which 0° is at the right and angle increases counter-clockwise.)

Figure 21.5 is an *elevation pattern* that shows the antenna’s gain at all vertical angles. In this case, the horizon at 0° is located to both sides of the antenna and the zenith (directly overhead) at 90°. The plot shown in Figure 21.5 assumes a ground plane (drawn from 0° to 0°) but in free-space, the plot would include the missing semicircle with -90° at the bottom. Without the ground reference, the term “elevation” has little meaning, however.

You’ll also encounter E-plane and H-plane radiation patterns. These show the antenna’s

radiation pattern in the plane parallel to the E-field or H-field of the antenna. It’s important to remember that the E-plane and H-plane do not have a fixed relationship to the Earth’s surface. For example, the E-plane pattern from a horizontal dipole is an azimuthal pattern, but if the same dipole is oriented vertically, the E-plane pattern becomes an elevation pattern.

Antenna radiation patterns can also be plotted on rectangular coordinates with gain on the vertical axis in dB and angle on the horizontal axis as shown in **Figure 21.6**. This is particularly useful when several antennas are being compared. Multiple patterns in polar coordinates can be difficult to read, particularly close to the center of the plot.

The amplitude scale of antenna patterns is almost always in dB. The scale rings can be calibrated in several ways. The most common is for the outer ring to represent the peak amplitude of the antenna’s strongest lobe as 0 dB. All other points on the pattern represent *relative gain* to the peak gain. The antenna’s *absolute gain* with respect to an isotropic (dBi) antenna or dipole (dBd) is printed as a label somewhere near the pattern. If several antenna radiation patterns are shown on the same plot for comparison, the pattern with the largest gain value is usually assigned the role of 0 dB reference.

The gain amplitude scale is usually divided in one of two ways. One common division is to have rings at 0, -3, -6, -12, -18, and -24 dB. This makes it easy to see where the gain has fallen to one-half of the reference or peak value (-3 dB), one-quarter (-6 dB), one-sixteenth (-12 dB), and so on. Another popular division of the amplitude scale is 0, -10, -20, -30, and -40 dB with intermediate rings or tick marks to show the -2, -4, -6, and -8 dB levels. You will encounter a number of variations on these basic scales.

## RADIATION PATTERN MEASUREMENTS

Given the basic radiation pattern and scales, it becomes easy to define several useful measurements or metrics by which antennas are compared, using their azimuthal patterns. Next to gain, the most commonly-used metric for directional antennas is the *front-to-back ratio* (F/B) or just “front-to-back.” This is the difference in dB between the antenna’s gain in the specified “forward” direction and in the opposite or “back” direction. The front-to-back ratio of the antenna in Figure 21.4 is about 11 dB. *Front-to-side ratio* is also used and is the difference between the antenna’s “forward” gain and gain at right angles to the forward direction. This assumes the radiation pattern is symmetric and is of most use to antennas such as Yagis and quads that have elements arranged in parallel planes. The front-to-side ratio of the antenna in Figure 21.4 is more than 30 dB. Because the antenna’s rear-ward pattern can have large amplitude variations, the *front-to-rear ratio* is sometimes used. Front-to-rear uses the average of rear-ward gain over a specified angle, usually the 180° semicircle opposite the direction of the antenna’s maximum gain, instead of a single gain figure at precisely 180° from the forward direction.

The antenna’s *beamwidth* is the angle over which the antenna’s main lobe gain is within 3 dB of the peak gain. Stated another way, the beamwidth is the angle between the directions at which the antenna’s gain is -3 dB. In Figure 21.4, the antenna’s main lobe beamwidth is about 54°, since the pattern crosses the -3 dB gain scale approximately 27° to either side of the peak direction. Antenna patterns with comparatively small beamwidths are referred to as “sharp” or “narrow.”

An antenna with an azimuthal pattern that shows equal gain in all directions is called

*omnidirectional*. This is not the same as an isotropic antenna that has equal gain in all directions, both vertical both horizontal.

### 21.1.9 Elevation Angle

For long-distance HF communication, the (vertical) *elevation angle* of maximum radiation, or *radiation angle*, is of considerable importance. You will want to erect your antenna so that its strongest radiation occurs at vertical angles resulting in the best performance at the distances over which you want to communicate. In general, the greater the height of a horizontally polarized antenna, the stronger its gain will be at lower vertical angles. **Figure 21.7** shows this effect at work in horizontal dipole antennas. (See the **Propagation** chapter and the *ARRL Antenna Book* for more information about how to determine the best elevation angles for communication.)

Since low radiation angles usually are most effective for long distance communications, this generally means that horizontal antennas should be high — higher is usually better. (The optimum angle for intercontinental contacts on the HF bands is generally 15° or lower.) Experience shows that satisfactory results can be attained on the bands above 14 MHz with antenna heights between 40 and 70 feet.

Higher vertical angles can be useful for medium to short-range communications. For example, elevation angles between 20° and 65°

are useful on the 40 and 80 meter bands over the roughly 550 mile path between Cleveland and Boston. Even higher angles may be useful on shorter paths when using these lower HF frequencies. A 75 meter dipole between 30 and 70 feet high works well for ranges out to several hundred miles.

For even shorter-range communications centered on your location, such as for emergency communications and regional nets, a very low antenna is used, generating its strongest radiation straight up. This is referred to as *Near-Vertical Incidence Skywave (NVIS)* communication. The antenna should be less than  $\frac{1}{4} \lambda$  above ground and the frequency used should be below the ionosphere's critical frequency so that the signal is completely reflected back toward the ground over a wide area.

Azimuthal patterns must also specify at what elevation angle the antenna gain is measured or calculated. While an azimuthal pattern may be in the plane of the antenna (an elevation angle of 0°), for antennas located above ground, the gain will vary strongly with elevation angle.

### 21.1.10 Imperfect Ground

Earth conducts, but is far from being a perfect conductor. This influences the radiation pattern of the antennas that we use. The effect is most pronounced at high vertical angles (the ones most important for short-range

communications and least important for long-distance communications) for horizontally polarized antennas. The consequences for vertical antennas are greatest at low angles, and are quite dramatic as can be clearly seen in **Figure 21.8**, where the elevation pattern for a 40 meter vertical half-wave dipole located over average ground is compared to one located over saltwater. At 10° elevation, the saltwater antenna has about 7 dB more gain than its landlocked counterpart.

An HF vertical antenna may work very well for a ham living in an area with rich soil. Ground of this type has very good conductivity. By contrast, a ham living where the soil is rocky or in a desert area may not be satisfied with the performance of a vertical HF antenna over such poorly conducting ground. Regardless of ground conductivity, the use of a ground screen of radial wires for HF verticals on land is necessary for good results.

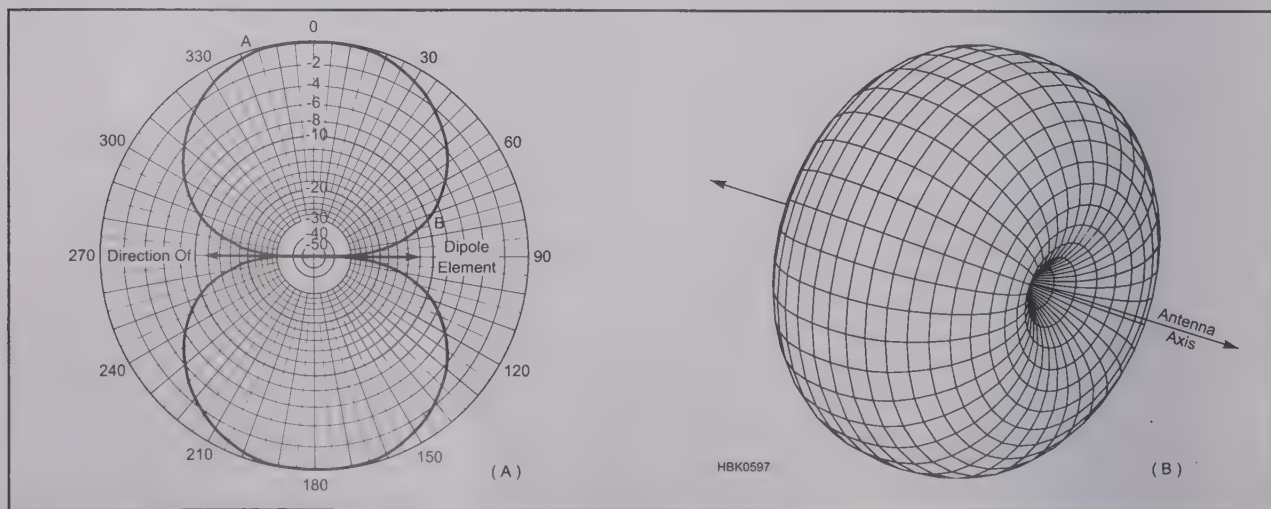

When evaluating or comparing antennas, it is also important to include the effects of ground on antenna gain. Depending on height above ground and the qualities of the ground, reflections can increase apparent antenna gain by up to 6 dB. Because the actual installation of the antenna is unlikely to duplicate the environment in which the gain with reflections is claimed or measured, it is preferable to rely on free-space gain measurements or specifications that are independent of reflecting surfaces.

## 21.2 Dipoles and the Half-Wave Antenna

A fundamental form of antenna is a wire whose length is half the transmitting wavelength. It is the unit from which many more complex forms of antennas are constructed and is known as a *dipole antenna*. (The name

di—meaning *two* and—pole meaning *electrical terminal* comes from the antenna having two distinct regions of electrical polarity as shown in **Figure 21.1**.) A dipole is resonant when it is electrically  $\frac{1}{2} \lambda$  long so that the current

and voltage in the antenna are exactly 90° out of phase as shown in **Figure 21.1**. (Even though the magnitude of current and voltage along the antenna are 90° out of phase at resonance, the actual RF current and voltage

**Figure 21.9** — Response of a dipole antenna in free space in the plane of the antenna with the antenna oriented along the 90° to 270° axis (A). The full three-dimensional pattern of the dipole is shown at (B). The pattern at A is a cross-section of the three-dimensional pattern taken perpendicularly to the axis of the antenna.

are in-phase and the feed point impedance is entirely resistive at resonance.)

The actual length of a resonant  $\frac{1}{2}\lambda$  antenna will not be exactly equal to the half wavelength of the radio wave of that frequency in free space, but depends on the thickness of the conductor in relation to the wavelength as shown in Figure 21.3. An additional shortening effect occurs with wire antennas supported by insulators at the ends because of current flow through the capacitance at the wire ends due to the end effect. Interaction with the ground and any nearby conductors also affects the resonant length of the physical antenna.

The following formula is sufficiently accurate for dipoles below 10 MHz at heights of  $\frac{1}{8}$  to  $\frac{1}{4}\lambda$  and made of common wire sizes. To calculate the length of a half-wave antenna in feet,

$$\text{Length (ft)} = \frac{492 \times 0.95}{f \text{ (MHz)}} = \frac{468}{f \text{ (MHz)}} \quad (3B)$$

Example: A half-wave antenna for 7150 kHz (7.15 MHz) is  $468/7.15 = 65.5$  feet, or 65 feet 6 inches. This length is from end insulator to end insulator, including the loops of wire through the insulator and the length of wires that connect to the feed line. The loops and extra connections will add a small amount of electrical length to the antenna, so be prepared to make small adjustments in antenna length before making a final installation.

For antennas at higher frequencies and/or higher above ground, the best approach is to build the initial dipole using a numerator value of 485 to 490. Make temporary connections at the end insulators. Install the antenna and measure its SWR or impedance. Calculate the percentage difference between the desired and measured resonant frequencies. Adjust the antenna's length by the same amount. For example, for a high dipole at 14.150 MHz, start with an antenna that is  $490 / 14.150 = 34.63$  feet long. If the antenna's measured frequency of minimum SWR is 14.6 MHz, the antenna is  $100 \times 14.6 / 14.150 = 3.2\%$  too long and should be shortened by that amount, removing an equal amount of wire from each end of the antenna.

Above 30 MHz use the following formulas, particularly for antennas constructed from rod or tubing. *K* is taken from Figure 21.3.

$$\text{Length (ft)} = \frac{492 \times K}{f \text{ (MHz)}} \quad (4A)$$

$$\text{Length (in)} = \frac{5904 \times K}{f \text{ (MHz)}} \quad (4B)$$

Example: Find the length of a half-wave antenna at 50.1 MHz, if the antenna is made of  $\frac{1}{2}$  inch-diameter tubing. At 50.1 MHz, a half wavelength in space is

$$\frac{492}{50.1} = 9.82 \text{ ft}$$

The ratio of half wavelength to conductor diameter (changing wavelength to inches) is

$$\frac{(9.82 \text{ ft} \times 12 \text{ in./ft})}{0.5 \text{ in.}} = 235.7$$

From Figure 21.3, *K* = 0.945 for this ratio. The length of the antenna, from equation 3B is

$$\frac{492 \times 0.945}{50.1} = 9.28 \text{ ft}$$

or 9 feet 3- $\frac{3}{8}$  inches. The answer is obtained directly in inches by substitution in equation 4

$$\frac{5904 \times 0.945}{50.1} = 111.4 \text{ in}$$

Regardless of the formula used to calculate the length of the half-wave antenna, the effects of ground and conductive objects within a wavelength or so of the antenna usually make it necessary to adjust the installed length in order to obtain the lowest SWR at the desired frequency. Use of antenna modeling software may provide a more accurate initial length than a single formula.

The value of the SWR indicates the quality of the match between the impedance of the antenna and the feed line. If the lowest SWR obtainable is too high, an impedance-matching network may be used, as described in the **Transmission Lines** chapter. (High SWR may cause modern transmitters with solid-state power amplifiers to reduce power output as a protective measure for the output transistors.)

### 21.2.1 Radiation Characteristics

The radiation pattern of a dipole antenna in free space is strongest at right angles to the wire as shown in Figure 21.9. In an actual installation, the figure-8 pattern is less directive due to reflections from ground and other conducting surfaces. As the dipole is raised to  $\frac{1}{2}\lambda$  or greater above ground, nulls off the ends of the dipole become more pronounced. Sloping the antenna and coupling to the feed line tend to distort the pattern somewhat.

As a horizontal antenna is brought closer to ground, the elevation pattern peaks at a higher elevation angle as shown in Figure 21.7. Figure 21.10 illustrates what happens to the directional pattern as antenna height changes. Figure 21.10C shows that there is significant radiation off the ends of a low horizontal dipole. For the  $\frac{1}{2}\lambda$  height (solid line), the radiation off the ends is only 7.6 dB lower than that in the broadside direction.

Figure 21.10 also shows that for short-range communication that depends on high

vertical angles of radiation (NVIS communications), a dipole can be too high. For these applications, the dipole should be installed at or below  $\frac{1}{4}\lambda$  so that the antenna radiates strongly at high vertical angles and with little horizontal directivity.

### 21.2.2 Feed Methods

A feed line is attached directly to the dipole, generally at the center, where an insulator separates the antenna's conductor into two sections or "legs." This is the antenna's *feed point*. One conductor of the feed line is attached to each leg. Figures 21.11A and 21.11B show how the two types of feed lines

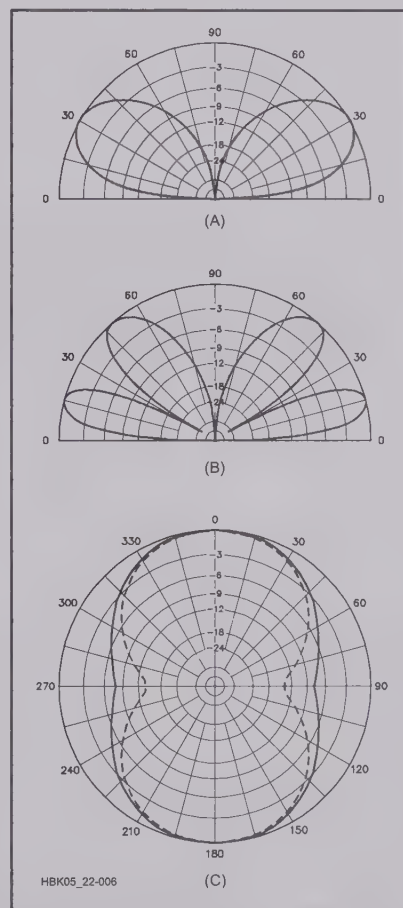

Figure 21.10 — At A, the elevation response pattern of a dipole antenna placed  $\frac{1}{2}\lambda$  above a perfectly conducting ground. At B, the pattern for the same antenna when raised to  $1\lambda$ . For both A and B, the conductor is coming out of the paper at a right angle. C shows the azimuth patterns of the dipole for the two heights at the most-favored elevation angle, the solid-line plot for the  $\frac{1}{2}\lambda$  height at an elevation angle of 30°, and the broken-line plot for the  $1\lambda$  height at an elevation angle of 15°. The conductor in C lies along the 90° to 270° axis.

are attached. There are numerous variations, of course

The low feed point impedance of the half-wave dipole at its resonant frequency,  $f_0$ , and odd harmonics results in a low SWR when fed with coaxial cable. The feed point impedance and resulting SWR with coaxial cable or "coax" will be high at even harmonics and other frequencies.

When fed with ladder line and a wide-range impedance-matching unit, a center-fed antenna can be used on nearly any frequency, including non-resonant frequencies.

(An example of such an antenna system is presented as a project farther along in this section.) Another variation, shown in Figure 21.11B, is the *Zepp* (or *end-fed half wave*, *EFHW*) named for its original application as an antenna deployed from Zeppelin airships. The feed point impedance of a "Zepp" is quite high, requiring open-wire feed line and impedance matching techniques to deliver power effectively.

The EFHW has become popular for portable, low-power operation since it can be temporarily installed with only one support

and a short coax feed line to an impedance-matching transformer at the feed point. The EFHW can also be used as variation of the *random-wire antenna* where it is attached directly to the output of the transmitter as described later in this chapter.

A dipole can be fed anywhere along its length, although the impedance of the antenna will vary as discussed earlier. One common variation is the *off-center-fed (OCF)* dipole (Figure 21.11C) where the feed point is off-set from center by some amount and an impedance transformer matches the resulting

**Figure 21.12—** A choke or current balun (see the *Transmission Lines* chapter) is recommended at the feed point of a dipole fed by coaxial cable. The balun decouples the outer surface of the coax shield (see text). Baluns are not used with open-wire feed line.

moderately-high impedance to that of coaxial cable. The impedance transformer is usually paired with a choke balun to decouple the feed line. The OCF can also be fed with open-wire line. OCF dipoles are discussed further later in this chapter.

### 21.2.3 Feed Point Baluns

Open-wire transmission lines and centered dipole antennas are *balanced*, that is, each conductor or section has the same impedance to earth ground. This is different from *unbalanced* coaxial cable, in which the shield is generally connected to an earth ground at some point, generally at the transmitter. To use balanced open-wire transmission lines with unbalanced equipment — most amateur equipment is unbalanced — a *balun* is required to make the transition between the balanced and unbalanced parts of the antenna system. “Balun” is an abbreviation of “balanced-to-unbalanced,” the function of the device — it allows power to be transferred between the balanced and unbalanced portions of an antenna system in either direction. The most common application of baluns is to connect an unbalanced feed line to a balanced antenna. (Baluns and the related *ununs* are discussed in the *Transmission Lines* chapter.) Because dipoles are balanced, a balun is often used at the feed point when a dipole is fed with coax.

Due to the skin effect discussed in the *RF Techniques* chapter, the inside and outside of the coaxial cable shield act as separate conductors at RF. This “third conductor” of a coaxial cable unbalances the symmetry of the dipole antenna when the coax is connected directly to the dipole as shown in Figure 21.11A. As a result, RF current can flow on the outside of the cable shield to the enclosures of station equipment connected to the cable. This combination of the dipole and feed line shield is likely to have a different resonant frequency and feed point impedance than what was intended.

In order to *decouple* the coax shield from the antenna, a *choke* or *current balun* is recommended as shown in Figure 21.12. The choke balun creates a high impedance on the outside

of the coax shield while leaving currents inside the coax unaffected. See the *Transmission Lines* chapter for choke balun designs.

Shield currents can also impair the function of instruments connected to the line (such as SWR meters and SWR-protection circuits in the transmitter). The shield current also produces some feed line radiation, which changes the antenna radiation pattern, and allows objects near the cable to affect the antenna-system performance.

The consequences may be negligible: A slight skewing of the antenna pattern usually goes unnoticed. Or, they may be significant: False SWR readings may cause the transmitter to reduce power unnecessarily; radiating coax near a TV feed line may cause strong local interference from overload. Therefore, it is better to eliminate feed line radiation whenever possible, and a choke balun should be used at any transition between balanced and unbalanced systems. Even so, balanced or unbalanced systems without a balun often operate with no apparent problems. For temporary or emergency stations, do not let the lack of a balun deter you from operating.

### 21.2.4 Building Dipoles and Other Wire Antennas

The purpose of this section is to offer information on the actual physical construction of wire antennas. Because the dipole, in one of its configurations, is probably the most common amateur wire antenna, it is used in the following examples. The techniques described here, however, enhance the reliability and safety of all wire antennas.

#### WIRE

Choosing the right type of wire for the project at hand is the key to a successful antenna — the kind that works well and stays up through a winter ice storm or a gusty spring wind storm. What gauge of wire to use is the first question to settle; the answer depends on strength, ease of handling, cost, availability and visibility. Generally, antennas that are expected to support their own weight, plus

the weight of the feed line should be made from #12 AWG or larger wire. (The National Electrical Code (NEC) specifies a minimum size of #10 AWG for external antennas.) Horizontal dipoles, Zepps, some long wires and the like fall into this category. Antennas supported in the center, such as inverted-V dipoles and delta loops, may be made from lighter material, such as #14 AWG wire.

The type of wire to be used is the next important decision. The wire specifications table in the *Component Data and References* chapter shows popular wire styles and sizes. The strongest wire suitable for antenna service is *copper-clad steel*, also known as *copperweld*. The copper coating is necessary for RF service because steel is a relatively poor conductor. Practically all of the RF current is confined to the copper coating because of skin effect. Copper-clad steel is outstanding for permanent installations, but it can be difficult to work with because of the stiffness of the steel core. Kinks, abrasion, or repeated flexing can crack the copper cladding, leading to rusting of the inner steel core. Damage to the cladding can result in increased resistance and loss. Rusting of the inner core will eventually weaken the antenna. Regularly inspecting the antenna visually or checking SWR for changes can help spot problems.

Solid-copper wire, either hard-drawn or soft-drawn, is another popular material. Easier to handle than copper-clad steel, solid copper is available in a wide range of sizes. It is generally more expensive however, because it is all copper. Soft-drawn stretches under tension, so periodic pruning of the antenna may be necessary in some cases. Enamel-coated *magnet-wire* is a suitable choice for experimental antennas because it is easy to manage, and the coating protects the wire from the weather. Although it stretches under tension, the wire may be pre-stretched before final installation and adjustment. A local electric motor rebuilder might be a good source for magnet wire.

Hook-up wire, speaker wire or even ac lamp cord are suitable for temporary installations. Almost any copper wire may be used,

Figure 21.13 — (A) and (B) show examples of commercial center insulators: a dog-bone insulator and a Budwig HQ-1 insulator. (C) The correct way to attach a wire to a strain or “egg” insulator.

as long as it is strong enough for the demands of the installation.

Aluminum wire can be used for antennas, but is not as strong as copper or steel for the same diameter and soldering it to feed lines requires special techniques. Galvanized and steel wire, such as that used for electric fences, is inexpensive, but it is a much poorer conductor at RF than copper and should be avoided.

Kinking, which severely weakens wire, is a potential problem when handling any solid conductor. When uncoiling solid wire of any type — copper, steel, or aluminum — take care to unroll the wire or untangle it without pulling on a kink to straighten it. A kink is actually a very sharp twist in the wire and the wire will break at such a twist when flexed, such as from vibration in the wind.

Solid wire also tends to fail at connection or attachment points at which part of the wire is rigidly clamped. The repeated flexing from wind and other vibrations eventually causes metal fatigue and the wire breaks. Stranded wire is preferred for antennas that will be subjected to a lot of vibration and flexing. If stranded wire is not suitable, use a heavier gauge of solid wire to compensate.

### Insulated vs Bare Wire

Losses are the same (in the HF region at

least) whether the antenna wire is insulated or bare. If insulated wire is used, a 3 to 5% shortening from the length calculated for a bare wire is required to obtain resonance at the desired frequency. This is caused by the increased distributed capacitance resulting from the higher dielectric constant of the plastic insulating material compared to air. The actual length for resonance must be determined experimentally by pruning and measuring because the dielectric constant of the insulating material varies from wire to wire. Wires that might come into contact with humans or animals should be insulated to reduce the chance of shock or burns.

### INSULATORS

Wire antennas must be insulated at the ends and usually at the feed point. Commercially available insulators are made from ceramic, glass or plastic. Insulators are available from many Amateur Radio dealers. Local hardware and farm stores are other possible sources of insulators for electric fences. Ceramic or glass insulators will usually outlast the wire, so they are highly recommended for a safe, reliable, permanent installation. Figure 21.13A shows the proper way to attach a wire to a strain or “egg” insulator. Figures 21.13B and 21.13C show examples of center insulators. Figure

21.13B is popularly known as a “dog bone” insulator and is available in glass, ceramic, and plastic. The ridges are to prevent water or dust from forming a conductive path across the insulator. Figure 21.13C shows a Budwig HQ-1 insulator with a built-in SO-239 and wires for attaching to the antenna. Acceptable homemade insulators may be made from a variety of material including (but not limited to) polycarbonate sheet or rod, PVC tubing or plumbing fixtures, or fiberglass rod. Temporary or emergency antennas can even make use of stiff plastic from a discarded container or dry wood. Figures 21.14A and 21.14B show some homemade insulators. If you make your own insulators, be sure the material is sturdy enough to withstand the mechanical stress and UV-resistant to be suitable for prolonged outdoor use.

### ATTACHING FEED LINES

Most wire antennas require an insulator at the feed point. Although there are many ways to connect the feed line, there are a few things to keep in mind. If you feed your antenna with coaxial cable, you have two choices. You can install an SO-239 connector on the center insulator and use a PL-259 on the end of your coax, or you can separate the center conductor from the braid, creating a pigtail

(A)

(B)

Figure 21.14 — (A) Some ideas for homemade antenna insulators. (B) Some homemade dipole center insulators. The one in the center includes a built-in SO-239 connector. Others are designed for direct connection to the feed line. Be sure to use UV-resistant plastic for insulators.

connection, and attach the feed line directly to the antenna wire. Although it costs less to connect directly to the antenna, the use of connectors offers several advantages. (See the **Transmission Lines** chapter for more information about selecting and installing feed lines.)

Coaxial cable braid acts as a wick to soak up water. If you do not adequately seal the antenna end of the feed line, water will find its way into the braid. Water in the feed line will contaminate the braid, causing high losses and rendering the coax useless long before its normal lifetime is up. It is not uncommon for water to drip from the end of the coax inside the shack after a year or so of service if the antenna connection is not properly waterproofed. Use of a PL-259/SO-239 combination (or other connector of your choice) makes the task of waterproofing connections much easier. Another advantage to using the PL-259/SO-239 combination is that feed line replacement is much easier, should that become necessary or desirable.

Whether you use coaxial cable, ladder line, or twin lead to feed your antenna, an often-overlooked consideration is the mechanical strength of the connection. Wire antennas and feed lines tend to move a lot in the wind, and unless the feed line is attached securely, the connection will weaken with time. The resulting failure can range from a frustrating intermittent electrical connection to a complete separation of feed line and antenna. Figure 21.14B illustrates several different ways of attaching the feed line to the antenna. An idea for supporting ladder line is shown in **Figure 21.15**.

## PUTTING IT TOGETHER

If made from the right materials and installed in the clear, the dipole should give years of maintenance-free service. As you build your antenna, keep in mind that if you get it right the first time, you won't have to do it again for a long time.

Figure 21.11 shows details of antenna construction. Although a dipole is used for the examples, the techniques illustrated here apply to any type of wire antenna. **Table 21.1** shows dipole lengths for the amateur HF bands. These lengths do not include the extra wire required to attach the wire to the insulator as shown in Figure 21.11. Determine the extra amount of wire required by experimenting with the insulator you intend to use. Add twice this amount of wire to the leg lengths in Table 21.1, one extra length for each insulator. (Four such attachments are required for each dipole — two on each leg.)

Most dipoles require a little pruning to reach the desired resonant frequency due to the effects of ground and nearby conducting objects and surfaces. (See the beginning of

this section for an explanation.) Table 21.1 includes lengths based on the classic 468/f formula and on 490/f intended to be a starting length. Record the constructed length with all insulators attached. (The constructed length is measured between the ends of the loops at each

end of the wire and includes the length of any feed line-to-antenna connections.) Next, raise the dipole to the working height and find the frequency at which minimum SWR occurs. Multiply the frequency of the SWR minimum by the antenna length and divide the result by

**Figure 21.15** — A piece of cut polycarbonate can be used as a center insulator and to support a ladder-line feeder. The vertical section acts to reduce the flexing of the wires where they connect to the antenna. Tape or UV-resistant wire ties can be used to hold the line to the insulator.

the desired  $f_0$ . The result is the finished length; trim both ends equally to reach that length and you're done. For example, if you want the SWR minimum to occur at 14.1 MHz and the first attempt with a constructed length of 33.8 feet results in an SWR minimum at 13.9 MHz, the final length for the antenna is

$$33.8 \times (13.9/14.1) = 33.3 \text{ ft}$$

In determining how well your antenna will work over the long term, how well you put the pieces together is second only to the ultimate strength of the materials used. Even the smallest details, such as how you connect the wire to the insulators, contribute significantly to antenna longevity. Where wires are soldered, use only enough heat to make a good connection. Excessive heat, such as from a propane torch, can anneal the wire, weakening it at the solder point.

By using plenty of wire at the end insulators and wrapping it tightly, you will decrease the possibility of the wire pulling loose in the wind. There is no need to solder the wire once it is wrapped. There is no electrical connection here, only mechanical.

Similarly, the feed line connection at the center insulator should be made to the antenna wires after they have been secured to the insulator. This way, you will be assured of a good electrical connection between the antenna and feed line without compromising the mechanical strength. Do a good job of soldering the antenna and feed line connections. Use a heavy iron or a soldering gun (200 W is a good size to use for this job), and be sure to clean the materials thoroughly before starting the job. If possible, solder the connections at a workbench, where the best possible joints may be made. Poorly soldered or unsoldered connections will become headaches as the wire oxidizes and the electrical integrity degrades with time. Besides degrading your antenna performance, poorly made joints can even be a cause of TVI because of rectification. Spray the connections with a UV-resistant acrylic coating or use a brush-on insulation coating for waterproofing.

### ATTACHING ANTENNA SUPPORTS

If towers, masts, or buildings are available, attaching the antenna support ropes or cables is fairly straightforward. Pulleys or guides such as stainless steel or aluminum carabiners or large screw eyes rated for the expected load should be used. Counterweights or springs can be used to allow the antenna to move in the wind.

Trees are a time-honored and very common solution to holding the antenna up in the air. They present some difficulties in attaching the support rope or cable, however. The most important consideration is safety. Any time a tree support is being considered, take care to ensure that there are no power lines

at any voltage in or near the tree. The lines are not always easily visible. If a weight is propelled over or through the tree, it may fly well beyond the tree and cause the trailing line to contact power lines that way. In any case, don't become a statistic! Check the entire area around the tree for hazards.

If you can climb the tree and attach the support hardware, the main problem involves providing enough tension and flexibility to allow the supports to move with the tree during wind and storms. Climbing or hiring a tree climber can pay benefits over the long term with tree-supported antennas since a pulley and halyard can be securely attached to the tree. (More information on tree-mounting antennas can be found in the *ARRL Antenna Book*.)

If climbing is not an option, such as for a temporary or portable station or for trees not suitable for climbing, getting a line into the tree is a challenge. Hams have devised many different methods of getting a line over a branch, from the "Armstrong method" (throwing a weight such as an arborist's weight bag or a tennis ball throwing toy), to various fishing techniques, and even archery.

**Figure 21.16** — When limited space is available for a dipole antenna, the ends can be bent downward as shown at A, or back on the radiator as shown at B. The inverted-V at C can be erected with the ends bent parallel with the ground when the available supporting structure is not high enough.

Two very popular current methods are the slingshot and the compressed-air "spud gun." Both launch a small projectile attached to lightweight monofilament fishing through or over a tree. (Hint — paint the projectile a bright color so it's easy to find in brush or long grass.) That line is used to pull a length of twine or string over the branch and then the rope or cable that forms the final support. (The *QST* article "The W4SSY Spudgun" is available in this book's downloadable supplemental content and several vendors offer commercial versions of the compressed-air or slingshot launcher.)

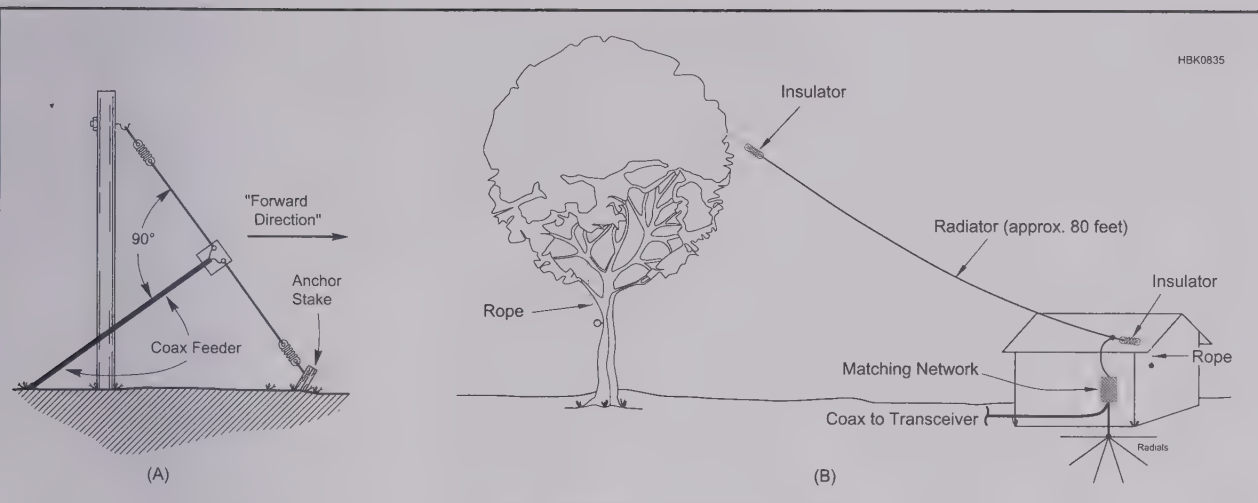

Another option is the use of an RPV (remotely-piloted vehicle) better known as a "drone." The lightest line is attached to the drone which is then piloted over the tree and back to the ground where the next line is attached as with the launcher or slingshot. Drones can rarely be flown *through* a tree, limiting line placement to the uppermost branches. This results in the highest possible support point but the branches are the smallest on the tree.

If you use a pulley, select a size that prevents the rope from slipping between the sheave and housing as the antenna and ropes move in the wind. So that the antenna stays up after installation, keep it away from tree branches and other objects that might rub or fall on the antenna. If the supports for the antenna move in the wind, such as trees, leave enough slack in the antenna that it is not pulled overly tight in normal winds. Other options are to use pulleys and counterweights to allow the antenna supports to flex without pulling on the antenna. (This and other installation topics are covered in the *ARRL Antenna Book*.)

For long spans or heavy wire antennas, it may be necessary to know the expected amount of sag across the span. There are online cable sag calculators, such as at [www.easycalculation.com/analytical/cable-sag-error.php](http://www.easycalculation.com/analytical/cable-sag-error.php). You will need to know the weight per unit length of the wire (and rope, if significant), the span to be covered, and the weight of feed line attached to the antenna. You can experiment with the tension on the support ropes to get the desired sag or enter the desired tension and calculate the resulting sag. The tables Copper Wire Specifications and Antenna Wire Strength in the **Component Data and References** chapter will be useful.

### ANTENNA SUPPORT ROPE

A good rope for holding up wire antennas with spans up to 150 or 200 feet is  $\frac{1}{4}$ -inch nylon rope, and UV-resistant  $\frac{5}{32}$ - or  $\frac{3}{16}$ -inch Dacron rope is also popular. After an installation with any new rope, it will be necessary to repeatedly take up the slack created by stretching. This process will continue over a period of several weeks, at which time most

**Figure 21.17** — At A, an example of a sloping  $\frac{1}{2} \lambda$  dipole, or *full sloper*. B shows an end-fed half-wave (EFHW) antenna that behaves similarly to the sloping dipole but is fed at one end through a matching network. Note the radials that form a counterpoise for the antenna. On the lower HF bands, maximum radiation for both antennas over poor to average earth is off the sides and in the forward direction as indicated, if a non-conductive support is used. A metal support will alter this pattern by acting as a parasitic element. How it alters the pattern is a complex issue depending on the electrical height of the mast, what other antennas are located on the mast and on the configuration of any guy wires.

of the stretching will have taken place. Even a year after installation, however, some slack may still arise from stretching.

Make certain that the rope ends will not unravel. Most supply stores will cut the length with a hot knife; that will do the best job of sealing the ends. You can do it at home by simply melting the ends with a match or cigarette lighter. An alternative is to tightly wrap a few layers of electrical tape or heat shrink tubing around the ends. Be sure to tape the ends of all your ropes to protect them.

### 21.2.5 Dipole Configuration

Dipole antennas need not be installed horizontally and in a straight line. They are generally tolerant of bending, sloping or drooping. Bent dipoles may be used where antenna space is at a premium. **Figure 21.16** shows a couple of possibilities; there are many more. Bending distorts the radiation pattern somewhat and may affect the impedance as well, but compromises may be acceptable when the situation demands them. When an antenna bends back on itself (as in **Figure 21.16B**) some of the signals are canceled; avoid this if possible. Remember that dipole antennas are RF conductors. For safety's sake, mount all antennas away from conductors (especially power lines), combustibles and well beyond the reach of passersby.

### 21.2.6 Inverted-V Dipole

An *inverted-V* dipole is supported at the center with a single support, such as a tree or mast. While *V* describes the shape of this antenna, this antenna should not be confused

with long-wire horizontal-V antennas, which are highly directive.

The inverted-V's radiation pattern and feed point impedance depend on the *apex angle* between the legs: As the apex angle decreases, so does feed point impedance, and the radiation pattern becomes less directive. At apex angles below 90°, the antenna efficiency begins to decrease, as well.

The proximity of ground to the antenna ends will lower the resonant frequency of the antenna so that a dipole may have to be shortened in the inverted-V configuration. Losses in the ground increase when the antenna ends are close to the ground. Keeping the ends eight feet or higher above ground reduces ground loss and also prevents humans and animals from coming in contact with the antenna.

Remember that antenna current produces the radiated signal, and current is maximum at the dipole center. Therefore, performance is best when the central area of the antenna is high and clear of nearby objects.

### 21.2.7 Sloping Dipole and End-Fed Half-Wave (EFHW)

A sloping dipole is shown in **Figure 21.17A**. This antenna is often used to favor one direction (the *forward direction* in the figure). With a non-conducting support and poor ground, signals off the back are somewhat weaker than those off the front. With a non-conducting mast and good ground, the response is omnidirectional.

A conductive support such as a tower can act as a parasitic element. (So does the coax

shield, unless it is routed at 90° from the antenna or decoupled with a choke balun.) The parasitic effects vary with ground quality, support height and other conductors on the support (such as a beam at the top or other wire antennas). With such variables, performance is very difficult to predict although modeling may give some insight into how the antenna will perform.

Losses increase as the antenna ends approach the support or the ground, so the same cautions about the height of the antenna ends applies as for the inverted-V antenna. To prevent feed line radiation, route the coax away from the feed point at 90° from the antenna as far as possible or use a choke balun.

**Figure 21.17B** shows a variation of the sloping dipole that has become popular for temporary and portable operation. The EFHW antenna is a sloping dipole, fed at one end. The open end is supported by a tree or mast or other convenient attachment point and the feed point is close to the ground. The feed point impedance must be transformed to a lower value so that coax can be used. A 49:1 impedance transformer (7:1 turn ratio) is a popular choice. High-ratio baluns (9:1 or 16:1) may also work. Some variations place the feed point a few feet from the end of the wire to lower the impedance and make it a little easier to match.

Regardless of whether a feed line is used or the antenna connected directly to the output of the transmitter, the EFHW requires a counterpoise or a few ground radials to work well. These conductors form part of the antenna system and will be "hot" with RF. For directly attached EFHW wires, the station equipment (and even the operator)

will be part of the antenna system as well. A variation of the EFHW that avoids the need for a counterpoise connection is described in the article “An Off-Center End-Fed Dipole for Portable Operation on 40 to 6 Meters” by Kai Siwiak in the March 2015 issue *QST*. The article is included in the downloadable supplemental content for this book.

### 21.2.8 Shortened Dipoles

Inductive loading increases the electrical length of a conductor without increasing its physical length. Therefore, we can build physically-short dipole antennas by placing inductors in the antenna. These are called *loaded dipoles*, and *The ARRL Antenna Book* includes information on how to design them. There are some trade-offs involved: Inductively loaded antennas are less efficient and have narrower bandwidths than full-size antennas. Generally they should not be shortened more than 50%. David Birnbaum, K2LYV explains the process of designing loaded dipoles that work on two bands in an article contained in this book’s downloadable supplemental information.

### 21.2.9 Half-Wave Vertical Dipole (HVD)

Unlike its horizontal counterpart, which has a figure-8 pattern, the azimuthal pattern of a vertical dipole is omnidirectional. In other words, it looks like a circle. Look again at Figures 21.7 and 21.8 and note the comparison between horizontal and vertical dipole elevation patterns. These two figures illustrate the fact that performance of a horizontal dipole depends to a great extent on its height above ground. By contrast, *half-wave vertical dipole (HVD)* performance is highly dependent on ground conductivity and dielectric constant.

Experiments by K8CH show that an HVD can compete favorably with horizontal dipole or inverted-V antennas at a similar height. The HVD only requires one main support (see the caution below on feed line orientation) which makes it a good choice for portable or temporary operation.

Figure 21.18 shows the elevation patterns for the vertical dipole and for the reference dipole at a pattern peak and at a null. The large lobe in the HVD pattern at 48° is caused by the antenna being elevated 14 feet above ground. This lobe will shrink at lower heights. The pattern of both antennas depend strongly on antenna height.

Another advantage of the HVD is its radiation resistance at low heights. Look back at Figure 21.2 at the curve for the vertical half-wave antenna. With its base just above ground, the HVD will have a radiation resistance of over 90 Ω. That can easily be turned to an advantage. Capacitive loading will lower the radiation resistance *and* shorten the antenna. It is possible to make a loaded vertical dipole that is half the height of an HVD and that has a good SWR when fed with 50 Ω coax.

One challenge to building the HVD is feed line decoupling. The feed line attached in the middle must be routed away from the antenna at right angles to prevent excessive shield current from distorting the antenna’s pattern, even if a choke balun is used. This can be mechanically challenging.

### 21.2.10 Folded Dipoles

Figure 21.19 shows a *folded dipole* constructed from open-wire transmission line. The dipole is made from a  $\frac{1}{2} \lambda$  section of open-wire line with the two conductors connected together at each end of the antenna. The top conductor of the open-wire length is continuous from end to end. The lower conductor, however, is cut in the middle and the feed line attached at that point. Open-wire transmission line is then used to connect the transmitter.

A folded dipole has exactly the same gain and radiation pattern as a single-wire dipole. However, because of the mutual coupling between the upper and lower conductors that divides antenna current equally between the conductors, the feed point impedance of a single-wire dipole is multiplied by the square of the number of conductors in the antenna. In this case, there are two conductors in the antenna, so the feed point impedance is  $2^2 = 4$  times that of a single-wire dipole. (A three-wire folded dipole would have a nine times higher feed point impedance and so forth.)

A common use of the folded dipole is to raise the feed point impedance of the antenna to present a better impedance match to high impedance feed line. For example, if a very long feed line to a dipole is required, open-wire feed line would be used. By raising the dipole’s feed point impedance, the SWR on the open-wire line is reduced from that of a single-wire dipole fed with open-wire feed line. Impedance matching to the usual 50 Ω can then be done at the transmitter.

A variation of the folded dipole called the *twin-folded terminated dipole (TFTD)* adds a resistor in the top conductor. Values of 300 to 600 Ω are used. The function of the resistor is to act as a *swamping* load, reducing the higher feed point impedances over a wide frequency range. A TFTD  $\frac{1}{2} \lambda$  long at 80 meters can be constructed to cover the entire 2 to 30 MHz range with SWR of 3:1 or less. The resistor dissipates some of the transmitter power (more

than 50% at some frequencies!), but the improvement in SWR allows a coaxial feed line to be used without an impedance-matching unit. The increased convenience and installation outweigh the reduction in radiated signal. TFTD antennas are popular for emergency communications and where only a single HF antenna can be installed and high performance is not required, such as for regional coverage via NVIS as described below.

### 21.2.11 Multiband Dipole Systems

There are several ways to construct coax-fed multiband dipole systems. These techniques apply to dipoles of all orientations. Each method requires a little more work than a single dipole, but the materials don't cost much.

#### PARALLEL (FAN) DIPOLES

Parallel dipoles (also called *fan dipoles*) as shown in **Figure 21.20** are a simple and convenient answer. Center-fed dipoles have low feed point impedances near  $f_0$  and its odd harmonics, and high impedances at other frequencies. This lets us construct simple multiband systems in which the antenna for the desired band is automatically active. Consider a 50  $\Omega$  resistor connected in parallel with a 5 k $\Omega$  resistor. A generator connected across the two resistors will see 49.5  $\Omega$ , and 99% of the current will flow through the 50  $\Omega$  resistor. When resonant and non-resonant antennas are connected in parallel, the same result occurs: The non-resonant antenna has a high impedance, so little current flows in it and it has little effect on the total feed point impedance. Thus, we can connect several dipoles together at the feed point, and power naturally flows to the resonant antenna.

There are some limits, however. Wires in close proximity tend to be strongly coupled. In parallel dipoles, this coupling means that the resonant length of the shorter dipoles lengthens a few percent. Shorter antennas don't affect longer ones much, so adjust for resonance in order from longest to shortest. Coupling also reduces the bandwidth of shorter dipoles, so an impedance-matching unit may be needed to achieve an acceptable SWR across all bands covered. These effects can be reduced by spreading the ends of the dipoles apart. (This is where the name "fan dipole" comes from.)

Also, the power-distribution mechanism requires that only one of the parallel dipoles is near resonance on any amateur band. Separate dipoles for 80 and 30 meters should not be connected in parallel because the higher band is near an odd harmonic of the lower band ( $80/3=30$ ) and center-fed dipoles have low impedance near odd harmonics. (The 40 and 15 meter bands have a similar relationship.) This means that you must either ac-

cept the performance of the low-band antenna operating on a harmonic or erect a separate antenna for those odd-harmonic bands. For example, four parallel-connected dipoles cut for 80, 40, 20 and 10 meters (fed by a single impedance-matching unit and coaxial cable) work reasonably on all HF bands from 80 through 10 meters.

#### TRAP DIPOLES

*Trap dipoles* (also called "trapped dipoles") provide multiband operation from a coax-fed single-wire dipole. **Figure 21.21** shows a two-band trap antenna. A trap consists of inductance and capacitance in parallel with a resonant frequency on the higher of the two bands of operation. The high impedance of the trap at its resonant frequency acts as a switch that effectively disconnects the wire beyond the trap. Thus, on the higher of the two bands of operation at which traps are resonant, only the portion of the antenna between the traps is active.

Above resonance, the trap presents a capacitive reactance. Below resonance, the trap is inductive. On the lower of the two bands of operation, then, the inductive reactance of the trap acts as a loading coil to create a shortened or loaded dipole with

the wire beyond the trap.

Traps may be constructed from coiled sections of coax or from discrete inductors and capacitors. (Traps are also available commercially.) Choose capacitors (C1 in the figure) that are rated for high current and voltage. Mica transmitting capacitors are good. Ceramic "doorknob" transmitting capacitors will work but be sure to use NP0 temperature coefficient parts to minimize changes in capacitance with temperature. Use large wire for the inductors to reduce loss. Any reactance ( $X_L$  and  $X_C$ ) above 100  $\Omega$  (at  $f_0$ ) will work, but bandwidth increases with reactance (up to several thousand ohms). Check trap resonance before installation. This can be done with a grid-dip meter and a receiver or with an SWR analyzer or impedance bridge.

To construct a trap antenna, build a dipole for the higher band of operation and connect the pre-tuned traps to its ends. It is fairly complicated to calculate the additional wire needed for each band, so just add enough wire to achieve  $\frac{1}{2}$ -wave resonance on the lower band of operation, pruning it as necessary. Because the inductance in each trap reduces the physical length needed for resonance, the finished antenna will be shorter than a simple  $\frac{1}{2}$   $\lambda$  dipole on the lower band.

**Figure 21.20** — Multiband antenna using paralleled dipoles, all connected to a common 50 or 75  $\Omega$  coax line. The  $\frac{1}{2}$   $\lambda$  dimensions may be either for the centers of the various bands or selected for favorite frequencies in each band. Be prepared to adjust the length of the various elements — both longer and shorter — because of interaction among them. See text.

**Figure 21.21** — Example of a trap dipole antenna. L1 and C1 can be tuned to the desired frequency by means of a grid-dip meter or SWR analyzer *before* they are installed in the antenna.

## Turn a Horizontal Antenna Vertical

An option for adding at least one more band to a flat-top or inverted-V dipole is to turn it into a flat-top T vertical antenna. (See the T and Inverted-L Antennas section.) To do this, disconnect the feed line at the ground level, short the feed line conductors together, and connect them to the transmitter as a single wire. The remaining connection to the transmitter should be connected to a ground rod (as shown), counterpoise, or system of ground radials. (The antenna system's safety ground connection is still required.) A coaxial feed line is shown but the same technique works just as well for open-wire feed lines. An antenna tuner is required for either type of feed line.

This technique often allows a dipole to be used effectively at frequencies below those at which its horizontal section is resonant. For example, a 40 meter dipole can be used this way on 160 and 80 meters.

**Figure 21.A1** — A dipole can be fed as a flat-top T vertical antenna by reconfiguring the feed line connections and exciting the antenna against ground.

### 21.2.12 NVIS Antennas

The use of very low dipole antennas that radiate at very high elevation angles has become popular in emergency communications (“emcomm”) systems. This works at low frequencies (3 to 10 MHz) that are lower than the ionosphere’s critical frequency — the highest frequency for which a signal traveling vertically will be reflected. (See the **Propagation** chapter.) The most common band for NVIS communication is 75 meters because the critical frequency is almost always above 4 MHz. 60 meters is growing in popularity and 40 meters is often useful for NVIS communication through the day.

No special antenna construction techniques are required for NVIS antennas — just build a  $\frac{1}{2} \lambda$  dipole and install it at a height of  $0.10 - 0.25 \lambda$ . Good results can be obtained above and below this range but at heights below  $0.05 \lambda$  ground losses may become significant and at increasing heights, a high-angle null develops in the antenna pattern, reducing NVIS effectiveness considerably. See the References entry for Witvliet for a recent paper on the subject.

At these low heights, the dipole’s resonant frequency will be reduced because of the effects of ground. Shorten the antenna to achieve the desired resonant frequency, although feed point impedance will drop.

### Project: Multiband Center-Fed Dipole

An 80 meter dipole fed with ladder line is a versatile antenna. If you add a wide-range matching network, you have a low-cost antenna system that works well across the entire HF spectrum, and even 6 meters. Countless hams have used one of these in single-antenna stations and for Field Day operations.

**Figure 21.22** shows a typical installation for such an antenna. The inverted-V configuration is shown, lowering the total antenna length to 130 feet from the 135 feet used if the entire antenna is horizontal. Either configuration will work well. You can use a balanced impedance-matching unit with a balun between it and the transmitter. Many amateurs are successful in using unbalanced impedance-matching units with a balun at either the output or the input of the tuner.

**Figure 21.22** — Details for an inverted-V fed with open-wire line for multiband HF operation. The included angle between the two legs should be greater than  $90^\circ$  for best performance.

Don’t be afraid to experiment!

This configuration is popular with other lengths for the antenna:

- 105 feet — 80 through 10 meters
- 88 feet — 80 through 10 meters

The next lower band may also be covered if the impedance-matching unit has sufficient range, although the adjustment will be fairly sharp. Six meter coverage is possible, but depends on the station layout, length of feed line, and impedance-matching unit abilities. Again, don’t be afraid to experiment!

For best results place the antenna as high as you can, and keep the antenna and ladder line clear of metal and other conductive objects. Despite significant SWR on some bands, the open-wire feed line keeps system losses low as described in the **Transmission Lines** chapter.

ARRL staff analyzed a 135 foot dipole at 50 feet above typical ground and compared that to an inverted-V with the center at 50 feet, and the ends at 10 feet. The results show that on the 80 meter band, it won’t make much difference which configuration you choose. The inverted-V exhibits additional losses because of its proximity to ground. (Radiation patterns are available in the downloadable supplemental information.)

Installed horizontally, or as an inverted-V, the 135 foot center-fed dipole is a simple antenna that works well from 3.5 to 30 MHz (and on 1.8 MHz if the impedance-matching unit has sufficient range). The feed line impedance at the transmitter end may be out of range for the impedance-matching unit. In such a case, add  $\frac{1}{4}$  wavelength of feed line at that frequency. This may change the impedance to a value the impedance-matching unit can handle..

## Project: 40 to 15 Meter Dual-Band Dipole

As mentioned earlier, dipoles have harmonic resonances at odd multiples of their fundamental resonances. Because 21 MHz is the third harmonic of 7 MHz, 7 MHz dipoles are harmonically resonant in the popular ham band at 21 MHz. This is attractive because it allows you to install a 40 meter dipole, feed it with coax, and use it without an antenna tuner on both 40 and 15 meters.

But there's a catch: The third harmonic resonance is actually higher than three times the fundamental resonant frequency. This is because there is no end effect in the center portion of the antenna where there are no insulators.

An easy fix for this, as shown in **Figure 21.23**, is to add capacitive loading to the antenna about  $\frac{1}{4} \lambda$  wavelength (at 21.2 MHz) away from the feed point in both halves of the dipole. Known as *capacitance hats*, the simple loading wires shown lower the antenna's resonant frequency on 15 meters without substantially affecting resonance on 40 meters. This scheme can also be used to build a dipole that can be used on 80 and 30 meters and on 75 and 10 meters. (A project for a 75 and 10 meter dipole is included with the downloadable supplemental content.)

Measure, cut and adjust the dipole to resonance at the desired 40 meter frequency. Then, cut two 2-foot-long pieces of stiff wire (such as #12 or #14 AWG house wire) and solder the ends of each one together to form two loops. Twist the loops in the middle to form figure-8s, and strip and solder the wires where they cross. Install these capacitance hats on the dipole by stripping the antenna wire (if necessary) and soldering the hats to the dipole about a third of the way out from the feed point (placement isn't critical) on each wire. To resonate the antenna on 15 meters, use an antenna analyzer to adjust the loop shapes until the SWR is acceptable in the desired segment of the 15 meter band. Conversely, you can move the hats back and forth along the antenna until the desired SWR is achieved and then solder the hats to the antenna.

**Figure 21.23** — Figure-8-shaped capacitance hats made and placed as described in the text, can make a 40 meter dipole resonate anywhere in the 15 meter band.

## Project: W4RNL Rotatable Dipole Inverted-U Antenna

This simple rotatable dipole was designed and built by L.B. Cebik, W4RNL (SK), for use during the ARRL Field Day. For this and other portable operations we look for three antenna characteristics: simplicity, small size and light weight. Today, a number of lightweight collapsible masts are available. When properly guyed, some will support antennas in the 5 to 10 pound range. Most are suitable for 10 meter tubular dipoles and allow the user to hand-rotate the antenna. Extend the range of the antenna to cover 20 through 10 meters, and you put these 20 to 30 foot masts to even better use. The inverted-U meets this need. **Figure 21.24** shows the basic kit for the antenna. Complete construction details and more information about antenna performance are available with the downloadable supplemental content.

A dipole's highest current occurs within the first half of the distance from the feed point to the outer tips. Therefore, very little performance is lost if the outer end sections are bent. The W4RNL inverted-U starts with a 10 meter tubular dipole. You add wire extensions for 12, 15, 17 or 20 meters to cover those bands.

You only need enough space to erect a

10 meter rotatable dipole. The extensions hang down. **Figure 21.25** shows the relative proportions of the antenna on all bands from 10 to 20 meters. The 20 meter extensions are the length of half the 10 meter dipole.

Not much signal strength is lost by drooping up to half the overall element length straight down. What is lost in bidirectional gain shows up in decreased side nulls. There is an undetectable decrease in gain between the 10 meter and 15 meter versions. The 20 meter version shows a little over  $\frac{1}{2}$  dB gain decrease and a signal increase off the antenna ends.

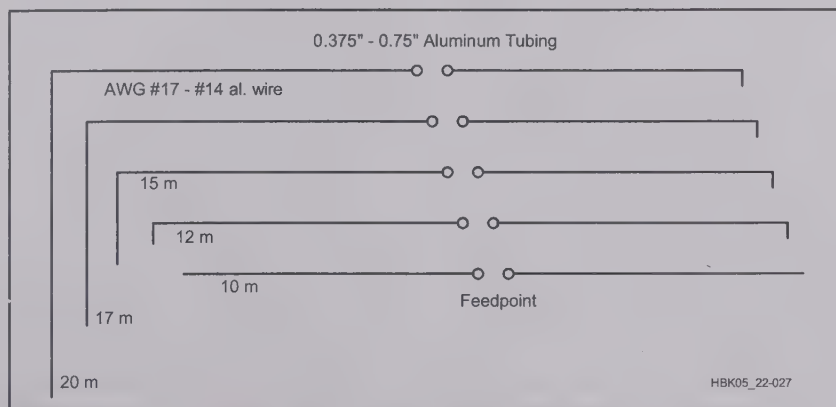

The feed point impedance of the inverted-U remains well within acceptable limits for virtually all equipment, even at 20 feet above ground. Also, the SWR curves are very broad, so it's not as critical to find exact dimensions, even for special field conditions.

Changing bands is a simple matter. Remove the extensions for the band you are using and install the ends for the new band. An SWR check and possibly one more adjustment of the end lengths will put you back on the air.

With a dipole having drooping ends, safety is very important. At any power level, the ends of a dipole have high RF voltages, and we must keep them out of contact with human

body parts. Do not use the antenna unless the wire ends for 20 meters are higher than any person can touch when the antenna is in use. Even with QRP power levels, the RF voltage on the wire ends can be dangerous. With the antenna at 20 feet at its center, the ends should be at least 10 feet above ground.

### Project: Two W8NX Multiband, Coax-Trap Dipoles

Two different antennas are described here. The first covers the traditional 80, 40, 20, 15 and 10 meter bands, and the second covers 80, 40, 17 and 12 meters. (The complete article describing these antenna projects is available as part of this book's downloadable supplemental information package.) Each uses the same type of W8NX trap — connected for different modes of operation — and a pair of short capacitive stubs to enhance coverage. The W8NX coaxial-cable traps have two different modes: a high- and a low-impedance mode. The inner-conductor windings and shield windings of the traps are connected in series for both modes. However, either the low- or high-impedance point can be used as the trap's output terminal. For low-impedance trap operation, only the center conductor turns of the trap windings are used. For high-impedance operation, all turns are used, in the conventional manner for a trap. The short stubs on each antenna are strategically sized and located to permit more flexibility in adjusting the resonant frequencies of the antenna.

#### 80, 40, 20, 15 AND 10 M DIPOLE

Figure 21.26 shows the configuration of

the 80, 40, 20, 15 and 10 meter antenna. The radiating elements are made of #14 AWG stranded copper wire. The element lengths are the wire span lengths in feet. These lengths do not include the lengths of the pigtails at the balun, traps and insulators. The 32.3-foot-long inner 40 meter segments are measured from the eyelet of the input balun to the tension-relief hole in the trap coil form. The 4.9 foot segment length is measured from the tension-relief hole in the trap to the 6 foot stub. The 16.1 foot outer-segment span is measured from the stub to the eyelet of the end insulator.

#### 80, 40, 17 AND 12 METER DIPOLE

Figure 21.27 shows the configuration of the 80, 40, 17 and 12 meter antenna. Notice that the capacitive stubs are attached immediately outboard after the traps and are 6.5 feet long, ½ foot longer than those used in the other antenna. The traps are the same as those of the other antenna, but are connected for the high-impedance parallel-resonant output mode. Since only four bands are covered by this antenna, it is easier to fine tune it to precisely the desired frequency on all bands.

### Project: Triband Dipole for 30, 17, and 12 Meters

(This antenna was originally described in the article “A Triband Dipole for 30, 17, and 12 Meters” by Zack Lau, W1VT in the Mar/Apr 2015 issue of *QEX*. A similar design by W1VT for 10, 20, and 40 meters described in the article “A Compact Multiband Dipole” from the March 2016 issue of *QST*. Both articles are available as PDF files with the

Figure 21.28 — Basic configuration of the triband dipole, consisting of a 58-foot doublet fed with 35.5 feet of 600 Ω open-wire feed line. SWR at the balun input is approximately 1.5:1 on 17 meters and 2.4:1 on 12 meters and 30 meters.

downloadable supplemental content.)

The triband dipole in Figure 21.28 is a 58 foot doublet made out of #14 THHN solid house wire fed with a 35.5 foot matching section of 600 Ω ladder line having a velocity factor of 0.91. It has modest gain over a dipole on all three of the design bands and SWR at the balun input is approximately 1.5:1 on 17 meters and 2.4:1 on 12 meters and 30 meters. These values of SWR are all easily matched to 1:1 with the auto-tuner built into many transceivers or with an external impedance matching unit.

If the antenna will be installed at a significantly different height, the length of the doublet and the open-wire feed line may have to be adjusted to obtain resonances in all three bands. The length of the 50 Ω cable feed line isn't critical.

The #14 THHN house wire has two layers of insulation: 15 mils of PVC and another 4 mils of nylon. While the nylon typically flakes off in less than a year, the antenna was modeled in *EZNEC* using an insulation thickness of 19 mils and a dielectric constant of 3.5. Changing the insulation thickness to 15 mils doesn't appreciably change the resonance points.

The somewhat low velocity factor of the open-wire line assumes it is constructed using the same insulated wire as the doublet. A spacing of 3 inches is recommended for constructing the 600 Ω open-wire line. If other wire types are used to construct the open-wire line, an accurate approximation for the impedance of air-insulated open-wire line is:

$$Z_0 = 276 \log_{10} (2S/d) \quad (5)$$

where  $S$  is the center-to-center distance between the conductors and  $d$  is the diameter of the conductors in the same units as  $S$ . ( $Z_0$  for open-wire line is discussed in detail

in the “Fundamentals” section of the Transmission Lines chapter.)

A 1:1 current or choke balun is required between the open wire feed line and the coax to prevent the outside of the coax shield from becoming a radiating antenna element and affecting feed point impedance. (See the section on Baluns and Transmission Line Transformers” in the Transmission Lines chapter.) The author recommends 11 turns of RG-58A/U on an FT-140-43 core as working well from 10 to 30 MHz. Steve Hunt, G3TXQ published an excellent balun design using 11 turns of RG-58 on a stacked pair of FT-240-52 toroids that provides a higher choking impedance which may be necessary if the antenna is to be used on other bands than 30, 17, or 12 meters where the open-wire line length does not result in a low impedance.

Assuming a height of 42 feet, on 17 meters the antenna has a clean, bidirectional pattern, with maximum gain of 8.9 dBi broadside to the wires, just like a dipole. (All antenna patterns are included in the full article.) On 30 meters, the antenna also has gain broadside to the wires of 6.9 dBi. On 12 meters the antenna has an azimuthal radiation pattern with four main lobes having 8.2 dBi gain, 90° off broadside. The broadside lobes are 1.5 dB weaker than the main lobes.

### 21.2.13 Off-Center-Fed (OCF) Dipoles

The usual practice is to feed a  $\lambda/2$  dipole at the center where the feed point impedance is low and makes a suitable match to coaxial cables. The dipole will accept energy from a feed point anywhere along its length, however, assuming that the source is matched to the higher impedance that is presented away from the center point.

The *off-center-fed* dipole takes advantage of placing the feed point in a location along the dipole at which the impedance is similar on more than one band, generally in the neighborhood of 150-300  $\Omega$ . A suitable impedance matching device such as an impedance transformer is then used to reduce the feed point impedance to something closer to 50  $\Omega$ . Note that the feed point impedance of the antenna varies with height above ground and so will SWR.

Figure 21.29 shows two off-center-fed or OCF dipoles. Because it is similar in appearance, this antenna is often mistakenly called a “Windom,” or sometimes a “coax-fed Windom.” The two antennas are not the same, since the Windom is driven against an earth ground, while the OCF dipole is fed like a

**Figure 21.29 – Off-center-fed (OCF) dipoles for use on several bands. Length A is generally  $\lambda/2$  on the lowest frequency of operation. Length B is usually approximately  $\frac{1}{3}$  of A. The impedance transformer is typically a 4:1 or 6:1 design. A feed line choke at the impedance transformer will provide feed line isolation, if desired. Feed point impedance and SWR will be affected by the antenna’s height above ground.**

regular dipole — just not at its center. The extreme case of an OCF is the end-fed Zepp where the feed point is moved all the way to the end of the antenna.

The OCF dipole, fed  $\frac{1}{3}$  of its length from one end, may be used on its fundamental and even harmonics. Its free-space antenna-terminal impedance at 3.5, 7 and 14 MHz is on the order of 150 to 200  $\Omega$ . At the 6th harmonic, 21 MHz, the antenna is three wavelengths long and fed at a voltage maximum instead of a current maximum. The feed point impedance at this frequency is high, a few thousand ohms, so the antenna is unsuitable for use on this band. OCF dipole designs for various HF bands by NT4B, K1BQT, K1LI, and KE4PT are included in the downloadable supplemental material for this chapter.

#### IMPEDANCE TRANSFORMER AND BALUN REQUIREMENTS

All OCF dipole antennas require an impedance transformer at the feed point. A 4:1 or 6:1 ratio typically provides good results. A choke balun on the feed line is also required to reduce coupling between the antenna and feed line which can affect feed point impedance. Height above ground also affects feed

point impedance — be prepared to adjust the dipole length to achieve an acceptable match on the bands to be used.

Because the OCF dipole is not fed at the center of the radiator, the feed line is not placed symmetrically with respect to the antenna’s radiated field. As a result, common-mode current will flow on the feed line, usually coaxial cable. How much current flows depends on the impedance of the coax shield’s outer surface which, in turn, depends on the orientation of the cable, how long it is, height above ground, and so forth. (Some of the common-mode current results from the slightly unequal impedances presented by the OCF legs but most of the shield current results from the feed line’s asymmetric location in the antenna’s field.)

Regardless of how the common-mode current is caused to flow on the feed line, it is generally viewed as undesirable and a current or choke balun is used to increase the impedance of coax shield’s outer surface. Radiation from the feed line may not be a problem in your installation and may even improve the antenna’s radiation pattern by filling in nulls. In that case, no choke balun is required. (Feed line chokes are discussed in the chapter Transmission Lines.)

## Antenna Modeling by Computer

Modern computer programs have made it a *lot* easier for a ham to evaluate antenna performance. The elevation plots for the 135 foot long center-fed dipole were generated using a sophisticated computer program known as *NEC*, short for "Numerical Electromagnetics Code." *NEC* is a general-purpose antenna modeling program, capable of modeling almost any antenna type, from the simplest dipole to extremely complex antenna designs. Various mainframe versions of *NEC* have been under continuous development by US government researchers for several decades.

But because it is a general-purpose program, *NEC* can be very slow when modeling some antennas — such as long-boom, multi-element Yagis. There are other, specialized programs that work on Yagis much faster than *NEC*. Indeed, *NEC* has developed a reputation for being accurate (if properly applied!), but decidedly difficult to learn and use. A number of commercial software developers have risen to the challenge and created more *user-friendly* versions such as *EZNEC* and *4nec2* which are advertised in *QST*.

*NEC* uses a *Method of Moments* algorithm. The mathematics behind this algorithm are pretty formidable to most hams, but the basic principle is simple. An antenna is broken down into a set of straight-line wire *segments*. The fields resulting from the current in each segment and from the mutual interaction between segments are vector-summed in the far field to create azimuth and elevation-plane patterns.

The most difficult part of using a *NEC*-type of modeling program is setting up the antenna's geometry — you must condition yourself to think in three-dimensional coordinates. Each end point of a wire is represented by three numbers: an *x*, *y* and *z* coordinate. An example should help sort things out. See **Figure 21.A2**, showing a *model* for a 135 foot center-fed dipole, made of #14 wire placed 50 feet above flat ground. This antenna is modeled as a single, straight wire.

For convenience, ground is located at the *origin* of the coordinate system, at (0, 0, 0) feet, directly under the center of the dipole. The dipole runs parallel to, and above, the *y*-axis. Above the origin, at a height of 50 feet, is the dipole's feed point. The *wingspread* of the dipole goes toward the left (that is, in the *negative y* direction) one-half the overall length, or -67.5 feet. Toward the right, it goes +67.5 feet. The *x* dimension of our dipole is zero. The dipole's ends are thus represented by two points, whose coordinates are: (0, -67.5, 50) and (0, 67.5, 50) feet. The thickness of the antenna is the diameter of the wire, #14 gauge.

Figure 21.A2 — Model of a 135 foot center-fed dipole.

To run the program you must specify the number of segments into which the dipole is divided for the method-of-moments analysis. The guideline for setting the number of segments is to use at least 10 segments per half-wavelength. In **Figure 21.A2**, our dipole has been divided into 11 segments for 80 meter operation. The use of 11 segments, an odd rather than an even number such as 10, places the dipole's feed point (the *source* in *NEC*-parlance) right at the antenna's center and at the center of segment number six.

Since we intend to use our 135 foot long dipole on all HF amateur bands, the number of segments used actually should vary with frequency. The penalty for using more segments in a program like *NEC* is that the program slows down roughly as the square of the segments — double the number and the speed drops to a fourth. However, using too few segments will introduce inaccuracies, particularly in computing the feed point impedance. The commercial versions of *NEC* handle such nitty-gritty details automatically.

Let's get a little more complicated and specify the 135 foot dipole, configured as an inverted-V. Here, as shown in **Figure 21.A3**, you must specify *two* wires. The two wires join at the top, (0, 0, 50) feet. Now the specification of the source becomes more complicated. The easiest way is to specify two sources, one on each end segment at the junction of the two wires. If you are using the *native* version of *NEC*, you may have to go back to your high-school trigonometry book to figure out how to specify the end points of our droopy dipole, with its 120° included angle. **Figure 21.A3** shows the details, along with the trig equations needed.

So, you see that antenna modeling isn't entirely a cut-and-dried procedure. The commercial programs do their best to hide some of the more unwieldy parts of *NEC*, but there's still some art mixed in with the science. And as always, there are trade-offs to be made — segments versus speed, for example.

However, once you do figure out exactly how to use them, computer models are wonderful tools. They can help you while away a dreary winter's day, designing antennas on-screen — without having to risk life and limb climbing an ice-covered tower. And in a relatively short time a computer model can run hundreds, or even thousands, of simulations as you seek to optimize an antenna for a particular parameter. Doesn't that sound better than trying to optimally tweak an antenna by means of a thousand cut-and-try measurements, all the while hanging precariously from your tower by a climbing harness?!

## 21.3 Vertical (Ground-Plane) Antennas

One of the more popular amateur HF antennas is the *vertical*. It usually refers to a single radiating element erected vertically over a *ground plane* of radial wires. A typical vertical is an electrical  $\frac{1}{4} \lambda$  long and is constructed of wire or tubing. The vertical antenna is more accurately named the ground plane because the conductive surface (the ground plane) creates a path for return currents to the feed point, effectively creating the “missing half” of a  $\frac{1}{2} \lambda$  antenna. Another name for this type of antenna is the *monopole* (sometimes *unipole*).

The ground plane can be a solid, conducting surface, such as a vehicle body at VHF/UHF mobile antenna. At HF, this is impractical and systems of *ground radials* are used; wires laid out on the ground radially from the base of the antenna. One conductor of the feed line is attached to the vertical radiating element of the antenna and the remaining conductor is attached to the ground plane. The radial wires form a *ground screen* that gives the return currents a low-resistance path instead of flowing through lossy soil.

Single vertical antennas are omnidirectional radiators. This can be beneficial or detrimental, depending on the situation. On transmission there are no nulls in any direction, unlike most horizontal antennas. However, QRM on receive can't be nulled out from the directions that are not of interest unless multiple verticals are used in an array.

Ground-plane antennas need not be mounted vertically. A ground-plane antenna can operate in any orientation as long as the ground plane is perpendicular to the radiating element. Other considerations, such as minimizing cross-polarization between stations, may require a specific mounting orientation though. In addition, due to the size of HF antennas, mounting them vertically is usually the most practical solution.

A vertical antenna can be mounted at the Earth's surface, in which case it is a *ground-mounted vertical*. The ground plane is then constructed on the surface of the ground. A vertical antenna and the associated ground plane can also be installed above the ground. This often reduces ground losses, but it is more difficult to install the necessary number of radials. *Ground-independent* verticals are often mounted well above the ground because their operation does not rely on a ground plane.

### 21.3.1 Ground Systems

When compared to horizontal antennas, verticals also suffer more acutely from two main types of losses — *ground return losses* for currents in the near field, and *far-field*

*ground losses*. Ground losses in the near field can be minimized by using many ground radials. This is covered in the sidebar, “Optimum Ground Systems for Vertical Antennas.”

Far-field losses are highly dependent on the conductivity and dielectric constant of the soil around the antenna, extending out as far as 100 wavelengths from the base of the antenna. There is very little that someone can do to change the character of the ground that far away — other than moving to a small island surrounded by saltwater! Far-field losses greatly affect low-angle radiation, causing the radiation patterns of practical vertical antennas to fall far short of theoretical patterns over *perfect ground*, often seen in classical texts.

Figure 21.30 shows the elevation pattern response for two different 40 meter quarter-

Figure 21.30 — Elevation patterns for two quarter-wave vertical antennas over different ground. One vertical is placed over perfect ground, and the other is placed over average ground. The far-field response at low elevation angles is greatly affected by the quality of the ground — as far as 100  $\lambda$  away from the vertical antenna.

Figure 21.31 — Radiation resistance (solid curve) and reactance (dotted curve) of vertical antennas as a function of their electrical height.

wave verticals. One is placed over a theoretical infinitely large, infinitely conducting ground. The second is placed over an extensive radial system over average soil, having a conductivity of 5 mS/m and a dielectric constant of 13. This sort of soil is typical of heavy clay found in pastoral regions of the US mid-Atlantic states. At a 10° elevation angle, the real antenna losses are almost 6 dB compared to the theoretical antenna; at 20° the difference is about 3 dB. See *The ARRL Antenna Book* chapter on the effects of ground for further details.

While real verticals over real ground are not a magic method to achieve low-angle radiation, cost versus performance and ease of installation are incentives that inspire many antenna builders. For use on the lower frequency amateur bands — notably 160 and 80 meters — it is not always practical to erect a full-size vertical. At 1.8 MHz, a full-sized quarter-wave vertical is 130 feet high. In such instances it is often necessary to accept a shorter radiating element and use some form of loading.

Figure 21.31 provides curves for the physical height of verticals in wavelength versus radiation resistance and reactance. Although the plots are based on perfectly conducting ground, they show general trends for installations where many radials have been laid out to make a ground screen. As the radiator is made shorter, the radiation resistance decreases — with 6  $\Omega$  being typical for a 0.1  $\lambda$  high antenna. The lower the radiation resistance, the more the antenna efficiency depends on ground conductivity and the effectiveness of the ground screen. Also, the bandwidth decreases markedly as the length is reduced toward the left of the scale in Figure 21.31. It can be difficult to develop suitable matching networks when radiation resistance is very low.

Generally a large number of shorter radials results in a better ground system than a few longer ones. For example, eight  $\frac{1}{4} \lambda$  radials are preferred over four  $\frac{1}{4} \lambda$  radials. Optimum radial lengths are described in the sidebar.

The conductor size of the radials is not especially significant. Wire gauges from #4 to #20 AWG have been used successfully by amateurs. Copper wire is preferred, but where soil is low in acid (or alkali), aluminum wire can be used. The wires may be bare or insulated, and they can be laid on the earth's surface or buried a few inches below ground. Insulated wires will have greater longevity by virtue of reduced corrosion and dissolution from soil chemicals.

When property dimensions do not allow a classic installation of equally spaced radial wires, they can be placed on the ground as space permits. They may run away from the antenna in only one or two compass directions. They may be bent to fit on your property. Hardware cloth and chicken wire are also quite effective, although the galvanizing must be of high-quality to prevent rapid rusting.

A single ground rod, or group of them bonded together, is seldom as effective as a collection of random-length radial wires. (A ground rod at the vertical's base should be used for lightning protection.)

All radial wires should be connected together at the base of the vertical antenna. The electrical bond needs to be of low resistance. Best results will be obtained when the wires are soldered together at the junction point. When a grounded vertical is used, the ground wires should be affixed securely to the base of the driven element.

Ground return losses are lower when vertical antennas and their radials are elevated above ground, a point that is well-known by those using ground plane antennas on their roofs. Even on 160 or 80 meters, effective vertical antenna systems can be made with as few as four  $\frac{1}{4} \lambda$  long radials elevated 10 to 20 feet off the ground.

### 21.3.2 Full-Size Vertical Antennas

When it is practical to erect a full-size  $\frac{1}{4} \lambda$  vertical antenna, the forms shown in **Figure 21.32** are worthy of consideration. The example at A is the well-known *vertical ground plane*. The ground system consists of four above-ground radial wires. The length of the driven element and  $\frac{1}{4} \lambda$  radials is derived from the standard equation

$$L(\text{ft}) = 234 / f(\text{MHz}) \quad (6)$$

With four equidistant radial wires drooped at approximately  $30^\circ$  (Figure 21.32A), the feed point impedance is roughly  $50 \Omega$ . When the radials are at right angles to the radiator (Figure 21.32B) the impedance approaches  $36 \Omega$ .

Besides minimizing ground return losses, another major advantage in this type of vertical antenna over a ground-mounted type is that the system can be elevated well above nearby conductive objects (power lines, trees, buildings and so on). When drooping radials are used, they can also serve as guy wires for the mast that supports the antenna. The coax shield braid is connected to the radials, and the center conductor to the driven element.

The *Marconi* vertical antenna shown in **Figure 21.32C** is the classic form taken by a ground-mounted vertical. It can be grounded

at the base and *shunt fed*, or it can be isolated from ground, as shown, and *series fed*. As always, this vertical antenna depends on an effective ground system for efficient performance. If a perfect ground were located below the antenna, the feed impedance would be near  $36 \Omega$ . In a practical case, owing to imperfect ground, the impedance is more likely to be in the vicinity of  $50 \Omega$ .

Vertical antennas can be longer than  $\frac{1}{4} \lambda$ , too;  $\frac{3}{8} \lambda$ ,  $\frac{1}{2} \lambda$ , and  $\frac{5}{8} \lambda$  verticals can

all be used with good results, although none will present a  $50 \Omega$  feed point impedance at the base. Non-resonant lengths have become popular for the same reasons as non-resonant horizontal antennas; when fed with low-loss feed line and a wide-range impedance matching unit, the antenna can be used on multiple bands. Various matching networks, described in the **Transmission Lines** chapter, can be employed. Antenna lengths above  $\frac{1}{2} \lambda$  are not recommended because the radiation pattern

## Optimum Ground Systems for Vertical Antennas

A frequent question brought up by old-timers and newcomers alike is: "So, how many ground radials do I *really* need for my vertical antenna?" Most hams have heard the old standby tales about radials, such as "if a few are good, more must be better" or "lots of short radials are better than a few long ones."

John Stanley, K4ERO, eloquently summarized a study he did of the professional literature on this subject in his article "Optimum Ground Systems for Vertical Antennas" in December 1976 *QST*. His approach was to present the data in a sort of "cost-benefit" style in **Table 21.A**, reproduced here. John somewhat wryly created a new figure of merit — the total amount of wire needed for various radial configurations. This is expressed in terms of wavelengths of total radial wire.

**Table 21.A**  
Optimum Ground-System Configurations

Configuration Designation	A	B	C	D	E	F
Number of radials	16	24	36	60	90	120
Length of each radial in wavelengths	0.1	0.125	0.15	0.2	0.25	0.4
Spacing of radials in degrees	22.5	15	10	6	4	3
Total length of radial wire installed, in wavelengths	1.6	3	5.4	12	22.5	48
Power loss in dB at low angles with a quarter-wave radiating element	3	2	1.5	1	0.5	0*
Feed point impedance in ohms with a quarter-wave radiating element	52	46	43	40	37	35

Note: Configuration designations are indicated only for text reference.

\*Reference. The loss of this configuration is negligible compared to a perfectly conducting ground.

The results almost jumping out of this table are:

- If you can only install 16 radials (Case A), they needn't be very long —  $0.1 \lambda$  is sufficient. You'll use  $1.6 \lambda$  of radial wire in total, which is about 450 feet at 3.5 MHz.
- If you have the luxury of laying down 120 radials (Case F), they should be  $0.4 \lambda$  long, and you'll gain about 3 dB over the 16 radial case. You'll also use  $48 \lambda$  of total wire — For 80 meters, that would be about 13,500 feet!
- If you can't put out 120 radials, but can install 36 radials that are  $0.15 \lambda$  long (Case C), you'll lose only 1.5 dB compared to the optimal Case F. You'll also use  $5.4 \lambda$  of total wire, or 1,500 feet at 3.5 MHz.
- A  $50 \Omega$  SWR of 1:1 isn't necessarily a good thing — the worst-case ground system in Case A has the lowest SWR.

Table 21.A represents the case for "Average" quality soil, and it is valid for radial wires either laid on the ground or buried several inches in the ground. Note that such ground-mounted radials are detuned because of their proximity to that ground and hence don't have to be the classical quarter-wavelength that they need to be in "free space."

In his article John also made the point that ground-radial losses would only be significant on transmit, since the atmospheric noise on the amateur bands below 30 MHz is attenuated by ground losses, just as actual signals would be. This limits the ultimate signal-to-noise ratio in receiving.

So, there you have the tradeoffs — the loss in transmitted signal compared to the cost (and effort) needed to install more radial wires. You take your pick.

begins to break up into more than one lobe, developing a null at the horizon at  $1\lambda$ .

A gamma-match feed system for a grounded  $\frac{1}{4}\lambda$  vertical is presented in Figure 21.32D. (The gamma match is also discussed in the **Transmission Lines** chapter.) Some rules of thumb for arriving at workable gamma-arm and capacitor dimensions are to make the rod length  $0.04$  to  $0.05\lambda$ , its diameter  $\frac{1}{2}$  to  $\frac{1}{2}$  that of the driven element and the center-to-center spacing between the gamma arm and the driven element roughly  $0.007\lambda$ . The capacitance of  $C1$  at a  $50\Omega$  matched condition will be about  $7\text{ pF}$  per meter of wavelength. The absolute value of  $C1$  will depend on whether the vertical is resonant and on the precise value of the radiation resistance. For best results, make the radiator approximately  $3\%$  shorter than the resonant length.

Amateur antenna towers lend themselves to use as shunt-fed verticals, even though an HF-band beam antenna is usually mounted on the tower. The overall system should be close to resonance at the desired operating frequency if a gamma feed is used. The HF-band beam will contribute somewhat to *top loading* of the tower. The natural resonance of such a system can be checked by dropping a #12 or #14 AWG wire from the top of the tower (connecting it to the tower top) to form a folded monopole (Figure 21.32E). A four- or five-turn link can be inserted between the lower end of the drop wire and the ground system. A dip meter is then inserted in the link or an antenna analyzer coupled to the link to determine the resonant frequency. Shunt feeding towers is discussed extensively in the *ARRL Antenna Book* and in ON4UN's *Low Band DXing*.

If the tower is equipped with guy wires, they should be broken up with strain insulators to prevent unwanted loading of the vertical. In such cases where the tower and beam antennas are not able to provide  $\frac{1}{4}\lambda$  resonance, portions of the top guy wires can be used as top-loading capacitance. Experiment with the guy-wire lengths (using the dip-meter technique) while determining the proper dimensions. Modeling can save a lot of time in this part of the design.

A folded-monopole is depicted in Figure 21.32E. This system has the advantage of increased feed point impedance. Furthermore, an impedance-matching unit can be connected between the bottom of the drop wire and the ground system to permit operation on more than one band. For example, if the tower is resonant on 80 meters, it can be used as shown on 160 and 40 meters with reasonable results, even though it is not electrically long enough on 160 to act as a full-size antenna. The drop wire need not be a specific distance from the tower, but you might try spacings between 12 and 30 inches.

The method of feed shown at Figure

Figure 21.32 — Various types of vertical antennas.

Figure 21.33 — Vertical antennas that are less than one-quarter wavelength in height.

21.32F is commonly referred to as *slant-wire feed*. The guy wires and the tower combine to provide quarter-wave resonance. A matching network is placed between the lower end of one guy wire and ground and adjusted for an SWR of 1:1. It does not matter at which level on the tower the guy wires are connected, assuming that the impedance-matching unit is capable of effecting a match to 50  $\Omega$ .

### 21.3.3 Physically Short Verticals

A group of short vertical radiators is presented in **Figure 21.33**. Illustrations A and B are for top and center loading. A capacitance hat is shown in each example. The hat should be as large as practical to increase the radiation resistance of the antenna and improve the bandwidth. The wire in the loading coil is chosen for the largest gauge consistent with ease of winding and coil-form size. The larger wire diameters will reduce the resistive ( $I^2R$ ) losses in the system. The coil-form material should have a medium or high dielectric constant. Phenolic or fiberglass tubing is entirely adequate.

A base-loaded vertical is shown at C of **Figure 21.33**. The primary limitation is that the high current portion of the vertical exists in the coil rather than the driven element. With center loading, the portion of the antenna below the coil carries high current, and in the top-loaded version the entire vertical element carries high current. Since the high-current part of the antenna is responsible for most of the radiating, base loading is the least effective of the three methods. The radiation resistance of the coil-loaded antennas shown is usually less than 16  $\Omega$ .

A method for using guy wires to top load a short vertical is illustrated in **Figure 21.33D**. This system works well with gamma feed. The loading wires are trimmed to provide an electrical quarter wavelength for the overall system. This method of loading will result in a higher radiation resistance and greater bandwidth than the systems shown at A through C. If an HF or VHF array is at the top of the tower, it will simply contribute to the top loading.

A three-wire monopole is shown in **Figure 21.33E**. Two #8 AWG drop wires are connected to the top of the tower and brought to ground level. The wires can be spaced any convenient distance from the tower — normally 12 to 30 inches from the sides. C1 is adjusted for best SWR. This type of vertical has a fairly narrow bandwidth, but because C1 can be motor driven and controlled from the operating position, frequency changes can be accomplished easily. This technique will not be suitable for matching to 50  $\Omega$  line unless the tower is less than an electrical quarter wavelength high.

A different method for top loading is shown

in **Figure 21.33F**. Barry Boothe, W9UCW, described this method in December 1974 *QST*. An extension is used at the top of the tower to create an electrical quarter-wavelength vertical. L1 is a loading coil with sufficient inductance to provide antenna resonance. This type of antenna lends itself to operation on 160 meters.

### Project: Top-Loaded Low-Band Antenna

The short, top-loaded vertical antenna described here by Dick Stroud, W9SR, is of interest to hams with limited space or who are portable operators. It has been used on 40, 80 and 160 meters. The antenna uses a single 10 foot TV mast section for the vertical radiator, along with a capacitance hat, loading coil and short top mast. The overall height is less than 15 feet, as seen in **Figure 21.34**. The capacitance hat and loading coil assembly can be used with longer vertical radiators with changes to the coil inductance. A drawing showing complete dimensions and construction details is available with the downloadable supplemental content.

#### CAPACITANCE HAT

The capacitance hat consists of a hub that mounts to the top mast above the coil and six elements made from aluminum rod. The machining, drilling and tapping of the hub assembly can be done by nearly any machine shop if you don't have the facilities. Be sure to use stainless steel hardware throughout. (Thanks to Fred Gantzer, WØAWD, for building the original hub.)

The hub is made of two pieces of ½ inch thick aluminum as shown in **Figure 21.35**. The two pieces are bolted together to form the hub, which slides over the 1½ inch top mast. It is held in place with three 10-32 screws. The six elements of the capacitance hat are made from ⅜ inch aluminum rod,

**Figure 21.34** — W9SR's short vertical uses top loading and a capacitance hat with a 10 foot TV mast to make a compact antenna for 160, 80 or 40 meters.

each 4.5 feet long. These are held in place with 6-32 screws.

#### LOADING COIL

The coil form is made from fiberglass tubing. A 6 inch length of 1.25 inch OD fiberglass tubing is centered over a 10 inch length of 1 inch OD tubing. The tubes telescope tightly and it may be necessary to lightly sand the smaller tube for a smooth fit.

The loading coil is wound on the 1.25 inch OD fiberglass tube. After the coil is optimized, it is covered with a length of shrink sleeving for weather protection. Coil winding information in the drawing in the downloadable supplemental content is for use with a 10 foot mast.

The bottom section of the coil assembly fits directly into the tapered upper section of the TV mast and the exposed upper fiberglass section of the coil assembly fits into a 2.5 foot long, 1.125 inch OD, aluminum upper mast. Stainless 8-32 screws join the pieces together and also provide a connection point for the loading coil wires. If you use a painted steel mast, be sure to remove paint from the connection point, and then weather-seal it after adjustment is complete.

The capacitance hat hub slides over the upper mast and is held in place with three

screws. The hub is about 6 inches above the coil, but the location can be moved to change the resonance of the antenna slightly.

The completed capacitance hat and loading coil assembly are shown in Figure 21.35. A dab of Glyptal (exterior varnish or Loctite also works) locks the screws in place once adjustments have been made and the antenna is ready for installation.

The coaxial feed line attaches to the bottom of the TV mast. Again, use an 8-32 screw for attachment and clean any paint from the metal. To match the antenna to a 50 Ω transmission line, a small parallel (shunt) inductance is needed at the base. The inductor is air-wound with #16 AWG wire (see Table 21.2).

### MOUNTING THE ANTENNA

A glass beverage bottle serves well as the base insulator, with the neck of the bottle fitting snugly into the TV mast. To support the base insulator, drill a hole large enough to accept the base of the bottle in the center of a 2 × 6 board about 14 inches long. Nail a piece of 1/4 inch plywood over the bottom to keep the bottle from slipping through. To keep the base support board from moving around, drill a couple of holes and secure it to the ground with stakes.

The antenna is top-heavy and will need to be guyed. A simple insulated guy ring can be made from a 2 inch PVC coupling and placed on the mast just below the loading coil. The PVC is locked to the mast with three 1/4-20 bolts. They are 1 inch long and have nuts on the inside and outside of the PVC. Three 1/4 inch holes are drilled for the guy lines, made from lengths of 3/8 inch nonabsorbent rope.

### OPERATION

On-air results with a 10 foot mast have been very good, even with low power. The ground system for the early tests was nothing more than an 8 foot ground rod hammered into Hoosier soil. With this setup, and using about 90 W, many DX contacts were made over one week's time and stateside contacts were plentiful.

There is plenty of room to experiment however. Performance could be improved by using an extended radial system or raised and insulated radials. (Expect much better performance over average ground with a system of radials) Two, or even three, mast

sections could be used with additional guys and proper loading coil inductance. If you use multiple masts, be sure to make a good electrical connection at the joints. The upper assembly is now permanently used to top load a 60 foot pole for transmitting on 160 meters.

### 21.3.4 Cables and Control Wires on Towers

Most vertical antennas of the type shown in Figure 21.32 and 21.33C-E consist of towers, usually with HF or VHF beam antennas at the top. The rotator control wires and the coaxial feeders to the top of the tower will not affect antenna performance adversely. In fact, they become a part of the composite antenna. To prevent unwanted RF currents from following the wires into the shack, simply dress them close to the tower legs and bring them to ground level. (Running the cables inside the tower works even better.) This decouples the wires at RF. The wires should then be routed along the earth surface (or buried underground) to the operating position. It is not necessary to use bypass capacitors or RF chokes in the rotator control leads if this is done, even when maximum legal power is employed.

### 21.3.5 Multiband Trap Verticals

The two-band trap vertical antenna of Figure 21.36 operates in much the same manner as a trap dipole or trap Yagi. The notable difference is that the vertical is one-half of a dipole. The radial system (in-ground or above-ground) functions as a ground plane for the antenna, and provides an equivalent for the missing half of the dipole. Once again, the more effective the ground system, the better will be the antenna performance.

Trap verticals usually are designed to work as 1/4 λ radiators. The portion of the antenna below the trap is adjusted as a 1/4 λ radiator at the higher proposed operating frequency. That is, a 20/15 meter trap vertical would be a resonant quarter wavelength at 15 meter from the feed point to the bottom of the trap. The trap and that portion of the antenna above the trap (plus the 15 meter section below the trap) constitute the complete antenna during 20 meter operation. But because the trap is in the circuit, the overall physical length of the vertical antenna will be slightly less than that of a single-band, full-size 20 meter vertical.

"Ground-independent" multiband vertical antennas also have traps, but are designed to be electrically longer than 1/4 λ. A common electrical length, is 3/8 λ, for example. The "traps" in these antennas are generally not parallel-LC circuits as described above. A variety of techniques are used with both parallel-LC traps and short resonant structures similar to stubs being used to change the antenna's electrical length at different frequencies.

Figure 21.36 — A two-band trap vertical antenna. The trap should be resonated by itself as a parallel resonant circuit at the center of the operating range for the higher frequency band. The reactance of either the inductor or the capacitor range from 100 to 300 Ω. At the lower frequency the trap will act as a loading inductor, adding electrical length to the total antenna.

### TRAPS

The trap functions as the name implies: the high impedance of the parallel resonant circuit "traps" the 15 meter energy and confines it to the part of the antenna below the trap. (See the **Electrical Fundamentals** chapter for more information on resonant LC circuits.) During 20 meter operation it allows the RF energy to reach all of the antenna. The trap in this example is tuned as a parallel resonant circuit to 21 MHz. At this frequency it electrically disconnects the top section of the vertical from the lower section because it presents a high impedance at 21 MHz, blocking 21 MHz current. Generally, the trap inductor and capacitor have a reactance of 100 to 300 Ω. Within that range it is not critical.

The trap is built and adjusted separately from the antenna. It should be resonated at the center of the portion of the band to be operated. Thus, if one's favorite part of the 15 meter band is between 21.0 and 21.1 MHz, the trap should be tuned to 21.05 MHz.

Resonance is checked by using a dip meter and detecting the signal in a calibrated receiver. An SWR analyzer can also be used. Once the trap is adjusted it can be installed

in the antenna, and no further adjustment will be required. It is easy, however, to be misled after the system is assembled: Attempts to check the trap resonance in the antenna will suggest that the trap has moved much lower in frequency (approximately 5 MHz lower in a 20/15 meter vertical). This is because the trap is now part of the overall antenna, and the resultant resonance is that of the total antenna. Measure the trap's resonant frequency separately from the rest of the antenna.

Multiband operation is quite practical by using the appropriate number of traps and tubing sections. The construction and adjustment procedure is the same, regardless of the number of bands covered. The highest frequency trap is always closest to the feed end of the antenna, and the lowest frequency trap is always the farthest from the feed point. As the operating frequency is progressively lowered, more traps and more tubing sections become a functional part of the antenna.

Traps should be weatherproofed to prevent moisture from detuning them. Several coatings of high dielectric compound are effective, such as polystyrene QDope or insulating varnish (see the article on weatherproofing by Dick Sander, K5QY, included with the downloadable supplemental content). Alternatively, a protective sleeve of heat-shrink tubing can be applied to the coil after completion. The coil form for the trap should be of high insulating quality and be rugged enough to sustain stress during periods of wind.

## 21.4 T and Inverted-L Antennas

The T and inverted L are variations on the vertical antenna. **Figure 21.37** shows a flat-top T vertical. The T is basically a shortened  $\frac{1}{4} \lambda$  vertical with the flat-top T section acting as capacitive loading to length the antenna electrically. Dimension H should be as large as possible (up to  $\frac{1}{4} \lambda$ ) for best results. The horizontal section, L, is adjusted to a length that provides resonance. Maximum radiation is polarized vertically despite the horizontal top-loading wire because current in each horizontal half creates out-of-phase radiation that cancels.

A variation of the T antenna is depicted in **Figure 21.38**. This antenna is commonly referred to as an *inverted-L* and is basically a  $\frac{1}{2} \lambda$  vertical bent in the middle so that the top section runs parallel to the ground. Similarly to the T antenna, the vertical section should be as long as possible. L is then added to provide an electrical  $\frac{1}{2} \lambda$  overall.

Because the horizontal section does carry some current, there will be some horizontally-polarized radiation at high angles. This is often considered desirable because it provides local and regional coverage. The horizontal section need not be perfectly horizontal — sloping the wire at a shallow angle from horizontal does not greatly affect antenna performance. This allows the inverted-L to be constructed

with a single vertical support.

A sidearm or a length of line attached to a tower can be used to support the vertical section of the T or inverted-L antenna. (Keep the vertical section of the antennas as far from the tower as is practical. Certain combinations of tower height and top loading can create a resonance that interacts severely with the antennas — a 70 foot tower and a 5-element Yagi, for example.)

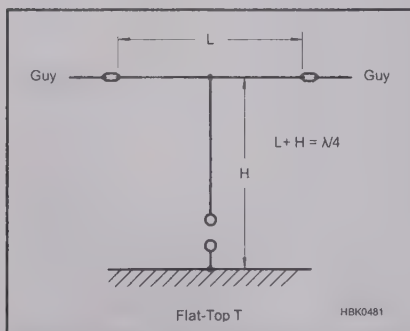

Both the T and inverted-L antennas are ground-plane antennas and require a good ground system to be effective. If the T or inverted-L are used with a very good ground system, the feed-point impedance will approach 35 to 40  $\Omega$  so that the SWR approaches 1.4:1. The inverted-L or T can be constructed to be longer than needed for resonance as illustrated in **Figure 21.38**. This increases the feed point resistance increases to 50  $\Omega$  plus some inductive reactance due to the extra

length. A series capacitor at the feed point then cancels the reactance, leaving a 50  $\Omega$  impedance suitable for direct connection by coaxial cable. **Table 21.3** provides values of capacitance for some combinations of vertical and horizontal height. A transmitting variable capacitor is recommended to allow the impedance match to be tuned.

# 21.5 Slopers and Vertical Dipoles

## 21.5.1 Half-Sloper Antenna

Many hams have had excellent results with *half-sloper* antennas, while others have not had such luck. Investigations by ARRL Technical Advisor John S. Belrose, VE2CV, have brought some insight to the situation through computer modeling and antenna-range tests. The following is taken from VE2CV's Technical Correspondence in Feb 1991 *QST*, pp 39 and 40. Essentially, the half-sloper is a top-fed vertical antenna that uses the structure at the top of the tower plane (such as a grounded Yagi antenna) as a ground plane and the tower acts as a reflector. See Figure 21.39.

For half-slopers, the input impedance, the resonant length of the sloping wire and the antenna pattern all depend on the tower height, the angle (between the sloper and tower) the type of Yagi and the Yagi orientation. Here are several configurations extracted from VE2CV's work:

**At 160 meters** — a 40 meter beam on top of a 95 foot tower with a 55° sloper apex angle. The radiation pattern varies little with Yagi type. The pattern is slightly cardioid with about 8 dB front-to-back ratio at a 25° takeoff angle (see Figure 21.39B and C).

Input impedance is about 50 Ω.

**At 80 meters** — a 20 meter beam on top of a 50 foot tower with a 55° sloper apex angle. The radiation pattern and input impedance are similar to those of the 160 meter half-sloper.

**At 40 meters** — a 20 meter beam on top of a 50 foot tower with a 55° sloper apex angle. The radiation pattern and impedance depend strongly on the azimuth orientation of the Yagi. Impedance varies from 76 to 127 Ω depending on Yagi direction.

There are many configurations that will produce a reasonable feed point impedance and acceptable radiation pattern. Experimentation is usually required to find a design that works for a particular installation.

### Project: Half-Wave Vertical Dipole (HVD)

Chuck Hutchinson, K8CH, describes a 15 meter vertical dipole (HVD) that he built for the ARRL book, *Simple and Fun Antennas for Hams*. The performance of this antenna, with its base at 14 feet, compares favorably with a horizontal dipole at 30 feet when making intercontinental QSOs.

### CONSTRUCTION OF A 15 METER HVD

The 15 meter HVD consists of four 6 foot lengths of 0.875 inch aluminum tube with 0.058 wall thickness. In addition there are two 1 foot lengths of 0.75 inch tubing for splices, and two 1 foot lengths of 0.75 inch fiberglass rod for insulators. See Table 21.4 for dimensions.

Start by cutting off 1 foot from a 6 foot length of 0.875 inch tubing. Next, insert six inches of one of the 1-foot-long 0.75 inch tubes into the machine-cut end of your tubing and fasten the tubes together. Now, slide an end of a 6 foot length of 0.875 tube over the

**Table 21.4**  
HVD Dimensions

Length using 0.875-inch aluminum tubing

MHz	Feet	Inches
18.11	33	11
21.2	22	0
24.94	18	9
28.4	16	5

These lengths should be divided by two to determine the length of the dipole legs

**Figure 21.39** — The half-sloper antenna (A). B is the vertical radiation pattern in the plane of a half sloper, with the sloper to the right. C is the azimuthal pattern of the half sloper (90° azimuth is the direction of the sloping wire). Both patterns apply to 160 and 80 meter antennas described in the text.

**Figure 21.40** — Element splice uses a 1 foot length of 0.75 inch tubing inserted into the 0.875 inch sections to join them together. Self-tapping sheet-metal screws are used in this photo, but aluminum pop rivets or machine screws with washers and nuts can be used.

protruding end of the 0.75 tube and fasten them together. Repeat this procedure with the remaining 0.875 inch tubing.

You should now have two 11-foot-long elements. As you can see in **Figure 21.40**, K8CH was temporarily out of aluminum pop rivets, so he used sheet metal screws. Either will work fine, but pop rivets can easily be drilled out and the antenna disassembled if you ever want to make changes.

Because hand-made cuts are not perfectly square, put those element ends at the center of the antenna. Slip these cut ends over the ends of a 1 foot length of 0.75 inch fiberglass rod. This rod serves as the center insulator. Leave about a 1 inch gap at the center. Drill aluminum and fiberglass for #8 hardware as shown in **Figure 21.41**.

Now, slip half of the remaining 1 foot length of 0.75 inch fiberglass rod into one end of the dipole. (This end will be the bottom end or base.) Drill and secure with #8 hardware. See **Figure 21.42**.

The final step is to secure the guy wires to your vertical. You can see how K8CH did that in **Figure 21.43**. Start by drilling a pilot hole and then drive a sheet metal screw into the antenna about a foot above the center. The purpose of that screw is to prevent the clamp and guys from sliding down the antenna.

The guys are continuous lengths of  $\frac{3}{16}$  inch Dacron line. (The Dacron serves a dual purpose: it supports the antenna vertically, and it acts as an insulator.) Tie secure knots into the guy ends and secure these knotted ends to the antenna with a stainless-steel worm-screw-type hose clamp. Take care to not over tighten the clamps. You don't want the clamp to slip (the knots and the sheet-metal screw will help), but you especially don't want to cut your guy lines. Your antenna is ready for installation.

## INSTALLATION

Installation requires two things. First, a place to sit or mount the base insulator. Second, you need anchors for the support guys.

K8CH used a piece of 2 × 6 lumber to make a socket to hold the HVD base securely

in place. He drilled a  $\frac{3}{4}$  inch-deep hole with a  $\frac{3}{4}$  inch spade bit. A couple of pieces of 2 × 2 lumber at the ends of the base form a saddle which nicely straddles the ridge at the peak of his garage roof. You can see this in **Figure 21.44**. The dimensions are not critical. Paint your base to protect it from the weather.

## BALUN

This antenna needs a common-mode choke balun to ensure that RF doesn't flow on the shield of the coax. (See the **Transmission Lines** chapter for more information on choke baluns.) Unlike a horizontal dipole, don't consider it an option to omit the common-mode choke when building and installing an HVD.

You can use 8 feet of the RG-213 feed

**Figure 21.41** — The center insulator of the 15 meter HVD is a 1 foot length of 0.75 inch fiberglass rod. Insulator and elements have been drilled to accept #8 hardware.

**Figure 21.42** — The HVD base insulator is a 1 foot length of 0.75 inch fiberglass rod.

line wound into 7 turns for a balun. Secure the turns together with electrical tape so that each turn lies parallel with the next turn, forming a solenoid coil. Secure the feed line and balun to one of the guy lines with UV-resistant cable ties.

Because the feed line slants away from the antenna, you'll want to do *all* that you can to eliminate common-mode currents from the feed line. For that reason, make another balun about 11.5 feet from the first one. This balun also consists of 8 feet of the RG-213 feed line wound into 7 turns. See **Figure 21.45** for a photo of the installed antenna.

## Project: Compact Vertical Dipole (CVD)

An HVD for 20 meters will be about 33 feet tall, and for 30 meters, it will be around 46 feet tall. Even the 20 meter version can prove to be a mechanical challenge. The compact vertical dipole (CVD), designed by Chuck Hutchinson, K8CH, uses capacitance loading to shorten the antenna. Starting with the 15 meter HVD described in the previous project, Chuck added capacitance loading wires to lower the resonance to 30 meters. Later, he shortened the wires to move resonance to the 20 meter band. This project describes those two CVDs.

### PERFORMANCE ISSUES

Shortened antennas frequently suffer reduced performance caused by the shortening. A dipole that is less than  $\frac{1}{2} \lambda$  in length is a compromise antenna. The issue becomes how much is lost in the compromise. In this case there are two areas of primary interest, radiation efficiency and SWR bandwidth.

### Radiation Efficiency

Capacitance loading at the dipole ends is the most efficient method of shortening the antenna. Current distribution in the high-current center of the antenna remains virtually unchanged. Since radiation is related directly to current, this is the most desirable form of loading. Computer modeling shows that radiation from a 30 meter CVD is only 0.66 dB less than that from a full-size 30 meter HVD when both have their bases 8 feet above ground. The angle of maximum radiation shifts up a bit for the CVD. Not a bad compromise when you consider that the CVD is 22 feet long compared to the approximately 46 foot length of the HVD.

### SWR and SWR Bandwidth

Shortened antennas usually have lower radiation resistance and less SWR bandwidth than the full-size versions. The amount of change in the radiation resistance is related to the amount and type of loading (shortening), being lower with shorter the antennas. This

can be a benefit in the case of a shortened vertical dipole. In Figure 21.2 you can see that vertical dipoles have a fairly high radiation resistance. With the dipole's lower end  $\frac{1}{8} \lambda$  above ground, the radiation resistance is roughly  $80 \Omega$ . In this case, a shorter antenna can have a better SWR when fed with  $50 \Omega$  coax.

SWR bandwidth tends to be wide for vertical dipoles in general. A properly designed CVD for 7 MHz or higher should give you good SWR (1.5:1 or better) across the entire band!

As you can see, in theory the CVD provides excellent performance in a compact package. Experience confirms the theory.

### CONSTRUCTION

To convert the K8CH 15 meter HVD to 20 or 30 meters, you'll need to add four loading wires at the top and four more at the bottom of the HVD. The lengths are given in the table in Figure 21.46. The upper wires droop at a  $45^\circ$  angle and the lower wires run horizontally. The antenna is supported by four guy lines. You can connect the wires to the vertical portion with #8 hardware. Crimp and solder terminals on the wire ends to make connections easier. The technique is illustrated in Figure 21.47.

The upper loading wires can be extended with insulated line and used for additional guying. The lower wires are extended with insulated line and fasten to the guy lines so that the lower wires run horizontally.

Prune the lower wires for best SWR across the band of interest. The K8CH CVD has its base at 14 feet. This antenna has an SWR of less than 1.2:1 on 30 meters and less than 1.3:1 across the entire 20 meter band.

Figure 21.46 — The CVD consists of a vertical dipole and loading wires. Only one set of the four loading wires and only one guy line is shown in this drawing. See text for details.

Figure 21.47 — CVD loading wires can be attached using #8 hardware. Crimp and solder terminals on the wire ends to make connections easier.

## EXPERIENCE

The 30 meter CVD was compared to a ground-mounted quarter-wave vertical and a horizontal dipole at 30 feet. In tests, the CVD was always the superior antenna.

Later, the CVD loading wires were shortened for operation on 20 meters. Once again the results were very encouraging.

### Project: All-Wire 30 Meter CVD

If you have a tree or other support that will support the upper end of a CVD at 32 feet above the ground, you might want to consider an all-wire version of the 30 meter CVD. The vertical is 24 feet long and it will have an SWR of less than 1.1:1 across the band. The four loading wires at top and bottom are each 5 feet, 2 inches long.

The configuration is shown in **Figure 21.48**. As with any vertical dipole, you'll need to use a balun between the feed line and the antenna.

Alternatively you can use two loading wires at the top and two at the bottom. In this case each of the loading wires is 8 feet, 1.5 inches long.

**Figure 21.48** — The all-wire 30 meter CVD consists of a vertical dipole and loading wires. It can be made entirely with #14 AWG wire. Support lines have been omitted for simplicity. See text for details.

## 21.6 Yagi Antennas

Most antennas described earlier in this chapter have unity gain compared to a dipole, or just slightly more. For the purpose of obtaining gain and directivity it is convenient to use a Yagi-Uda *beam* antenna. The former is commonly called a *Yagi*. There are other forms of directive antennas, but the Yagi is by far the most popular used by amateurs. (For more information on phased arrays and other types of directive antennas, see the *ARRL Antenna Book*.)

Most operators prefer to erect these antennas for horizontal polarization, but they can be used as vertically polarized antennas merely by rotating the elements by 90°. In effect, the beam antenna is turned on its side for vertical polarization. The number of elements used will depend on the gain desired and the limits of the supporting structure. At HF, many amateurs obtain satisfactory results with only two elements in a beam antenna, while others have four or five elements operating on a single amateur band, called a *mono-*

*band beam*. On VHF and above, Yagis with many elements are common, particularly for simplex communication without repeaters. For fixed point-to-point communications, such as repeater links, Yagis with three or four elements are more common.

Regardless of the number of elements used, the height-above-ground considerations discussed earlier for dipole antennas remain valid with respect to the angle of radiation. This is demonstrated in **Figure 21.49** at A and B where a comparison of radiation characteristics is given for a 3 element Yagi at one-half and one wavelength above average ground. It can be seen that the higher antenna (Figure 21.49B) has a main lobe that is more favorable for DX work (roughly 15°) than the lobe of the lower antenna in Figure 21.49A (approximately 30°). The pattern at B shows that some useful high-angle radiation exists also, and the higher lobe is suitable for short-skip contacts when propagation conditions dictate the need.

**Figure 21.49** — Elevation-plane response of a 3 element Yagi placed  $\frac{1}{2} \lambda$  above perfect ground at A and the same antenna spaced  $1 \lambda$  above ground at B.

**Figure 21.50** — Azimuthal pattern of a typical three-element Yagi in free space. The Yagi's boom is along the 0° to 180° axis.

The azimuth pattern for the same antenna is provided in **Figure 21.50**. (This is a free-space pattern, so the pattern is taken in the plane of the antenna. Remember that azimuth patterns taken over a reflecting surface must also specify the elevation angle at which the pattern was measured or calculated.) Most of the power is concentrated in the main lobe at 0° azimuth. The lobe directly behind the main lobe at 180° is often called the *back lobe* or *rear lobe*. The front-to-back ratio (F/B) of this antenna is just less than 12 dB — the peak power difference, in decibels, between the main lobe at 0° and the rearward lobe at 180°. It is infrequent that two 3 element Yagis with different element spacing and tuning will yield the same lobe patterns. The patterns also change with frequency of operation. The pattern of Figure 21.50 is shown only for illustrative purposes.

### 21.6.1 Parasitic Excitation

In a Yagi antenna only one element (the *driven element*) is connected to the feed line. The additional elements are *coupled* to the driven element because they are so close. (Element-to-element spacing in a Yagi antenna is generally on the order of  $\frac{1}{4}$  to  $\frac{1}{2}$  wavelength.) This *mutual coupling* results in currents being induced in the non-driven elements from the radiated field of the driven element. These elements are called *parasitic elements* and the Yagi antenna is therefore a *parasitic array*. (An antenna in which multiple elements all receive power from the transmitter is called a *driven array*.) The currents induced in the parasitic elements also result in radiated fields, just as if the current were the result of power from a feed line. This is called *re-radiation*, and it has a 180° phase shift from the current-inducing field. The combination of the field radiated by the driven element, the fields from the parasitic elements, and the physical spacing of the elements results in the

fields having the proper phase relationship so as to focus the radiated energy in the desired direction and reject it in other directions.

The parasitic element is called a *director* when it reinforces radiation along a line pointing to it from the driven element, and a *reflector* in the opposite case. Whether the parasitic element is a director or reflector depends on the parasitic element tuning, which is usually adjusted by changing its length. The structure on which the elements are mounted is called the *boom* of the antenna.

### 21.6.2 Yagi Gain, Front-to-Back Ratio and SWR

The gain of a Yagi antenna with parasitic elements varies with the spacing and tuning of the elements. Element tuning is a function of length, diameter and *taper schedule* (the steps in length and diameter) if the element is constructed with telescoping tubing. For any given number of elements and the spacing between them, there is a tuning condition that will result in maximum gain. However, the maximum front-to-back ratio seldom, if ever, occurs at the same condition that gives maximum forward gain. The impedance of the driven element in a parasitic array, and thus the SWR, also varies with the tuning and spacing.

It is important to remember that all these parameters change as the operating frequency is varied. For example, if you operate both the CW and phone portions of the 20 meter band with a Yagi antenna, you probably will want an antenna with consistent performance over most of the band. Such designs typically must sacrifice a little gain in order to achieve good F/B and SWR performance across the band.

Gain and F/B performance generally improve with the number of elements. In Yagi antennas with more than three elements (a driven element and one director and reflector), the additional elements are added as directors, since little additional benefit is obtained from multiple reflectors. Wider spacing also improves gain and F/B up to a certain point, depending on a number of factors, beyond which performance begins to fall. Optimizing element spacing is a complex problem and no single spacing satisfies all design requirements. For the lower HF bands, the size of the antenna quickly becomes impractical for truly *optimal* designs, and compromise is necessary.

### 21.6.3 Two-Element Beams

A two-element beam is useful — especially where space or other considerations prevent the use of a three-element, or larger, beam. The general practice is to tune the parasitic element as a reflector and space it about

**Figure 21.51** — Gain vs element spacing for a two-element Yagi, having one driven and one parasitic element. The reference point, 0 dB, is the field strength from a half-wave antenna alone.

0.15  $\lambda$  from the driven element, although some successful antennas have been built with 0.1- $\lambda$  spacing and director tuning.

Gain vs element spacing for a two-element antenna is given in **Figure 21.51** for the special case where the parasitic element is resonant. It is indicative of the performance to be expected under maximum-gain tuning conditions. Changing the tuning of the driven element in a Yagi or quad will not materially affect the gain or F/R. Thus, only the spacing and the tuning of the single parasitic element have any effect on the performance of a 2 element Yagi.

In Figure 21.51, the greatest gain is in the direction A (in which the parasitic element is acting as a director) at spacings of less than 0.14  $\lambda$ , and in direction B (in which the parasitic element is a reflector) at greater spacings. The front-to-back ratio is the difference in decibels between curves A and B along the boom of the antenna. The figure also shows variation in radiation resistance of the driven element.

These curves are for the special case of a self-resonant parasitic element, but are representative of how a two-element Yagi works. At most spacings the gain as a reflector can be increased by slight lengthening of the parasitic element; the gain as a director can be increased by shortening. This also improves the front-to-rear ratio.

Most two-element Yagi designs achieve a compromise F/R of about 10 dB, together with an acceptable SWR and gain across a frequency band with a percentage bandwidth less than about 4%.

### 21.6.4 Three-Element Beams

A theoretical investigation of the three-element case (director, driven element and reflector) has indicated a maximum gain of about 9.7 dBi (7.6 dBd). A number of experimental investigations have shown that

**Figure 21.52 — General relationship of gain of three-element Yagi vs director spacing, the reflector being fixed at  $0.2 \lambda$ . This antenna is tuned for maximum forward gain.**

the spacing between the driven element and reflector for maximum gain is in the region of  $0.15$  to  $0.25 \lambda$ . With  $0.2 \lambda$  reflector spacing, **Figure 21.52** shows that the gain variation with director spacing is not especially critical. Also, the overall length of the array (boom length in the case of a rotatable antenna) can be anywhere between  $0.35$  and  $0.45 \lambda$  with no appreciable difference in the maximum gain obtainable.

If maximum gain is desired, wide spacing of both elements is beneficial because adjustment of tuning or element length is less critical and the input resistance of the driven element is generally higher than with close

spacing. A higher input resistance improves the efficiency of the antenna and makes greater bandwidth possible. However, a total antenna length, director to reflector, of more than  $0.3 \lambda$  at frequencies of the order of 14 MHz introduces difficulty from a construction standpoint. Lengths of  $0.25$  to  $0.3 \lambda$  are therefore used frequently for this band, even though they are less than optimum from the viewpoint of maximum gain.

In general, Yagi antenna gain drops off less rapidly when the reflector length is increased beyond the optimum value than it does for the corresponding decrease below the optimum value. The opposite is true of a director. It

\*These sizes are extruded; all other sizes are drawn tubes. therefore advisable to err, if necessary, on the long side for a reflector and on the short side for a director. This also tends to make the antenna performance less dependent on the exact frequency at which it is operated. An increase above the design frequency has the same effect as increasing the length of both parasitic elements, while a decrease in frequency has the same effect as shortening both elements. By making the director slightly short and the reflector slightly long, there will be a greater spread between the upper and lower frequencies at which the gain starts to show a rapid decrease.

### 21.6.5 Construction of Yagi Antennas

Most beams and verticals are made from sections of aluminum tubing. Compromise beams have been fashioned from less-expensive materials such as electrical conduit (steel) or bamboo poles wrapped with conductive tape or aluminum foil. The steel conduit is heavy, is a poor conductor and is subject to rust. Similarly, bamboo with conducting material attached to it may deteriorate rapidly in the weather. Given the drawbacks of alternative materials, aluminum tubing (or rod for VHF and UHF Yagis) is far and away the best choice for antenna construction.

For reference, **Table 21.5** details the standard sizes of aluminum tubing, available in many metropolitan areas. Metal distributors, local and online, usually stock popular sizes of aluminum tubing. Several *QST* advertisers stock an extensive line of tubing specifically for antenna construction and cut to shippable lengths. Tubing usually comes in 12 foot lengths, although 20 foot lengths are available in some sizes. Your aluminum dealer will probably also sell aluminum plate in various thicknesses needed for boom-to-mast and boom-to-element connections.

Aluminum is rated according to its hardness. The most common material used in antenna construction is grade 6061-T6. This material is relatively strong and has good workability. In addition, it will bend without taking a *set*, an advantage in antenna applications where the pieces are constantly flexing in the wind. The softer grades (5051, 3003 and so on) will bend much more easily, while harder grades (7075 and so on) are more brittle.

Wall thickness is of primary concern when selecting tubing. It is of utmost importance that the tubing fits snugly where the element sections join. Sloppy joints will make a mechanically unstable antenna. The magic wall thickness is 0.058 inch. For example (from **Table 21.5**), 1 inch outside diameter (OD) tubing with a 0.058 inch wall has an inside diameter (ID) of 0.884 inch. The next smaller size of tubing,  $\frac{3}{8}$  inch, has an OD of 0.875 inch. The 0.009 inch difference provides just the right amount of clearance for a snug fit.

**Figure 21.53** shows several methods of fastening antenna element sections together. The slot and hose clamp method shown at the upper left is probably the best for joints where adjustments are needed. Generally, one adjustable joint on each side of the element is sufficient to tune the antenna — usually the tips at each end of an element are made adjustable. Stainless steel hose clamps (beware — some “stainless steel” models do not have a stainless screw and will rust) are recommended for longest antenna life.

The remaining photos show possible fastening methods for joints that are not adjustable. At the upper right, machine screws and nuts hold the elements in place. At the lower left, sheet metal screws are used. At the lower right, rivets secure the tubing. If the antenna is to be assembled permanently, rivets are the best choice. Once in place, they are permanent. Properly installed, they rarely

work free, regardless of vibration or wind. If aluminum rivets with aluminum mandrels are employed, they will never rust. Also, being aluminum, there is no danger of corrosion from interaction between dissimilar metals. If the antenna is to be disassembled and moved periodically, either machine or sheet metal screws will work. If machine screws are used, however, take precautions to keep the nuts from vibrating free. Use of lock washers, lock nuts and flexible adhesive such as silicone bathtub sealant or a thread-locking compound will keep the hardware in place. For portable or temporary use, such as Field Day, rivets may be held in place with electrical tape and removed when the operation is finished.

Use of a conductive grease at the element joints is essential for long life. Left untreated, the aluminum surfaces will oxidize in the weather, resulting in a poor connection. Some trade names for this conductive grease are Penetrox, OxGard, and Noalox. Many electrical supply houses and hardware stores carry these products.

#### DRIVEN ELEMENT

The ARRL recommends *plumbers delight* construction, in which all elements are mounted directly on, and grounded to, the boom. This puts the entire array at dc ground potential, affording better lightning protection. A gamma- or T-match section can be used for matching the feed line to the array.

An alternative method is to insulate the driven element from the boom, but use a *hairpin* or *beta match*, the center point of which is electrically neutral and can be attached directly to the boom, restoring the dc ground for the driven element.

*Direct feed* designs in which the feed point impedance of the driven element is close to 50  $\Omega$ , require no impedance matching structure. Like hairpin-matched designs, the driven element must be insulated from the boom, requiring some additional mechanical complexity.

Regardless of the design, a current or choke balun should be used (see the **Transmission Lines** chapter) to prevent the outer surface of the feed line shield from interacting with the antenna directly or by picking up the radiated signal. Such interaction can degrade the antenna's radiation pattern, especially by compromising signal rejection to the side and rear.

#### BOOM MATERIAL

The boom size for a rotatable Yagi or quad should be selected to provide stability to the entire system. The best diameter for the boom depends on several factors, but mostly the element weight, number of elements and overall length. Two-inch-diameter booms should not be made any longer than 24 feet unless additional support is given to reduce

**Figure 21.53** — Some methods of connecting telescoping tubing sections to build beam elements. See text for a discussion of each method.

Figure 21.54 — A long boom needs both vertical and horizontal support. The cross-bar mounted above the boom can support a double truss, which will help keep the antenna in position.

Figure 21.55 — The boom-to-element plate at A uses muffer-clamp-type U-bolts and saddles to secure the round tubing to the flat plate. The boom-to-mast plate at B is similar to the boom-to-element plate. The main difference is the size of materials used.

both vertical and horizontal bending forces. Suitable reinforcement for a long 2 inch boom can consist of a truss or a truss and lateral support, as shown in Figure 21.54.

A boom length of 24 feet is about the point where a 3 inch diameter begins to be very worthwhile. This dimension provides a considerable amount of improvement in overall mechanical stability as well as increased clamping surface area for element hardware. The latter is extremely important to prevent rotation of elements around the boom if heavy icing is commonplace. Pinning an element to the boom with a large bolt helps in this regard. On smaller diameter booms, however, the elements sometimes work loose and tend to elongate the pinning holes in both the element and the boom. After some time the elements shift their positions slightly (sometimes from day to day) and give a ragged appearance to the system, even though this may not harm the electrical performance.

A 3 inch diameter boom with a wall thickness of 0.065 inch is very satisfactory for antennas up to about a five-element, 20 meter

array that is spaced on a 40 foot boom. A truss is recommended for any boom longer than 24 feet. One possible source for large boom material is irrigation tubing sold at farm supply houses.

### PUTTING IT TOGETHER

Once you assemble the boom and elements, the next step is to fasten the elements to the boom securely and then fasten the boom to the mast or supporting structure using mounting plates as shown in Figure 21.55. Be sure to leave plenty of material on either side of the

U-bolt holes on the element-to-boom mounting plates. The U-bolts selected should be snug fit for the tubing. If possible, buy muffer-clamp U-bolts that come with saddles.

The boom-to-mast plate shown in Figure 21.55B is similar to the boom-to-element plate in 21.55A. The size of the plate and number of U-bolts used will depend on the size of the antenna. Generally, antennas for the bands up through 20 meters require only two U-bolts each for the mast and boom. Longer antennas for 15 and 20 meters (35 foot booms and up) and most 40 meter

beams should have four U-bolts each for the boom and mast because of the torque that the long booms and elements exert as the antennas move in the wind. When tightening the U-bolts, be careful not to crush the tubing. Once the wall begins to collapse, the connection begins to weaken. Many aluminum suppliers sell ¼ inch or ⅜ inch thick plates just right for this application. Often they will shear pieces to the correct size on request. As with tubing, the relatively hard 6061-T6 grade is a good choice for mounting plates.

The antenna should be put together with good-quality hardware. Stainless steel or galvanized hardware is best for long life and is available from several Amateur Radio dealers. Stainless steel hardware can develop surface defects called *galling* that can cause threads on nuts and bolts to seize. On hardware ¼ inch and larger, the use of an anti-seize compound is recommended. Anti-seize compound is available from auto parts stores or a small amount of grease or anti-oxidation compound can help lubricate the threads.

Rust will attack plated steel hardware after a short time, making nuts difficult, if not impossible, to remove. If you use plated hardware, paint it with a good zinc-chromate primer and a finish coat or two.

Good-quality hardware is more expensive initially, but if you do it right the first time, you won't have to take the antenna down after a few years and replace the hardware. Also, when repairing or modifying an installation, nothing is more frustrating than fighting rusty hardware at the top of a tower.

### Project: Family of Computer-Optimized HF Yagis

Yagi designers are now able to take advantage of powerful personal computers and software to optimize their designs for the parameters of gain, F/R and SWR across frequency bands. Dean Straw, N6BV, has designed a family of Yagis for HF bands. These can be found in **Tables 21.6 to 21.10**, for the 10, 12, 15, 17 and 20 meter amateur bands, respectively.

For 12 through 20 meters, each design has been optimized for better than 20 dB F/R, and an SWR of less than 2:1 across the entire amateur frequency band. For the 10 meter band, the designs were optimized for the lower 800 kHz of the band, from 28.0 to 28.8 MHz. Each Yagi element is made of telescoping 6061-T6 aluminum tubing, with 0.058 inch thick walls. This type of element can be telescoped easily, using techniques shown in Figure 21.53. Measuring each element to an accuracy of ⅛ inch results in performance remarkably consistent with the computations, without any need for tweaking or fine-tuning when the Yagi is on the tower.

The dimensions shown are designed for

specific telescoping aluminum elements, but the elements may be scaled to different sizes by using the information about tapering and scaling in *The ARRL Antenna Book*, although with a likelihood of deterioration in performance over the whole frequency band.

Each element is mounted above the boom with a heavy rectangular aluminum boom-to-element plate, by means of galvanized U-bolts with saddles, as shown in Figure 21.55. This method of element mounting is rugged and stable, and because the element is mounted away from the boom, the amount of element detuning due to the presence of the boom is minimal. The element dimensions given in each table already take into account any element detuning due to the mounting plate. The element mounting plate for all the 10 meter Yagis is a 0.250 inch thick flat aluminum plate, 4 inches wide by 4 inches long. For the 12 and 15 meter Yagis, a 0.375 inch thick flat aluminum plate, 5 inches wide by 6 inches long is used, and for the 17 and 20 meter Yagis, a 0.375 inch thick flat aluminum plate, 6 inches wide by 8 inches long is used. Where the plate is rectangular, the long dimension is in line with the element.

Each design table shows the dimensions for *one-half* of each element, mounted on one side of the boom. The other half of each element is the same, mounted on the other side of the boom. Use a tubing sleeve inside the center portion of the element so that the element is not crushed by the mounting U-bolts. Each telescoping section is inserted 3 inches into the next size of tubing. For example, in the 310-08 design for 10 meters (3 elements on an 8 foot boom), the reflector tip, made out of 1/2 inch OD tubing, sticks out 66.75 inches from the 3/4 inch OD tubing. For each 10 meter element, the overall length of each 3/4 inch OD piece of tubing is 21 inches, before insertion into the 3/4 inch piece. Since the 3/4 inch OD tubing is 24 inches long on each side of the boom, the center portion of each element is actually 48 inches of uncut 3/4 inch OD tubing.

The boom for all these antennas should be constructed with at least 2 inch OD tubing, with 0.065 inch wall thickness. Because each boom has three inches of extra length at each end, the reflector is actually placed three inches from one end of the boom. For the 310-08 design, the driven element is placed 36 inches ahead of the reflector, and the di-

**Figure 21.56 — Illustrations of gamma and T matching systems. At A, the gamma rod is adjusted along with the capacitor until the lowest SWR is obtained. A T match is shown at B. It is the same as two gamma-match rods. A 4:1 coaxial balun transformer for use with the T match is shown at C.**

reflector is placed 54 inches ahead of the driven element. The antenna is attached to the mast with the *boom-to-mast* mounting plate shown in Figure 21.55.

Each antenna is designed with a driven element length appropriate for a gamma or T matching network, as shown in Figure 21.56. The variable gamma or T capacitors can be housed in small plastic enclosures for weatherproofing; receiving-type variable capacitors with close plate spacing can be used at powers up to a few hundred watts. Maximum capacitance required is usually 140 pF at 14 MHz and proportionally less at the

higher frequencies.

The driven-element's length may require slight readjustment for best match, particularly if a different matching network is used. *Do not change either the lengths or the telescoping tubing schedule of the parasitic elements* — they have been optimized for best performance and will not be affected by tuning of the driven element.

## TUNING ADJUSTMENTS

To tune the gamma match, adjust the gamma capacitor for best SWR, then adjust the position of the shorting strap or bar that connects the gamma rod to the driven element. Repeat this alternating sequence of adjustments until a satisfactory SWR is reached.

To tune the T-match, the position of the shorting straps and C1 and C2 are adjusted alternately for a best SWR. To maintain balance of the antenna, the position of the straps and capacitor settings should be the same for each side and adjusted together. A coaxial 4:1 balun transformer is shown at Figure 21.56C. A toroidal balun can be used in place of the coax model shown. The toroidal version has a broader frequency range than the coaxial one. The T match is adjusted for 200  $\Omega$  and the balun steps this balanced value down to 50  $\Omega$ , unbalanced. Or the T match can be set for 300  $\Omega$ , and the balun used to step this down to 75  $\Omega$  unbalanced.

Dimensions for the gamma and T match rods will depend on the tubing size used, and the spacing of the parasitic elements of the beam. Capacitors C1 and C2 can be 140 pF for 14 MHz beams. Somewhat less capacitance will be needed at 21 and 28 MHz.

Preliminary matching adjustments can be done on the ground. The beam should be aligned vertically so that the reflector element is closest to and a few feet off the ground, with the beam pointing upward. The matching system is then adjusted for best SWR. When the antenna is raised to its operating height, only slight touch-up of the matching network may be required.

A *choke balun* (see the **Transmission Lines** chapter) should be used to isolate the coaxial feed line shield from the antenna. Secure the feed line to the boom of the antenna between the feed point and the supporting mast.

## 21.7 Quad and Loop Antennas

One of the more effective DX antennas is the *quad*. It consists of two or more loops of wire, each supported by a bamboo or fiberglass cross-arm assembly. The loops are  $\frac{1}{4} \lambda$  per side (one full wavelength overall). One loop is driven and the other serves as a parasitic element — usually a reflector. The design of the quad is similar to that of the Yagi, except that the elements are loops instead of dipoles. A two-element quad can achieve better F/R, gain and SWR across a band, at the expense of greater mechanical complexity compared to a two-element Yagi and very nearly the same performance as a three-element Yagi.

A variation of the quad is called the *delta loop*. The electrical properties of both antennas are the same. Both antennas are shown in **Figure 21.57**. They differ mainly in their physical properties, one being of plumber's delight construction, while the other uses insulating support members. One or more directors can be added to either antenna if additional gain and directivity are desired, though most operators use the two-element arrangement.

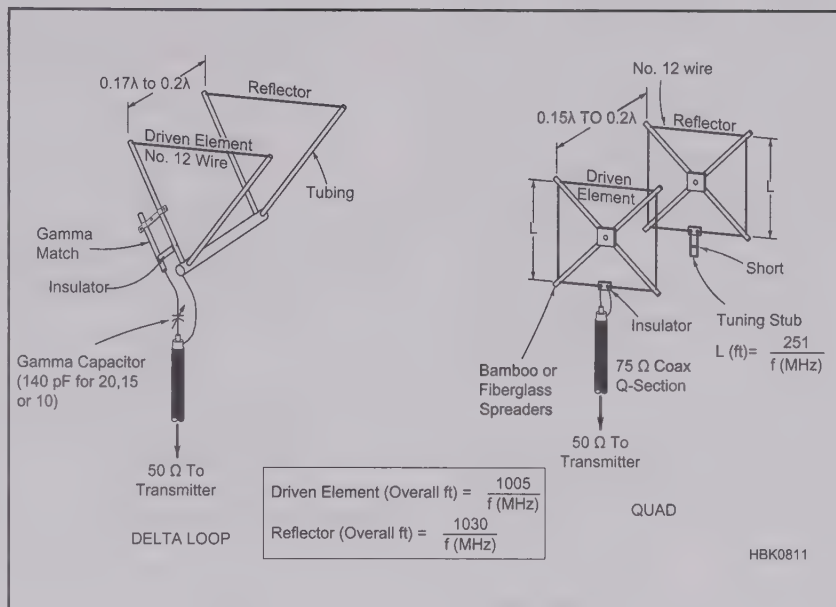

It is possible to interlace quads or deltas for two or more bands, but if this is done the lengths calculated using the formulas given in **Figure 21.57** may have to be changed slightly to compensate for the proximity effect of the second antenna. Using a tuning capacitor as shown in the following project allows the antenna to be adjusted for peak performance without cumbersome adjustment of wire lengths.

If multiple arrays are used, each antenna should be tuned separately for maximum forward gain, or best front-to-rear ratio, as observed on a field-strength meter. The reflector stub on the quad should be adjusted for this condition. The resonance of the antenna can be found by checking the frequency at which the lowest SWR occurs. By lengthening or shortening it, the driven element length can be adjusted for resonance in the most-used portion of the band.

A gamma match can be used at the feed point of the driven element to match the impedance to that of coaxial cable. Because the loop's feed point impedance is *higher* than that of 50  $\Omega$  coaxial cable, a *synchronous transmission line transformer* or *Q-section* (see the **Transmission Lines** chapter) with an impedance intermediate to that of the loop and the coaxial cable can be used.

### Project: Five-Band, Two-Element HF Quad

Two multi-band quad designs covering 20 through 10 meters are described in this project. One was constructed by William A.

**Figure 21.57** — Information on building a quad or a delta-loop antenna. The antennas are electrically similar, but the delta-loop uses plumber's delight construction. The  $\frac{1}{4} \lambda$  length of 75  $\Omega$  coax or Q-section acts as a synchronous transmission-line transformer from the approximate 100  $\Omega$  feed point impedance of the quad to the 50  $\Omega$  feed line.

Stein, KC6T, from scratch, and the other was built by Al Doig, W6NBH, using modified commercial triband quad hardware. The principles of construction and adjustment are the same for both models, and the performance results are also essentially identical. One of the main advantages of this design is the ease of (relatively) independent performance adjustments for each of the five bands. These quads were described by William A. Stein, KC6T, in *QST* for April 1992. Both models use 8-foot-long, 2 inch diameter booms, and conventional X-shaped spreaders (with two sides of each quad loop parallel to the ground).

Each driven element is fed separately, but running five separate feed lines to the shack would be unwieldy. A remote coax switch on the boom is used to select the feed line for each element. A gamma match or quarter-wave synchronous transmission line transformer is used to match the feed point impedance of the element to 50  $\Omega$ .

These designs can also be simplified to monoband quads by using the formulas in **Figure 21.57** for loop dimensions and spacing. It is recommended to the antenna builder unfamiliar with quads that a monoband quad be attempted first in order to become acquainted with the techniques of building a quad. Once comfortable with constructing and erecting the quad, success with a multi-band design is much easier to achieve.

Complete construction details and more

information about the performance of these designs are available with the downloadable supplemental content.

### 21.7.1 Loop Antennas

The loop antennas described in this section are continuous loops at least one wavelength in circumference and formed into open shapes with sides that are approximately equal, such as triangles, diamonds, squares, or circles. Smaller loops used for receiving purposes are discussed in the *ARRL Antenna Book*. Loops with ratios of side lengths greater than 2 or 3:1 begin to have special characteristics beyond the scope of this chapter.

A  $1 \lambda$  loop can be thought of as two  $\frac{1}{2} \lambda$  dipoles with their ends connected together and pulled apart into an open shape as described above. The feed point of one dipole is replaced with a short circuit so that there is only one feed point on the antenna. As such, the current and voltage distribution around the loop is an extension of **Figure 21.1**. Three typical loop shapes and the current distributions on them are shown in **Figure 21.58**. Note that the current flow reverses at points  $\frac{1}{4} \lambda$  to either side of the feed point. That means the current direction opposite the feed point is the same as at the feed point.

The maximum radiation strength of a  $1 \lambda$  loop is perpendicular to the plane of the loop and minimum in the plane of the loop. If the

loop is horizontal, the antenna radiates best straight up and straight down and poorly to the sides. The gain of a  $1 \lambda$  loop in the direction of maximum radiation is approximately 1 dBd.

If the plane of the three loops shown in Figure 21.58 is vertical, the radiation is horizontally polarized because the fields radiated by the vertical components of current are symmetrical and opposing, so they cancel, leaving only the horizontally polarized fields that will cancel, leaving a vertically polarized field, still maximum perpendicular to the plane of the loop. If the feed point of the antenna is moved to a vertical side or the antenna is rotated  $90^\circ$ , it is the horizontally polarized fields that will cancel, leaving a vertically polarized field, still maximum perpendicular to the plane of the loop. Feeding the loop at some other location, rotating the loop by some intermediate value, or constructing the loop in an asymmetrical shape will result in polarization somewhere between vertical and horizontal, but the maximum radiation will still occur perpendicular to the plane of the loop.

In contrast to straight-wire antennas, the electrical length of the circumference of a  $1 \lambda$  loop is shorter than the actual length. For a loop made of bare #18 AWG wire and operating at a frequency of 14 MHz, so that the length-to-diameter ratio is very large, the loop will be close to resonance in free space when:

$$\text{Length (feet)} = 1032/f \text{ (MHz)} \quad (7)$$

The radiation resistance of a resonant  $1 \lambda$  loop is approximately  $120 \Omega$  under these conditions. Since the loop dimensions are larger than those of a  $1/2 \lambda$  dipole, the radiation efficiency is high and the SWR bandwidth of the antenna significantly larger than for the dipole.

The loop antenna is resonant on all frequencies at which it is an integral number of wavelengths in circumference;  $f_0$ ,  $2f_0$ ,  $3f_0$ , etc. That means an 80 meter  $1 \lambda$  loop will also have a relatively low feed point impedance on 40, 30, 20, 15, 12, and 10 meters. As each side of the loop becomes longer electrically, the radiation pattern of the loop begins to develop nulls perpendicular to the plane of the loop and lobes that are closer to the plane of the loop. A horizontal diamond-shaped loop with legs more than a wavelength long is a *rhombic* antenna and can develop significant gain along the long axis of the antenna. (The diamond-shaped rhombic is the origin of the symbol of the ARRL and many other radio organizations.)

### Project: Low-Band Quad and Delta Loops

(The following material is summarized from Chapter 10 of *ON4UN's Low-Band DXing, Fifth Edition*.) Dimensions for these

**Figure 21.58** — At A and B, loops have sides  $1/4 \lambda$  long, and at C having sides  $1/3 \lambda$  long for a total conductor length of  $1 \lambda$ . The polarization depends on the orientation of the loop and on the position of the feed point (terminals X-Y) around the perimeter of the loop.

designs assume an operating frequency of 3.75 MHz. The dimensions for the loops in this section may be scaled to frequencies in the 160, 60, 40 or 30 meter bands. The performance of the loops will vary with height above ground and ground conductivity.

### SQUARE LOOP

Figure 21.59 shows the vertical-plane radiation patterns for a quad loop over very poor ground and over very good ground on the same dB scale for both horizontal and vertical polarization. Polarization of the loop

**Figure 21.59** — Superimposed patterns for horizontally and vertically polarized square quad loops (shown at A) over very poor ground (B) and very good ground (C). In the vertical polarization mode the ground quality has a large effect on antenna performance as it does with all vertically-polarized antennas.

depends on the location of the feed point as shown in the figure.

The vertically polarized quad loop can be considered as two shortened top-loaded vertical dipoles, spaced  $\frac{1}{4}\lambda$  apart. Broadside radiation from the horizontal elements of the quad is very low because the currents in the horizontal legs are approximately equal but in opposite directions in each half of the leg. The radiation angle in the broadside direction will be essentially the same as for either of the vertical members.

The resulting radiation angle will depend on the quality of the ground up to several wavelengths away from the antenna, as is the case with all vertically polarized antennas. The quality of the ground is as important as it is for any other vertical antenna, meaning that vertically polarized loops close to the ground will not work well over poor soil. In a typical situation on 80 meters, a vertically-polarized quad loop will radiate an excellent low-angle signal (lobe peak at approximately  $21^\circ$ ) when operated over average ground. Over poorer ground, the peak elevation angle would be closer to  $30^\circ$ . The horizontal directivity is rather poor and amounts to approximately 3.3 dB of side rejection at any elevation angle.

A horizontally polarized quad-loop antenna can be thought of as two stacked short dipoles with a peak elevation angle dependent on the height of the loop. The low horizontally polarized quad (top at  $0.3\lambda$ ) radiates most of its energy right at or near zenith angle (straight up). At low wave angles ( $20^\circ$  to  $45^\circ$ ) the horizontally polarized loop shows more front-to-side ratio (5 to 10 dB) than the vertically polarized rectangular loop.

With a horizontally polarized quad loop the angle of peak radiation is very dependent on the antenna height but not so much on the quality of the ground. At very low heights, the angle of peak radiation varies between  $50^\circ$  and  $60^\circ$  (but is rather constant all the way up to  $90^\circ$ ). This is very good for NVIS and regional communication but not very good for DX. As far as gain is concerned, there is a 2.5-dB gain difference between very good and very poor ground, which is only half the difference found with the vertically polarized loop.

Comparing the gains of the horizontally and vertically polarized loops, Figure 21.59 shows that at very low antenna heights the gain is about 3 dB better for the horizontally polarized loop. But this gain exists at a high wave angle ( $50^\circ$  to  $90^\circ$ ) while the vertically polarized loop at very low heights radiates at  $17^\circ$  to  $25^\circ$ .

At heights from 3 to 6 meters for the bottom leg, feed point resistance for the horizontally polarized loop is approximately 100 to 120  $\Omega$  over average ground. For vertical polarization, feed point resistance varies from 200 to 170  $\Omega$ .

The quad loop feed point should be symmetrical, whether you feed the quad in the middle of the vertical or the horizontal wire. At the feed point, use a common-mode choke balun (see the **Transmission Lines** chapter) as current flowing on the outside of the coaxial feed line could upset the radiation pattern.

### DELTA LOOP

Figure 21.60 shows the configuration as well as the superimposed elevation patterns for vertically and horizontally polarized low-height equilateral triangle delta loops over two different types of ground (same dB scale). The model was constructed for a frequency of 3.75 MHz. The base is 2.5 meters above ground, which puts the apex at 26.8 meters. Over good ground, the vertically polarized delta loop shows nearly 3 dB front-to-side ratio at the peak radiation angle of  $22^\circ$ . With average ground the gain is 1.3 dBi.

Over very poor ground, the horizontally polarized delta loop is better than the vertically polarized loop for all wave angles above  $35^\circ$ . Below  $35^\circ$  the vertically polarized loop takes over, but quite marginally. The maximum gain of the vertically and the horizontally polarized loops differs by only 2 dB but the big difference is that for the horizontally polarized loop, the gain occurs at almost  $90^\circ$ , while for the vertically polarized loop it occurs at  $25^\circ$ . The vertically polarized antenna also gives good high-angle rejection (rejection of local signals), while the horizontally polarized loop will not.

Over very good ground, the performance at low angles is greatly improved for both polarizations. The vertically polarized loop is still better at any elevation angle under  $30^\circ$  than when horizontally polarized. At a  $10^\circ$  radiation angle the difference is as high as 10 dB. This makes the vertically polarized delta over good ground far superior for DX operating.

Most practical delta loops show a feed point impedance between 50 and 100  $\Omega$ , depending on the exact geometry and coupling to other antennas. The antenna can be fed directly with a 50 or 70  $\Omega$  coaxial cable, or via a 70  $\Omega$  quarter-wave transformer (see the **Transmission Lines** chapter) if the feed point impedance is near 100  $\Omega$ . At the feed point, use a common-mode choke balun (see the **Transmission Lines** chapter) as current flowing on the outside of the coaxial feed line could upset the radiation pattern.

### THE BOTTOM-CORNER-FED DELTA LOOP

Figure 21.61 shows the layout of the delta loop being fed at one of the two bottom corners. The antenna is slightly compressed from the previous section with a slightly lower apex and longer base than the loop described in the previous section. Because of the "incorrect"

location of the feed point, cancellation of radiation from the base wire is incomplete, resulting in a significant horizontally polarized radiation component. The total field has a very uniform gain coverage (within 1 dB) from  $25^\circ$  to  $90^\circ$ . This may be a disadvantage for the rejection of high-angle signals when working DX at low angles.

Due to the feed point location, the end-fire radiation (radiation in line with the loop) has become asymmetrical with a side null of nearly 12 dB at the peak radiation angle of  $29^\circ$ . The loop actually radiates its maximum signal about  $18^\circ$  off the broadside direction. This feed point configuration greatly affects the pattern of the loop so use bottom-corner-feed with care.

Figure 21.60 — Superimposed patterns for horizontally and vertically polarized delta quad loops (shown at A) over very poor ground (B) and very good ground (C). Over better ground, the vertically polarized loop performs much better at low radiation angles, while over both good and poor ground the vertically polarized loop gives good discrimination against high-angle local signals.

## Project: Two-Band Loop for 30 and 40 Meters

The following antenna design is from a *QST* Hints and Kinks entry by James Brenner, NT4B, in the May 1989 issue. The version shown in Figure 21.62 is fed at the apex of a delta loop but can be adapted to a square or quad loop shape.

The original design was derived from "The Mini X-Q Loop" in *All About Cubical Quad Antennas* by Bill Orr, W6SAI (now out of print) which is  $1\frac{1}{2}\lambda$  in circumference, with an open circuit opposite the feed point. That antenna has approximately 1 dB of additional gain over a  $1\lambda$  loop. Since 30 and 40 meters are close to the same  $1\frac{1}{2}\lambda$  ratio, one loop can be converted between  $1\lambda$  on 40 meters and  $1\frac{1}{2}\lambda$  on 30 meters with a switch.

A large, ceramic SPST knife switch is installed in the center of the delta loop's bottom leg as shown in Figure 21.62. With the switch open, the loop acts a  $1\frac{1}{2}\lambda$  loop at 10.5 MHz, so 18 inch wires were added to the loop on either side of the switch to lengthen the antenna and lower the resonant frequency to 10.1 MHz. Closing the switch shorts out the wires and the loop becomes a regular  $1\lambda$  continuous loop for 40 meters.

Note that there is fairly high voltage present at the switch when transmitting on 30 meters. If a relay is used, be sure the contact spacing is sufficient to avoid arcing or use additional pairs of contacts to increase the overall spacing.

The antenna is fed through a quarter-wave transformer (see the **Transmission Lines** chapter) of  $75\ \Omega$  RG-11 coax, approximately 23 feet long. According to the author, when configured for 40 meters, the loop has a satisfactory SWR of less than 2:1 on 15 meters. In addition, the 30 meter configuration can be used successfully on 80 meters with the use of an antenna tuner.

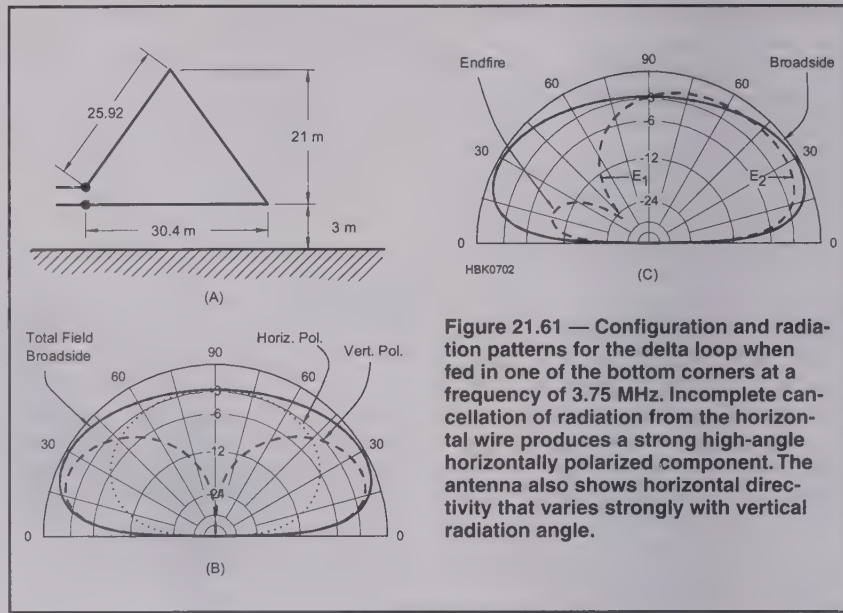

Figure 21.61 — Configuration and radiation patterns for the delta loop when fed in one of the bottom corners at a frequency of 3.75 MHz. Incomplete cancellation of radiation from the horizontal wire produces a strong high-angle horizontally polarized component. The antenna also shows horizontal directivity that varies strongly with vertical radiation angle.

Figure 21.62 — NT4B's 30 and 40 meter loop is fed at the top via a quarter-wave 40 meter matching transformer made of  $75\ \Omega$  coax. Note the 18 inch tuning wires used to lower the antenna's 30 meter resonance from 10.5 to 10.1 MHz. Adjust the length of these wires to set the 30 meter resonant frequency.

Figure 21.63 — Two methods of installing the insulators at the loop corners.

**Project: Multiband Horizontal Loop Antenna**

Along with the multiband, non-resonant dipole, many amateurs operate on HF with great success using a horizontal loop antenna. All that is required are at least three supports able to hold the corners of the antenna 20 or more feet above the ground (and even that is negotiable) and enough room for a loop of wire one wavelength or more in circumference at the lowest frequency of operation. (Smaller loops can be used with an impedance-matching unit.)

Start by calculating the total length of wire using Equation 7. You'll need one insulator for each support and lengths of rope that are at least twice the height to which the insulator will be raised. You can feed the antenna at one of the corner insulators or anywhere along the wire with a separate insulator. Examples of corner insulators are shown in Figure 21.63. Using floating insulators allows the wire to move as the antenna flexes. One of the insulators should be of the fixed type, or the antenna can be fed at one corner with the loop wires attached to a pair of insulators sharing a common support rope. This holds the antenna feed point in place.

If the loop is only going to be used on the band for which it is resonant, coaxial cable can be used as the feed line, since SWR will be low. A choke balun at the feed point is recommended. For multiband use, open-wire feed line should be used, with an impedance-matching unit in the shack. See Figure 21.15 for an example of how open-wire line can be attached at the feed point.

Figure 21.64 — An example of a horizontal full-wave loop designed for 1.9 MHz. The antenna can be fed with any length of open-wire or ladder line. The loop is usable on all HF bands..

The impedance at the station end of the open-wire line can be matched to 50 Ω for coaxial cable with a balanced ATU or a balun and regular ATU. The impedance will vary widely so do not expect a fixed-ratio balun (1:1, 4:1, 9:1, and so on) to provide a match over wide frequency range. The balun's function is to connect the open-wire line to unbalanced equipment or feed lines.

On its fundamental frequency, the antenna's maximum radiation will be straight up, making it most useful for regional communications at high elevation angles with the occasional DX contact. At higher frequencies, the loop will radiate more strongly at lower angles for better signal strengths at long distances. An example design is shown in Figure 21.64.

# 21.8 HF Mobile Antennas

HF mobile operation has been part of Amateur Radio since the 1930s. Mobile operation has become very popular with advances in antenna design and excellent mobile radios. Material in this section was contributed and updated by Alan Applegate, KØBG, whose website ([www.k0bg.com](http://www.k0bg.com)) has many useful pages on HF mobile stations and operating.

High frequency (HF) mobile antennas come in every size and shape imaginable, from simple whips to elaborate, computer-controlled behemoths. Regardless of the type and construction, an HF mobile antenna should have a few important attributes.

- **Sturdiness:** It should be permanently mounted (without altering the vehicle's safety equipment) to stay upright at highway speeds with a minimum of sway.
- **Mechanically stable:** Sudden stops or sharp turns won't cause it to sway about, endangering others.
- **Flexibly mounted:** Permits bending around branches and obstacles at low speeds.
- **Weatherproof:** Withstands the effects of wind, rain, snow and ice.
- **Tunable:** If multiband operation is desired, be tunable to different HF bands without stopping the vehicle.
- Be easily removable when required.
- Be as efficient as possible.

Of all the antenna choices available, the *whip* antenna — a self-supporting rod or wire mounted at its base — has passed the test of time as providing all of these attributes in one way or another. The following sections discuss the different types of whips, how they are attached to and interact with the vehicle, and how they are connected to the transmitter.

## 21.8.1 Simple Whips

The simplest of antennas is a quarter-wave whip, but it's only practical on the upper HF bands because of the required length. For example, a 10 meter quarter-wavelength antenna is about 8 feet long. It doesn't require a loading coil, so its efficiency is approximately 80%. The reason efficiency isn't 100% is because of resistive losses in the whip itself, stray capacitance losses in the mounting hardware and ground losses, which we'll cover later. The end result is that the feed point impedance at the antenna's base is very close to 50 Ω.

As we move lower in frequency, the physical length must increase for an equivalent electrical length, but there is a limit. In most localities, the maximum height at the tip of the antenna needs to be less than 13.5 feet (4.1 meters). This generally limits whip length to 10.5 feet (3.2 meters) for an average installation on a vehicle. Creating a resonant antenna below this length on 10 or 12 meters isn't a problem. On the 15 meter and lower

frequency bands, 10.5 feet is not long enough for a resonant whip antenna and additional electrical measures are required.

### WHIP RADIATION RESISTANCE

The power radiated by the antenna is equal to the radiation resistance times the square of the antenna current. The radiation resistance,  $R_r$ , of an electrically small antenna is given by:

$$R_r = 395 \times \left(\frac{h}{\lambda}\right)^2 \quad (8)$$

where

- $h$  = radiator height in meters
- $\lambda$  = wavelength in meters =  $300 / f$  in MHz

Since radiation resistance of these electrically small antennas is a function of height, the antenna must be lengthened physically or electrically to increase it. Increasing radiation

resistance improves efficiency as shown next.

The efficiency of the antenna,  $\eta$ , equals the radiation resistance,  $R_r$ , divided by the resistive component of the feed point impedance,  $R_{fp}$ , which for actual antennas includes ground losses and losses in the antenna:

$$\eta = \frac{R_r}{R_{fp}} \times 100\% \quad (9)$$

Since an electrically short antenna has a low radiation resistance, careful attention must be paid to minimizing losses in the antenna system that can greatly reduce the antenna's effectiveness.

### WHIP CAPACITANCE

As we shorten an antenna to less than  $\frac{1}{4} \lambda$ , its radiation resistance decreases and the capacitance drops as shown in **Table 21.11**. **Figure 21.65** shows that capacitance is not very

sensitive to frequency for  $h/\lambda$  less than 0.075.

The capacitance in pF of an electrically small antenna is given approximately by:

$$C = \frac{55.78 \times h}{[(\text{den1}) \times (\text{den2})]} \quad (10)$$

where

$$(\text{den1}) = (\ln(h/r) - 1)$$

$$(\text{den2}) = [1 - (f \times h/75)^2]$$

$\ln$  = natural logarithm

$r$  = conductor radius in meters

$f$  = frequency in MHz

Radiation resistance rises in a nonlinear fashion and the capacitance drops just as dramatically with increase in the ratio  $h/\lambda$ . Figure 21.65 can be used for estimating antenna capacitance for other heights and shows that capacitance is not very sensitive to frequency for  $h/\lambda$  less than 0.075 which occurs at 8 MHz in this case.

## 21.8.2 Coil-Loaded Whips

To bring an electrically-short whip antenna to resonance, we must add inductance in the form of a loading coil. The coil can take many forms, and it may be placed almost anywhere along the length of the radiating element. It cancels out the capacitive reactance by introducing an equal but opposite inductive reactance. Some coils are mounted at the base of the mast — a base-loaded antenna — and some are mounted near the center (center-loaded) or the top (top-loaded).

As the coil is moved higher, the radiation resistance increases (a good thing), but the necessary coil reactance also increases as do resistive losses in the coil. Therefore it becomes a balancing act, which requires a thorough understanding of the parameters involved, to choose the optimal coil location.

Table 21.11 lists the characteristics of an 8 foot (2.4 meter) mobile whip in both base-loaded and center-loaded configurations. The table shows the required loading coil inductance to bring the antenna to resonance on the different bands. The matching coil inductance is placed across the feed point to bring the impedance to 50  $\Omega$ .

Note that center-loading approximately doubles both the required inductance and the coil's resistive losses. The radiation resistance also increases, but only in that part of the antenna above the loading coil. If ground losses are included in the calculations, the coil's optimal position changes, but it is typically close to the center of the antenna.

It is important to note that the total amount of stray capacitance from the mounting hardware and proximity of the whip to the vehicle may be much higher depending on where and how the antenna is mounted. The higher

the stray capacitance, the less efficient the antenna will be.

**Table 21.12** compares different types of HF mobile antennas against an unloaded whip antenna. The simple whip is assumed to be a full-size  $\frac{1}{4}$  wavelength. The effects of mounting are not included.

### LOADING COIL Q

Antenna system Q is limited by the Q of the coil. The bandwidth between 2:1 SWR points of the system =  $0.36 \times f/Q$ . On 80 meters, the bandwidth of the 10.5 foot whip =  $0.36 \times 3.5/200 = 6.3$  kHz. If we could double the Q of the coil, the efficiency would double and the bandwidth would be halved. The converse is also true. In the interest of efficiency, the highest possible Q should be used!

Loading coil Q is especially important on the lower HF bands where coil losses can exceed ground losses. The factors involved include wire size, wire spacing, length-to-diameter ratio and the materials used in constructing the coil. All of the factors interact with one another, making coil design a compromise — especially when wind loading and weight become major considerations.

In general — the larger the coil, the higher the Q. The more mass within the field of the coil (metal end caps for example) the lower the Q. Short, fat coils are better than long, skinny ones. However, the coil's length-to-diameter ratio (L/D) for the highest Q increases as the inductance increases. It ranges from 1:1 on the upper HF bands to as much as 4:1 on the lower bands where the inductance is large. Practical mechanical considerations for coils with large reactance values above 1000  $\Omega$  (160 meter coils for example) require the length-to-diameter ratio to increase, which lowers Q. **Table 21.13** suggests loading coil dimensions that maximize Q.

Another significant factor arises from high Q. Let's assume that we deliver 100 W on 80 meters to the 7.43  $\Omega$  at the antenna terminals. The current is 3.67 A and flows through the 1375  $\Omega$  reactance of the coil giving rise to  $1375 \times 3.67 = 5046$  V<sub>RMS</sub> (7137 V<sub>peak</sub>) across the coil! This is a significant voltage and may cause arcing if the coil is wet or dirty.

With only 30.6 pF of antenna capacitance, the presence of significant stray capacitance

at the antenna base shunts currents away from the antenna. RG-58 coax presents about 21 pF/foot. A 1.5 foot length of RG-58 would halve the radiation efficiency of our example antenna. For cases like the whip at 3.5 MHz, the matching network has to be right at the antenna!

## 21.8.3 Base vs Center vs Continuous Loading

There are a few important aspects to be kept in mind when selecting or building an HF mobile antenna. As the antenna becomes longer, less loading inductance is required and the coil Q can become higher, improving efficiency. Also, for longer antennas, the better the mounting location has to be in order to optimize efficiency. We'll cover mounting and efficiency later. (See the section on Physically Short Verticals earlier in this chapter for more on loading vertical antennas.)

Placing the loading coil at the base results in the current distribution shown in **Figure 21.66A**. If we move the coil to the center, the current curve looks like the one in **Figure 21.66B**. The location of the optimal position between the two extremes depends on the ground losses, and to a lesser degree on loading coil Q and overall length. For

Figure 21.66 — Relative current distribution on a base-loaded antenna is shown at A and for a center-loaded antenna at B.

example, if the ground losses were zero, the best position would be at the bottom. As the ground losses increase, the optimal position gets closer to the center. If the ground losses are high enough, the optimal position is in the top one-third of the antenna's length, but efficiency is very poor.

Center-loading increases the current in the lower half of the whip as shown in Figure 21.66B. Capacitance for the section above the coil can be calculated just as for the base-loaded antenna. This permits calculation of the loading inductance. The center-loaded antenna is often operated without any base matching in which case the resistive component can be assumed to be  $50 \Omega$  for purposes of calculating the current rating and selecting wire size for the inductor. The reduced size of the top section results in reduced capacitance which requires a much larger loading inductor.

Because of the high value of inductance required for center-loading, high-Q coils are very large. The large wind resistance necessitates a very sturdy mount for operation at highway speed. One manufacturer of this type of coil does not recommend their use in rain or inclement weather. The higher Q of these large coils results in a lower feed point impedance, necessitating the use of a base matching element in the form of either a tapped inductor or a shunt capacitor to match to  $50 \Omega$ . (See this chapter's section on Mobile HF Antenna Matching.) Another manufacturer places the coil above the center and uses a small extendable whip or wand for tuning.

Antennas known by the trade name "Hamsticks" shown in Figure 21.67 aren't really continuously-loaded. Instead, a small diameter enameled wire loosely wound around a fiberglass tube forms the base section of the antenna. Approximately half way up the antenna, the wire is close wound to form a lumped-element loading coil and a metal whip or stinger is attached at the top to complete the whip. A heat-shrink sleeve covers the wound section of the antenna. The stinger's length can be adjusted to tune the antenna to the desired operating frequency.

In recent years, these lightweight antennas have become very popular. Their input impedance is near  $50 \Omega$  in part because of their low-Q base and loading coil sections. Thus they don't require matching once the length of the top whip or stinger is adjusted. They are light in weight (about a pound), short in length (typically 6 to 8 feet) and thus easy to mount. For temporary use, easy mounting may be more important than high efficiency. This type of antenna is most effective on 20 meters and higher frequency bands.

The wound base section of these antennas is a very weak radiator, acting more like a transmission line or distributed element than a linear radiating element. The long and thin coil has low Q, as well, increasing antenna loss. The close-wound section acts like a lumped element and does not radiate.

In the interests of efficiency, electrical

Figure 21.67 — Continuously-loaded whip antennas are short and lightweight. The base section consists of a fiberglass tube wound with wire to form the loading inductor. length matters because radiation resistance increases as the square of electrical length. Higher radiation resistance in a mobile antenna results in higher efficiency. All else being equal, a 12 foot antenna will have 4 times the radiation resistance than one 6 feet long. As pointed out above, the maximum physical height should be less than 13.5 feet

## Designing a Base Loading System

This design procedure was contributed by Jack Kuecken, KE2QJ. To begin, estimate the capacitance, capacitive reactance and radiation resistance as shown at the beginning of this section. Then calculate the expected loss resistance of the loading coil required to resonate the antenna. There is generally additional resistance amounting to about half of the coil loss which must be added in. As a practical matter, it is usually not possible to achieve a coil  $Q$  in excess of 200 for such applications.

Using the radiation resistance plus 1.5 times the coil loss and the power rating desired for the antenna, one may select the wire size. For high efficiency coils, a current density of 1000 A/inch<sup>2</sup> is a good compromise. For the 3.67 A of the example we need a wire 0.068 inch diameter, which roughly corresponds to #14 AWG. Higher current densities can lead to a melted coil.

Design the coil with a pitch equal to twice the wire diameter and the coil diameter approximately equal to the coil length. These proportions lead to the highest  $Q$  in air core coils.

The circuit of **Figure 21.A4** will match essentially all practical HF antennas on a car or truck. The circuit actually matches the antenna to 12.5  $\Omega$  and the transformer boosts it up to 50  $\Omega$ . Actual losses alter the required values of both

**Figure 21.A4** — The base-matched mobile whip antenna

the shunt inductor and the series capacitor. At a frequency of 3.5 MHz with an antenna impedance of 0.55  $-j1375 \Omega$  and a base capacitance of 2 pF results in the values shown in **Table 21.B**. Inductor and capacitor values are highly sensitive to coil  $Q$ .

**Table 21.B**  
Values of L and C for the Circuit of **Figure 21.A4** on 3.5 MHz

Coil $Q$	L ( $\mu$ H)	C (pF)	System Efficiency (%)
300	44	11.9	8.3
200	29.14	35	3.72
100	22.2	58.1	1.4

Furthermore, the inductor values are considerably below the 62.5  $\mu$ H required to resonate the antenna.

This circuit has the advantage that the tuning elements are all at the base of the antenna. The whip radiator itself has minimal mass and wind resistance. In addition, the rig is protected by the fact that there is a dc ground on the radiator so any accidental discharge or electrical contact is kept out of the cable and rig. Variable tuning elements allow the antenna to be tuned to other frequencies.

Connect the antenna, L and C. Start with less inductor than required to resonate the antenna. Tune the capacitor to minimum SWR. Increase the inductance and tune for minimum SWR. When the values of L and C are right, the SWR will be 1:1.

(4.1 meters). As discussed in this chapter's section on Physically Short Antennas, one way to increase the electrical length but not the physical length, is top-loading. A mobile HF antenna is top-loaded by using a *capacitance hat* or "cap hat."

As their name implies, cap hats add capacitance at the top of the antenna, above any loading coil. This increases radiation resistance by as much as four times under ideal conditions, but at the expense of increased weight, wind loading and complexity. Not all antennas, especially small screwdriver types, are sturdy enough to support a large cap hat. For those that are, or if the antenna can be guyed or stiffened, cap hats offer increased efficiency and bandwidth.

The actual placement of the cap hat is important, too. If mounted too close to the loading coil, efficiency is lower than with no cap hat at all. Thus, the best mounting location is at the very top of the antenna.

The physical design of the cap hat is limited by practical concerns. The largest are approximately 3 feet in diameter and require additional bracing or guying of the antenna. Most are constructed of straight radial wires without an outer rim. The loop design shown

**Figure 21.68** — A typical capacitance hat or "cap hat" added at the top of a mobile whip antenna. The antenna is a Scorpion (scorpionantennas.com).

in **Figure 21.68** is more efficient than straight wires, but tends to snag more on errant limbs. See the referenced *QEX* article by Griffith and the *QST* article by Clement for more on capacitance hats and top loading of mobile antennas.

### 21.8.5 Remotely Controlled HF Mobile Antennas

Remotely controlled (motorized) HF mobile antennas are commonly referred to as *screwdriver antennas*. Don Johnson,

W6AAQ (SK), is credited by many as the father of the screwdriver antenna. His design was not the first motorized antenna, but he certainly popularized it. There are now over 50 commercial versions available.

They're called screwdrivers because the first examples used a stripped-down rechargeable electric screwdriver assembly to adjust the resonant frequency of the antenna. The motor turns a threaded rod in and out of a nut attached to the bottom of the coil. This in turn moves the coil in and out of the lower mast section. Contacts at the top of the mast slide on the outside of the coil, thus adjusting the resonance point. Position sensors may be used to keep track of the location of the coil tap. Nowadays, calling them screwdrivers is a bit of a misnomer as the electric screwdriver motors have been replaced with much more reliable gear motors.

There are several remotely controlled HF mobile antennas that don't change length as true screwdrivers do. Both base and center loaded models are available (see **Figure 21.69**). Whether or not they're more efficient is dependent on the factors discussed in the previous section, rather than the method used to adjust the coil.

**Figure 21.69** — The screwdriver-style remotely-controlled whip antenna. A small motor in the base mast moves a coil past contacts at the top of the metal base section. The top whip section is attached to the top of the coil. As the coil moves out of the mast, more inductance is connected in series between the base section and top section. Screwdriver antennas are popular because they offer multiband coverage. [Joel Hallas, W1ZR, photo]

## RF CHOKES

The motors and position sensors of all remotely-controlled antennas operate above vehicle body potential. The amount of RF present on the leads depends on several factors, especially where and how the antenna is mounted and its overall (electrical) length. Thus the RF current coupled onto the leads must be minimized with an RF choke before entering the vehicle. An inadequate choke may result in erratic controller operation and possible interference with transceiver operation.

The choke should have an impedance of at least two orders of magnitude greater than the impedance of the circuit. In other words, at least 5 k $\Omega$ , and perhaps two or three times that in some cases (stubby antennas and poor mounting schemes are examples). Mix 31 ferrite split beads are ideal for this application, but it takes eight turns to obtain a 5 k $\Omega$

## Determining the Radiation Efficiency of a Center Loaded Mobile Whip

We can measure the radiation efficiency by measuring ground wave field strength  $E$  (dB referenced to  $\mu\text{V}/\text{m}$ ). For the average radio amateur, a field strength meter is not a part of his ham shack gear. We can predict performance using readily available antenna modeling software (one of the many available versions of *NEC*) provided we have a measure of actual losses.

There are a number of loss parameters we do not know. We do not know the  $Q$  factor for the center loading coil ( $R_L$ ), and we do not know the ground-induced loss resistance ( $R_g$ ). In fact we do not know with certainty the radiation resistance ( $R_r$ ), since the antenna sees an image of itself in the ground. *NEC* only gives us the sum of the various resistances.

$$R_{as} = R_r + R_C + R_g + R_L$$

$R_C$ , the only parameter not discussed above, is the conductor loss resistance.

We need to know  $R_r$  if we are going to compute radiation efficiency, since radiation efficiency is given by:

$$\eta = \frac{R_r}{R_{as}}$$

So what do we do? We can measure  $R_{as}$  using the SWR analyzer, by adjusting the tuning so the reactance at the base of the antenna is equal to zero. We can then use *NEC* to predict the base impedance (resistive component), by changing the  $Q$  factor of the inductor so that  $R_{as}$  predicted equals  $R_{as}$  measured. We can then predict the ground field strength (dB $\mu\text{V}/\text{m}$ ) at say 100 m for a transmitter power of 1 kW. We then reference this predicted field strength to that for an electrically small lossless vertical antenna (129.54 dB $\mu\text{V}/\text{m}$  at 100 m for 1 kW transmitter power — which corresponds to the commonly quoted value of 300 mV/m at 1 km). This gives us a pretty good estimate of the radiation efficiency of our mobile whip. — Jack Belrose, VE2CV

choking impedance. Depending on the wire size and insulation, you'll need to use the  $\frac{1}{2}$  or  $\frac{3}{4}$  inch ID cores. Snap-on ferrite beads are available from most Amateur Radio dealers. (More information on this type of RF choke may be found in the **RF Techniques** chapter.)

The choke shown in **Figure 21.70** consists of 13 turns of #18 AWG wire, wound on a  $\frac{3}{4}$  inch ID, mix 31 split bead. It has an impedance of approximately 10 k $\Omega$  at 10 MHz. When winding the chokes, try not to overlap or twist the wires as this reduces the effectiveness.

## 21.8.6 Ground Losses

High frequency mobile ground loss data first appeared in a 1953 issue of *QST*, in an article written by Jack Belrose, VE3BLW (now VE2CV). In the article, Belrose said that the current flowing at the base of the antenna must be returned to the base of the antenna by currents induced in the ground beneath the radiator (antenna). These currents must be collected by the car body and through the capacitance of the car body to the ground. Since the maximum dimension of car body is considerably less than a quarter wavelength on most HF bands, only a portion of these currents will be collected by the car frame itself, and the rest will be collected by ground currents flowing through

the capacitance of the car to the ground. Since the ground is not lossless, quite a large loss resistance ( $R_g$ ) is found.

From that article, the accepted ground loss figure for HF mobile applications varies between 12  $\Omega$  (for 80 meters) and 2  $\Omega$  (for 10 meters). However, these figures do not include stray capacitance from the mounting location and method. Stray capacitance has the same effect as ground losses: reduced efficiency. As a result, in the real world, ground losses can be double the accepted values, reducing an otherwise efficient antenna to mediocrity.

## 21.8.7 Antenna Mounting

### PERMANENT OR TEMPORARY

There are many reasons to install any mobile antenna permanently on a vehicle. The decision to drill holes in sheet metal to mount antennas is hotly debated. While no-hole mounts can be used satisfactorily, it is best to look at all sides of the issue before installing any antenna.

A common concern about drilling a hole for an antenna mount is with regard to a leased vehicle. Leases don't necessarily preclude properly installed antenna mounting holes. What lease agreements are primarily concerned with is body damage such as from an accident or mistreatment. Properly installed NMO mounts, for example, are often acceptable. It's always prudent to ask before leasing the vehicle.

Drilled holes and waterproof mounts also help minimize common-mode current on the coaxial feed line. This helps reduce RFI to or from on-board computers and electrical devices. Aside from the hole itself, a permanent mount also minimizes damage to the finish.

Here is an important caveat to keep in mind: While the roof of a vehicle is a very good place to mount an antenna, more and more new vehicles are equipped with side curtain air bags. They typically are mounted along the edges of the headliner, including the rear seat area if there is one. The wiring to these devices is routed through any one (or more) of the roof pillars. Extra care is required when installing antennas in vehicles so equipped. If you are the least bit apprehensive about installing a roof-mounted antenna, seek professional help from your dealer or a qualified installer.

Mobile antenna mounting hardware runs the gamut from mundane to extravagant. Choosing the correct hardware is based on need, as well as on personal preference. There are too many variables with respect to mounting HF mobile antennas on modern vehicles to cover in a short discussion. It is easier to explain what not to do and adapt those guidelines to your own personal circumstances: the antenna mount should:

- Be permanently mounted;
- Be strong enough to support the antenna;
- Have as much metal area under it as possible;
- Be well-grounded to the chassis or body;
- Not interfere with doors, trunks, or access panels and
- Be removable with minimal damage to the vehicle.

Aside from maximizing performance by minimizing ground and stray capacitance losses, there are also safety reasons for using a permanent mount with HF antennas. If you need to use a temporary mount, use the multiple-magnet mounts for their superior

holding strength. Any mobile HF antenna attached to a vehicle traveling at highway speed by a single-magnet mount is a tenuous situation at best.

### TYPE OF MOUNT

The type of mount is dictated by several conditions. These include a decision whether or not to drill holes, the size, weight and length of the antenna. If you want to operate HF mobile operation regularly, you are better off with a permanent mount. If you're not, a trunk lip, angle bracket, or license plate mount, and a lightweight, continuously-loaded antenna may meet your needs.

Ground plane losses directly affect a mobile antenna's efficiency. From this standpoint, mounts positioned high on the vehicle are preferred over a trailer hitch, bumper or other locations that place the antenna where the vehicle body will be close to the radiating element.

The ground plane of a mobile vertical antenna begins where the coax shield connects. When the feed line shield couples to the vehicle body capacitively as in a mag-mount, or when the mass of the vehicle is far below the feed point (long extension sections attached to trailer hitch mounts), ground losses escalate dramatically. Running a ground strap to the nearest connecting point to the vehicle body does not eliminate ground losses. Remember that the ground connection is part of the antenna system, and it is the efficiency of the whole system that is important.

While it is difficult to mount an HF antenna without at least part of the mast being close to the body, the coil must be kept free and clear

or tuning problems and reduced efficiency will result. In some cases, vans and SUVs for example, front-mounting may become necessary to avoid excessive coil-to-body interaction.

One drawback to trunk lip and similar clip mounts is the stress imposed on them as the lids and doors are open and closed. In most cases, angle brackets that attach to the inner surfaces with screws are a better choice.

Sometimes, the only solution is a custom-made bracket like the one shown later in this chapter. Here too, the circumstances dictate the requirements. Keep in mind that removing permanently installed antenna mounts such as the ball mount shown in **Figure 21.71** will always leave some body damage, but temporary ones do, too. Only the severity is in question, and that's in the eyes of the beholder.

## 21.8.8 Mobile HF Antenna Matching

Modern solid-state transceivers are designed for loads close to 50  $\Omega$  impedance. Depending on the design of the antenna (primarily depending on coil position and Q), overall length and the ground losses present, the input impedance is usually closer to 25  $\Omega$  but may vary from 18  $\Omega$  to more than 50  $\Omega$ . Note that a vehicle is an inadequate ground plane for any HF mobile antenna. Typical ground loss varies from 20  $\Omega$  (160 meters) to 2  $\Omega$  (10 meters). Stray capacitance losses may further increase the apparent ground losses.

It's important to remember two important facts. First, as the coil is moved past the center of the antenna toward the top, the coil's resistive losses begin to dominate, and the input impedance gets closer to 50  $\Omega$ . Second, short stubby antennas require more inductance than longer ones, which increases resistive losses in the coil (low Q). While no matching is required in either case, efficiency suffers, and may actually drop below 1% on the lower bands. Another way to look at the situation is that an antenna with no matching required implies a low efficiency.

Ground loss, coil position, coil Q, mast size, whip size and a few other factors determine the feed point impedance, which averages about 25  $\Omega$  for a typical quality antenna and mount. This represents an input SWR of 2:1, so some form of impedance matching is required for the transceiver. There are three ways to accomplish the impedance transformation: capacitive, transmission-line transformer and inductive matching as shown in **Figure 21.72**. Each has its own unique attributes and drawbacks.

Transmission line transformers, in this case an unun in **Figure 21.72A**, do provide a dc ground for the antenna. They can be tapped or switched to match loads as low as a few ohms. Their broadband nature makes them ideal for HF mobile antenna matching. Since a remotely-controlled HF mobile

**Figure 21.71** — A simple ball mount is sturdy but requires drilling holes in the vehicle body.

antenna's input impedance varies over a wide range, transmission line transformers are best utilized for matching monoband antennas.

Inductive matching in Figure 21.72B borrows a little capacitance from the antenna ( $C_a$ ) — the antenna is adjusted to a frequency slightly higher than the operating frequency, making the input impedance capacitive. This forms a high-pass L-network, which transforms the input impedance to the 50  $\Omega$  transmission line impedance. It is ideal for use with remotely-controlled antennas, as its reactance increases with frequency. By selecting the correct inductance, a compromise can be reached such that the impedance transformation will result in a low SWR from 160 through 10 meters. The approximate value is 1  $\mu\text{H}$ , but may vary between 0.7 and 1.5  $\mu\text{H}$ .

Adjusting the shunt coil can be done without transmitting by using an antenna analyzer and takes about 10 minutes. (Full instructions for properly adjusting a shunt coil may be found at [www.k0bg.com/coil.html](http://www.k0bg.com/coil.html).) Because no further adjustment is necessary, shunt coil matching is ideal for remotely-controlled HF mobile antennas.

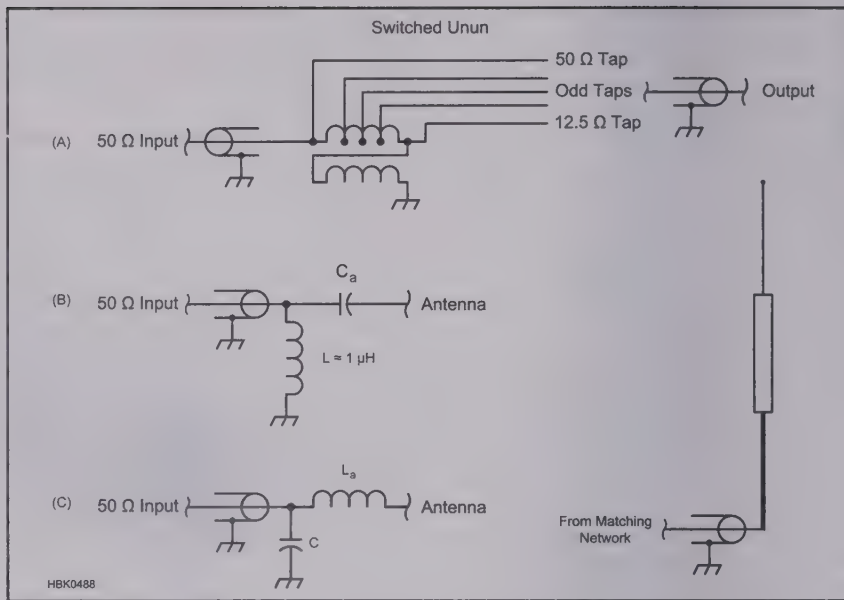

Capacitive matching in Figure 21.72C borrows a little inductance from the antenna ( $L_a$ ) — the antenna is adjusted to a frequency slightly lower than the operating frequency, making the input impedance inductive. This forms a low-pass L-network, which transforms the input impedance to the 50  $\Omega$  transmission line impedance. While it works quite well, it has two drawbacks. First, capacitive matching presents a dc ground for the antenna, which tends to increase the static levels on receive. Second, the capacitance changes with frequency, so changing bands also requires a change in capacitance. This can be a nuisance with a remotely controlled antenna.

An important point should be made about dc grounding in addition to the static issue. If the antenna element should come in contact with a low-hanging high tension wire, or if lightning should strike it, dc grounding offers an additional level of protection for you and your transceiver.

### 21.8.9 Remotely-Tuned Antenna Controllers

There are three basic types of remote controllers: manual, position sensing and SWR sensing. Manual controllers consist of a DPDT center-off switch that changes the polarity of the current to the motor. Some commercial models include an interface with the radio that causes the radio to transmit a low-power carrier for tuning. Reading the SWR is left to the user. Some manual controllers incorporate a position readout to aid the operator in correctly positioning the antenna.

Position sensing controllers incorporate a magnet attached to the motor output shaft.

**Figure 21.72** — A well-constructed and mounted HF mobile antenna will have an average input impedance around 25  $\Omega$ , requiring some matching to the feed line. The unun transmission line transformer (A) is a 4:1 configuration with taps added to match intermediate impedance values between 50 and 12.5  $\Omega$ . The high-pass L-network (B) uses some of the antenna's capacitive reactance as part of the network and the low-pass L-network (C) uses some of the antenna's inductive reactance as part of the network. Both (A) and (B) result in an antenna at dc ground, an important safety issue.

**Figure 21.73** — A screwdriver antenna controller made to work with the IC-7000 transceiver.

The magnet opens and closes a reed switch. During set up, the antenna is set to one end of its range or the other. Then the resonant points are found (you have to do this yourself) and stored in multiple memory locations. As long as power remains applied to the controller, a simple button push will move the antenna to a specific preset point. Some controllers use band or frequency data from a port on the radio and reset the antenna to the nearest preset based on that information.

SWR-sensing controllers either read data from the radio or from a built-in SWR bridge. Depending on the make and model, a push of the radio's tuner button (or one on the controller) causes the radio to transmit at a reduced power setting. The controller then powers the antenna's tuning motor. When the preset SWR threshold is reached, the controller stops the transmission and shuts off the motor. **Figure 21.73** shows an example of a controller made to work with a specific transceiver.

Automatic controllers are far less distracting than manual ones. Most offer a parking function that collapses the coil of a screw-driver antenna into the mast (highest frequency position, lowest overall length). If you garage your vehicle, this is a welcome feature.

### 21.8.10 Efficiency

Length matters! All else being equal, a 9 foot antenna will be twice as efficient as a 6 foot antenna, because radiation resistance relates directly to the square of the physical length. Further, longer antennas require less reactance to resonate, hence coil Q is higher, and resistive losses lower.

Mounting methodology matters! It is the mass under the antenna, not alongside, that counts. The higher the mounting, the less capacitive coupling there will be between the antenna and the surface of the vehicle and the lower ground losses will be.

### Project: Mounts for Remotely-Tuned Antennas

Remotely tuned antennas have become very popular, but they all have one thing in common: they're difficult to mount. They require both a coaxial feed line and a dc power connection, and no one makes a universal mount for them. The short, stubby ones aren't any more difficult to mount than a small whip antenna, but the "full-sized" ones (8 feet and longer) require special consideration.

These antennas are heavy (up to 18 pounds), so the mounting medium must be extra strong, and well anchored. As a result, many hams opt for a bumper or trailer hitch mount, even though the low mounting position reduces efficiency.

For some, efficiency is paramount which dictates mounting the antenna as high as possible. Doing either low or high mounting often requires custom fabrication. The accompanying photos illustrate the two different strategies that show Amateur Radio ingenuity at its finest.

Figures 21.74 and 21.75 depict the mobile installation of Fokko Vos, PA3VOS. Except for a Hi-Q heavy-duty quick-disconnect, the complete mount was custom engineered by Fokko. The mount bolts to a frame extension, which in turn is bolted to the undercarriage using existing bolts. Note that the rear hatch may be opened without the antenna being removed. Had the trailer hitch been used, this would not be the case.

Figure 21.76 depicts installation on a Ford F350 based motor home owned by Hal Wilson, KE5DKM. Hal designed the bracket, and had a local machine shop do the hard work. It is made of 1/4 inch, high-strength

aluminum, and the seams are welded. A powder-coat finish tops off the fabrication.

Shown here during installation, the bracket just fits into the right-side hood seam. The piece jutting out from the mount was to be used to further brace the mount. However, after all of the bolts were installed, additional bracing became unnecessary.

Figure 21.74 — The PA3VOS antenna mount easily supports a large screw-driver antenna and is offset to allow the hatch to open and close without removing the antenna.

### Project: Retuning a CB Whip Antenna

The most efficient HF mobile antenna is a full-size quarter-wavelength whip. Wouldn't it be nice if we could use one on every band? Alas, we cannot, but we can use one easily on 10 and 12 meters since the overall length will be less than 10 feet. If we start with a standard-length 102 inch whip and its base spring, we just need to shorten it a little for 10 meters, and lengthen it a little for 12 meters. Here's how to do it.

The formula for calculating the length of a  $\frac{1}{4} \lambda$  antenna in feet is  $234/f$ , where  $f$  is the frequency (MHz). Since the formula is for wire antennas, and the whip is larger in diameter, the resulting length will be slightly too long. This is a good thing because it is easier to remove a little length than it is to add some. This makes tuning easier.

Using the formula, we discover the needed length for 10 meters (28.5 MHz) is 98.5 inches. Thus, we need to remove 3.5 inches and account for the length of the base spring (about 6 inches), for a total of 9.5 inches to be removed. This is best accomplished by filing a notch on opposite sides of the tip of the whip, and snapping it in two. Protect your eyes when you do this, as shards and splinters can fly off the broken ends. If a fiberglass whip is being modified, clip the internal wire at the top of the remaining base section. Remove the plastic cap from the discarded top section and replace it over the new top of the antenna.

Depending on the mount used, the actual resonant frequency will be lower than 28.5 MHz as the mounts adds effective length.

Figure 21.77 — CB whips are easily re-tuned for 10 meter (A) and 12 meter (B) mobile operation.

A standard CB antenna ball mount will easily support a whip. The finished antenna is shown in **Figure 21.77A**.

Once the antenna is mounted on the vehicle, simply trimming the overall length  $\frac{1}{2}$  inch at a time will eventually produce a low SWR at your desired frequency.

### LENGTHENING FOR 12 METER OPERATION

Lengthening a CB whip for 12 meters requires a little more work. Thankfully, there's a easy solution if you have a CB radio or truck stop near you. Wilson and other vendors sell short masts designed for the CB market. They have the requisite  $\frac{3}{8} \times 24$  threads to accept a standard whip, and they come with a female-to-female coupler. The 10 inch model is ideal for our use, and costs under \$10.

Using our formula  $234/f$ , the overall length needs to be 112.6 inches for 24.93 MHz. Adding 6 inches for the spring, 10 inches

for the extension mast, and 102 inches for the whip, gives us 118 inches. So we need to remove 5.4 inches from the whip. Then just trim off  $\frac{1}{2}$  inch at a time as above to resonate the antenna. The finished antenna is shown in **Figure 21.77B**.

### FINISHING UP

There are two more things to consider. If a metal whip was modified, you'll need to replace the corona ball at the tip of the antenna. It helps reduce static from corona discharge. It's held on by a set screw and has little effect on tuning. Most CB shops sell them.

The other consideration is ground loss. Theoretically, a  $\frac{1}{4}\lambda$  vertical will have an input impedance of  $36 \Omega$ . In a mobile installation, we have ground losses and stray capacitance losses in the mounting hardware. As a result, the real-world input impedance should be very close to  $42 \Omega$ , yielding a rather low SWR and good efficiency.

## 21.9 VHF/UHF Mobile Antennas

The simple  $\frac{1}{4}\lambda$ ,  $\frac{1}{2}\lambda$ , and  $\frac{3}{4}\lambda$  ground-plane whips are the most common VHF/UHF mobile antennas. Collinear antennas with higher gain are available. However, high gain and the lower radiation angle that goes with it isn't always a desirable attribute.

When using repeaters in urban areas, where higher angles of radiation are preferred, you're typically better off with a unity-gain antenna — a  $\frac{1}{4}\lambda$  whip. It all depends on the HAAT (height above average terrain) of the repeater being used with respect to the mobile station's HAAT. In mountainous areas you're always better off with a unity gain antenna as the repeaters are much higher in elevation than the mobile station is.

If you're working simplex and living in a suburban or rural area, a high-gain antenna might have a slight edge. However, where, and how the antenna is mounted is more important than gain. A  $\frac{1}{4}\lambda$  ground plane mounted in the center of the roof will typically out perform a gain antenna mounted on the trunk lid.

Sturdiness is also an important attribute, given the unintended abuse to which mobile antennas are subjected. The simple quarter-wave ground plane has the advantage here, as it isn't much more than a springy piece wire. If you look closely at some of the higher-gain antennas, you'll notice they have very small phasing coils, usually held together by small set screws. Hit one hard enough with a low-hanging limb and your antenna will break whereas a simple quarter-wave whip will only bend. A little straightening and you're back on the air.

### 21.9.1 VHF/UHF Mobile Antenna Mounts

Without doubt, the best VHF/UHF mobile mount ever devised is the NMO (New

Motorola) shown in **Figure 21.78**. When properly installed in vehicle sheet metal, the mount will not leak even when the antenna is removed for car washing. SO-239 and threaded or snap-in mounts often leak even with the antenna attached.

Glass-mounted antennas are rather lossy, especially at lower VHF frequencies (2 meters). Many new vehicles use window glass with a metallic, anti-glare (passivated) coating that interferes with capacitive coupling through the glass. These antennas also transfer mechanical abuse to the glass, risking breaking the glass the antenna is mounted on.

### MOUNTING LOCATION

As mentioned above, the center of the roof is an ideal mounting location for a VHF/UHF antenna. However, many mobile operators share a reluctance to drill the proper mounting holes fearing that doing so will depreciate the value of the vehicle. Instead, they rely on a mag-mount which has its own set of negatives including where and how to route the coax cable into the vehicle. They tend to collect metallic road debris, primarily brake pad dust, marring and scratching the painted surface under them, often causing more damage than would the hole for an NMO mount. For these reasons alone, mag-mounts should only be used for temporary installations, such as emergency communication. Paint scratches can be avoided during temporary operation by using a Tyvek pad under the magnet. Tyvek is a tough material used for envelopes, and other similar material will work, as well.

Roof mounting has a few caveats. Modern vehicle roofs have strengthening supports to protect the occupants should the vehicle rollover due to a crash. Do not drill through these supports!

The various side pillars supporting the roof contain wiring for lighting, side airbags, and other accessories, which can make routing of the coax difficult. If you're at all reticent about roof mounting, see a dealer or professional installer.

As an alternative, a trunk lip mount may fit the bill. However, they too have some

drawbacks. They're stressed every time the trunk is opened or closed, and tend to work loose over time. Thus regular maintenance is required to assure a good electrical ground to the trunk lid. In any case, do not sand the paint down to bare metal as this removes the zinc undercoating which in turn promotes rust. It is also important to bond across the trunk hinges to assure a good ground.

Angle brackets work well, too. They're thin enough to fit into the seam of hoods, trunk lids, and back hatches. Coax routing under or around the weather seals can be a problem with the latter two.

### ADJUSTING SWR

Setting the SWR of a VHF/UHF antenna is an important installation procedure, but not one to worry about unless the SWR suddenly makes a large change. Unlike the HF bands, most VHF antennas will cover the whole band segment without the need to retune. That is to say, the SWR will be low across the FM portion of the respective bands. An in-line SWR meter is generally not required as the vertically-polarized antenna is not intended to be used in the weak-signal portion of the bands where horizontal polarization is the norm.

### 21.9.2 VHF/UHF Mobile Antennas for SSB and CW

Operating SSB and CW on 6 meters, 2 meters, and 70 cm offers some exciting

**Figure 21.78** — The NMO (New Motorola) mount is widely used for VHF and UHF mobile antennas. It is available in mag-mount, trunk and lip mount and through-body mounting styles.

**Figure 21.79** — The halo is a popular horizontally polarized mobile antenna for 6 meters through 70 cm. This version was made by Jerry Clement, VE6AB, and the construction article is available online (see text).

prospects for all license classes. While FM communications on the VHF bands are often considered line-of-site, propagation *beyond* line-of-site is common, as discussed in the **Propagation of Radio Waves** chapter.

Modern mobile SSB/CW transceivers usually output 100 W PEP on 6 meters and at least 50 W PEP on 2 meters and 70 cm. Under good band conditions, using horizontally polarized antennas, *beyond* line-of-sight distances can exceed 200 miles even without any sky-wave or tropospheric scatter present!

There's a catch, however. FM communications utilize vertically polarized antennas. Vertical polarization can be used for SSB and CW, but depending on the propagation path, signal strength from a vertically polarized

mobile antenna can have a disadvantage of up to 20 dB compared to a horizontally polarized antenna due to cross-polarization.

Fortunately, horizontally-polarized antennas are of manageable size on the VHF and UHF bands, although they are not as simple to construct as vertically polarized whips. Dipoles and small beams present too much wind resistance to withstand the normal mobile environment. The usual solution is a loop antenna.

**Figure 21.79** shows a horizontally polarized 6 meter loop called a *halo* that was made by Jerry Clement, VE6AB. (Complete construction plans are available in his article "6 Meter halo Antenna for DXing" in the February 2017 issue of *QST* which is

available in this book's downloadable supplemental material.) Square versions, such as those commercially available from M<sup>2</sup> Antenna Systems ([www.m2inc.com](http://www.m2inc.com)) are called *squalos*. Both have a roughly omnidirectional pattern. The "Big Wheel" design is another option and the article "A New Spin on the Big Wheel" by L.B. Cebik, W4RNL, and Bob Cerreto, WA1FXT, from the March 2008 issue of *QST* is included with the downloadable supplemental content, as well. Equivalent antennas for 2 meters and 70 cm are common. Mounting loop antennas on a vehicle can be less cumbersome than mounting an HF antenna because they don't require a ground plane. A simple hitch-mounted mast will suffice, with no body holes needed!

## 21.10 VHF/UHF Antennas

Improving an antenna system is one of the most productive moves open to the VHF enthusiast. It can increase transmitting range, improve reception, reduce interference problems and bring other practical benefits. The work itself is by no means the least attractive part of the job. Even with high-gain antennas, experimentation is greatly simplified at VHF and UHF because an array is a workable size, and much can be learned about the nature and adjustment of antennas. No large investment in test equipment is necessary.

Whether we buy or build our antennas, we soon find that there is no one *best* design for all purposes. Selecting the antenna best suited to our needs involves much more than scanning gain figures and prices in a manufacturer's catalog. The first step should be to establish priorities for the antenna system as a whole. Once the objectives have been sorted out in a general way, we face decisions on specific design features, such as polarization, length and type of transmission line, matching methods, and mechanical design.

### 21.10.1 Gain

As has been discussed previously, shaping the pattern of an antenna to concentrate radiated energy, or received signal pickup, in some directions at the expense of others is the only possible way to develop gain. Radiation patterns can be controlled in various ways. One is to use two or more driven elements, fed in phase. Such arrays provide gain without markedly sharpening the frequency response, compared to that of a single element. More gain per element, but with some sacrifice in frequency coverage, is obtained by placing parasitic elements into a Yagi array.

### 21.10.2 Radiation Pattern

Antenna radiation can be made omnidirectional, bidirectional, practically unidirectional, or anything between these conditions. A VHF net operator may find an omnidirectional system almost a necessity but it may be a poor choice otherwise. Noise pickup and other interference problems tend to be greater with omnidirectional antennas. Maximum gain and low radiation angle are usually prime interests of the weak-signal DX aspirant. A clean pattern, with lowest possible pickup and radiation off the sides and back, may be important in high-activity areas, where the noise level is high, or for challenging modes like EME (Earth-Moon-Earth).

### 21.10.3 Height Gain

In general, the higher a VHF antenna is installed, the better will be the results. If raising the antenna clears its view over nearby obstructions, it may make dramatic improvements in coverage. Within reason, greater height is almost always worth its cost, but height gain must be balanced against increased transmission line loss. Line losses can be considerable at VHF and above, and they increase with frequency. The best available line may be none too good, if the run is long in terms of wavelength. Consider line losses in any antenna planning.

### 21.10.4 Physical Size

A given antenna design for 432 MHz, say a 5-element Yagi on a  $1\lambda$  boom, will have the same gain as one for 144 MHz, but being only one-third the size it will intercept only one-ninth as much energy in receiving. Thus,

to be equal in communication effectiveness, the 432 MHz array should be at least equal in physical size to the 144 MHz one, requiring roughly three times the number of elements. With all the extra difficulties involved in going higher in frequency, it is better to be on the big side in building an antenna for the UHF bands.

### 21.10.5 Polarization

Whether to position the antenna elements vertically or horizontally has been a question since early VHF operation. Originally, VHF communication was mostly vertically polarized, but horizontal gained favor when directional arrays became widely used. Tests of signal strength and range with different polarizations show little evidence on which to set up a uniform polarization policy. On long paths there is no consistent advantage, either way. Shorter paths tend to yield higher signal levels with horizontal in some kinds of terrain. Man-made noise, especially ignition interference, tends to be lower with horizontal polarization. Vertically polarized antennas, however, are markedly simpler to use in omnidirectional systems and in mobile work, resulting in a standardization on vertical polarization for mobile and repeater operation on FM and for digital communications. Horizontal polarization is the standard for weak signal VHF and UHF operation. (Circular polarization is preferred for satellite work as described below.) A loss in signal strength of 20 dB or more can be expected with cross-polarization so it is important to use antennas with the same polarization as the stations with which you expect to communicate.

## 21.10.6 Circular Polarization

Polarization is described as *horizontal* or *vertical*, but these terms have no meaning once the reference of the Earth's surface is lost. Many propagation factors can cause polarization change — reflection or refraction and passage through magnetic fields (Faraday rotation), for example. Polarization of VHF waves is often random, so an antenna capable of accepting any polarization is useful. Circular polarization, generated with helical antennas or with crossed elements fed 90° out of phase, will respond to any linear polarization.

The circularly polarized wave in effect threads its way through space, and it can be left- or right-hand polarized. These polarization senses are mutually exclusive, but either will respond to any plane (horizontal or vertical) polarization. A wave generated with right-hand polarization, when reflected from the moon, comes back with left-hand polarization, a fact to be borne in mind in setting up EME circuits. Stations communicating on direct paths should have the same polarization sense.

Both senses can be generated with crossed dipoles, with the aid of a switchable phasing harness. With helical arrays, both senses are provided with two antennas wound in opposite directions.

## 21.10.7 Transmission Lines

The most common type of transmission line at VHF through the low microwave bands is unbalanced coaxial cable. Small coax such as RG-58 or RG-59 should never be used in VHF work if the run is more than a few feet. Half-inch lines (RG-8 or RG-11) work fairly well at 50 MHz, and runs of 50 feet or less are acceptable at 144 MHz. Lines with foam rather than solid insulation have about 30% less loss. Low-loss cable is required for all but the shortest runs above 222 MHz and *waveguide* is used on microwave frequencies. (See the **Transmission Lines** chapter for a discussion of waveguides.)

Solid aluminum-jacketed *hardline* coaxial cable with large inner conductors and foam insulation are well worth the cost. Hardline can sometimes even be obtained for free from local Cable TV operators as *end runs* — pieces at the end of a roll. The most common CATV variety is ½ inch OD 75 Ω hardline. Hardline is considered *semi-rigid* in that it can be bent, but only with a large radius to avoid kinking and repeated bending should be avoided.

Waterproof commercial connectors for hardline are fairly expensive, but enterprising amateurs have *home-brewed* low-cost connectors. If they are properly waterproofed,

Figure 21.80 — Matching methods commonly used in VHF antennas. In the delta match, A and B, the line is fanned out to tap on the dipole at the points of best impedance match. The gamma match, C, is for direct connection of coax. C1 tunes out inductance in the arm. Folded dipole of uniform conductor size, D, steps up antenna impedance by a factor of four. Using a larger conductor in the unbroken portion of the folded dipole, E, gives higher orders of impedance transformation.

connectors and hardline can last almost indefinitely. See *The ARRL Antenna Book* for details on connectors and techniques for working with hardline.

Properly-built open-wire line can operate with very low loss in VHF and even UHF installations. A line made of #12 AWG wire, spaced ¼ inch or less with Teflon spreaders, and running essentially straight from antenna to station, can be better than anything but the most expensive hardline at a fraction of the cost. Line loss under 2 dB per 100 feet at 432 MHz is readily obtained. This assumes the use of high-quality baluns to match into and out of the balanced line, with a short length of low-loss coax for the rotating section from the top of the tower to the antenna. Such an open-wire line could have a line loss under 1 dB at 144 MHz.

Effects of weather on transmission lines should not be ignored. A well-constructed open-wire line works well in nearly any weather, and it stands up well. TV-type twin-lead is almost useless in heavy rain, wet snow or icing conditions. The best grades of coax and hardline are impervious to weather. They can be run underground, fastened to metal towers without insulation, or bent into

almost any convenient position, with no adverse effects on performance. However, beware of bargain coax. Lost transmitter power can be made up to some extent by increasing power, but once lost in the transmission line a weak signal can never be recovered in the receiver.

## 21.10.8 Impedance Matching

Theory and practice in impedance matching are discussed in detail in the **Transmission Lines** chapter, and in theory, at least, are the same for frequencies above 50 MHz. Practice may be similar, but physical size can be a major modifying factor in choice of methods.

### DELTA MATCH

Probably the first impedance match was made when the ends of an open line were fanned out and tapped onto a half-wave antenna at the points of most efficient power transfer, as in **Figure 21.80A**. Both the side length and the points of connection either side of the center of the element must be adjusted for minimum reflected power in the line, but the impedances need not be known. The delta

makes no provision for tuning out reactance, so the length of the dipole is pruned for best SWR.

Once thought to be inferior for VHF applications because of its tendency to radiate if adjusted improperly, the delta has come back to favor now that we have good methods for measuring the effects of matching. It is very handy for phasing multiple-bay arrays with low-loss open lines, and its dimensions in this use are not particularly critical.

### GAMMA MATCH

The gamma match is shown in Figure 21.80C and is covered in more detail in the preceding section on HF Yagi antennas and in the **Transmission Lines** chapter. The center of a half-wave dipole being electrically neutral, the outer conductor of the coax is connected to the element at this point, which may also be the junction with a metallic or non-conductive boom. The inner conductor is connected to the element at the matching point. Inductance of the connection to the element is canceled by means of C1. Both the point of contact with the element and the setting of the capacitor are adjusted for minimum SWR using an antenna analyzer or SWR bridge.

The capacitor C1 can be a variable unit during adjustment and then replaced with a suitable fixed unit when the required capacitance value is found. Maximum capacitance should be about 100 pF for 50 MHz and 35 to 50 pF for 144 MHz. The capacitor and arm can be combined with the arm connecting to the driven element by means of a sliding clamp, and the inner end of the arm sliding inside a sleeve connected to the inner conductor of the coax. It can be constructed from concentric pieces of tubing, insulated by plastic sleeving or shrink tubing. RF voltage across the capacitor is low, once the match is adjusted properly, so with a good dielectric, insulation presents no great problem. A clean, permanent, high-conductivity bond between arm and element is important, as the RF current is high at this point.

Because it is inherently somewhat unbalanced, the gamma match can sometimes introduce pattern distortion, particularly on long-boom, highly directive Yagi arrays. The T-match, essentially two gamma matches in series creating a balanced feed system, has become popular for this reason. (See the preceding discussion on T-matches in the HF Yagi section.) A coaxial balun like that shown in Figure 21.80B is used from the balanced T-match to the unbalanced coaxial line going to the transmitter. To maintain a symmetrical pattern, the feed line should be run along the antenna boom at the centerline of the elements to the mast. A choke balun is often used to minimize currents that might be induced on the outer surface of the feed line shield.

Figure 21.81 — Conversion from unbalanced coax to a balanced load can be done with a half-wave coaxial balun, A. The half-wave balun gives a 4:1 impedance step up. Electrical length of the looped section should be checked with an antenna analyzer with the far end of the line open, as in B. The lowest frequency at which the line impedance is a minimum is the frequency at which the line is  $\frac{1}{4} \lambda$  long. Multiply that frequency by two to obtain the  $\frac{1}{2} \lambda$  frequency.

### FOLDED DIPOLE

The impedance of a half-wave dipole feed point at its center is  $72 \Omega$ . If a single conductor of uniform size is folded to make a half-wave dipole, as shown in Figure 21.80D, the impedance is stepped up four times. Such a folded dipole can thus be fed directly with  $300 \Omega$  line with no appreciable mismatch. Coaxial feed line of  $70$  to  $75 \Omega$  impedance may then be used with a 4:1 impedance transformer. Higher impedance step-up can be obtained if the unbroken portion is made larger in cross-section than the fed portion, as in Figure 21.80E. The folded dipole is discussed further in the *ARRL Antenna Book*.

### 21.10.9 Baluns and Impedance Transformers

Conversion from balanced loads to unbalanced lines, or vice versa, can be performed with electrical circuits, or their equivalents made of coaxial line. A balun made from flexible coax is shown in Figure 21.81A. The looped portion is an electrical half-wave. This type of balun gives an impedance step-up of 4:1, 50 to  $200 \Omega$ , or 75 to  $300 \Omega$  typically. See the **RF Techniques** and **Transmission Lines** chapters for a detailed discussion of baluns and impedance transformers.

The physical length of the line section depends on the propagation factor of the line used, so it is best to check its resonant frequency, as shown at B. One end of the line is left open and an antenna analyzer used to find the lowest frequency at which the impedance at the other end of the line is a minimum, the frequency at which the section of line is  $\frac{1}{4} \lambda$  long. Multiply the frequency by two to find the frequency at which the section is  $\frac{1}{2} \lambda$  long.

Coaxial baluns giving a 1:1 impedance transfer are shown in Figure 21.82. The coaxial sleeve, open at the top and connected to the outer conductor of the line at the lower end (Figure 21.82A) is the preferred type. A conductor of approximately the same size as

Figure 21.82 — The balun conversion function, with no impedance change, is accomplished with quarter-wave lines, open at the top and connected to the coax outer conductor at the bottom. The coaxial sleeve shown at A is preferred.

the line is used with the outer conductor to form a quarter-wave stub, in Figure 21.82B. Another piece of coax, using only the outer conductor, will serve this purpose. Both baluns are intended to present a high impedance to any RF current that might otherwise tend to flow on the outer conductor of the coax. Choke baluns made of ferrite beads of the proper material type or mix may also be used. See the **RF Techniques** chapter for information about ferrite use at VHF and UHF.

### Project: Simple, Portable Ground-Plane Antenna

The ground-plane antenna is shown in Figure 21.83 and uses a female chassis-mount connector to support the element and two radials. With only two radials, it is essentially two dimensional, which makes it easier to store when not in use. UHF connectors work well for 144 and 222 MHz, but you may prefer to use Type N connectors. N connectors are recommended for 440 MHz

and higher frequencies. BNC connectors can be used for the shorter antennas on 915 and 1280 MHz but are not particularly sturdy.

If the antenna is sheltered from weather, copper wire is sufficiently rigid for the radiating element and radials. Antennas exposed to the wind and weather can be made from brazing rod, which is available at welding supply stores. Alternatively, #12 or #14 AWG copper-clad steel wire could be used to construct this antenna.

To eliminate sharp ends, it's a good idea to bend the element and radial ends into a circle or to terminate them with a crimp terminal as in Figure 21.84. The crimp terminal approach is easier with stiff wire. Crimp and then solder the terminal to the wire. Make the overall length of the element and radials the same as shown in Figure 21.83, measuring to the outer tip of the loop or terminal.

Radials may be attached directly to the mounting holes of the coaxial connector. Bend a hook at one end of each radial for insertion through the connector. Solder the

**Figure 21.84** — Alternate methods for terminating element and radial tips on the simple ground-plane antenna. See text. (Photo by K8CH)

radials to the connector using a large soldering iron or propane torch.

Solder the element to the center pin of the connector. If the element does not fit inside the solder cup, use a short section of brass tubing as a coupler (a slotted 1/8 inch ID tube will fit over an SO-239 or N receptacle center pin).

If necessary, prune the antenna to raise the frequency of minimum SWR. Then adjust the radial droop angle for minimum SWR — this should not affect the frequency at which the minimum SWR occurs.

One mounting method for fixed-station antennas appears in Figure 21.83. The feed line and connector are inside the mast, and a hose clamp squeezes the slotted mast end to tightly grip the plug body. Once the antenna is mounted and tested, thoroughly seal the open side of the coaxial connector with silicone sealant, and weatherproof the connections with rust-preventative paint.

A related simple antenna is the crossed-dipole which has an omnidirectional pattern and requires no ground plane. Paul Wade, W1GHZ, rescaled a design found in an IEEE journal that was originally designed for 1.7 GHz. His construction article from the *Proceedings of Microwave Update 2016* is included with the downloadable supplemental information for this book.

### Project: Coaxial Dipole for VHF or UHF

(The following antenna was originally described in July 2009 *QST* by John Portune, W6NBC, and was also reprinted in *The ARRL Antenna Compendium Volume 8*.)

Here is a homebrew coaxial dipole built from a small stainless whip, a length of threaded table-lamp tubing and some 1/4 inch copper and PVC fittings. The one shown is for 440 MHz but it can readily be scaled for 146 or 222 MHz.

For homebrew vertical VHF antennas, coaxial dipoles often play second fiddle to J-poles. That's because the center connection to coax is often difficult to fabricate in the home workshop. Yet both antennas have the same performance. They're both full sized,

**Figure 21.83** — A simple ground-plane antenna for the 144, 222 or 440 MHz bands. The feed line and connector are inside the mast, and a hose clamp squeezes the slotted mast end to tightly grip the plug body. Element and radial dimensions given in the drawing are good for the entire band.

half wave vertical dipoles, and the coaxial is shorter.

### MAKING A COAXIAL DIPOLE

If you start with a common half wave ( $\lambda/2$ ) stainless whip and extend it all the way down through a  $\lambda/2$  long support tubing, here made from a threaded table lamp tube, the lower part of the whip becomes the center conductor of a short length of rigid coax feeding the center of the antenna. Now connection to normal coax is easily made below the antenna. To form the rigid coax section, you'll need to insulate the center conductor (lower part of the stainless whip) from the lamp tubing with some  $1/4$  inch inside diameter (ID) polyethylene tubing. Hardware stores normally carry it. This short length of rigid coax formed in this way isn't precisely  $50 \Omega$  characteristic impedance, but the difference is totally insignificant. The drawing in Figure 21.85 shows the details.

### Assembly Details

The bottom half ( $\lambda/4$ ) of the radiating dipole is a coaxial sleeve made from  $3/4$  inch copper pipe and a pipe cap. The coax feed runs up its center to the connector at the bottom of the lamp tubing. Support and insulation of the bottom of the sleeve is provided by a  $3/4$  inch CPVC plastic pipe cap. For those not familiar with CPVC fittings, they're made to mate with copper pipe and can handle high water temperatures. That's not true of common PVC fittings. Most hardware stores now carry CPVC. Drill a  $3/8$  inch hole in the center top of the copper and the CPVC caps for the lamp tubing to pass through.

The whole antenna is held together by two lamp tubing nuts and a plastic lamp finial, also readily available at hardware stores (see Figure 21.86). Note that a lamp tubing nut is also required inside the copper pipe cap. Drill a small hole in the middle of the lamp finial for the stainless whip. On the bottom of lamp tubing below the antenna install a  $1\ 1/4$  inch common PVC pipe cap, and secure it with two more lamp tubing nuts. This gives you a way to easily mount the antenna on top of any convenient length of  $1/2$  inch PVC

pipe. Run the coax feed down through the PVC pipe. (Note that lamp parts are generally not intended for use outside and may rust or corrode without being painted or otherwise protected against the weather.

### Hooking it Up

A conventional PL-259 UHF type coax connector for RG-8 coax will actually screw onto the bottom of the lamp tubing. The threads are not a perfect fit, but will tighten satisfactorily. The stainless whip runs down all the way to the very tip of the PL-259 connector. Solder it in there. Before doing so however, install all the pieces of the antenna onto the threaded lamp tubing.

Many hams may think that stainless steel won't solder. It definitely will with a hot iron and acid flux. Scrape the end of the whip and dip it in hydrochloric swimming pool acid. With a little action from the tip of the soldering iron the whip will tin perfectly well. Before soldering, however, grind two or three small side notches in the bottom end of the whip. A Dremel tool works well for this. The notches will help the solder securely lock the whip into the tip of the PL-259 connector. Neutralize any leftover acid with baking soda solution.

Perhaps surprising to some, it really isn't

(A)

(B)

necessary to solder any other parts of the antenna. There is adequate mating surface at the joints for the RF to cross over efficiently. Do, however, seal all possible water access spots with common silicone sealant and or plastic electrical tape.

### MAKE IT FOR THE BAND YOU LIKE

There isn't an exact length required for the lamp tubing or the stainless whip. These merely need to provide enough space for all the pieces of the antenna to go together.

The author had a 48 inch whip on hand that he used uncut for the 146 MHz coaxial dipole and a similar 17 inch uncut whip for 440 MHz. He cut the lamp tubing to an appropriate length to fit the whips. What does matter, however, is the length of the whip above the top of the lamp tubing as well as the length of the coaxial sleeve. These need to be close to a  $\lambda/4$  — for 440 MHz, 6½ inches; for 222 MHz, 13 inches; and 19 inches for 146 MHz. These antennas are quite broad band and will cover the entire band in each case with these sizes. No cutting or pruning

is necessary.

For ruggedness, or perhaps for stealth, you can install the whole antenna inside of 2 inch PVC water or ABS soil pipe and close the ends with end caps. The author lives in a mobile home park where antennas are not permitted, but the landlord thinks these coaxial dipoles (in ABS pipe) are vent pipes.

Try out one of these homebrew coaxial dipoles. You may find you prefer its smaller size, less obvious appearance and superior weatherproofing as compared to a J-pole.

## 21.11 VHF/UHF Beams

Without doubt, the Yagi is king of home-station antennas these days. Today's best designs are computer optimized. For years amateurs as well as professionals designed Yagi arrays experimentally. Now we have powerful (and inexpensive) personal computers and sophisticated software for antenna modeling. These have brought us antennas with improved performance, with little or no element pruning required. A more complete discussion of Yagi design can be found earlier in this chapter and in the *ARRL Antenna Book*.

### 21.11.1 Stacking Yagis

Where suitable provision can be made for supporting them, two Yagis mounted one above the other and fed in-phase may be preferable to one long Yagi having the same theoretical or measured gain. The pair will require a much smaller turning space for the same gain, and their lower radiation angle can provide interesting results. On long ionospheric paths a stacked pair occasionally may show an apparent gain much greater than the 2 to 3 dB that can be measured locally as the gain from stacking.

Optimum spacing for Yagis with booms longer than  $1 \lambda$  is one wavelength, but this may be too much to handle for many builders of 50 MHz antennas. Worthwhile results are possible with separations of as little as  $\frac{1}{2} \lambda$  (10 feet), but  $\frac{3}{4} \lambda$  (12 feet) is markedly better. At 50 MHz, the difference between 12 and 20 foot spacing may not be worth the added structural problems.

The closer spacings give lowered measured gain, but the antenna patterns are cleaner (less power in the high-angle elevation lobes) than with  $1 \lambda$  spacing. Extra gain with wider spac-

ings is usually the objective on 144 MHz and higher bands, where the structural problems are not quite as severe as on 50 MHz.

One method for feeding two 50  $\Omega$  antennas, as might be used in a stacked Yagi array, is shown in **Figure 21.87**. The transmission lines from each antenna, with a balun feeding each antenna (not shown in the drawing for simplicity), to the common feed point must be equal in length and an odd multiple of  $\frac{1}{4} \lambda$ . This line acts as a quarter-wave (Q-section) impedance transformer, raises the feed impedance of each antenna to 100  $\Omega$ , and forces current to be equal in each driven element. When the feed lines are connected in parallel at the coaxial tee connector, the resulting impedance is close to 50  $\Omega$ .

### Project: Three and Five-Element Yagis for 6 Meters

Boom length often proves to be the deciding factor when one selects a Yagi design. Dean Straw, N6BV, created the designs shown in **Table 21.14**. Straw generated the designs in the table for convenient boom lengths (6

**Figure 21.87** — A method for feeding a stacked Yagi array. Note that baluns at each antenna are not specifically shown. Good practice is to use choke baluns made up of ferrite beads slipped over the outside of the coax and taped to prevent movement. See the *RF Techniques and Transmission Lines* chapter for details.

and 12 feet). The 3 element design has about 8 dBi gain, and the 5 element version has about 10 dBi gain. Both antennas exhibit better than 22 dB front-to-rear ratio, and both cover 50 to 51 MHz with better than 1.6:1 SWR.

Element lengths and spacings are given in the table. Elements can be mounted to the boom as shown in **Figure 21.88**. Two muffler clamps hold each aluminum plate to the boom, and two U bolts fasten each element to the plate, which is 0.25 inches thick and 4.4 inches square. Stainless steel is the best choice for hardware. However, galvanized hardware can be substituted. Automotive muffler clamps do not work well in this application, because they are not galvanized and quickly rust once exposed to the weather.

The driven element is mounted to the boom on a phenolic plate of similar dimension to the other mounting plates. A 12 inch piece of Plexiglas rod is inserted into the driven element halves. The Plexiglas allows the use of a single clamp on each side of the element and also seals the center of the elements against moisture. Self-tapping screws are used for electrical connection to the driven element.

Refer to **Figure 21.89** for driven element and hairpin match details. A bracket made from a piece of aluminum is used to mount the three SO-239 connectors to the driven element plate. A 4:1 transmission-line balun connects the two element halves, transforming the 200  $\Omega$  resistance at the hairpin match to 50  $\Omega$  at the center connector. Note that the electrical length of the balun is  $\lambda/2$ , but

**Figure 21.88** — The boom-to-element clamp. Galvanized U-bolts are used to hold the element to the plate, and 2 inch galvanized muffler clamps hold the plates to the boom.

the physical length will be shorter due to the velocity factor of the particular coaxial cable used. The hairpin is connected directly across the element halves. The exact center of the hairpin is electrically neutral and should be fastened to the boom. This has the advantage of placing the driven element at dc ground potential.

The hairpin match requires no adjustment as such. However, you may have to change the length of the driven element slightly to obtain the best match in your preferred portion of the band. Changing the driven-element length will not adversely affect antenna performance. *Do not adjust the lengths or spacings of the other elements*

— they are optimized already. If you decide to use a gamma match, add three inches to each side of the driven element lengths given in the table for both antennas.

## Project: Medium-Gain 2 Meter Yagi

This project was designed and built by L. B. Cebik, W4RNL (SK). Practical Yagis for 2 meters abound. What makes this one a bit different is the selection of materials. The elements, of course, are high-grade aluminum. However, the boom is PVC and there are only two #6 nut-bolt sets and two #8 sheet metal screws in the entire antenna. The remaining fasteners are all hitch-pin clips. The result is a very durable six-element Yagi that you can disassemble with fair ease for transport. The complete construction details and more discussion of the antenna are included with the downloadable supplemental content.

### THE BASIC ANTENNA DESIGN

The 6 element Yagi presented here is a derivative of the *optimized wide-band antenna* (OWA) designs developed for HF use by NW3Z and WA3FET. **Figure 21.90** shows the general outline. The reflector and first director largely set the impedance. The next 2 directors contribute to setting the operating bandwidth. The final director (Dir. 4) sets the gain. This account is over-simplified, since every element plays a role in every facet of Yagi performance. However, the notes give

some idea of which elements are most sensitive in adjusting the performance figures.

Designed using *NEC-4*, the antenna uses 6 elements on a 56 inch boom. Table 21.15 gives the specific dimensions for the version described in these notes. The parasitic elements are all 1/8 inch aluminum rods. For ease of construction, the driver is 1/2 inch aluminum tubing. Do not alter the element diameters without referring to a source, such as RSGB's *The VHF/UHF DX Book*, edited by Ian White, G3SEK, (Chapter 7), for information on how to recalculate element lengths.

The OWA design provides about 10.2 dB of free-space gain with better than 20 dB front-to-back (or front-to-rear) ratio across the entire 2 meter band. Azimuth (or E-plane) patterns show solid performance across the entire band. This applies not only to forward gain but rejection from the rear.

One significant feature of the OWA design is its direct 50 Ω feed point impedance that requires no matching network. Of course, a choke balun to suppress any currents on the feed line is desirable, and a simple ferrite bead balun (see the **Transmission Lines**

**Figure 21.91** — SWR curve for the 2 meter, 6 element OWA Yagi as modeled using *NEC-4*.

chapter) works well in this application. The SWR, shown in Figure 21.91, is very flat across the band and never reaches 1.3:1. The SWR and the pattern consistency together create a very useful utility antenna for 2 meters, whether installed vertically or horizontally. The only remaining question is how to effectively build the beam in the average home shop.

The six-element OWA Yagi for 2 meters performs well. It serves as a good utility antenna with more gain and directivity than the usual three-element general-use Yagi. When vertically polarized, the added gain confirms the wisdom of using a longer boom and more elements. With a length under five feet, the antenna is still compact. The ability to disassemble the parts simplifies moving the antenna to various portable sites.

### Project: Utility Yagi for 432 MHz

The following design was developed by Zack Lau, W1VT (see References) and is included in the downloadable supplemental information for this chapter. This six-element Yagi has a wide bandwidth for gain, F/B ratio, and SWR, covering almost all of the 70 cm band. The short 30-inch boom is small enough to fit in the trunk of a compact sedan, perfect for portable or emergency operation. The optimized design is shown in Figure

21.92 which includes the table of element lengths and placement. Changing the boom or element mounting may require adjusting the element lengths. The antenna uses a simple T-match to preserve a symmetrical radiation pattern.

### Project: Cheap Yagis by WA5VJB

If you're planning to build an EME array, don't use these antennas. But if you want to put together a VHF rover station with less than \$500 in the antennas, read on as Kent Britain, WA5VJB, shows you how to put together a VHF/UHF Yagi with QRO performance at a QRP price. (This material is adapted from Kent's on-line paper "Controlled Impedance 'Cheap' Antennas" at [www.wa5vjb.com/references.html](http://www.wa5vjb.com/references.html).) First, a bit of history on the design of these antennas. In 1993 at the Oklahoma City Central States VHF Society Conference, Arnie, CO2KK, spoke on the difficulties building VHF antennas in non-industrialized nations. Just run down to the store and pick up some Delrin insulators and 0.141 inch Teflon coax? Arnie's tales were the motivation to use advanced technology to come up with something simple.

The simplified feed uses the structure of the antenna itself for impedance matching. So the design started with the feed and the elements were built around it. The antennas were designed with *YagiMax*, tweaked in *NEC*, and the driven elements experimentally determined on the antenna range.

Typically a high-gain antenna is designed in the computer, then you try to come up with a driven element matching arrangement for whatever feed point impedance the computer comes up with. In this design, compromises for the feed impedance, asymmetrical feed, simple measurements, wide bandwidth, the ability to grow with the same spacing, and trade-offs for a very clean pattern cost many dB of gain. But you can build these antennas for about \$5!

Construction of the antennas is straightforward. The boom is 3/4 inch square, or 1/2 inch by 3/4 inch wood. To install an element, drill a hole through the boom and insert the element. A drop of cyanoacrylate "super glue," epoxy, or silicone adhesive is used to hold the elements in place. There is no boom-to-mast plate — drill holes in the boom and use a U-bolt to attach it to the mast!

The life of the antenna is determined by what you coat it with. The author had a 902 MHz version, varnished with polyurethane, in the air for two years with little deterioration.

The parasitic elements on prototypes have been made from silicon-bronze welding rod, aluminum rod, brass hobby tubing, and #10 or

#12 AWG solid copper ground wire. So that you can solder to the driven element, use the welding rod, hobby tubing, or copper wire. The driven element is folded at one end with its ends inserted through the boom.

Figure 21.93 shows the basic plan for the antenna and labels the dimensions that are given in the table for each band. All table dimensions are given in inches.

Figure 21.94 shows how the driven element is constructed for each antenna. Trim the free end of the driven element to tune it for minimum SWR at the desired frequency.

Figure 21.95 shows how to attach coaxial cable to the feed point. Sliding a quarter-wave sleeve along the coax had little effect, so there's not much RF on the outside of the coax. You may use a ferrite bead choke balun if you like, but these antennas are designed for minimum expense!

### 144 MHz Yagi

While others have reported good luck with 16 element long-boom wood antennas, six elements was about the maximum for most rovers. The design is peaked at 144.2 MHz, but performance is still good at 146.5 MHz. All parasitic elements are made from 3/16 inch aluminum rod and the driven element is made from 1/8 inch rod. Lengths and spacings are given in Table 21.16.

### 222 MHz Yagi

This antenna is peaked at 222.1 MHz, but performance has barely changed at 223.5 MHz. You can drill the mounting holes to mount it with the elements horizontal or vertical. All parasitic elements are made from

3/16 inch aluminum rod and the driven element is made from 1/8 inch rod. Lengths and spacings are given in Table 21.17.

### 432 MHz Yagi

At this band the antenna is getting very

practical and easy to build. All parasitic elements are made from 1/8 inch diameter rod and the driven element is made from #10 AWG solid copper wire. Lengths and spacings are given in **Table 21.18**.

#### 435 MHz Yagi for AMSAT

KA9LNV provided help and motivation for these antennas. A high front-to-back ratio (F/B) was a major design consideration of all versions. The model predicts 30 dB F/B for the six-element and over 40 dB for the others. For gain, *NEC* predicts 11.2 dBi for the six-element, 12.6 dBi for the eight-element, and 13.5 dBi for the 10 element, and 13.8 dBi for the 11 element.

Using 3/4 inch square wood for the boom makes it easy to build two antennas on the same boom for cross-polarization. Offset the two antennas 6 1/2 inches along the boom and feed them in-phase for circular polarization, or just use one for portable operations. All

parasitic elements are made from 1/8 inch diameter rod and the driven element is made from #10 AWG solid copper wire. Lengths and spacings are given in **Table 21.19**. The same element spacing is used for all four versions of the antenna.

#### 450 MHz Yagi

For FM, this six-element Yagi is a good, cheap antenna to get a newcomer into a repeater or make a simplex-FM QSO during a contest. The author used 1/8 inch diameter aluminum ground wire in the prototype for all the elements except the driven element, which is made from #10 AWG solid copper wire. Other 1/8 inch diameter material could be used. Lengths and spacings are given in **Table 21.20**.

#### 902 MHz Yagi

This was the first antenna the author built using the antenna to control the driven element impedance. The 2.5 foot length has proven very practical. All parasitic elements are made from 1/8 inch diameter rod and the driven element is made from #10 AWG solid copper wire. Lengths and spacings are given in **Table 21.21**.

#### 1296 MHz Yagi

This antenna is the veteran of several "Grid-peditions" and has measured 13.5 dBi on the Central States VHF Society antenna range. Dimensions must be followed with great care. The driven element is small enough to allow 0.141 inch semi-rigid coax to be used. The prototype antennas use 1/8 inch

#### 421.25 MHz 75 Ω Yagi for ATV

421 MHz vestigial sideband video is popular in North Texas for receiving the FM video input repeaters. These antennas are made for 421 MHz use and the driven element is designed for 75 Ω. RG-59 or an F adapter to RG-6 can be directly connected to a cable-TV converter or cable-ready TV on channel 57. All parasitic elements are made from 1/8 inch diameter rod and the driven element is made from #10 AWG solid copper wire. Lengths and spacings are given in **Table 21.23**. The same spacing is used for all versions.

### Project: Fixed Moxons for Satellite Operation

The following project is based on the article, "A Simple Fixed Antenna for VHF/UHF Satellite Work" by the late L.B. Cebik, W4RNL, from the August 2001 issue of *QST*. The complete article is available with the

downloadable supplemental content. This design produces a simple, reliable, fixed antenna that provides nearly hemispherical coverage for satellite operation on 145 and 435 MHz.

Many fixed-position satellite antennas for VHF and UHF have used a version of the *turnstile*. The word "turnstile" actually refers to two different ideas. One is a particular antenna: two crossed dipoles fed 90° out of phase, usually with a reflecting screen behind the dipoles. The other is the principle of obtaining omnidirectional patterns by diving almost any crossed antennas 90° out of phase. The second idea opens the door to adapting many possible antenna designs to omnidirectional coverage.

**Figure 21.96** shows a general method of obtaining the 90° phase shift for omnidirectional patterns. Note that the coax center conductor connects to only one of the two crossed elements. A 1/4-λ section of transmission line that has the same characteristic impedance as the natural feed point impedance of the first antenna element alone connects one element to the next. The opposing ends of the two elements go to the shield at each end of the transmission line. The resulting impedance at the overall antenna feed point will be exactly half the impedance of one element alone. If

dipoles are used, the feed point impedance will be approximately 35 Ω.

The dual Moxon rectangle array, shown in outline form on the right of **Figure 21.98**, offers some advantages over the traditional turnstile. (The article "Having a Field Day with the Moxon Rectangle," by L.B. Cebik describes the Moxon in detail and is included with the downloadable supplemental content.) First, it yields a somewhat better dome-like pattern. Second, it is relatively easy to build and compact to install. The Moxon pair, with lower but smoother gain across the dome of the sky, offers the fixed-antenna user the chance to build a successful beginning satellite antenna.

**Figure 21.98** shows the elevation patterns of a turnstile-and-screen and of a pair of Moxon rectangles when both are 2λ above the ground. A 1λ height will reduce the low angle ripples even more, if that height is feasible. The elevation patterns show the considerably smoother pattern dome of the Moxon pair over the traditional turnstile. The middle of the turnstile dome has nearly 2 dB less gain than its peaks, while the top valleys are nearly 3 dB lower than the peaks. The peaks and valleys can make the difference between successful communications and broken-up transmissions.

Without requiring a reflecting screen which would narrow the antenna's beamwidth, the azimuthal pattern will be circular within under a 0.2-dB difference for 145.5 to 146.5 MHz, and within 0.5 dB for the entire 2 meter band. Since satellite work is concentrated in the 145.8 to 146.0 MHz region, the broadbanded antenna will prove fairly easy to build with

success. A 435.6 MHz version, designed to cover the 435 to 436.2 MHz region of satellite activity will have an even larger bandwidth.

Like the dipole-based turnstile, the Moxons are fed 90° out of phase with a 1/4-λ phasing line of 50-Ω coaxial cable as shown in Figure 21.96. Since the natural feed point impedance of a single Moxon rectangle of the design used here is 50 Ω, the pair will show a 25-Ω feed-point impedance. Paralleled 1/4-λ sections of 70- to 75-Ω coaxial cable, such as RG-59, will transform the low impedance to a good match for the main 50-Ω coaxial feed line.

Figure 21.99 shows the critical dimensions for a Moxon rectangle. The lettered

references are keys to the dimensions in Table 21.24. The design frequencies for the two satellite antenna pairs are 145.9 MHz and 435.5 MHz, the centers of the satellite activity on these two bands. The 2 meter Moxon prototype uses 3/16-inch diameter rod, while the 435 MHz version uses #12 AWG wire with a nominal 0.0808-inch diameter. Going one small step up or down in element diameter will still produce a usable antenna, but major diameter changes will require that the dimensions be recalculated. (Complete construction details and drawings are available with the downloadable supplemental content.)

The antennas can be mounted on the same

Two are required for each antenna. The phase-line is 50-Ω coaxial cable and the matching line is parallel sections of 75-Ω coaxial cable. Low power cables less than 0.15 inches in outer diameter were used in the prototypes. See Figure 21.99 for letter references. All dimensions are in inches.

mast. However, for similar patterns, they should each be the same number of wavelengths above ground. For example, if the 2 meter antenna is about two wavelengths up at about 14 feet or so, then the bottom of the 435-MHz antenna should be only about 4.5 feet above the ground. Placing the higher-frequency antenna below the 2 meter assembly will create some small irregularities in the desired dome pattern, but not serious enough to affect general operation.

There is no useful adjustment to these antennas except for making the gap between the drivers and reflectors as accurate as possible. Turnstile antennas show a very broad SWR curve. Across 2 meters, for example,

**Figure 21.99** — The basic dimensions of a *loxón* rectangle. Two identical rectangles are required for each “turnstiled” pair. See Table 21.24 for letter references.

The highest SWR is under 1.1:1. However, serious errors in the phasing line length can result in distortions to the desired circular pattern. There is no substitute for checking the lengths of the phasing line and the matching section several times before cutting. The correct length is from one junction to the next, including the portions of exposed cable interior.

## 21.12 Radio Direction Finding Antennas

Radio direction finding (RDF) is almost as old as radio communication. It gained prominence when the British Navy used it to track the movement of enemy ships in World War I. Since then, governments and the military have developed sophisticated and complex RDF systems. Fortunately, simple equipment, purchased or built at home, is quite effective in Amateur Radio RDF.

In European and Asian countries, direction-finding contests are foot races. The object is to be first to find four or five transmitters in a large wooded park. Young athletes have the best chance of capturing the prizes. This sport is known as *foxhunting* (after the British hill-and-dale horseback events) or *ARDF* (Amateur Radio direction finding). It is growing in popularity here in North America. Today, most competitive hunts worldwide are for 144 MHz FM signals, though other VHF bands are also used. Some international foxhunts include 3.5 MHz events.

In North America and England, most RDF contests involve mobiles — cars, trucks, and vans, even motorcycles. It may be possible to drive all the way to the transmitter, or there may be a short hike at the end, called a *sniff*. These competitions are also called *foxhunting* by some, while others use *bunny hunting*, *fox-hunting* or the classic term *hidden transmitter hunting*.

Even without participating in RDF contests, you will find knowledge of the techniques useful. They simplify the search for a neighborhood source of power-line interference or TV cable leakage. RDF must be used to track down emergency radio beacons, which signal

the location of pilots and boaters in distress. Amateur Radio enthusiasts skilled in transmitter hunting are in demand by agencies such as the Civil Air Patrol and the US Coast Guard Auxiliary for search and rescue support. RDF is an important part of the evidence-gathering process in interference cases.

The most basic RDF system consists of a directional antenna and a method of detecting and measuring the level of the radio signal, such as a receiver with signal strength indicator. RDF antennas range from a simple tuned loop of wire to an acre of antenna elements with an electronic beam-forming network. Other sophisticated techniques for RDF use the Doppler effect or measure the time of arrival difference of the signal at multiple antennas.

All of these methods have been used from 2 to 500 MHz and above. However, RDF practices vary greatly between the HF and VHF/UHF portions of the spectrum. For practical reasons, high gain beams, Dopplers and switched dual antennas find favor on VHF/UHF, while loops and phased arrays are the most popular choices on 6 meters and below. Signal propagation differences between HF and VHF also affect RDF practices. But many basic transmitter-hunting techniques, discussed later in this chapter, apply to all bands and all types of portable RDF equipment.

Several RDF projects may be found with the downloadable supplemental content along with a thorough article on Direction-Finding Techniques and mobile RDF system installation, including some examples of mobile RDF antenna mounting.

### 21.12.1 RDF Antennas for HF Bands

Below 50 MHz, gain antennas such as Yagis and quads are of limited value for RDF. The typical tribander installation yields only a general direction of the incoming signal, due to ground effects and the antenna’s broad forward lobe. Long monoband beams at greater heights work better, but still cannot achieve the bearing accuracy and repeatability of simpler antennas designed specifically for RDF.

#### RDF LOOPS

An effective directional HF antenna can be as uncomplicated as a small loop of wire or tubing, tuned to resonance with a capacitor. When immersed in an electromagnetic field, the loop acts much the same as the secondary winding of a transformer. The voltage at the output is proportional to the amount of flux passing through it and the number of turns. If the loop is oriented such that the greatest amount of area is presented to the magnetic field, the induced voltage will be the highest. If it is rotated so that little or no area is cut by the field lines, the voltage induced in the loop is zero and a null occurs.

To achieve this transformer effect, the loop must be small compared with the signal wavelength. In a single-turn loop, the conductor should be less than  $0.08 \lambda$  long. For example, a 28 MHz loop should be less than 34 inches in circumference, giving a diameter of approximately 10 inches. The loop may be smaller, but that will reduce its voltage output. Maximum output from a small loop antenna is in directions corresponding to the

plane of the loop; these lobes are very broad. Sharp nulls, obtained at right angles to that plane, are more useful for RDF.

For a perfect bidirectional pattern, the loop must be balanced electrostatically with respect to ground. Otherwise, it will exhibit two modes of operation, the mode of a perfect loop and that of a non-directional vertical antenna of small dimensions. This dual-mode condition results in mild to severe inaccuracy, depending on the degree of imbalance, because the outputs of the two modes are not in phase.

The theoretical true loop pattern is illustrated in **Figure 21.100A**. When properly balanced, there are two nulls exactly 180° apart. When the unwanted antenna effect is appreciable and the loop is tuned to resonance, the loop may exhibit little directivity, as shown in **Figure 21.100B**. By detuning the loop to shift the phasing, you may obtain a useful pattern similar to **Figure 21.100C**. While not symmetrical, and not necessarily at right angles to the plane of the loop, this pattern does exhibit a pair of nulls.

By careful detuning and amplitude balancing, you can approach the unidirectional pattern of **Figure 21.100D**. Even though there may not be a complete null in the pattern, it resolves the 180° ambiguity of **Figure 21.100A**. Korean War era military loop antennas, sometimes available on today's surplus market, use this controlled antenna effect principle.

An easy way to achieve good electrostatic balance is to shield the loop, as shown in **Figure 21.101**. The shield, represented by the dashed lines in the drawing, eliminates the antenna effect. The response of a well-constructed shielded loop is quite close to the ideal pattern of **Figure 21.100A**.

For 160 through 30 meters, single-turn loops that are small enough for portability are usually unsatisfactory for RDF work. Multi-turn loops are generally used instead. They are easier to resonate with practical capacitor values and give higher output voltages. This type of loop may also be shielded. If the total conductor length remains below  $0.08 \lambda$ , the directional pattern is that of **Figure 21.100A**.

### FERRITE ROD ANTENNAS

Another way to get higher loop output is to increase the permeability of the medium in the vicinity of the loop. By winding a coil of wire around a form made of high-permeability material, such as ferrite rod, much greater flux is obtained in the coil without increasing the cross-sectional area.

Modern magnetic core materials make compact directional receiving antennas practical. Most portable AM broadcast receivers use this type of antenna, commonly called a *loopstick*. The loopstick is the most popular RDF antenna for portable/mobile work on 160 and 80 meters.

Like the shielded loop discussed earlier,

the loopstick responds to the magnetic field of the incoming radio wave, and not to the electrical field. For a given size of loop, the output voltage increases with increasing flux density, which is obtained by choosing a ferrite core of high permeability and low loss at the frequency of interest. For increased output, the turns may be wound over two rods taped together. A practical loopstick antenna is described later in this chapter.

A loop on a ferrite core has maximum signal response in the plane of the turns, just as an air core loop. This means that maximum response of a loopstick is broadside to the axis of the rod, as shown in **Figure 21.102**. The loopstick may be shielded to eliminate the antenna effect; a U-shaped or C-shaped channel of aluminum or other form of "trough" is best. The shield must not be closed, and

its length should equal or slightly exceed the length of the rod.

### SENSE ANTENNAS

Because there are two nulls 180° apart in the directional pattern of a small loop or loopstick, there is ambiguity as to which null indicates the true direction of the target station. For example, if the line of bearing runs east and west from your position, you have no way of knowing from this single bearing whether the transmitter is east of you or west of you.

If bearings can be taken from two or more positions at suitable direction and distance from the transmitter, the ambiguity can be resolved and distance can be estimated by triangulation, as discussed later in this chapter. However, it is almost always desirable to be able to resolve the ambiguity immediately by having a unidirectional antenna pattern available.

You can modify a loop or loopstick antenna pattern to have a single null by adding a second antenna element. This element is called a *sense antenna*, because it senses the phase of the signal wavefront for comparison with the phase of the loop output signal. The sense element must be omnidirectional, such as a short vertical. When signals from the loop and the sense antenna are combined with 90° phase shift between the two, a heart-shaped (cardioid) pattern results, as shown in **Figure 21.103A**.

**Figure 21.103B** shows a circuit for adding a sense antenna to a loop or loopstick. For

the best null in the composite pattern, signals from the loop and sense antennas must be of equal amplitude. R1 adjusts the level of the signal from the sense antenna.

In a practical system, the cardioid pattern null is not as sharp as the bidirectional null of the loop alone. The usual procedure when transmitter hunting is to use the loop alone to obtain a precise line of bearing, then switch in the sense antenna and take another reading to resolve the ambiguity.

### PHASED ARRAYS AND ADCOCK ANTENNAS

Two-element phased arrays are popular for amateur HF RDF base station installations. Many directional patterns are possible, depending on the spacing and phasing of the elements. A useful example is two  $\frac{1}{2} \lambda$  elements spaced  $\frac{1}{4} \lambda$  apart and fed  $90^\circ$  out of phase. The resultant pattern is a cardioid, with a null off one end of the axis of the two antennas and a broad peak in the opposite direction. The directional frequency range of this antenna is limited to one band, because of the critical length of the phasing lines.

The best-known phased array for RDF is the Adcock, named after the man who invented it in 1919. It consists of two vertical elements fed  $180^\circ$  apart, mounted so the array may be rotated. Element spacing is not critical, and may be in the range from 0.1 to  $0.75 \lambda$ . The two elements must be of identical lengths, but need not be self-resonant; shorter elements are commonly used. Because neither the element spacing nor length is critical in terms of wavelengths, an Adcock array may operate over more than one amateur band.

Figure 21.104 is a schematic of a typical Adcock configuration, called the H-Adcock because of its shape. Response to a vertically polarized wave is very similar to a conventional loop. The passing wave induces currents  $I_1$  and  $I_2$  into the vertical members. The output current in the transmission line is equal to their difference. Consequently, the directional pattern has two broad peaks and two sharp nulls, like the loop. The magnitude of the difference current is proportional to the spacing ( $d$ ) and length ( $l$ ) of the elements. You will get somewhat higher gain with larger dimensions. The Adcock of Figure 21.105,

designed for 40 meters, has element lengths of 12 feet and spacing of 21 feet (approximately  $0.15 \lambda$ ).

Figure 21.106 shows the radiation pattern of the Adcock. The nulls are broadside to the axis of the array, becoming sharper with increased element spacing. When element spacing exceeds  $\frac{3}{4} \lambda$ , however, the antenna begins to take on additional unwanted nulls off the ends of the array axis.

**Figure 21.106** — The pattern of an Adcock array with element spacing of  $\frac{1}{2}$  wavelength. The elements are aligned with the vertical axis.

The Adcock is a vertically polarized antenna. The vertical elements do not respond to horizontally polarized waves, and the currents induced in the horizontal members by a horizontally polarized wave (dotted arrows in Figure 21.104) tend to balance out regardless of the orientation of the antenna.

Since the Adcock uses a balanced feed system, a coupler is required to match the unbalanced input of the receiver. T1 is an air-wound coil with a two-turn link wrapped around the middle. The combination is resonated with C1 to the operating frequency. C2 and C3 are null-clearing capacitors. Adjust them by placing a low-power signal source some distance from the antenna and exactly broadside to it. Adjust C2 and C3 until the deepest null is obtained.

While you can use a metal support for the mast and boom, wood is preferable because of its non-conducting properties. Similarly, a mast of thick-wall PVC pipe gives less distortion of the antenna pattern than a metallic mast. Place the coupler on the ground below the wiring harness junction on the boom and connect it with a short length of 300  $\Omega$  twin-lead-feed line.

### LOOPS VS PHASED ARRAYS

Loops are much smaller than phased arrays for the same frequency, and are thus the obvious choice for portable/mobile HF RDF. For base stations in a triangulation network, where the 180° ambiguity is not a problem, Adcocks are preferred. In general, they give sharper nulls than loops, but this is in part a function of the care used in constructing and feeding the individual antennas, as well as of the spacing of the elements. The primary construction considerations are the shielding and balancing of the feed line against unwanted signal pickup and the balancing of the antenna for a symmetrical pattern. Users report that Adcocks are somewhat less sensitive to prox-

imity effects, probably because their larger aperture offers some space diversity.

### Skywave Considerations

Until now we have considered the directional characteristics of the RDF loop only in the two-dimensional azimuthal plane. In three-dimensional space, the response of a vertically oriented small loop is doughnut-shaped. The bidirectional null (analogous to a line through the doughnut hole) is in the line of bearing in the azimuthal plane and toward the horizon in the vertical plane. Therefore, maximum null depth is achieved only on signals arriving at 0° elevation angle.

Skywave signals usually arrive at nonzero wave angles. As the elevation angle increases, the null in a vertically oriented loop pattern becomes shallower. It is possible to tilt the loop to seek the null in elevation as well as azimuth. Some amateur RDF enthusiasts report success at estimating distance to the target by measurement of the elevation angle with a tilted loop and computations based on estimated height of the propagating ionospheric layer. This method seldom provides high accuracy with simple loops, however.

Most users prefer Adcocks to loops for skywave work, because the Adcock null is present at all elevation angles. Note, however, that an Adcock has a null in all directions from signals arriving from overhead. Thus for very high angles, such as under-250-mile skip on 80 and 40 meters, neither loops nor Adcocks will perform well.

### ELECTRONIC ANTENNA ROTATION

State-of-the-art fixed RDF stations for government and military work use antenna arrays of stationary elements, rather than mechanically rotatable arrays. The best-known type is the *Wullenweber antenna*. It has a large number of elements arranged in a circle, usually outside of a circular reflecting screen. Depending on the installation, the circle may be anywhere from a few hundred feet to more than a quarter of a mile in diameter. Although the Wullenweber is not practical for most amateurs, some of the techniques it uses may be applied to amateur RDF.

The device, which permits rotating the antenna beam without moving the elements, has the classic name *radio goniometer*, or simply *goniometer*. Early goniometers were RF transformers with fixed coils connected to the array elements and a moving pickup coil connected to the receiver input. Both amplitude and phase of the signal coupled into the pickup winding are altered with coil rotation in a way that corresponded to actually rotating the array itself. With sufficient elements and a goniometer, accurate RDF measurements can be taken in all compass directions.

### Beam Forming Networks

By properly sampling and combining signals from individual elements in a large array, an antenna beam is electronically rotated or steered. With an appropriate number and arrangement of elements in the system, it is possible to form almost any desired antenna pattern by summing the sampled signals in appropriate amplitude and phase relationships. Delay networks and/or attenuation are added in line with selected elements before summation to create these relationships.

To understand electronic beam forming, first consider just two elements, shown as A and B in Figure 21.107. Also shown is the wavefront of a radio signal arriving from a distant transmitter. The wavefront strikes element A first, then travels somewhat farther before it strikes element B. Thus, there is an interval between the times that the wavefront reaches elements A and B.

We can measure the differences in arrival times by delaying the signal received at element A before summing it with that from element B. If two signals are combined directly, the amplitude of the sum will be maximum when the delay for element A exactly equals the propagation delay, giving an in-phase condition at the summation point. On the other hand, if one of the signals is inverted and the two are added, the signals will combine in a 180° out-of-phase relationship when the element A delay equals the propagation delay, creating a null. Either way, once the time delay is determined by the amount of delay required for a peak or null, we can convert it to distance. Then trigonometry calculations provide the direction from which the wave is arriving.

Altering the delay in small increments steers the peak (or null) of the antenna. The system is not frequency sensitive, other than the frequency range limitations of the array elements. Lumped-constant networks are suitable for delay elements if the system is used only for receiving. Delay lines at installations used for transmitting and receive-

ing employ rolls of coaxial cable of various lengths, chosen for the time delay they provide at all frequencies, rather than as simple phasing lines designed for a single frequency.

Combining signals from additional elements narrows the broad beamwidth of the pattern from the two elements and suppress unwanted sidelobes. Electronically switching the delays and attenuations to the various elements causes the formed beam to rotate around the compass. The package of electronics that does this, including delay lines and electronically switched attenuators, is the beam-forming network.

## 21.12.2 Methods for VHF/UHF RDF

Three distinct methods of mobile RDF are commonly in use by amateurs on VHF/UHF bands: directional antennas, switched dual antennas and Dopplers. Each has advantages over the others in certain situations. Many RDF enthusiasts employ more than one method when transmitter hunting.

### DIRECTIONAL ANTENNAS

Ordinary mobile transceivers and handhelds work well for foxhunting on the popular VHF bands. If you have a lightweight beam and your receiver has an easy-to-read S meter, you are nearly ready to start. All you need is an RF attenuator and some way to mount the setup in your vehicle.

Amateurs seldom use fractional wavelength loops for RDF above 60 MHz because they have bidirectional characteristics and low sensitivity, compared to other practical VHF antennas. Sense circuits for loops are difficult to implement at VHF, and signal reflections tend to fill in the nulls. Typically VHF loops are used only for close-in sniffing where their compactness and sharp nulls are assets, and low gain is of no consequence.

### Phased Arrays

The small size and simplicity of two-element driven arrays make them a common choice of newcomers at VHF RDF. Antennas such as phased ground planes and ZL Specials have modest gain in one direction and a null in the opposite direction. The gain is helpful when the signal is weak, but the broad response peak makes it difficult to take a precise bearing.

As the signal gets stronger, it becomes possible to use the null for a sharper S meter indication. However, combinations of direct and reflected signals (called *multipath*) will distort the null or perhaps obscure it completely. For best results with this type of antenna, always find clear locations from which to take bearings.

### Parasitic Arrays

Parasitic arrays are the most common RDF antennas used by transmitter hunters in high competition areas such as Southern California. Antennas with significant gain are a necessity due to the weak signals often encountered on weekend-long T-hunts, where the transmitter may be over 200 miles distant. Typical 144 MHz installations feature Yagis or quads of three to six elements, sometimes more. Quads are typically home-built, using data from *The ARRL Antenna Book* and *Transmitter Hunting* (see Bibliography).

Two types of mechanical construction are popular for mobile VHF quads. One model uses thin gauge wire (solid or stranded), suspended on wood dowel or fiberglass rod spreaders. It is lightweight and easy to turn rapidly by hand while the vehicle moves. Many hunters prefer to use larger gauge solid wire (such as #10 AWG) on a PVC plastic pipe frame. This quad is more rugged and has somewhat wider frequency range, at the expense of increased weight and wind resistance. It can get bent going under a branch, but it is easily reshaped and returned to service.

Yagis are a close second to quads in popularity. Commercial models work fine for VHF RDF, provided that the mast is attached at a good balance point. Lightweight and small-diameter elements are desirable for ease of turning at high speeds.

A well-designed mobile Yagi or quad installation includes a method of selecting wave polarization. Although vertical polarization is the norm for VHF-FM communications, horizontal polarization is allowed on many T-hunts. Results will be poor if a VHF RDF antenna is cross-polarized to the

transmitting antenna, because multipath and scattered signals (which have indeterminate polarization) are enhanced, relative to the cross-polarized direct signal. The installation of **Figure 21.108** features a slip joint at the boom-to-mast junction, with an actuating cord to rotate the boom, changing the polarization. Mechanical stops limit the boom rotation to 90°.

### Parasitic Array Performance for RDF

The directional gain of a mobile beam (typically 8 dB or more) makes it unexcelled for both weak signal competitive hunts and for locating interference such as TV cable leakage. With an appropriate receiver, you can get bearings on any signal mode, including FM, SSB, CW, TV, pulses and noise. Because only the response peak is used, the null-fill problems and proximity effects of loops and phased arrays do not exist.

You can observe multiple directions of arrival while rotating the antenna, allowing you to make educated guesses as to which signal peaks are direct and which are from non-direct paths or scattering. Skilled operators can estimate distance to the transmitter from the rate of signal strength increase with distance traveled. The RDF beam is useful for transmitting, if necessary, but use care not to damage an attenuator in the coax line by transmitting through it.

The 3 dB beamwidth of typical mobile-mount VHF beams is on the order of 80°. This is a great improvement over 2 element driven arrays, but it is still not possible to get pinpoint bearing accuracy. You can achieve errors of less than 10° by carefully reading the S meter. In practice, this is not a major hindrance to successful mobile RDF. Mobile users are not as concerned with precise bearings as fixed station operators, because mobile readings are used primarily to give the general direction of travel to “home in” on the signal. Mobile bearings are continuously updated from new, closer locations.

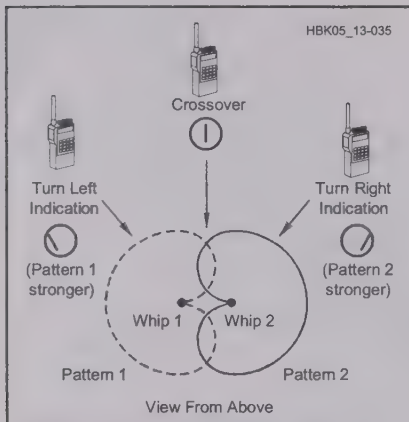

Amplitude-based RDF may be very difficult when signal level varies rapidly. The transmitter hider may be changing power, or the target antenna may be moving or near a well-traveled road or airport. The resultant rapid S meter movement makes it hard to take accurate bearings with a quad. The process is slow because the antenna must be carefully rotated by hand to “eyeball average” the meter readings.

### SWITCHED ANTENNA RDF UNITS

Three popular types of RDF systems are relatively insensitive to variations in signal level. Two of them use a pair of vertical dipole antennas, spaced  $\frac{1}{2} \lambda$  or less apart, and alternately switched at a rapid rate to the input

**Figure 21.108** — The mobile RDF installation of WB6ADC features a thin wire quad that can be switched between vertical and horizontal polarization.

**Figure 21.109** — In a switched pattern RDF set, the responses of two cardioid antenna patterns are summed to drive a zero center indicator.

of the receiver. In use, the indications of the two systems are similar, but the principles are different.

### Switched Pattern Systems

The switched pattern RDF set (Figure 21.109) alternately creates two cardioid antenna patterns with lobes to the left and the right. The patterns are generated in much the same way as in the phased arrays described above. PIN RF diodes select the alternating patterns. The combined antenna outputs go to a receiver with AM detection. Processing after the detector output determines the phase or amplitude difference between the patterns' responses to the signal.

Switched pattern RDF sets typically have a zero center meter as an indicator. The meter swings negative when the signal is coming from the user's left, and positive when the signal source is on the right. When the plane of the antenna is exactly perpendicular to the direction of the signal source, the meter reads zero.

The sharpness of the zero crossing indication makes possible more precise bearings than those obtainable with a quad or Yagi. Under ideal conditions with a well-built unit, null direction accuracy is within 1°. Meter deflection tells the user which way to turn to zero the meter. For example, a negative (left) reading requires turning the antenna left. This solves the 180° ambiguity caused by the two zero crossings in each complete rotation of the antenna system.

Because it requires AM detection of the switched pattern signal, this RDF system finds its greatest use in the 120 MHz aircraft band, where AM is the standard mode. Commercial manufacturers make portable RDF sets with switched pattern antennas and built-in receivers for field portable use. These sets can usu-

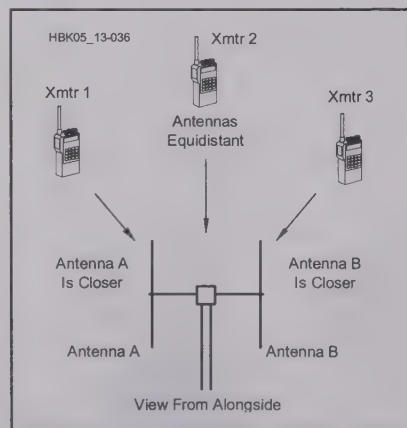

ally be adapted to the amateur 144 MHz band. Other designs are adaptable to any VHF receiver that covers the frequency of interest and has an AM detector built in or added.

Switched pattern units work well for RDF from small aircraft, for which the two vertical antennas are mounted in fixed positions on the outside of the fuselage or simply taped inside the windshield. The left-right indication tells the pilot which way to turn the aircraft to home in. Since street vehicles generally travel only on roads, fixed mounting of the antennas on them is undesirable. Mounting vehicular switched-pattern arrays on a rotatable mast is best.

### Time-of-Arrival Systems

Another kind of switched antenna RDF set uses the difference in arrival times of the signal wavefront at the two antennas. This narrow-aperture Time-Difference-of-Arrival (TDOA) technology is used for many sophisticated military RDF systems. The rudimentary TDOA implementation of Figure 21.110 is quite effective for amateur use. The signal from transmitter 1 reaches antenna A before antenna B. Conversely, the signal from transmitter 2 reaches antenna B before antenna A. When the plane of the antenna is perpendicular to the signal source (as transmitter 2 is in the figure), the signal arrives at both antennas simultaneously.

If the outputs of the antennas are alternately switched at an audio rate to the receiver input, the differences in the arrival times of a continuous signal produce phase changes that are detected by an FM discriminator. The resulting short pulses sound like a tone in the receiver output. The tone disappears when the antennas are equidistant from the signal source, giving an audible null.

**Figure 21.110** — A dual-antenna TDOA RDF system has a similar indicator to a switched pattern unit, but it obtains bearings by determining which of its antennas is closer to the transmitter.

The polarity of the pulses at the discriminator output is a function of which antenna is closer to the source. Therefore, the pulses can be processed and used to drive a left-right zero-center meter in a manner similar to the switched pattern units described above. Left-right LED indicators may replace the meter for economy and visibility at night.

RDF operations with a TDOA dual antenna RDF are done in the same manner as with a switched antenna RDF set. The main difference is the requirement for an FM receiver in the TDOA system and an AM receiver in the switched pattern case. No RF attenuator is needed for close-in work in the TDOA case.

Popular designs for practical do-it-yourself TDOA RDF sets include the Simple Seeker (described elsewhere in this chapter) and the W9DUU design (see article by Bohrer in the Bibliography). Articles with plans for the Handy Tracker, a simple TDOA set with a delay line to resolve the dual-null ambiguity instead of LEDs or a meter, are listed in the Bibliography.

### Performance Comparison

Both types of dual antenna RDFs make good on-foot "sniffing" devices and are excellent performers when there are rapid amplitude variations in the incoming signal. They are the units of choice for airborne work. Compared to Yagis and quads, they give good directional performance over a much wider frequency range. Their indications are more precise than those of beams with broad forward lobes.

Dual-antenna RDF sets frequently give inaccurate bearings in multipath situations, because they cannot resolve signals of nearly equal levels from more than one direction. Because multipath signals are a combined pattern of peaks and nulls, they appear to change in amplitude and bearing as you move the RDF antenna along the bearing path or perpendicular to it, whereas a non-multipath signal will have constant strength and bearing.

The best way to overcome this problem is to take large numbers of bearings while moving toward the transmitter. Taking bearings while in motion averages out the effects of multipath, making the direct signal more readily discernible. Some TDOA RDF sets have a slow-response mode that aids the averaging process.

Switched antenna systems generally do not perform well when the incoming signal is horizontally polarized. In such cases, the bearings may be inaccurate or unreadable. TDOA units require a carrier type signal such as FM or CW; they usually cannot yield bearings on noise or pulse signals.

Unless an additional method is employed to measure signal strength, it is easy to "overshoot" the hidden transmitter location with a TDOA set. It is not uncommon to see a TDOA

foxhunter walk over the top of a concealed transmitter and walk away, following the opposite 180° null, because there is no display of signal amplitude.

## DOPPLER RDF SETS

RDF sets using the Doppler principle are popular in many areas because of their ease of use. They have an indicator that instantaneously displays direction of the signal source relative to the vehicle heading, either on a circular ring of LEDs or a digital readout in degrees. A ring of four, eight or more antennas picks up the signal. Quarter-wavelength monopoles on a ground plane are popular for vehicle use, but half-wavelength vertical dipoles, where practical, perform better.

Radio signals received on a rapidly moving antenna experience a frequency shift due to the Doppler effect, a phenomenon well-known to anyone who has observed a moving car with its horn sounding. The horn's pitch appears higher than normal as the car approaches, and lower as the car recedes. Similarly, the received radio frequency increases as the antenna moves toward the transmitter and vice versa. An FM receiver will detect this frequency change.

Figure 21.111 shows a  $\frac{1}{4}\lambda$  vertical antenna being moved on a circular track around point P, with constant angular velocity. As the antenna approaches the transmitter on its track, the received frequency is shifted higher. The highest instantaneous frequency occurs when the antenna is at point A, because tangential velocity toward the transmitter is maximum at that point. Conversely, the lowest frequency occurs when the antenna reaches point C, where velocity is maximum away from the transmitter.

Figure 21.112 shows a plot of the component of the tangential velocity that is in the direction of the transmitter as the antenna moves around the circle. Comparing Figures 21.111 and 21.112, notice that at B in Figure 21.112, the tangential velocity is crossing zero from the positive to the negative and the antenna is closest to the transmitter. The Doppler shift and resulting audio output from the receiver discriminator follow the same plot, so that a negative-slope zero-crossing detector, synchronized with the antenna rotation, senses the incoming direction of the signal.

Figure 21.111 — A theoretical Doppler antenna circles around point P, continuously moving toward and away from the source at an audio rate.

The amount of frequency shift due to the Doppler effect is proportional to the RF frequency and the tangential antenna velocity. The velocity is a function of the radius of rotation and the angular velocity (rotation rate). The radius of rotation must be less than  $\frac{1}{4}\lambda$  to avoid errors. To get a usable amount of FM deviation (comparable to typical voice modulation) with this radius, the antenna must rotate at approximately 30,000 RPM (500 Hz). This puts the Doppler tone in the audio range for easy processing.

Mechanically rotating a whip antenna at this rate is impractical, but a ring of whips, switched to the receiver in succession with RF PIN diodes, can simulate a rapidly rotating antenna. Doppler RDF sets must be used with receivers having FM detectors. The Dopple ScAnt and Roanoke Doppler (see Bibliography) are mobile Doppler RDF sets designed for inexpensive home construction.

## Doppler Advantages and Disadvantages

Ring-antenna Doppler sets are the ultimate in simplicity of operation for mobile RDF. There are no moving parts and no manual antenna pointing. Rapid direction indications are displayed on very short signal bursts.

Many units lock in the displayed direction after the signal leaves the air. Power variations in the source signal cause no difficulties, as long as the signal remains above the RDF detection threshold. A Doppler antenna goes on

Figure 21.112 — Frequency shift versus time produced by the rotating antenna movement toward and away from the signal source.

top of any car quickly, with no holes to drill. Many Local Interference Committee members choose Dopplers for tracking malicious interference, because they are inconspicuous (compared to beams) and effective at tracking the strong vertically polarized signals that repeater jammers usually emit.

A Doppler does not provide superior performance in all VHF RDF situations. If the signal is too weak for detection by the Doppler unit, the hunt advantage goes to teams with beams. Doppler installations are not suitable for on-foot sniffing. The limitations of other switched antenna RDFs also apply: (1) poor results with horizontally polarized signals, (2) no indication of distance, (3) carrier type signals only and (4) inadvisability of transmitting through the antenna.

Readout to the nearest degree is provided on some commercial Doppler units. This does not guarantee that level of accuracy, however. A well-designed four-monopole set is typically capable of  $\pm 5^\circ$  accuracy on 2 meters, if the target signal is vertically polarized and there are no multipath effects.

The rapid antenna switching can introduce cross modulation products when the user is near strong off-channel RF sources. This self-generated interference can temporarily render the system unusable. While not a common problem with mobile Dopplers, it makes the Doppler a poor choice for use in remote RDF installations at fixed sites with high power VHF transmitters nearby.

## 21.13 Rotators

The rotator is an important component of directional antenna systems, turning the antenna to any direction with a repeatable accuracy of a few degrees. Once in position, the rotator must hold the antenna in place against the wind. The rotator must do this while supporting the weight of the mast and all of the antennas.

Although mechanical details vary, a rotator consists of a base assembly mounted to a fixed mast or tower and a rotating assembly atop it with a clamp in which the antenna support mast is held. The turning motor and gear train, brake, position indicator, and limit switches are installed in or on the base. The rotating assembly sits on a bearing race resting on the base assembly. A ring gear is the most common method of transferring the motor's rotation to the rotating housing, although worm gears are also used.

Rotators are usually installed inside a lattice tower section that uses a sleeve or thrust bearing to hold a mast and stabilize it against sideways torque. The sleeve is part of the tower's top section. A thrust bearing is mounted on a bearing plate at the top of the tower. The rotator is mounted on a rotator shelf that sits inside the tower and is sold as an accessory by the tower manufacturer. Smaller rotators usually come with a mast clamp so they can be mounted on a pipe or similar mast with the antenna directly above them. **Figure 21.113** shows typical installations.

### 21.13.1 Rotator Ratings

Rotators are expected to work for many years over a very wide range of temperatures while exposed to the elements, with little or no maintenance. To achieve those perfor-

mance goals, the rotator's specifications and installation requirements must be respected.

There are three primary rotator ratings: *wind load*, *braking ability*, and *turning torque*. Many rotators also specify a maximum *vertical load* in pounds or kilograms. **Table 21.25** lists manufacturers for rotators intended for fixed-station installations and **Table 21.26** shows the primary ratings for common rotators.

Wind load is specified both with the rotator mounted inside a tower and with the rotator outside a tower mounted on a mast (see **Figure 21.113**). When mounted inside a tower section, the tower holds the mast in place straight above the rotator, often using a thrust bearing to hold the mast in place. This eliminates any sideways load on the rotating assembly relative to the base. Wind load ratings are given as a maximum antenna area in

### "Rotator" or "Rotor"?

The piece of equipment installed on the tower that makes the antennas turn is a "rotator." A "rotor" is the rotary part of a motor or vehicle. For example, the blades of a helicopter form its rotor and the spinning shaft and armature of an electric motor form its rotor. The rotator includes the entire machine, both the stationary and moving parts, making the antenna system turn. Amateurs use both words, rotator and rotor, somewhat interchangeably, regardless.

## What is an Armstrong Rotator?

The term "armstrong" refers to anything turned or lifted manually, requiring a "strong arm." There are many examples of hams using gears or cranks to turn antennas but the most common is a rope tied to the antenna's boom and pulled from ground level. The antenna's mast turns freely in the tower or the antenna mount turns on the mast. This is a common temporary solution during antenna system repair or when operating during Field Day and portable.

square feet, and antenna manufacturers specify the area of their beams for this reason. In the US, wind load calculations are based on the standard EIA/TIA-222-G:2005-08-02. In Europe, EN 1991-1-4 is the current standard, corresponding to the German standard DIN 1055-4.

Braking ability is the maximum twisting force the rotator can withstand when stopped. This force is primarily created by the wind. The rotator's braking action is provided either by a solenoid-controlled wedge or bar inside the housing, or by a worm-gear drive that does not allow backward rotation of the mast under load. Turning torque is the maximum amount of torque the rotator can produce to turn the antennas. Both braking ability and turning torque are given in inch-pounds.

*Effective moment* is the product of antenna weight in pounds (or kilograms) and turning

radius in feet (or meters). Heavy antennas and bigger antennas are harder to turn and to hold in place against the wind, requiring a higher effective moment rating for the rotator. Hy-Gain uses effective moment as a maximum rating for its line of rotators.

It is important not to overload a rotator. If you live in a location that is prone to high winds, persistent winds, or large gusts, include a safety factor when selecting a rotator. Persistent twisting from winds can wear out a rotator's brake wedge or housing indentations that hold the brake in place. This can cause the brake to slip or jam. Rotators are not inexpensive, and a failed rotator brake can allow an antenna to "freewheel," damaging the feed line as well. A thrust bearing at the top of the tower can be used to hold the weight of a large antenna array, leaving only the turning load on the rotator.

## 21.13.2 Types of Rotators

Amateur rotators range from very light-duty models intended for TV antennas all the way to reconditioned "prop-pitch" rotators designed originally to control the pitch or angle of aircraft propeller blades. There are also models for portable and temporary use.

Light-duty antenna rotators are suitable for small VHF and UHF Yagis or log-periodic antennas. They should not be used with HF antennas, large microwave dishes, or antenna systems with a significant wind load.

Medium-duty rotators can handle a single, mid-sized HF tribander or log-periodic. A small VHF/UHF Yagi can be stacked with the HF beam. These rotators are also good choices for a stack of VHF/UHF antennas. Dish antennas should be evaluated to be sure they won't overload these rotators.

Heavy-duty rotators are able to handle the biggest amateur HF Yagis, including stacks of two or three antennas. Instead of a solenoid brake, some of these rotators use a gear train or worm-drive to provide the braking action. Be sure the tower and supporting hardware are rated to handle the antenna and mast load. These rotators are somewhat larger than the more common medium-duty models and may be difficult to install in smaller lattice-style towers.

Ring rotators, or orbital ring rotators, are a special type of rotator installed outside the tower, attached to its legs. The antenna is carried by a motorized cradle that moves around the tower on a circular, toothed track that acts as a drive gear. Ring rotators are generally used at big stations which use large, stacked HF Yagis.

It is also possible to simply rotate the entire tower with a variety of antennas mounted directly on the tower. The guy wires are attached to bearing rings, allowing the tower to turn inside them.

## 21.13.3 Rotator Control

### TURNING CONTROL

There are two steps in controlling turning; releasing the brake, if any, and energizing a motor to turn in the desired direction.

An electrically controlled brake consists of a heavy-duty solenoid and a spring-loaded brake wedge or bar that fits into indentations inside the rotating assembly. The rotator's braking torque is determined by how securely the brake is held by the indentations or, if worm gears are used, by the resistance to the gears turning backward under load. To turn the rotator, the solenoid is energized, pulling the brake out of the indentations. Energizing the solenoid is usually the largest current draw of the rotator.

The most common rotator motor is a 2-phase ac motor with a starting capacitor.

Figure 21.113 — Rotators can be mounted directly on masts or inside lattice-style towers. Rotators can also be mounted directly on the top of towers (not shown).

## One Control for All

Each rotator family (Ham-IV, Yaesu, M<sup>2</sup>, and so on) comes with a custom control unit for turning and position display. There are also after-market control units that operate with any of the common rotators. The most widely used are the Green Heron controllers ([www.greenheronengineering.com](http://www.greenheronengineering.com)) and the EA4TX interfaces ([ea4tx.com](http://ea4tx.com)). Both can control most available models of rotators, allowing you to standardize in the shack and customize on the tower.

The capacitor is switched between phases to control direction of rotation. Because of gear reduction, the motor can be fairly small and does not draw much current. Unless blocked by an obstruction, rotators turn a full 360 degrees. Limit switches open at the ends of rotation, removing power from the motor at the extreme ends of travel to prevent feed line damage.

When rotation is complete, the solenoid is de-energized and the brake re-engages the indentations, holding the mast in place. Over time, the indentations or brake can wear out, allowing the rotating housing to slip under heavy loads. Wear is accelerated by de-en-

ergizing the solenoid while the mast is still turning, causing the brake to impact the sides of the indentations. To reduce the impact of sudden stops, some controllers allow the mast to stop turning before de-energizing the solenoid. Typical brake delays are about 5 seconds. (Retrofit delay modules are available for the Hy-Gain family of rotators.) If your rotator does not have a brake delay, practice keeping the brake energized for a few seconds after you release the turning controls to allow the antennas to stop moving first.

### POSITION INDICATION

There are two basic types of position in-

dication — resistance and pulse counting. The most common circuit is a potentiometer (“pot”) contained in the rotator’s housing and turned in sync with the rotator motor. Current through the pot (typically only a few milliamps) drives an analog meter in the control unit calibrated in degrees. Rotators using pulse counters use a switch to generate pulses that the control unit counts to calculate the number of degrees from one end of travel.

Most rotator controllers in North America are configured as “North center,” meaning they can turn an antenna from pointing directly south at one limit, through north at mid-travel, and all the way to south again at the opposite limit. North is the center position on the meter displaying the antenna’s direction. (South center meter scales are an option for most rotators.)

To calibrate a pot-indicator rotator’s direction, assuming North center, first adjust any meter calibration controls to mid-scale. Then move the rotator to its mid-travel orientation. Loosen the antenna mast clamp and rotate the mast until the antennas point directly north and re-tighten the clamp. (Using a compass or landmark is sufficient resolution for most

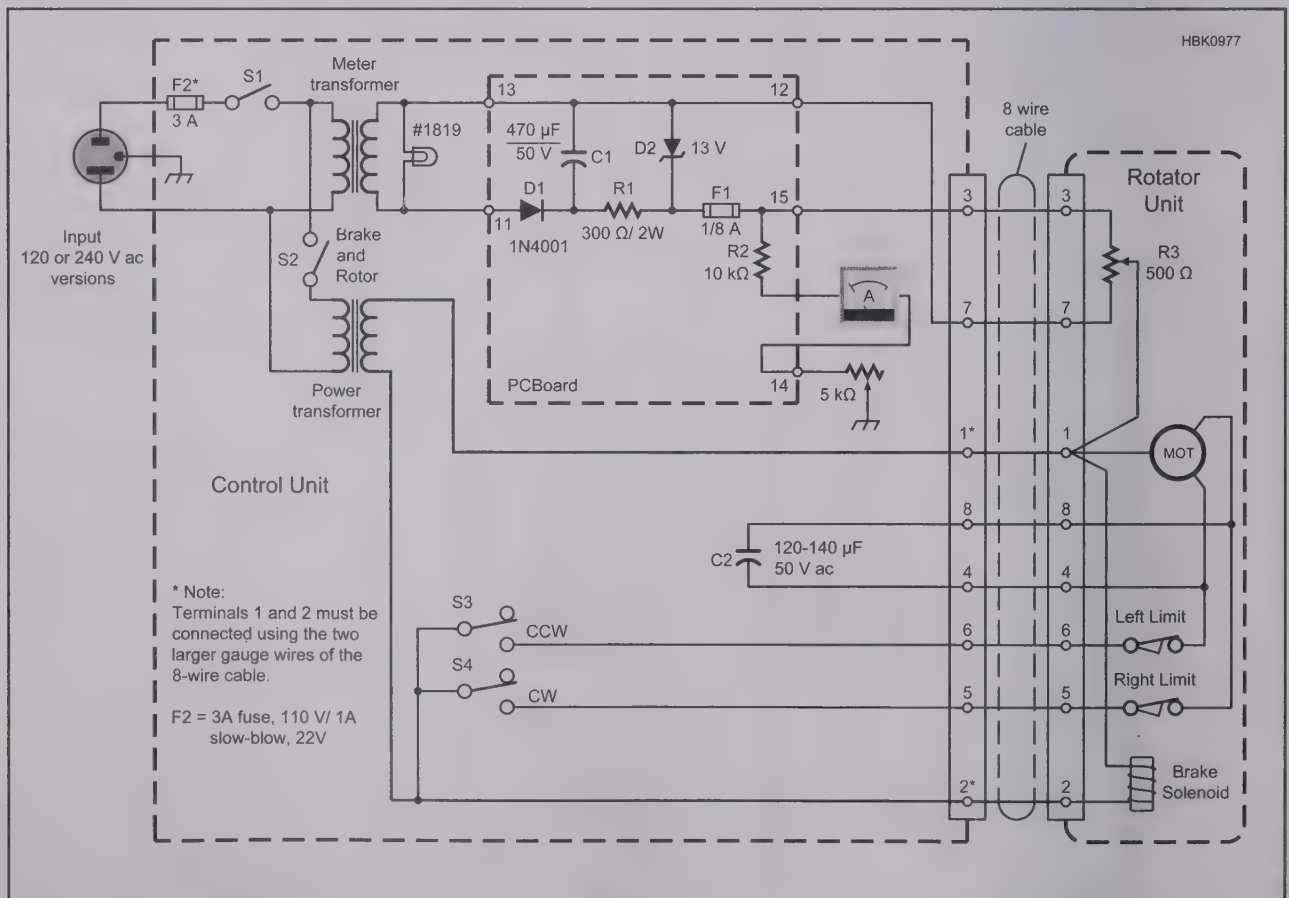

Figure 21.114 — The Hy-Gain Ham-IV/IVX control unit schematic. This control unit will also work with T2X rotators. (Circuit provided courtesy of Hy-Gain, Inc.)

## Rotator Software Control

Recently-designed rotator control units have RS-232 or USB interfaces which act as COM ports to PC software. There are several different protocols, the Yaesu protocol being the most common. The Rotor-EZ and ERC interfaces can be added to most rotators that don't have a software interface. Logging software often supports several different protocols and standalone software packages and utilities are also available - Internet searches for "antenna rotator software control" will find many programs.

the pigtail and cable are attached can also be used. Retrofit kits to replace terminal strips are available from several vendors. The Ham-IV family suggests an 8-pin Cinch-Jones connector with wiring and color code as shown in **Table 21.27**.

For terminal strip connections, use a weatherproofing grease found at electrical and automotive stores. Run the connecting cable down and away from the rotator to guide water away from it. Use a consistent color code at the rotator and the control unit.

Lightning protection is also recommended for rotator control cables. Several vendors make 8-line lightning protectors for rotators. The protector must be well-grounded and should be installed at a common entry point for all antenna system cables. See the **Safety** chapter for more about grounding and lightning protection practices.

Troubleshooting a rotator electrically can be done from the ground through resistance checks. **Table 21.27** shows the nominal resistance values for the Ham-IV family of rotators. When making resistance checks, the control unit must be disconnected. Include the resistance of the cable or test leads when making resistance checks.

amateur antennas.) When storing or testing a rotator, make a practice of leaving it set to mid-travel for ease of position calibration and mark or tag it for later reference. For a pulse-count rotator, the manufacturer's manual will provide the necessary directions.

### ROTATOR WIRING

The ARRL appreciates being granted permission by the Hy-Gain Company to reproduce the wiring diagram of the control unit for its widely used Ham-IV and Tailtwister T2X rotators as a convenience for readers. (See **Figure 21.114**.)

The connection from the control unit to the rotator requires a multi-conductor control cable (no shield necessary). Most rotators require either 6- or 8-conductor cable. Solenoid brake circuits need heavier wire due to the higher current. If the wire used is too small,

the extra resistance may cause enough voltage drop to result in erratic brake operation or slow turning. Check the manufacturer's recommendation for minimum wire size, which depends on the length of the cable. For the popular Ham-IV series, minimum recommended wire sizes are:

- Up to 125 feet: #18 (solenoid), #20 (all others)
- 125 to 200 feet: #16 (solenoid), #18 (all others)
- 200 to 300 feet: #14 (solenoid), #16 (all others)

Other rotators have similar requirements — consult the manufacturer's instructions.

At the rotator, connections can be made directly to a terminal strip under the unit or to a weatherproofed connector at the end of a short "pigtail." A nearby junction box where

## 21.14 Glossary

- Antenna** — An electrical conductor or array of conductors that radiates signal energy (transmitting) or collects signal energy (receiving).
- Antenna tuner** — A device containing variable reactances (and perhaps a balun) used to convert an antenna or feed line impedance to 50  $\Omega$ . (Also called transmatch, impedance-matching unit, matchbox).
- Apex angle** — The included angle between the legs of an inverted-V antenna.
- Azimuth (azimuthal) pattern** — A radiation pattern in a plane oriented parallel to the Earth's surface or at a specified angle to the Earth's surface.
- Balanced feed line** — A two-conductor feed line with each conductor having the same impedance with respect to a reference potential, usually an earth connection (also called open-wire line, ladder line, window line, twin-lead).
- Balun** — A device that transfers energy between a balanced and unbalanced system. A balun may or may not change the impedance ratio between the systems.
- Base loading** — Adding a coil to the base of a ground-plane antenna to increase its electrical length.
- Beamwidth** — The width in degrees of the major lobe of a directive antenna between the two angles at which the relative radiated power is equal to one-half its value ( $-3$  dB) at the peak of the lobe.
- Capacitance hat** — A conducting structure with a large surface area that is added to an antenna to add capacitive reactance at that point on the antenna.
- Center loading** — Adding a coil near the center of a ground-plane antenna to increase its electrical length.
- Coaxial cable (coax)** — A coaxial transmission line with a center conductor surrounded by a layer of insulation and then a tubular shield conductor and covered by an insulating jacket. (see also *unbalanced feed line*)
- Delta loop** — A full-wavelength loop, usually in the vertical plane, shaped like a triangle or delta.
- Delta match** — Center-feed technique used with antenna elements that are not split at the center in which the transmission line is spread apart and connected to the element symmetrically, forming a triangle or delta.
- Dipole** — An antenna, usually one-half wavelength long, divided into two parts at a feed point. An *off-center-fed (OCF) dipole* has a feed point offset from the center.
- Directivity** — The property of an antenna that concentrates the radiated energy to form one or more major lobes.
- Director** — An antenna element in a parasitic array that causes radiated energy from the driven element to be focused along the line from the driven element to the director.
- Doublet** — A more general name for a wire antenna fed in the center and that may or may not be resonant at the operating frequency.
- Driven array** — An array of antenna elements which are all driven or excited by means of a transmission line.
- Driven element** — An antenna element excited by means of a transmission line.
- E-plane** — The plane in which the electric field of an electromagnetic wave is maximum.
- Efficiency (antenna)** — The ratio of radiated power to input power.
- Elements** — The conductive parts of an antenna system that determine the antenna's characteristics.
- Elevation pattern** — A radiation pattern in a plane perpendicular to the Earth's surface.
- End effect** — The effect of capacitance at the end of an antenna element that acts to electrically lengthen the element.
- End-fed Half Wave (EFHW)** — A half-wavelength antenna fed at one end, usually with open-wire feed line.
- Feed line** — See *transmission line*
- Feed point** — location at which a transmission line delivers power to an antenna.
- Front-to-back ratio** — The ratio in dB of the radiation from an antenna in a favored direction to that in the opposite direction.
- Front-to-rear ratio** — The ratio in dB of the radiation from an antenna in a favored direction to an average of the radiation in the opposite direction across some specified angle.
- Front-to-side ratio** — The ratio in dB of the radiation from an antenna in a favored direction to that at right angles to the favored direction.
- Gain** — The increase in radiated power with respect to a reference antenna in the desired direction of the major lobe.
- Gamma match** — A matching system used with driven antenna elements in which a conductor is placed near the element and connected to the feed line with an adjustable capacitor at the end closest to the center and connected to the element at the other.
- Ground plane** — A system of conductors configured to act as a substitute for an earth ground to an antenna element and connected to one side of the transmission line.
- H-plane** — The plane in which the magnetic field of an electromagnetic wave is maximum.
- Hairpin match** — A U-shaped inductor that is connected across the feed point of a driven element for the purpose of creating a match to a feed line.
- Impedance** — The ratio of voltage to current in a feed line or along an antenna.
- Inverted-V** — A dipole antenna supported at its mid-point with halves angled down toward the ground.
- Isotropic** — An imaginary antenna that radiates and receives equally well in all directions.
- Ladder line** — See *balanced line*.
- Line loss** — The power lost in a transmission line, specified in dB per unit of length.
- Load** — The electrical system or component to which power is delivered.
- Lobe** — A region of increased radiation in an antenna's radiation pattern between two nulls. A *main lobe* is the largest lobe in the pattern and all other lobes are *side lobes*.
- Matching** — The process by which power at one impedance is transferred to a system having a different impedance.
- Monopole** — An antenna with a single element that functions in concert with a ground-plane.
- Null** — A point of minimum radiation in an antenna's radiation pattern.
- Open-wire line** — See *balanced line*.
- Parasitic array** — A set of elements that form a radiation pattern through coupling and re-radiation of energy from one or more driven elements.
- Polarization** — The orientation of an antenna or electromagnetic field, referring to the orientation of the E field.
- Q section** — A quarter-wavelength section of transmission line used for impedance-matching purposes.
- Quad** — A directive antenna based on the Yagi with elements that consist of one-wavelength loops.
- Radiation pattern** — The characteristics of an antenna's distribution of energy in a single plane. (See also *elevation pattern* and *azimuth pattern*.)
- Radiation resistance** — A resistance that represents the work done by the current in an antenna to radiate power.
- Reflector** — An antenna element in a parasitic array that causes radiated energy from the driven element to be focused along the line from the driven element away from the reflector.
- Sense Antenna** — An antenna added to a bidirectional array or loop that samples the incoming signal's phase for comparison to that of the main receiving antenna.
- Stacking** — Arranging two or more directive antennas such that their radiation pattern characteristics reinforce each other.
- SWR (VSWR)** — Standing-wave ratio. A measure of the match between a transmission line and a load such as an antenna.
- T-match** — A symmetrical version of the gamma match for a balanced antenna system.
- Top loading** — Addition of a reactance, usually capacitive, at the top of a ground-plane antenna so as to increase its electrical length.

**Transmatch** — See *antenna tuner*.  
**Trap** — A parallel LC-circuit used to isolate sections of an antenna.  
**Twin-lead** — See *balanced line*.

**Unbalanced feed line** — A transmission line such as coaxial cable with conductors that have different impedances with respect to a reference potential, usually an earth connection. One conductor is usually connected directly to the reference. (see also *balanced line*)

**Unipole** — See *monopole*.

**Yagi** — A parasitic array consisting of a driven element and one or more director and reflectors.

**Zepp** — (see *End-fed Half Wave*)

# Component Data and References

Radio amateurs are known for electronic experimentation and homebrew building. Using the wide variety of components available, they design and build impressive radio equipment. With the industry growth of components for wireless communications and surface mount technology (SMT), the choices available seem endless and selecting the proper component can seem a daunting task.

Fortunately, most amateurs tend to use a limited number of component types that have “passed the test of time,” making component selection in many cases easy and safe. Others are learning to design and build using the vast array of SMT parts.

New for the 2021 edition is information on common ac power connectors and wiring in section 22.9.

## 22.1 Component Data

This section provides reference information on the old and new components most often used by the Amateur Radio experimenter and homebrewer, and information for those wishing to learn more about component performance and selection.

### 22.1.1 EIA and Industry Standards

The American National Standards Institute (ANSI), the Electronic Industries Alliance (EIA), and the Electronic Components Association (ECA) establish the US standards for most electronic components, connectors, wire and cables. These standards establish component sizes, wattages, “standard values,” tolerances and other performance characteristics. A branch of the EIA sets the standards for Mil-spec (standard military specification) and special electronic components used by defense and government agencies. The Joint Electron Devices Engineering Council (JEDEC), another branch of the EIA, develops the standards for the semiconductor industry. The EIA cooperates with other standards agencies such as the International Electrotechnical Commission (IEC), a worldwide standards agency. You can often find published EIA standards in the engineering library of a college or university.

And finally, the International Organization of Standardization (ISO), headquartered in Geneva, Switzerland, sets the global standards for nearly everything from paper sizes to photographic film speeds. ANSI is the US representative to the ISO.

These organizations, or their acronyms, are familiar to most of us. They are much more than a label on a component. EIA and other industry standards are what mark components for identification, establishes the “preferred standard values” and ensures their reliable performance from one unit to the next, regardless of their source. Standards require that a 1.2 k $\Omega$  5% resistor from Ohmite Corp. has the same performance as a 1.2 k $\Omega$  5% resistor from Vishay-Dale, or a 2N3904 to have the same performance characteristics and physical packaging whether from ON Semi or Gold Star.

Much of the component data in this chapter is devoted to presenting these component standards, physical dimensions and the various methods of component identification and marking. By selecting components manufactured under these industry standards, building a project from the *Handbook* or other source will ensure nearly identical performance to the original design.

### 22.1.2 Other Sources of Component Data

There are many sources you can consult for detailed component data but the best source of component information and data sheets is the Internet. Most manufacturers maintain extensive websites with information and data on their products. Often, the quickest route to detailed product information is to enter “data sheet” and the part number into an Internet search engine. Distributors such as Digi-Key and Mouser include links to useful information

in their online catalogs as well. Some manufacturers still publish data books for the components they make, and parts catalogs themselves are often good sources of component data and application notes and bulletins.

Some of the tables printed in previous editions of this book have been moved to the downloadable supplemental content to make room for new material. If a table or figure you need is missing, check the downloadable supplemental content!

### 22.1.3 The ARRL Technical Information Service (TIS)

The ARRL Technical Information Service on the ARRL website ([www.arrl.org/technical-information-service](http://www.arrl.org/technical-information-service)) provides technical assistance to members and non-members, including information about components and useful references. The TIS includes links to detailed, commonly needed information in many technical areas. Questions may also be submitted via email ([tis@arrl.org](mailto:tis@arrl.org)); fax (860-594-0259); or mail (TIS, ARRL, 225 Main St, Newington, CT 06111).

### 22.1.4 Definitions

Electronic components such as resistors, capacitors, and inductors are manufactured with a *nominal* value — the value with which they are labeled. The component's *actual* value is what is measured with a suitable measuring instrument. If the nominal value is given as text characters, an "R" in the value (for example "4R7") stands for *radix* and is read as a decimal point, thus "4.7".

*Tolerance* refers to a range of acceptable

values above and below the nominal component value. For example, a 4700- $\Omega$  resistor rated for  $\pm 20\%$  tolerance can have an actual value anywhere between 3760  $\Omega$  and 5640  $\Omega$ . You may always substitute a closer-tolerance device for one with a wider tolerance. For most Amateur Radio projects, assume a 10% tolerance if none is specified.

The *temperature coefficient* or *tempco* of a component describes its change in value with temperature. Tempco may be expressed as a change in unit value per degree (ohms per degree Celsius) or as a relative change per degree (parts per million per degree). Except for temperature sensing components that may use Fahrenheit or Kelvin, Celsius is almost always used for the temperature scale. Temperature coefficients may not be linear, such as those for capacitors, thermistors, or quartz crystals. In such cases, tempco is specified by an identifier such as Z5U or C0G and an equation or graph of the change with temperature provided by the manufacturer.

### 22.1.5 Surface-Mount Technology (SMT)

"SMT" is used throughout this book to refer to components, printed-circuit boards or assembly techniques that involve surface-mount technology. SMT components are often referred to by the abbreviations "SMD" and "SMC," but all three abbreviations are considered to be effectively equivalent. *Through-hole* or *leaded* components are those with wire leads intended to be inserted into holes in printed-circuit boards or used in point-to-point wiring.

Many different types of electronic components, both active and passive, are now available in surface-mount packages. Each package is identified by a code, such as 1802 or SOT. Resistors in SMT packages are referred to by package code and not by power dissipation, as through-hole resistors are. The very small size of these components leaves little space for marking with conventional codes, so brief alphanumeric codes are used to convey the most information in the smallest possible space. You will need a magnifying glass to read the markings on the bodies of SMT components.

In many cases, vendors will deliver SMT components packaged in tape from master reels and the components will not be marked. This is often the case with SMT resistors and small capacitors. However, the tape will be marked or the components are delivered in a plastic bag with a label. Take care to keep the components separated and labeled or you'll have to measure their values one by one!

## HAMCALC Calculators

The *HAMCALC* package of software calculators by George Murphy, VE3ERP, is very handy. Covering dozens of topics from antenna lengths to impedance matching, the package can be downloaded free of charge from [www.cq-amateur-radio.com](http://www.cq-amateur-radio.com). *HAMCALC* utilities were written in GWBASIC. *Windows 7* and later users may not be able to run *HAMCALC* software depending on the version and configuration of their operating system.

## 22.2 Resistors

Most resistors are manufactured using EIA standards to establish common ratings for wattage, resistor values and tolerance regardless of the manufacturer. EIA marking methods for resistors utilize either an alphanumeric scheme or a color code to denote the value and tolerance.

In the earlier days of electronics, 10% and 20% tolerance resistors were the common and inexpensive varieties used by most amateurs. 1% tolerance resistors were considered the "precision resistors" and seldom used by the amateur due to their significantly higher cost.

Today, with improved manufacturing techniques, both 5% and 1% tolerance resistors are commonly available *and* inexpensive,

with precision resistors to 0.1% not uncommon.

### 22.2.1 Resistor Types

The major resistor types are carbon composition, carbon film, metalized film and wire-wound, as described below. (For additional discussion of the characteristics of the different types of resistors, see the **Electrical Fundamentals** chapter.)

*Carbon composition* resistors are made from a slurry of carbon and binder material formulated to achieve the desired resistance when compressed into a cylinder and encapsulated. This yields a resistor with tolerances in the 5% to 20% range. "Carbon comp"

resistors have a tendency to absorb moisture over time and to change value, but can withstand temporary "pulse" overloads that would damage or destroy a film-type resistor.

*Carbon film* resistors are made from a layer of carbon deposited on a dielectric film or substrate. The thickness of the carbon film is controlled to form the desired resistance with greater accuracy than for carbon composition. They are low cost alternatives to carbon composition resistors and are available with 1% to 5% tolerances.

*Metalized film* resistors replace carbon films with metal films deposited onto the dielectric using sputtering techniques to achieve very accurate resistances to 0.1% tolerances. Metal film resistors also generate

less thermal noise than carbon resistors.

All three of these resistor types are normally available with power ratings from  $\frac{1}{10}$  W to 2 W. **Figure 22.1** and **Tables 22.1** and **22.2** provide the body sizes and lead or pad spacing for through-hole and SMT resistors.

For new designs, carbon film and metalized film resistors should be used for their improved characteristics and lower cost compared to the older carbon composition resistors. Metalized films have lower residual inductance and often preferred at VHF. Most surface mount resistors (shown in **Figure 22.2**) are metalized films.

*Wire-wound* resistors, as the name implies, are made from lengths of wire wound around an insulating form to achieve the desired resistance for power ratings above 2 W. Wire-wound resistors have high parasitic inductance, caused by the wire wrapped around a form similar to a coil, and thus should not be used at RF frequencies. **Figure 22.3** (A, B and D) show three types of wire-wound resistors with wattage ranges in **Table 22.3**.

An alternative to wire-wound resistors is the new generation of resistors known as *thick-film power resistors*. They are rated up to 100 W and packaged in a TO-220 or similar case which makes it easy to mount them on heat sinks and printed-circuit boards. Most varieties are non-inductive and suitable for RF use. Metal-oxide (“cement”) resistors are also available in packages similar to that of **Figure 22.3B**. Similar to carbon composition resistors, metal-oxide resistors are non-inductive and useful at RF.

### 22.2.2 Resistor Identification

Resistors are identified by the IEC 60062:2016 standard as shown in **Figure 22.4**. The IEC numerical code is used worldwide. The IEC numerical code for resistor identification is widely used in industry. The nominal resistance, expressed in ohms, is identified by three digits for 2% (and greater) tolerance devices. The first two digits represent the significant figures; the last digit specifies the multiplier as the exponent of 10. (The multiplier is simply the number of zeros following the significant numerals.) For values less than 100  $\Omega$ , the letter R is substituted for one of the significant digits and represents a decimal point. An alphabetic character indicates the tolerance as shown in **Table 22.2**.

For example, a resistor marked with “122J” would be a 1200  $\Omega$ , or a 1.2 k $\Omega$  5% resistor. A resistor containing four digits, such as “1211,” would be a 1210  $\Omega$ , or a 1.21 k $\Omega$  1% precision resistor.

If the tolerance of the unit is narrower than  $\pm 2\%$ , the code used is a four-digit code where the first three digits are the significant figures and the last is the multiplier. The

letter R is used in the same way to represent a decimal point. For example, 1001 indicates a 1000-Ω unit, and 22R0 indicates a 22-Ω unit.

Here are some additional examples of resistor value markings:

Code	Value
101	10 and 1 zero = 100 Ω
224	22 and 4 zeros = 220,000 Ω
1R0	1.0 and no zeros = 1 Ω
22R	22.0 and no zeros = 22 Ω
R10	0.1 and no zeros = 0.1 Ω

The resistor color code, used only with through-hole components, assigns colors to the numerals one through nine and zero, as shown in **Table 22.4**, to represent the significant numerals, the multiplier and the tolerance. The color code is often memorized with a mnemonic such as “Big boys race our young girls, but Violet generally wins” to represent the colors black (0), brown (1), red (2), orange (3), yellow (4), green (5), blue (6), violet (7), gray (8) and white (9). You will no doubt discover other versions of this memory aid made popular over the years.

For example, a resistor with color bands black (1), red (2), red (2) and gold would be a 1200 Ω, or 1.2 kΩ 5% resistor, with the gold band signifying 5% tolerance.

The resistor color code should be memorized as it is also used for identifying capacitors, and inductors. It is also handy to use when connecting multi-conductor or ribbon cables.

Resistors are also identified by an “E” series classification, such as E12 or E48. The number following the letter E signifies the number of logarithmic steps per decade. The more steps per decade, the more choices of resistor values and tighter the tolerances can be. For example, in the E12 series, there are twelve resistor values between 1 kΩ and 10 kΩ with 10% tolerance; E48 provides 48 values between 1 kΩ and 10 kΩ at 1% tolerance. This system is often used with online circuit calculators to indicate the resistor accuracy and tolerance desired. The standard resistor values of the E12 (±10%), E24 (±5%), E48 (±2%) and E96 (±1%) series are listed in **Table 22.5**.

Resistors used in military electronics (Mil-spec) use the type identifiers listed in **Table 22.6**. In addition, Mil-spec resistors with paint-stripe value bands have an extra band indicating the reliability level to which they are certified.

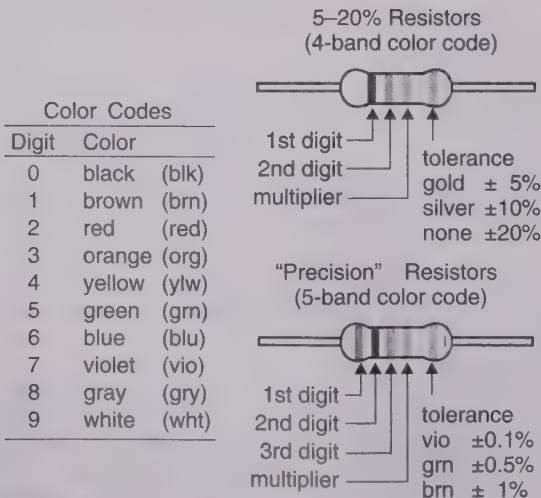

Surface-mount resistors are labeled with an alphanumeric code. There are several identification conventions, including the three-digit and four-digit value-and-exponent and an EIA-96 labeling standard described at [www.hobby-hour.com/electronics/smdcalc.php](http://www.hobby-hour.com/electronics/smdcalc.php).

# 22.3 Capacitors

Capacitors exhibit the largest variety of electronic components. So many varieties and types are available that selecting the proper capacitor for a particular application can be overwhelming. Ceramic and film capacitors are the two most common types used by the amateur. (For additional information on the characteristics of the different types of capacitors, see the **Electrical Fundamentals** chapter.)

Though capacitors are classified by dozens of characteristics, the EIA has simplified the selection process by organizing ceramic capacitors into four categories called Class 1, 2, 3 and 4. Class 1 capacitors are the most stable and Class 4 the least preferred. Many catalogs now list ceramic capacitors by their class, greatly simplifying component selection.

For capacitors used in frequency-sensitive circuits, such as the frequency determining

capacitors in oscillators or tuned circuits, select a Class 1 capacitor (C0G or NP0). For other applications, such as interstage coupling or bypass capacitors, components from Class 2 or Class 3 (X7R or Z5U) are usually sufficient. With modern manufacturing techniques, it is rare to find a Class 4 capacitor today.

Like resistors, capacitors are available in EIA standard series of values, E6 and E12, shown in **Table 22.7**. Most capacitors have a tolerance of 5% or greater. High-value capacitors used for filtering may have asymmetric tolerances, such as -5% and +10%, since the primary concern is for a guaranteed minimum value of capacitance.

## 22.3.1 Capacitor Types

Capacitor types can be grouped into ceramic dielectrics, film dielectrics and electrolytics. The type of capacitor can often be determined by their appearance, as shown in **Figs 22.5** and **22.6**. Capacitors with wire leads have two lead styles: *axial* and *radial*. Axial leads are aligned in opposite directions along a common axis, usually the largest dimension of the capacitor. Radial leads leave the capacitor body in the same direction and are usually arranged radially about the center of the capacitor body.

*Disc (or disk) ceramic* capacitors consist of two metal plates separated by a ceramic dielectric that establishes the desired capacitance. Due to their low cost, they are the most common capacitor type. The main disadvantage is their sensitivity to temperature changes (that is, a high temperature coefficient).

*Monolithic ceramic* capacitors are made by sandwiching layers of metal electrodes and ceramic layers to form the desired capacitance. "Monolithics" are physically smaller than disc ceramics for the same value of capacitance and cost, but exhibit the same high temperature coefficients.

*Polyester film* capacitors use layers of metal and polyester (Mylar) to make a wide

**Figure 22.6** — Aluminum and tantalum electrolytic capacitors.

range of capacitances. They have poor temperature coefficients and are not recommended for high frequency use, but are suitable for low frequency and audio circuits.

To improve the performance of film capacitors, other dielectrics are used, such as polypropylene, polystyrene or polycarbonate film, or silvered-mica. These are very stable capacitors developed for RF use. Their main disadvantages are higher cost and lower working voltages than other varieties.

Capacitors are particularly sensitive to temperature changes because the physical dimensions of the capacitor determine its value. Standard temperature coefficient codes are shown in **Table 22.8**. Each code is made up of one character from each column in the table. For example, a capacitor marked Z5U is suitable for use between +10 and +85°C, with a maximum change in capacitance of -56% or +22%.

Capacitors with highly predictable temperature coefficients of capacitance are sometimes used in circuits whose performance must remain stable with temperature. If an application called for a temperature coefficient of -750 ppm/°C (N750), a capacitor marked U2J would be suitable. The older industry code for these ratings is being replaced with the EIA code shown in **Table 22.8**. NPO (that is, N-P-zero) means "negative, positive, zero." It is a characteristic often specified for RF circuits requiring temperature stability, such as VFOs. A capacitor of the proper value marked COG is a suitable replacement for an NPO unit.

### 22.3.2 Electrolytic Capacitors

*Aluminum electrolytic* capacitors use aluminum foil "wetted" with a chemical agent and formed into layers to increase the effective area, and therefore the capacitance. Aluminum electrolytics provide high capacitance in small packages at low cost. Most varieties are polarized, that is, voltage should only be applied in one "direction." Polarized capacitors have a negative (-) and positive (+) lead. Standard dimensions of aluminum electrolytics are shown in **Figure 22.7** and **Table 22.9**. EIA standard values for aluminum electrolytics are given in **Table 22.10**.

Very old electrolytic capacitors should be used with care or, preferably, replaced. The wet dielectric agent can dry out during prolonged periods of non-use, causing the internal capacitor plates to form a short circuit when energized. Applying low voltage and gradually increasing it over a period of time may restore the capacitor to operation, but if the dielectric agent has dried out, the capacitor will have lost some or most of its value and will likely be lossy and prone to failure.

*Tantalum electrolytic* capacitors consist of tantalum pentoxide powder mixed with a

wet or dry electrolyte, then formed into a pellet or slug for a large effective area. Tantalums also provide high capacitance values in very small packages. Tantalums tend to be more expensive than aluminum electrolytic capacitors. Like the aluminum electrolytic capacitor, tantalum capacitors are also polarized for which care should be exercised. Some varieties of tantalums can literally explode or burst open if voltage is applied with reverse polarity or the voltage rating is exceeded. Tantalum electrolytics are used almost exclusively as high-value SMT components due to their small sizes. Capacitance values up to 1000 µF at 4 V are available with body sizes about a quarter-inch square.

Identifying the polarity markings of alumi-

num and tantalum electrolytics (shown in **Figure 22.6**) can be confusing. Most tantalum electrolytics are marked with a solid band indicating the positive lead. Aluminum electrolytics are available with bands or symbols

marking *either* the negative or positive lead. The positive lead of axial-lead electrolytic capacitors is usually manufactured to be longer than the negative lead and often enters the capacitor through fiber or plastic insulating material while the negative lead is connected directly to the metallic case of the capacitor. Misidentifying the polarity of capacitors is a common error during assembly or repair.

### 22.3.3 Surface Mount Capacitors

SMT capacitors are generally film, ceramic or tantalum electrolytics. Body sizes are shown in **Figure 22.8** and **22.9**. Although the IEC scheme is the standard method of labeling capacitor value, you may encounter a two-character alphanumeric code (see **Table 22.11**) consisting of a letter indicating the significant digits and a number indicating the multiplier. The code represents the capacitance in picofarads. For example, a chip capacitor marked "A4" would have a capacitance of 10,000 pF, or 0.01  $\mu$ F. A unit marked "N1" would be a 33-pF capacitor. If there is sufficient space on the device package, a tolerance code may be included. The standard SMT body sizes and pad spacing are provided in **Table 22.12**.

## 2.3.4 Capacitor Voltage Ratings

Capacitors are also rated by their maximum operating voltage. The importance of selecting a capacitor with the proper voltage rating is often overlooked. Exceeding the voltage rating, even momentarily, can cause excessive heating, a permanent shift of the capacitance value, a short circuit, or outright destruction. As a result, the voltage rating should be at least 25% higher than the working voltage across the capacitor; many designers use 50-100%.

Following the 25% guideline, filter capacitors for a 12-V system should have at least a 15-V rating ( $12\text{ V} \times 1.25$ ). However, 12-V systems such as 12-V power supplies and automotive 12-V electrical systems actually operate near 13.8 V and in the case of automotive systems, as high as 15 V. In such cases, capacitors rated for 15 V would be an insufficient margin of safety; 20 to 25-V capacitors should be used in such cases.

In large signal ac circuits, the maximum

voltage rating of the capacitor should be based on the peak-to-peak voltages present. For example, the output of a 5-W QRP transmitter is  $16\text{ V}_{\text{RMS}}$ , or about  $45\text{ V}_{\text{P-P}}$ . Capacitors exposed to the 5 W RF power, such as in the output low-pass filter, should be rated well above 50 V for the 25% rule. A 100 W transmitter produces RF voltages of about  $200\text{ V}_{\text{P-P}}$ .

Capacitors that are to be connected to primary ac circuits (directly to the ac line) for filtering or coupling *must* be rated for ac line use. These capacitors are listed as such in catalogs and are designed to minimize fire and other hazards in case of failure. Remem-

ber, too, that ac line voltage is given as RMS, with peak-to-peak voltage 2.83 times higher:  $120\text{ V}_{\text{RMS}} = 339\text{ V}_{\text{P-P}}$ .

Applying peak-to-peak voltages approaching the maximum voltage rating will cause excessive heating of the capacitor. This, in turn, will cause a permanent shift in the capacitance value. This could be undesirable in the output low pass filter example cited above in trying to maintain the proper impedance match between transmitter and antenna.

Exceeding the maximum voltage rating can also cause a breakdown of the dielectric material in the capacitor. The voltage can jump between the plates causing momentary or permanent electrical shorts between the capacitor plates.

In electrolytic and tantalum capacitors, exceeding the voltage rating can produce extreme heating of the oil or wetting agent used as the dielectric material. The expanding gases can cause the capacitor to burst or explode.

These over-voltage problems are easily avoided by selecting a capacitor with a voltage rating 25-50% above the normal peak-to-peak

### 22.3.5 Capacitor Identification

Capacitors are identified by the numerical or color code standard as shown in **Figure 22.10**. Since 2000, the IEC numerical code is the most dominant form of capacitor identification and is used on all capacitor types and body styles. Color coding schemes are becoming rare, used only by a few non-US manufacturers. Some thru-hole “gum drop” tantalum capacitors also still use the color codes of **Figure 22.11**. Electrolytic and tantalum capacitors are often labeled with capacitance and working voltage in  $\mu\text{F}$  and V as in **Figure 22.11C**.

Similar to the resistor IEC code, numerals are used to indicate the significant numerals and the multiplier, followed by an alphabetic character to indicate the tolerance. The multiplier is simply the number of zeros following the significant numerals. For example, a capacitor marked with “122K” would

be a 1200 pF 10% capacitor. The use of R to denote a decimal point in a value can be confusing if pF or  $\mu\text{F}$  are not specified. Generally, an inspection of the capacitor will determine which is correct but a capacitance meter may be required. Additional digits and codes may be encountered as shown in **Figure 22.12**.

Military-surplus equipment using the ob-

solete “postage stamp” capacitors is still encountered in Amateur Radio. These capacitors used the colored dot method of value identification shown in **Figure 22.13**.

European manufacturers often use nanofarads or nF, such that 10 nF, or simply 10N, indicates 10 nanofarads. This is equivalent to 10,000 pF or 0.01  $\mu\text{F}$ . This notational scheme, shown in **Table 22.14**, is more commonly found on schematic diagrams than actual part markings.

## 22.4 Inductors

Inductors, both fixed and variable are available in a wide variety of types and packages, and many offer few clues as to their values. Some coils and chokes are marked with the EIA color code shown in **Table 22.4**. See **Figure 22.14** for another marking system for cylindrical encapsulated RF chokes. The body of these components is often green to identify them as inductors and not resistors. Measure

the resistance of the component with an ohmmeter if there is any doubt as to the identity of the component. **Table 22.15** is a list of the EIA standard inductor values.

**Table 22.16** lists the properties of common powdered-iron cores. Formulas are given for calculating the number of required turns based on a given inductance and for calculating the inductance given a specific number of turns. Most powdered-iron toroid cores that amateurs use are manufactured by Micrometals

([www.micrometals.com](http://www.micrometals.com)). Paint is used to identify the material used in the core. The Micrometals color code is part of **Table 22.16**. **Table 22.17** gives the physical dimensions of powdered-iron toroids.

An excellent design resource for ferrite-based components is the Fair-Rite Materials Corp on-line catalog at [www.fair-rite.com](http://www.fair-rite.com). The Fair-Rite website’s Technical section also has free papers on the use of ferrites for EMI suppression and broadband transformers. The

Following list presents the general characteristics (material and composition and intended application) of Fair-Rite's ferrite materials:

- Type 31 (MnZn) — EMI suppression applications from 1 MHz up to 500 MHz.
- Type 43 (NiZn) — Suppression of conducted EMI, inductors and HF common-mode chokes from 20 MHz to 250 MHz.
- Type 44 (NiZn) — EMI suppression from

30 MHz to 500 MHz.

- Type 61 (NiZn) — Inductors up to 25 MHz and EMI suppression above 200 MHz.
- Type 67 (NiZn) — Broadband transformers, antennas and high-Q inductors up to 50 MHz.
- Type 73 (MnZn) — Suppression of conducted EMI below 50 MHz.

- Type 75 (MnZn) — Broadband and pulse transformers.

See **Table 22.18** for information about the magnetic properties of ferrite cores. Ferrite cores are not typically painted, so identification is often difficult. More information about the use of ferrites at RF is provided in the **RF Techniques** chapter.

**Powdered-Iron Toroidal Cores: Magnetic Properties**

There are differing conventions for referring to the type of core material: #, mix and type are all used. For example, all of the following designate the same material: #12, Mix 12, 12-Mix, Type 12 and 12-Type.

**Inductance and Turns Formula**

The turns required for a given inductance or inductance for a given number of turns can be calculated from:

$$N = 100 \sqrt{\frac{L}{A_L}} \quad L = A_L \left( \frac{N^2}{10,000} \right) \quad (\text{Amidon cores})$$

$$N = \sqrt{\frac{L}{A_L}} \quad L = A_L \times N^2 \quad (\text{Non-Amidon cores})$$

where N = number of turns; L = desired inductance; A<sub>L</sub> = inductance index (μH per 100 turns-squared for Amidon cores; nH or μH per turns-squared for non-Amidon cores; see core data sheet)

Amidon Associates literature gives the value of A<sub>L</sub> as inductance per 100 turns but the correct units are inductance per 100 turns-squared. The units of inductance are generally in nH but may also be mH. Make sure you understand which units apply and use the A<sub>L</sub> value and formula provided by the manufacturer of the core to calculate number of turns or inductance.

Toroid diameter is indicated by the number following "T" — T-200 is 2.00 in. dia; T-68 is 0.68 in. diameter, etc.

**Ferrite Toroids:  $A_L$  Chart (mH per 1000 turns-squared) Enameled Wire**

There are differing conventions for referring to the type of ferrite material: #, mix and type are all used. For example, all of the following designate the same ferrite material: #43, Mix 43, 43-Mix, Type 43, and 43-Type.

Fair-Rite Corporation ([www.fair-rite.com](http://www.fair-rite.com)) and Amidon ([www.amidoncorp.com](http://www.amidoncorp.com)) ferrite toroids can be cross-referenced as follows:

For Amidon toroids, "FT-XXX-YY" indicates a ferrite toroid, with XXX as the OD in hundredths of an inch and YY the mix. For example, an FT-23-43 core has an OD of 0.23 inch and is made of type 43 material. Additional letters (usually "C") are added to indicate special coatings or different thicknesses.

For Fair-Rite toroids, digits 1 and 2 of the part number indicate product type (59 indicates a part for inductive uses), digits 3 and 4 indicate the material type, digits 5 through 9 indicate core size, and the final digit indicates coating (1 for Paralene and 2 for thermo-set). For example, Fair-Rite part number 5943000101 is equivalent to the Amidon FT-23-43 core.

**Inductance and Turns Formula**

The turns required for a given inductance or inductance for a given number of turns can be calculated from:

$$N = 100 \sqrt{\frac{L}{A_L}} \quad L = A_L \left( \frac{N^2}{10,000} \right) \quad (\text{Amidon cores}) \quad N = \sqrt{\frac{L}{A_L}} \quad L = A_L \times N^2 \quad (\text{Non-Amidon cores})$$

where N = number turns; L = desired inductance;  $A_L$  = inductance index. Amidon specifies  $A_L$  as mH per 1000 turns-squared. See non-Amidon manufacturer's core data sheet to determine appropriate units for L and  $A_L$ , usually nH and nH/turns-squared. Make sure you understand which units apply and use the  $A_L$  value appropriate for your core.

## 22.5 Transformers

Many transformers, including power transformers, IF transformers, and audio transformers, are made to be installed on PC boards, and have terminals designed for that purpose. Some transformers are manufactured with wire leads that are color-coded to identify each connection. When colored wire leads are present, the color codes in **Tables 22.19, 22.20** and **22.21** usually apply. In addition, many miniature IF transformers are tuned with slugs, color-coded to signify their application. **Table 22.22** lists application versus slug color.

**Table 22.20**

### IF Transformer Wiring Color Codes

B+ lead:	Red
Grid (or diode) lead:	Green
Grid (or diode) return:	Black

Note: If the secondary of the IF transformer is center-tapped, the second diode plate lead is green-and-black striped, and black is used for the center-tap lead.

## 22.6 Semiconductors

Most semiconductors are labeled with industry standard part numbers, such as 1N4148 or 2N3904, and possibly a date or batch code. You will also encounter numerous manufacturer-specific part numbers and the so-called “house numbers” (marked with codes used by an equipment manufacturer instead of the standard part numbers). In such cases, it is often possible to find the standard equivalent or a suitable replacement by using one of the semiconductor cross-reference directories available from various replacement-parts distributors. If you look up the house number and find the recommended replacement part, you can often find other standard parts that are replaced by that same part.

Information on the use of semiconductors, common design practices, and the necessary circuit design equations can be found in the **Circuits and Components** chapter. Manu-

facturer websites are often a rich source of information on applying semiconductors, both in general and the specific devices they offer.

### 22.6.1 Diodes

The diode parameters of most importance are maximum forward current or power handling capacity, reverse leakage current, maximum peak inverse voltage (PIV), maximum reverse voltage and the forward voltage. (See **Table 22.23**) For switching or high-speed rectification applications, the time response parameters are also important.

Power dissipation in a diode is equal to the diode’s forward voltage drop multiplied by the average forward current. Although fixed voltages are often used for diodes in small-signal applications (0.6 V for silicon

PN-junction diodes, 0.3 V for germanium, for example), the actual forward voltage at higher currents can be significantly higher and must be taken into account for high-current applications, such as power supplies.

Most diodes are marked with a part number and some means of identifying the anode or cathode. A thick band or stripe is commonly used to identify the cathode lead or terminal. Stud-mount diodes are usually labeled with a small diode symbol to indicate anode and cathode. Diodes in axial lead packages are sometimes identified with a color scheme as shown in **Figure 22.15**. The common diode packaging standards are illustrated in **Figure 22.16** and the dimensions listed in **Table 22.24**. Many surface mount diodes are packaged in the same SMT packages as resistors.

Packages containing multiple diodes and rectifier bridge configurations are also

commonly available. Full-wave bridge packages are labeled with tildes (~) for the ac inputs and + and - symbols for the rectifier outputs. High-power diodes are often packaged in TO-220 packages with two leads. The package may be labeled with a diode symbol, but if not you will have to obtain the manufacturer's data sheet to identify the anode and cathode leads.

The common 1N914, 1N4148, and 1N5767 switching diodes are suitable for most all small signal applications. The 1N4000 family is commonly used for ac voltage rectification up to 1000 volts PIV. Schottky diodes are used when low forward voltages are required, particularly at high-currents, and exhibit voltages of 0.1-0.2 V at low currents.

Zener diodes, used as voltage references, are manufactured in a wide range of voltages and power handling capacities. Power dissipation in a Zener diode is equal to the Zener voltage multiplied by the average reverse current. The Zener voltage has a significant temperature coefficient and also varies with reverse current. To avoid excessive variations in Zener voltage, limit the diode's power dissipation to no more than 1/2 of the rated value and for precision uses, 1/3 to 1/10 of the rated power dissipation is recommended. Common varieties of Zener diodes are listed in Table 22.25.

Voltage-variable capacitance diodes, also called Varicaps, varactors or tuning diodes, are used in oscillator and tuned circuits where a variable capacitor is needed. Operated with reverse bias, the depletion region forms a

capacitor of variable width with a fairly linear voltage vs. capacitance function. Standard tuning diodes produce capacitances in the range of 5 to 40 pF. Hyper-abrupt tuning diodes produce variable capacitances to 100 pF or more for low frequency or wide tuning range applications. Some of the common voltage variable capacitance diodes are listed in Table 22.26.

Maximum capacitance occurs with minimum reverse voltage. As the reverse voltage is increased, the capacitance decreases. Tuning diodes are specified by the capacitance produced at two reverse voltages, usually 2 and 30 V. This is called the capacitance ratio and is specified in units of pF per volt. Beyond this range, capacitance change with voltage can become non-linear and may cause signal distortion.

All diodes exhibit some capacitance when reversed biased. Amateurs have learned to use reverse biased Zener and rectifier diodes to form tuning diodes with 20-30 pF maximum capacitance. These "poor man's" tuning diodes are widely used in homebrew projects. However, because the capacitance ratio varies widely from one diode to the next, requiring experimentation to find a suitable diode, they are seldom used in published construction articles.

Light emitting diodes (LED) are another common type of diode. The primary application is that of an illuminated visual indicator when forward biased. LEDs have virtually replaced miniature lamp bulbs for indicators and illumination. LED's are specified primar-

ily by their color, size, shape and output light intensity.

The "standard" size LED is the T-1 3/4; 5 mm or 0.20 in. diameter. The "miniature" size is the T-1; 3 mm or 0.125 in. diameter. Today, the "standard" and "miniature" size is a bit of a misnomer due to the wide variety of LED sizes and shapes, including SMT varieties. However, the T-1 and T-1 3/4 remain the most common for homebrew projects due to their inexpensive availability and ease of mounting with a simple panel hole. Their long leads are ideal for prototyping.

## 22.6.2 Transistors

The information in the tables of transistor data includes the most important parameters for typical applications of transistors of that type. The meaning of the parameters and their relationship to circuit design is covered in the Circuits and Components chapter or in the references listed at the end of that chapter.

The tables are organized by application; small-signal, general-purpose, RF power, and so on. Some obsolete parts are listed in these tables for reference in repair and maintenance of older equipment. Before using a device in a new design, it is recommended that you check the manufacturer's website to be sure that the device has not been replaced by a more capable part and that it is available for future orders.

## 22.6.3 Voltage Regulators

For establishing a well-regulated fixed voltage reference, the linear voltage regular ICs are often preferred over the Zener diode. Three-terminal voltage regulators require no external components and most have internal current limiting and thermal shutdown circuitry, making them virtually indestructible. (Three-terminal regulators are described in the Circuits and Components chapter.) The specifications and packages for common voltage regulators are listed in Table 22.27.

For fixed-voltage positive regulators, the 7800 family in the TO-220 package is the most common and reasonably priced. They are available in a variety of voltages and supply up to 1 A of current or more, depending on the input voltage. The part number identifies the voltage. For example, a 7805 is a 5-V regulator and a 7812 is a 12-V regulator. The 78L00 low-power versions in the TO-98 package or SOT-89 surface-mount package provide load currents up to 100 mA. The 317 and 340 are the most common adjustable-voltage regulators. Integrated voltage regulators can be used with a pass transistor to extend their load current capability as described in the device data sheets.

Three-terminal regulators are selected primarily for output voltage and maximum load

current. Dropout voltage — the minimum voltage between input and output for which regulation can be maintained — is also very important. For example, the dropout voltage for the 5-V 78L05 is 1.7 V. Therefore, the input voltage must be at least 6.7 V (5 + 1.7 V) to ensure output voltage regulation. The maximum input voltage should also not be exceeded.

Make sure to check the pin assignments for all voltage regulators. While the fixed-voltage positive regulators generally share a common orientation of input, output, and ground, negative-voltage and adjustable regulators do not. Installing a regulator with the wrong connections will usually destroy it and may allow excessive voltage to be applied to the circuit it supplies.

## 22.6.4 Analog and Digital Integrated Circuits

Integrated circuits (ICs) come in a variety of packages, including transistor-like metal cans, dual and single in-line packages (DIPs and SIPs), flat-packs and surface-mount packages. Most are marked with a part number and a four-digit manufacturer's date code indicating the year (first two digits) and week (last two digits) that the component was made. As mentioned in the introduction to this chapter, ICs are frequently house-marked and cross-reference directories can be helpful in identification and replacement.

IC part numbers provide a complete description of the device's function and ratings. For example, a 4066 IC contains four independent CMOS SPST switches. The 4066

is a CMOS device available from a number of different manufacturers in different package styles and ratings. The two- or three-letter prefix of the part number is generally associated with the part manufacturer. Next, the part type (4066 in this case) shows the function and pin assignments or "pin outs." Following the part type is an alphabetic suffix that describes the version of the part, package code, temperature range, reliability rating and possibly other information. For complete information on the part — any or all of which may be significant to circuit function — use the websites of the various manufacturers or enter "data sheet" and the part number into an Internet search engine.

placements, be wary of substituting "similar" devices, particularly in demanding applications, such as high-speed logic, sensitive receivers, precision instrumentation and similar devices. In particular, substitution of one type of logic family for another — even if the device functions and pin outs are the same — can cause a circuit to not function or function erratically, particularly at temperature extremes. For example, substituting LS TTL devices for HCMOS devices will result in mismatches between logic level thresholds. Substituting a lower-power IC may result in problems supplying enough output current. Even using a faster or higher clock-speed part can cause problems if signals change faster

or propagate more quickly than the circuit was designed for. Problems of this sort can be extremely difficult to troubleshoot unless you are skilled in circuit design. When necessary, you can add interface circuits or buffer amplifiers that improve the input and output capabilities of replacement ICs, but auxiliary circuits cannot improve basic device ratings, such as speed or bandwidth. Whenever possible, substitute ICs that are guaranteed or "direct" replacements and that are listed as such by the manufacturer.

ICs are available in different operating temperature ranges. Three standard ranges are common:

- Commercial: 0 °C to 70 °C

- Industrial: -25 °C to 85 °C
- Automotive: -40 °C to 85 °C
- Military: -55°C to 125°C

In some cases, part numbers reflect the temperature ratings. For example, an LM301A op amp is rated for the commercial temperature range; an LM201A op amp for the industrial range and an LM101A for the military range. It is usually acceptable, all other things being equal, to substitute ICs rated for a wider temperature range, but there are often other performance differences associated with the devices meeting wider temperature specifications that should be evaluated before making the substitution.

### 22.6.5 MMIC Amplifiers

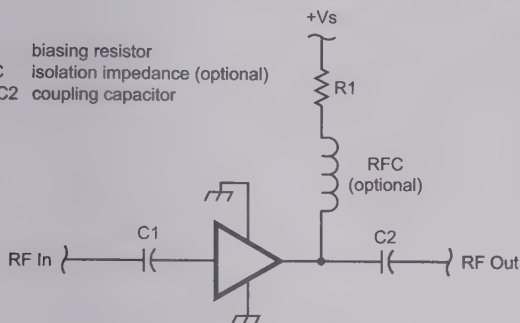

Monolithic microwave integrated circuit (MMIC) amplifiers are single-supply 50-Ω wideband gain blocks offering high dynamic range for output powers to about +15 dBm. MMIC amplifiers are becoming increasingly popular in homebrew communications circuits. With bandwidths over 1 GHz, they are well suited for HF, VHF, UHF and lower microwave frequencies.

MMIC amplifiers produce power gains from 10 dB to 30 dB. They also have a high third-order intercept point (IP3), usually in the +20 to +30 dBm range, easing the concerns about amplifier compression for most applications. They are used for RF and IF amplifiers, local oscillator amplifiers, transmitter drivers, and other medium power applications in 50-Ω systems. MMICs are especially well suited for driving 50-Ω double-balanced mixers (DBM). **Figure**

**22.17** shows the typical circuit arrangement for most MMIC amplifiers.

MMICs are available in a variety of packages, mostly surface mount as shown in **Figure 22.18**, requiring very few external components. Vendor data sheets and application notes, found on the manufacturer's websites, should be used for the proper selection of the biasing resistor, coupling capacitors, and other design criteria. Some of the popular MMIC amplifiers are listed in **Table 22.28**.

R1 biasing resistor  
 RFC isolation impedance (optional)  
 C1,C2 coupling capacitor

To calculate the value of R1:

$$R1 = \frac{+Vs - Vb}{I_d}$$

Bias voltage,  $V_b$ , as listed in the data sheet

HBK0473

Figure 22.17 — MMIC application.

Figure 22.18 — MMIC package styles.

The main disadvantage of MMIC amplifiers is their relatively high current demands, usually in the 30 mA to 80 mA range per device, making them unsuitable for battery-powered portable equipment. On the other hand, the high current demand is what establishes their high gain and high IP3 characteristics with 50-Ω loads.

Another disadvantage is their wide gain-bandwidth. Their gain should be band-limited

by input and output tuned circuits or filters to reduce the gain outside the desired ranges. For example, for an HF amplifier, 30 MHz low-pass filters can be used to reduce the gain outside the HF spectrum, or a band-pass filter used for the frequency band of interest.

Selecting the proper MMIC amplifier is fairly straightforward. First, select a device for the desired frequency bandwidth, gain, and output power. Ensure device current is

compatible with the design application. Calculate the value for the bias resistor ( $R_1$ ) in Figure 22.17) based on the biasing voltage ( $V_b$ ) listed in Table 22.28 and whatever value of supply voltage ( $V_s$ ) is available.

With increasing availability and ease of use, there are many circuits where MMIC amplifiers can be used. There are many MMIC amplifiers that are relatively inexpensive for hobby use.

Alphabetical subscripts (D = diode, P = pentode, T = triode and HX = hexode) indicate structures in multistucture tubes. Subscript CT indicates filament or heater center tap. Generally, when pin 1 of a metal-envelope tube (except all triodes) is shown connected to the envelope, pin 1 of a glass-envelope counterpart (suffix G or GT) is connected to an internal shield.

**Notes**

- <sup>1</sup>A circular mil (CM) is a unit of area equal to that of a one-mil-diameter circle ( $\pi/4$  square mils). The CM area of a wire is the square of the mil diameter.
- <sup>2</sup>Figures given are approximate only; insulation thickness varies with manufacturer.
- <sup>3</sup>Maximum wire temperature of 212°F (100°C) with a maximum ambient temperature of 135°F (57°C) as specified by the manufacturer. The *National Electrical Code* or local building codes may differ.
- <sup>4</sup>700 CM per ampere is a satisfactory design figure for small transformers, but values from 500 to 1000 CM are commonly used. The *National Electrical Code* or local building codes may differ.
- <sup>5</sup>Stranded wire construction is given as "count" x "strand size" (AWG).

**Aluminum Alloy Specifications**

**Common Alloy Numbers**

Type	Characteristic
2024	Good formability, high strength
5052	Excellent surface finish, excellent corrosion resistance, normally not heat treatable for high strength
6061	Good machinability, good weldability, can be brittle at high tempers
7075	Good formability, high strength

**General Uses**

Type	Uses
2024-T3	Chassis boxes, antennas, anything that will be bent or flexed repeatedly
7075-T3	
6061-T6	Mounting plates, welded assemblies or machined parts

**Common Tempers**

Type	Characteristics
T0	Special soft condition
T3	Hard
T6	Very hard, possibly brittle
XXXX	Three digit tempers—usually specialized high-strength heat treatments, similar to T6

## 22.8 Computer Connectors

Most connections between computers and their peripherals are made with some form of multi-conductor cable. Examples in-

clude shielded, unshielded and ribbon cable. **Table 22.59** shows a variety of computer connectors and pin outs, including some used for

internal connections, such as power supplies and disk drives.

# 22.9 AC and Power Connectors

The following tables show the most common connectors for ac power in the United States. Pay particular attention to whether the diagram shows the plug or receptacle and the

internal (wiring) side or external side of the connector. If you are unsure of how to connect the wiring, ask for professional help to avoid

a shock or fire hazard. This section will be expanded to include additional types of power connectors in future editions.

# 22.10 RF Connectors and Transmission Lines

There are many different types of transmission lines and RF connectors for coaxial cable, but the three most common for amateur use are the UHF, Type N and BNC families. The type of connector used for a specific job depends on the size of the cable, the frequency of operation and the power levels involved. **Table 22.61** shows the characteristics of many popular transmission lines, while **Table 22.62** details coax connectors.

## 22.10.1 UHF Connectors

The so-called UHF connector (the series name is not related to frequency) is found on most HF and some VHF equipment. It is the only connector many hams will ever see on coaxial cable. PL-259 is another name for the UHF male, and the female is also known as the SO-239. These connectors are rated for full legal amateur power at HF. They are poor for UHF work because they do not present a constant impedance, so the UHF label is a misnomer. PL-259 connectors are designed to fit RG-8 and RG-11 size cable (0.405-inch OD). Adapters are available for use with smaller RG-58, RG-59 and RG-8X size cable. UHF connectors are not weatherproof. Most PL-259s are nickel plated, but silver-plated connectors are much easier to solder and only slightly more expensive.

**Figure 22.19** shows how to install the solder type of PL-259 on RG-8 cable. Proper preparation of the cable end is the key to success. Follow these simple steps. Measure back about 3/4-inch from the cable end and slightly score the outer jacket around its circumference. With a sharp knife, cut through

the outer jacket, through the braid and through the dielectric — almost to the center conductor. Be careful not to score the center conductor. Cutting through all outer layers at once keeps the braid from separating. (Using a coax stripping tool with preset blade depth makes this and subsequent trimming steps much easier.)

Pull the severed outer jacket, braid and dielectric off the end of the cable as one piece. Inspect the area around the cut, looking for any strands of braid hanging loose and snip them off. There won't be any if your knife was sharp enough. Next, score the outer jacket about 1/16-inch back from the first cut. Cut through the jacket lightly; do not score the braid. This step takes practice. If you score the braid, start again. Remove the outer jacket.

Tin the exposed braid and center conductor, but apply the solder sparingly and avoid melting the dielectric. Slide the coupling ring onto the cable. Screw the connector body onto the cable. If you prepared the cable to the right dimensions, the center conductor will protrude through the center pin, the braid will actually thread onto the outer cable jacket. A very small amount of lubricant on the cable jacket will help the threading process. Solder the braid through the solder holes.

**Figure 22.20** — Installing PL-259 plugs on RG-58 or RG-59 cable requires the use of UG-175 or UG-176 adapters, respectively. The adapter screws into the plug body using the threads of the connector that grip the jacket on larger cables. (Courtesy Amphenol Electronic Components)

83-1SP (PL-259) Plug with adapters (UG-176/U OR UG-175/U)

1. Cut end of cable even. Remove vinyl jacket 3/4" - don't nick braid. Slide coupling ring and adapter on cable.
2. Fan braid slightly and fold back over cable.
3. Position adapter to dimension shown. Press braid down over body of adapter and trim to 3/8". Bare 5/8" of conductor. Tin exposed center conductor.
4. Screw the plug assembly on adapter. Solder braid to shell through solder holes. Solder center conductor to contact sleeve.
5. Screw coupling ring on plug assembly.

**Figure 22.19** — The PL-259, or UHF, connector is almost universal for amateur HF work and is popular for equipment operating in the VHF range. Steps A through E are described in detail in the text.

Solder through all four holes; poor connection to the braid is the most common form of PL-259 failure. A good connection between connector and braid is just as important as that between the center conductor and connector. Use a large soldering iron for this job. With practice, you'll learn how much heat to use. If you use too little heat, the solder will bead up, not really flowing onto the connector body. If you use too much heat, the dielectric will melt, letting the braid and center conductor touch. After soldering, to prevent distorting the dielectric do not move the connector or cable until both are cool. A damp rag or sponge can be used to cool the connector quickly.

Solder the center conductor to the center pin. The solder should flow on the inside, not the outside, of the center pin. If you wait until the connector body cools off from soldering the braid, you'll have less trouble with the dielectric melting. Trim the center conductor to be even with the end of the center pin. Use a small file to round the end, removing any solder that built up on the outer sur-

face of the center pin. Use a sharp knife, very fine sandpaper or steel wool to remove any solder flux from the outer surface of the center pin. Screw the coupling ring onto the body, and you're finished.

Figure 22.20 shows how to install a PL-259 connector on RG-58 or RG-59 cable. An adapter is used for the smaller cable with standard RG-8 size PL-259s. (UG-175 for RG-58 and UG-176 for RG-59.) Prepare the cable as shown. Once the braid is prepared, screw the adapter into the PL-259 shell and finish the job as you would a PL-259 on RG-8 cable.

Figure 22.21 shows the instructions and dimensions for crimp-on UHF connectors that fit all common sizes of coaxial cable. While amateurs have been reluctant to adopt crimp-on connectors, the availability of good quality connectors and inexpensive crimping tools make crimp technology a good choice, even for connectors used outside. Soldering the center conductor to the connector tip is optional.

UHF connectors are not waterproof and

must be waterproofed whether soldered or crimped as shown in the section of the **Safety** chapter on Antenna and Tower Safety.

## 22.10.2 BNC, N and F Connectors

The BNC connectors illustrated in Figure 22.22 are popular for low power levels at VHF and UHF. They accept RG-58 and RG-59 cable, and are available for cable mounting in both male and female versions. Several different styles are available, so be sure to use the dimensions for the type you have. Follow the installation instructions carefully. If you prepare the cable to the wrong dimensions, the center pin will not seat properly with connectors of the opposite gender. Sharp scissors are a big help for trimming the braid evenly. Crimp-on BNC connectors are also available, with a large number of

See [www.AmphenolRF.com](http://www.AmphenolRF.com) for assembly instructions for all other connector types. These dimensions only apply to Amphenol connectors and may not be correct for other manufacturers. \* Manufacturer's assembly dimensions incorrectly show 0.574 inches.

Step 1

**Step 1** Cut end of cable even. Strip cable to dimensions shown in table. All cuts are to be sharp and square. Do not nick braid, dielectric or center conductor. Tin center conductor avoiding excessive heat.

Step 2

**Step 2** Slide coupling nut and ferrule over cable jacket. Flair braid slightly as shown. Install cable into body assembly, so inner ferrule portion slides under braid, until braid butts shoulder. Slide outer ferrule over braid until it butts shoulder. Crimp ferrule with tool and die set indicated in table.

Step 3

**Step 3** Soft solder center conductor to contact. Avoid heating contact excessively to prevent damaging insulator. Slide/screw coupling nut over body.

**Standard Clamp**

1. Cut cable even. Strip jacket. Fray braid and strip dielectric. **Don't nick braid or center conductor.** Tin center conductor.

2. Taper braid. Slide nut, washer, gasket and clamp over braid. Clamp inner shoulder should fit squarely against end of jacket.

3. With clamp in place, comb out braid, fold back smooth as shown. Trim center conductor.

4. Solder contact on conductor through solder hole. Contact should butt against dielectric. Remove excess solder from outside of contact. Avoid excess heat to prevent swollen dielectric which would interfere with connector body.

5. Push assembly into body. Screw nut into body with wrench until tight. **Don't rotate body on cable to tighten.**

**Improved Clamp**

Follow 1, 2, 3 and 4 in BNC connectors (standard clamp) except as noted. Strip cable as shown. Slide gasket on cable with groove facing clamp. Slide clamp with sharp edge facing gasket. Clamp should cut gasket to seal properly.

**C. C. Clamp**

For Male Connectors (Plugs) (3/8" for Jacks)

1. Follow steps 1, 2, and 3 as outlined for the standard-clamp BNC connector.

2. Slide on bushing, rear insulator and contact. The parts must butt securely against each other, as shown.

3. Solder the center conductor to the contact. Remove flux and excess solder.

4. Slide the front insulator over the contact, making sure it butts against the contact shoulder.

5. Insert the prepared cable end into the connector body and tighten the nut. Make sure the sharp edge of the clamp seats properly in the gasket.

**Step 1** Place nut, washer, and gasket, with "V" groove toward clamp, over cable and cut off jacket to dimension a.

**Step 2** Comb out braid and fold out. Cut off cable dielectric to dim. c as shown.

**Step 3** Pull braid wires forward and taper toward center conductor. Place clamp over braid and push back against cable jacket.

**Step 4** Fold back braid wires as shown, trim braid to proper length and form over clamp as shown. Solder contact to center conductor.

**Step 5** Insert cable and parts into connector body. Make sure sharp edge of clamp seats properly in gasket. Tighten nut.

variations, including a twist-on version. A guide to installing these connectors is available with the downloadable supplemental content.

The Type N connector, illustrated in **Figure 22.23**, is a must for high-power VHF and UHF operation. N connectors are avail-

able in male and female versions for cable mounting and are designed for RG-8 size cable. Unlike UHF connectors, they are designed to maintain a constant impedance at cable joints. Like BNC connectors, it is important to prepare the cable to the right dimensions. The center pin must be positioned correctly to mate with the center pin

of connectors of the opposite gender. Use the right dimensions for the connector style you have. Crimp-on N connectors are also available, again with a large number of variations. A guide to installing these connectors is available with the downloadable supplemental content.

Type F connectors, used primarily on cable

### Crimp-style F-connector Installation

**Step 1** All parts of the connector are shown. A crimp tool is necessary to complete the connection.

**Step 2** Strip the conductor, dielectric, braid and jacket as per "RECOMMENDED CABLE STRIPPING DIM'S" in catalog.

**Step 3** Insert cable into the back of the main body gently, and feed it into the guide hole.

**Step 4** Crimp it with the crimp tool as shown.

### Compression-style F-connector Installation

**Step 1:** The connector is a one-piece design. Use a stripping tool and compression tool to install the connector.

**Step 2:** Strip the conductor, dielectric, braid, and jacket. (Refer to manufacturer's recommendations.)

**Step 3:** Insert the cable into the connector until the dielectric is flush with the internal connector base and the center conductor extends just past the threaded end of the connector.

**Step 4:** Place connector in compression tool and seat firmly.

**Step 5** Compress the connector until compression housing is completely installed.

Hbk0871

TV connections, are also popular for receive-only antennas and can be used with RG-59 or the increasingly popular RG-6 cable available at low cost. Crimp-on connectors are the only option for these connectors and **Figure 22.24** shows a general guide for installing them. The exact dimensions vary between connector styles and manufacturers — information on crimping is generally provided with the connectors. There are two styles of crimp; ferrule and compression. The ferrule crimp method is similar to that for UHF, BNC, and N connectors in which a metal ring is compressed around the exposed coax shield. The compression crimp forces a bushing into the back of the connector, clamping the shield against the connector body. In all cases, the exposed center conductor of the cable — a solid wire — must end flush with the end of the connector. A center conductor that is too short may not make a good connection.

### 22.10.3 Connector Identifier and Range Chart

The following pages of figures provide dimensions and side views to help identify the different types of connectors used for RF through microwave frequencies. Dimensions are provided in both imperial and metric units as appropriate. For mm-wave and microwave connectors, calipers or a micrometer may be required to provide an accurate measurement capable of distinguishing between similar connectors. These specifications are intended for connector identification only and should not be the sole dimensions used when laying out a circuit board or drilling a mounting hole.

These figures and chart were provided by Pasternack ([www.pasternack.com](http://www.pasternack.com)), a major distributor of coaxial connectors, cable, tools, and other RF materials and supplies.

**Figure 22.24** — Type F connectors, commonly used for cable TV connections, can be used for receive-only antennas with inexpensive RG-59 and RG-6 cable. The older crimp-style connectors have largely been replaced by the more reliable and weather-resistant compression-style connectors. Follow the manufacturer's instruction for the cable and connector selected. [Courtesy Amphenol Electronic Components and Technetix, Inc.]

## Avoiding Poor Quality UHF Connectors

[This guidance is provided by Hal Kennedy, N4GG, and is repeated in the *Station Construction* chapter. Many easily-avoided station problems are caused by poor-quality or poorly attached connectors or adapters — Ed.]

PL-259s have four parts: the outer sleeve called the “knurled nut,” the connector body, the insulator/dielectric and the center pin. All four components can be compromised to the point of making a bargain connector useless.

Problems frequently encountered:

- **Finish:** Bargain connectors sometimes have a finish you can't solder to! They may have a chrome-like appearance, but the plating may not take solder well and has to be filed down for a good connection.

- **Threading:** The internal threads at the rear of the body are there to accept a UG-style insert that narrows the connector barrel to accept smaller diameter coax such as RG-8X or RG-58. The threads may be metric! UG inserts also sometimes appear in the US market with metric threads. Either way, the insert will not screw into the body.

- **Dielectric:** Good connectors use quality phenolic or Teflon insulation between the center pin and the body. Bargain connectors might use anything, including materials such as polystyrene, which will melt when the center pin is soldered.

- **Center pin diameter:** This is one of the most common and insidious problems in mystery PL-259s. The center pin outer diameter (OD) is almost always slightly smaller than it should be and it's hard to notice. The center pin connection between a PL-259 and an SO-239 or barrel connector depends on the

male side pin OD being correct and the matching fingers on the female side being the correct diameter and made of the proper spring material.

- **Center socket spring tension:** If the SO-239 socket metal relaxes over time and/or temperature, an intermittent connection will be created that can be very hard to track down.

- **Mating indentions:** The indentations on the end of the SO-239 that mate to a PL-259 (the annulus flange) may only have four indentations to match up with the short prongs on the body of the male connector. A quality SO-239 or barrel connector has indentations all the way around. If the PL-259 and SO-239 don't seat completely, an intermittent connection is likely to develop.

- **Tee and right-angle (elbow) UHF adapters:** The center conductor has to make a right-angle turn inside the shell. In poor-quality adapters the right-angle connection is done with a spring contact — these do not hold up. Quality tee and right-angle adapters are reliable because the internal conductors are tapped and threaded — the conductors are screwed together within the body at the right angle junction.

How can we tell the good connectors? If the price is too good to be true — well, it is. PL-259s with good silver plating have a dull appearance. Good connectors have a part number and manufacturer's name stamped into them. You can look up the connector's specifications if it's marked. An example is the connectors made by Amphenol — all of which have parts numbers such as 83-1SP (PL-259) or 83-1R (SO-239) stamped into or onto the connector body.

## Abbreviations List

**A**

a—atto (prefix for  $10^{-18}$ )  
 A—ampere (unit of electrical current)  
 ac—alternating current  
 ACC—Affiliated Club Coordinator  
 ACSSB—amplitude-compandored single sideband  
 A/D—analogue-to-digital  
 ADC—analogue-to-digital converter  
 AF—audio frequency  
 AFC—automatic frequency control  
 AFSK—audio frequency-shift keying  
 AGC—automatic gain control  
 Ah—ampere hour  
 ALC—automatic level control  
 AM—amplitude modulation  
 AMRAD—Amateur Radio Research and Development Corporation  
 AMSAT—Radio Amateur Satellite Corporation  
 AMTOR—Amateur Teleprinting Over Radio  
 ANT—antenna  
 ARA—Amateur Radio Association  
 ARC—Amateur Radio Club  
 ARES—Amateur Radio Emergency Service  
 ARQ—Automatic repeat request  
 ARRL—American Radio Relay League  
 ARS—Amateur Radio Society (station)  
 ASCII—American National Standard Code for Information Interchange  
 ATV—amateur television  
 AVC—automatic volume control  
 AWG—American wire gauge  
 az-el—azimuth-elevation

**B**

B—bel; blower; susceptance; flux density, (inductors)  
 balun—balanced to unbalanced (transformer)  
 BC—broadcast  
 BCD—binary coded decimal  
 BCI—broadcast interference  
 Bd—baud (bits in single-channel binary data transmission)  
 BER—bit error rate  
 BFO—beat-frequency oscillator  
 bit—binary digit  
 bit/s—bits per second  
 BM—Bulletin Manager  
 BPF—band-pass filter  
 BPL—Brass Pounders League  
 BPL—Broadband over Power Line  
 BT—battery  
 BW—bandwidth  
 Bytes—Bytes

**C**

c—centi (prefix for  $10^{-2}$ )  
 C—coulomb (quantity of electric charge); capacitor  
 CAC—Contest Advisory Committee  
 CATVI—cable television interference

CB—Citizens Band (radio)  
 CBBS—computer bulletin-board service  
 CBMS—computer-based message system  
 CCITT—International Telegraph and Telephone Consultative Committee  
 CCTV—closed-circuit television  
 CCW—coherent CW  
 ccw—counterclockwise  
 CD—civil defense  
 cm—centimeter  
 CMOS—complementary-symmetry metal-oxide semiconductor  
 coax—coaxial cable  
 COR—carrier-operated relay  
 CP—code proficiency (award)  
 CPU—central processing unit  
 CRT—cathode ray tube  
 CT—center tap  
 CTCSS—continuous tone-coded squelch system  
 cw—clockwise  
 CW—continuous wave

**D**

d—deci (prefix for  $10^{-1}$ )  
 D—diode  
 da—deca (prefix for 10)  
 D/A—digital-to-analog  
 DAC—digital-to-analog converter  
 dB—decibel (0.1 bel)  
 dBi—decibels above (or below) isotropic antenna  
 dBm—decibels above (or below) 1 milliwatt  
 DBM—double balanced mixer  
 dBV—decibels above/below 1 V (in video, relative to 1 V P-P)  
 dBW—decibels above/below 1 W  
 dc—direct current  
 D-C—direct conversion  
 DDS—direct digital synthesis  
 DEC—District Emergency Coordinator  
 deg—degree  
 DET—detector  
 DF—direction finding; direction finder  
 DIP—dual in-line package  
 DMM—digital multimeter  
 DPDT—double-pole double-throw (switch)  
 DPSK—differential phase-shift keying  
 DPST—double-pole single-throw (switch)  
 DS—direct sequence (spread spectrum); display  
 DSB—double sideband  
 DSP—digital signal processing  
 DTMF—dual-tone multifrequency  
 DV—digital voice  
 DVM—digital voltmeter  
 DX—long distance; duplex  
 DXAC—DX Advisory Committee  
 DXCC—DX Century Club

**E**

e—base of natural logarithms (2.71828)  
 E—voltage

EA—ARRL Educational Advisor  
 EC—Emergency Coordinator  
 ECL—emitter-coupled logic  
 $\epsilon$ HF—extremely high frequency (30-300 GHz)  
 EIA—Electronic Industries Alliance  
 EIRP—effective isotropic radiated power  
 ELF—extremely low frequency  
 ELT—emergency locator transmitter  
 EMC—electromagnetic compatibility  
 EME—earth-moon-earth (moonbounce)  
 EMF—electromotive force  
 EMI—electromagnetic interference  
 EMP—electromagnetic pulse  
 EOC—emergency operations center  
 EPROM—erasable programmable read only memory

**F**

f—femto (prefix for  $10^{-15}$ ); frequency  
 F—farad (capacitance unit); fuse  
 fax—facsimile  
 FCC—Federal Communications Commission  
 FD—Field Day  
 FEMA—Federal Emergency Management Agency  
 FET—field-effect transistor  
 FFT—fast Fourier transform  
 FL—filter  
 FM—frequency modulation  
 FMTV—frequency-modulated television  
 FSK—frequency-shift keying  
 FSTV—fast-scan (real-time) television  
 ft—foot (unit of length)

**G**

g—gram (unit of mass)  
 G—giga (prefix for  $10^9$ ); conductance  
 GaAs—gallium arsenide  
 GB—gigabytes  
 GDO—grid- or gate-dip oscillator  
 GHz—gigahertz ( $10^9$  Hz)  
 GND—ground

**H**

h—hecto (prefix for  $10^2$ )  
 H—henry (unit of inductance)  
 HF—high frequency (3-30 MHz)  
 HFO—high-frequency oscillator; heterodyne frequency oscillator  
 HPF—highest probable frequency; high-pass filter  
 Hz—hertz (unit of frequency, 1 cycle/s)

**I**

I—current, indicating lamp  
 IARU—International Amateur Radio Union  
 IC—integrated circuit  
 ID—identification; inside diameter  
 IEEE—Institute of Electrical and Electronics Engineers  
 IF—intermediate frequency

IMD—intermodulation distortion  
in.—inch (unit of length)  
in./s—inch per second (unit of velocity)  
I/O—input/output  
IRC—international reply coupon  
ISB—independent sideband  
ITF—Interference Task Force  
ITU—International Telecommunication Union  
ITU-T—ITU Telecommunication Standardization Bureau

## J-K

*j*—operator for complex notation, as for reactive component of an impedance (+*j* inductive; −*j* capacitive)  
J—joule ( $\text{kg m}^2/\text{s}^2$ ) (energy or work unit); jack  
JFET—junction field-effect transistor  
k—kilo (prefix for  $10^3$ ); Boltzmann's constant ( $1.38 \times 10^{-23}$  J/K)  
K—kelvin (used without degree symbol) absolute temperature scale; relay  
kB—kilobytes  
kBd—1000 bauds  
kbit—1024 bits  
kbit/s—1024 bits per second  
kbyte—1024 bytes  
kg—kilogram  
kHz—kilohertz  
km—kilometer  
kV—kilovolt  
kW—kilowatt  
k $\Omega$ —kilohm

## L

l—liter (liquid volume)  
L—lambert; inductor  
lb—pound (force unit)  
LC—inductance-capacitance  
LCD—liquid crystal display  
LED—light-emitting diode  
LF—low frequency (30-300 kHz)  
LHC—left-hand circular (polarization)  
LO—local oscillator; Leadership Official  
LP—log periodic  
LS—loudspeaker  
lsb—least significant bit  
LSB—lower sideband  
LSI—large-scale integration  
LUF—lowest usable frequency

## M

m—meter (length); milli (prefix for  $10^{-3}$ )  
M—mega (prefix for  $10^6$ ); meter (instrument)  
mA—milliampere  
mAh—milliampere hour  
MB—megabytes  
MCP—multimode communications processor  
MDS—Multipoint Distribution Service; minimum discernible (or detectable) signal  
MF—medium frequency (300-3000 kHz)  
mH—millihenry  
MHz—megahertz

mi—mile, statute (unit of length)  
mi/h (MPH)—mile per hour  
mi/s—mile per second  
mic—microphone  
Mil—one-thousandth of an inch  
min—minute (time)  
MIX—mixer  
mm—millimeter  
MOD—modulator  
modem—modulator/demodulator  
MOS—metal-oxide semiconductor  
MOSFET—metal-oxide semiconductor field-effect transistor  
MS—meteor scatter  
ms—millisecond  
m/s—meters per second  
msb—most-significant bit  
MSI—medium-scale integration  
MSK—minimum-shift keying  
MSO—message storage operation  
MUF—maximum usable frequency  
mV—millivolt  
mW—milliwatt  
M $\Omega$ —megohm

## N

n—nano (prefix for  $10^{-9}$ ); number of turns (inductors)  
NBFM—narrow-band frequency modulation  
NC—no connection; normally closed  
NCS—net-control station; National Communications System  
nF—nanofarad  
NF—noise figure  
nH—nanohenry  
NiCd—nickel cadmium  
NM—Net Manager  
NMOS—N-channel metal-oxide silicon  
NO—normally open  
NPN—negative-positive-negative (transistor)  
NPRM—Notice of Proposed Rule Making (FCC)  
ns—nanosecond  
NTIA—National Telecommunications and Information Administration  
NTS—National Traffic System

## O

OBS—Official Bulletin Station  
OD—outside diameter  
OES—Official Emergency Station  
OO—Official Observer  
op amp—operational amplifier  
ORS—Official Relay Station  
OSC—oscillator  
OSCAR—Orbiting Satellite Carrying Amateur Radio  
OTC—Old Timer's Club  
oz—ounce ( $1/16$  pound)

## P

p—pico (prefix for  $10^{-12}$ )  
P—power; plug  
PA—power amplifier  
PACTOR—digital mode combining aspects of packet and AMTOR  
PAM—pulse-amplitude modulation  
PBS—packet bulletin-board system

PC—printed circuit  
PD—power dissipation  
PEP—peak envelope power  
PEV—peak envelope voltage  
pF—picofarad  
pH—picohenry  
PIC—Public Information Coordinator  
PIN—positive-intrinsic-negative (semiconductor)  
PIO—Public Information Officer  
PIV—peak inverse voltage  
PLC—Power Line Carrier  
PLL—phase-locked loop  
PM—phase modulation  
PMOS—P-channel (metal-oxide semiconductor)  
PNP—positive negative positive (transistor)  
pot—potentiometer  
P-P—peak to peak  
ppd—postpaid  
PROM—programmable read-only memory  
PSAC—Public Service Advisory Committee  
PSHR—Public Service Honor Roll  
PTO—permeability-tuned oscillator  
PTT—push to talk

## Q-R

Q—figure of merit (tuned circuit); transistor  
QRP—low power (less than 5-W output)  
R—resistor  
RACES—Radio Amateur Civil Emergency Service  
RAM—random-access memory  
RC—resistance-capacitance  
R/C—radio control  
RCC—Rag Chewer's Club  
RDF—radio direction finding  
RF—radio frequency  
RFC—radio-frequency choke  
RFI—radio-frequency interference  
RHC—right-hand circular (polarization)  
RIT—receiver incremental tuning  
RLC—resistance-inductance-capacitance  
RM—rule making (number assigned to petition)  
r/min (RPM)—revolutions per minute  
rms—root mean square  
ROM—read-only memory  
r/s—revolutions per second  
RS—Radio Sputnik (Russian ham satellite)  
RST—readability-strength-tone (CW signal report)  
RTTY—radioteletype  
RX—receiver, receiving

## S

s—second (time)  
S—siemens (unit of conductance); switch  
SASE—self-addressed stamped envelope  
SCF—switched capacitor filter  
SCR—silicon controlled rectifier  
SEC—Section Emergency Coordinator

SET—Simulated Emergency Test  
 SGL—State Government Liaison  
 SHF—super-high frequency (3-30 GHz)  
 SM—Section Manager; silver mica (capacitor)  
 S/N—signal-to-noise ratio  
 SPDT—single-pole double-throw (switch)  
 SPST—single-pole single-throw (switch)  
 SS—ARRL Sweepstakes; spread spectrum  
 SSB—single sideband  
 SSC—Special Service Club  
 SSI—small-scale integration  
 SSTV—slow-scan television  
 STM—Section Traffic Manager  
 SX—simplex  
 sync—synchronous, synchronizing  
 SWL—shortwave listener  
 SWR—standing-wave ratio

**T**  
 T—tera (prefix for  $10^{12}$ ); transformer  
 TA—ARRL Technical Advisor  
 TC—Technical Coordinator  
 TCC—Transcontinental Corps (NTS)  
 TCP/IP—Transmission Control Protocol/Internet Protocol

tfc—traffic  
 TNC—terminal node controller (packet radio)  
 TR—transmit/receive  
 TS—Technical Specialist  
 TTL—transistor-transistor logic  
 TTY—teletypewriter  
 TU—terminal unit  
 TV—television  
 TVI—television interference  
 TX—transmitter, transmitting

**U**  
 U—integrated circuit  
 UHF—ultra-high frequency (300 MHz to 3 GHz)  
 USB—upper sideband  
 UTC—Coordinated Universal Time (also abbreviated Z)  
 UV—ultraviolet

**V**  
 V—volt; vacuum tube  
 VCO—voltage-controlled oscillator  
 VCR—video cassette recorder  
 VDT—video-display terminal  
 VE—Volunteer Examiner

VEC—Volunteer Examiner Coordinator  
 VFO—variable-frequency oscillator  
 VHF—very-high frequency (30-300 MHz)  
 VLF—very-low frequency (3-30 kHz)  
 VLSI—very-large-scale integration  
 VMOS—V-topology metal-oxide-semiconductor  
 VOM—volt-ohmmeter  
 VOX—voice-operated switch  
 VR—voltage regulator  
 VSWR—voltage standing-wave ratio  
 VTVM—vacuum-tube voltmeter  
 VUCC—VHF/UHF Century Club

# Construction Techniques

Home construction of electronics projects and kits can be a fun part of Amateur Radio. A recent ARRL survey shows that more than half of active hams build electronic projects. There are many kit vendors with products ranging from simple introductory projects all the way to complete transceivers. Becoming familiar with building practices will help you repair and install commercial equipment as well.

Even experienced constructors will find valuable tips in this chapter. It discusses tools and their uses, electronic construction techniques, tells how to turn a schematic into a working circuit and then summarizes common mechanical construction practices. This chapter is maintained by Joe Eisenberg, KØNEB based on material originally written and compiled by Ed Hare, W1RF1, and Jim Duffey, KK6MC. Dale Grover, KD8KYZ, maintains the comprehensive introduction to the use of PCB design and layout software.

## 23.1 Electronic Shop Safety

Building, repairing and modifying equipment in home workshops is a longstanding ham radio tradition. In fact, in the early days, building your own equipment was the only option available. While times and interests change, home construction of radio equipment and related accessories remains popular and enjoyable. Building your own gear need not be hazardous if you become familiar with the hazards, learn how to perform the necessary functions and follow some basic safe practices including the ones listed below and in the section on soldering. Let’s start with our own abilities:

*Consider your state of mind.* Working on projects or troubleshooting (especially where high voltage is present) requires concentration. Don’t work when you’re tired or distracted. Be realistic about your ability to focus on the job at hand. Put another way, if we aren’t able to be highly alert, we should put off doing hazardous work until we are able to focus on the hazards.

*Think! Pay attention to what you are doing.* No list of safety rules can cover all possibilities. Safety is always your responsibility. You must think about what you are doing, how it relates to the tools and the specific situation at hand. When working with tools, avoid creating situations in which you can be injured or the project damaged if things don’t go “just right.”

*Take your time.* If you hurry, not only will you make more mistakes and possibly spoil the appearance of your new equipment, you won’t have time to think things through. Always plan ahead. Do not work with shop tools if you can’t concentrate on what you are doing — it’s not a race! Working when you are tired can also lead to problems, such as misidentification of parts or making poor or erroneous connections. Listening to the regular time notices on broadcast radio while you work will prompt you to take plenty of breaks so you do not work when you are too tired.

*Protect yourself.* Use of drills, saws, grinders and other wood- or metal-working equipment can release small fragments that could cause serious eye damage. Always wear safety glasses or goggles when doing work that might present a flying object hazard and that includes soldering, where small bits of molten solder can be flung a surprising distance. If you use hammers, wire-cutters, chisels and other hand tools, you will also need the protection that safety eyewear offers. Dress appropriately — loose clothing (or even hair) can be caught in exposed rotating equipment such as drill presses.

*Don’t work alone.* Have someone nearby who can help if you get into trouble when working with dangerous equipment, chemicals or voltages.

*Know what to do in an emergency.* Despite your best efforts to be careful, accidents may still occur from time to time. Ensure that everyone in your household knows basic first aid procedures and understands how to summon help in an emergency. They should also know where to find and how to safely shut down electrical power in your shack and shop. Get medical help when necessary. Every workshop should contain a good first-aid kit. Keep an eye-wash kit near any dangerous chemicals or power tools that can create chips or splinters. If you become injured, apply first aid and then seek medical help if you are not sure that you are okay. Even a small burn or scratch on your eye can develop into a serious problem if not treated promptly.

What about the equipment and tools involved in shop work? Here are some basic safety considerations that apply to them, as well:

*Read instructions and manuals carefully...and follow them.* The manufacturers of tools are the most knowledgeable about how to use their products safely. Tap their knowledge by carefully reading all operating instructions and warnings. Avoiding injuries with power tools

**Properties and Hazards of Chemicals often Used in the Shack or Workshop**

<i>Generic Chemical Name</i>	<i>Purpose or Use</i>	<i>Hazards</i>	<i>Ways to Minimize Risks</i>
Lead-tin solder	Bonding electrical components	Lead exposure (mostly from hand contact) Flux exposure (inhalation)	Always wash hands after soldering or touching solder. Use good ventilation.
Isopropyl alcohol	Flux remover	Dermatitis (skin rash)  Vapor inhalation  Fire hazard	Wear molded gloves suitable for solvents. Use good ventilation and avoid aerosol generation. Use good ventilation, limit use to small amounts, keep ignition sources away, dispose of rags only in tightly sealed metal cans.
Freons	Circuit cooling and general solvent	Vapor inhalation Dermatitis	Use adequate ventilation. Wear molded gloves suitable for solvents.
Phenols and methylene chloride	Enameled wire/paint stripper	Strong skin corrosive	Avoid skin contact; wear suitable molded gloves; use adequate ventilation.
Beryllium oxide	Ceramic insulator found in some power transistors and vacuum tubes that conducts heat well	Toxic when in fine dust form and inhaled	Avoid grinding, sawing or reducing to dust form.
Beryllium metal	Lightweight metal, alloyed with copper	Same as beryllium oxide	Avoid grinding, sawing, welding or reducing to dust. Contact supplier for special procedures.
Various paints	Finishing	Exposures to solvents  Exposures to sensitizers (especially urethane paint) Exposure to toxic metals (lead, cadmium, chrome, and so on) in pigments Fire hazard (especially when spray painting)	Adequate ventilation; use respirator when spraying. Adequate ventilation and use respirator. Adequate ventilation and use respirator.  Adequate ventilation; control of residues; eliminate ignition sources.
Ferric chloride	Printed circuit board etchant	Skin and eye contact	Use suitable containers; wear splash goggles and molded gloves suitable for acids.
Ammonium persulphate and mercuric chloride	Printed circuit board etchants	Skin and eye contact	Use suitable containers; wear splash goggles and molded gloves suitable for acids.
Epoxy resins	General purpose cement or paint	Dermatitis and possible sensitizer	Avoid skin contact. Mix only amount needed.
Sulfuric acid	Electrolyte in lead-acid batteries	Strong corrosive when on skin or eyes. Will release hydrogen when charging (fire, explosion hazard).	Always wear splash goggles and molded plastic gloves (PVC) when handling. Keep ignition sources away from battery when charging. Use adequate ventilation.

requires safe tool design as well as proper operation by the user. Keep the instructions in a place where you can refer to them in the future.

*Respect safety features of the equipment you work on and use.* Never disable any safety feature of any tool. If you do, sooner or later you or someone else will make the mistake

the safety feature was designed to prevent.

*Keep your shop or work area neat and organized.* A messy shop is a dangerous shop. A knife left laying in a drawer can cut someone looking for another tool; a hammer left on top of a shelf can fall down at the worst possible moment; a sharp tool left on a chair can be a dangerous surprise for the weary constructor

who sits down.

*Keep your tools in good condition.* Always take care of your investment. Store tools in a way to prevent damage or use by untrained persons (young children, for example). Keep the cutting edges of saws, chisels and drill bits sharp. Protect metal surfaces from corrosion. Frequently inspect the cords and plugs

of electrical equipment and make any necessary repairs. If you find that your power cord is becoming frayed, repair it right away. One solution is to buy a replacement cord with a molded connector already attached.

*Make sure your shop is well ventilated.* Paint, solvents, cleaners or other chemicals can create dangerous fumes. If you feel dizzy, get into fresh air immediately, and seek medical help if you do not recover quickly.

*Respect power tools.* Power tools are not forgiving. A drill can go through your hand a lot easier than metal. A power saw can remove a finger with ease. Keep away from the business end of power tools. Tuck in your shirt, roll up your sleeves and remove your tie before using any power tool. If you have long hair, tie it back so it can't become entangled in power equipment.

### 23.1.1 Chemicals

Chemicals such as cleaners, adhesives, construction materials, and coolants are used every day by amateurs without ill effects. Take the opportunity to become knowledgeable of the hazards associated with these materials and treat them with respect. **Table 23.1** summarizes the uses and hazards of chemicals and other materials used in the ham shack. It includes preventive measures that can minimize risk. For advanced information, the Centers for Disease Prevention and Control maintains an extensive database at [www.cdc.gov/niosh/topics/chemical-safety](http://www.cdc.gov/niosh/topics/chemical-safety). Meridian Engineering maintains a collection of materials safety information at [www.meridianeng.com/datasheets.html](http://www.meridianeng.com/datasheets.html).

## 23.2 Tools and Their Use

All electronic construction makes use of tools, from mechanical tools for chassis fabrication to the soldering tools used for circuit assembly. A good understanding of tools and their uses will enable you to perform most construction tasks.

While sophisticated and expensive tools often work better or more quickly than simple hand tools, with proper use, simple hand tools can turn out a fine piece of equipment. **Table 23.2** lists tools indispensable for construction of electronic equipment. These tools can be used to perform nearly any construction task. Add tools to your collection from time to time, as finances permit.

### 23.2.1 Sources of Tools

Electronic-supply houses, mail-order/web stores and most hardware stores carry the tools required to build or service Amateur

## Poison Control

If you think you have a chemical emergency, call your local poison control center immediately. Dial 1-800-222-1222 or use the map at [www.poison.org/otherPC](http://www.poison.org/otherPC) to find the center in your area or dial 911.

When in doubt, contact the manufacturer or distributor of the material for safety information or use an Internet search engine by entering the material name and "safety" into the search window.

Here are a few key suggestions for safely storing, handling, and using chemicals:

*Read the information that accompanies the chemical* and follow the manufacturer's recommended safety practices. If you would like more information than is printed on the label, ask for a material safety data sheet (MSDS). Manufacturers of brand-name chemical products usually post an MSDS on their product websites.

*Store chemicals properly*, away from sunlight and sources of heat. Secure their containers to prevent spills and so that children and untrained persons will not gain access. Always keep containers labeled so there is no confusion about the contents. It is best to use the container in which the chemical was purchased. If you transfer solvents to other containers, such as wash bottles, label the new container with exactly what it contains.

*Handle chemicals carefully* to avoid spills.

Clean up any spills or leaks promptly but don't overexpose yourself in the process. Never dispose of chemicals in household sinks or drains. Instead, contact your local waste plant operator, transfer station or fire department to determine the proper disposal procedures for your area. Many communities have household hazardous waste collection programs. Of course, the best solution is to only buy the amount of chemical that you will need, and use it all if possible. Always label any waste chemicals, especially if they are no longer in their original containers. Oil-filled capacitors and transformers were once commonly filled with oil containing PCBs. Never dispose of any such items that may contain PCBs in landfills – contact your county or city recycling office or local electric utility for information on proper disposal.

*Always use recommended personal protective equipment* (such as gloves, face shield, splash goggles and aprons). If corrosives (acids or caustics) are splashed on you *immediately* rinse with cold water for a minimum of 15 minutes to flush the skin thoroughly. If splashed in the eyes, direct a gentle stream of cold water into the eyes for at least 15 minutes. Gently lift the eyelids so trapped liquids can be flushed completely. Start flushing before removing contaminated clothing. Seek professional medical assistance. If using hazardous chemicals, it is unwise to work alone since people splashed with chemicals need the calm influence of another person.

*Food and chemicals don't mix.* Keep food, drinks and cigarettes *away* from areas where chemicals are used and don't bring chemicals to places where you eat.

Radio equipment. Bargains are available at ham flea markets or local neighborhood sales, but beware! Some flea-market bargains are really shoddy and won't work very well or last very long. Some used tools are offered for sale because the owner is not happy with their performance.

There is no substitute for quality! A high-quality tool, while a bit more expensive, will last a lifetime. Poor quality tools don't last long and often do a poor job even when brand new. You don't need to buy machinist-grade tools, but stay away from cheap tools; they are not the bargains they might appear to be.

### CARE OF TOOLS

The proper care of tools is more than a matter of pride. Tools that have not been cared for properly will not last long or work well. Dull or broken tools can be safety hazards. Tools that are in good condition do the work

for you; tools that are misused or dull are difficult to use.

Store tools in a dry place. Tools do not fit in with most living room decors, so they are often relegated to the basement or garage. Unfortunately, many basements or garages are not good places to store tools; dampness and dust are not good for tools. If your tools are stored in a damp place, use a dehumidifier. Sometimes you can minimize rust by keeping your tools lightly oiled, but this is a second-best solution. If you oil your tools, they may not rust, but you will end up covered in oil every time you use them. Wax or silicone spray is a better alternative.

Store tools neatly. A messy toolbox, with tools strewn about haphazardly, can be more than an inconvenience. You may waste a lot of time looking for the right tool and sharp edges can be dulled or nicked by tools banging into each other in the bottom of the box.

Right-angle, slotted and Phillips	Hammer, ball-peen, 12-oz head	Contact cleaner, liquid or spray can
	Hammer, tack	RTV sealant or equivalent
<i>Pliers, Sockets and Wrenches</i>	Bench vise, 4-in jaws or larger	Electrical tape, vinyl plastic
Long-nose pliers, 6- and 4-in	Center punch	Sandpaper, assorted
Diagonal cutters, 6- and 4-in	Plastic alignment tools	Emery cloth
Channel-lock pliers, 6-in	Mirror, inspection	Steel wool, assorted
Slip-joint pliers	Flashlight, penlight and standard	Cleaning pad, Scotchbrite or equivalent
Locking pliers (Vise Grip or equivalent)	Magnifying glass	Cleaners and degreasers
Socket nut-driver set, 1/16- to 1/2-in	Ruler or tape measure	Contact lubricant
Set of socket wrenches for hex nuts	Dental pick	Sheet aluminum, solid and perforated, 16- or 18-gauge, for brackets and shielding.
Allen (hex) wrench set	Calipers	Aluminum angle stock, 1/2 x 1/2-in and 1/4-in diameter round brass or aluminum rod (for shaft extensions)
Wrench set	Brush, wire	Machine screws: Round-head and flat head, with nuts and lockwashers to fit. Most useful sizes: 4-40, 6-32 and 8-32, in lengths from 1/4-in to 1 1/2 in (Nickel-plated steel is satisfactory except in strong RF fields, where brass should be used.)
Adjustable wrenches, 6- and 10-in	Brush, soft	Bakelite, Lucite, polystyrene and copper-clad PC-board scraps.
Tweezers, regular and reverse-action	Small paintbrush	Soldering lugs, panel bearings, rubber grommets, terminal-lug wiring strips, varnished-cambrix insulating tubing, heat-shrinkable tubing
Retrieval tool/parts holder, flexible claw	IC-puller tool	Shielded and unshielded wire
Retrieval tool, magnetic		Tinned bare wire, #22, #14 and #12
	<i>Hand-Powered Tools</i>	Enameled wire, #20 through #30
<i>Cutting and Grinding Tools</i>	Hand drill, 1/4-in chuck or larger	
File set consisting of flat, round, half-round, and triangular. Large and miniature types recommended	High-speed drill bits, #60 through 3/8-in diameter	
Burnishing tool		
Wire strippers	<i>Power Tools</i>	
Wire crimper	Motor-driven emery wheel for grinding	
Hemostat, straight	Electric drill, hand-held	
Scissors	Drill press	
Tin shears, 10-in	Miniature electric motor tool (Dremel or equivalent) and accessory drill press	
Hacksaw and blades		
Hand nibbling tool (for chassis-hole cutting)	<i>Soldering Tools and Supplies</i>	
	Soldering station, adjustable temp, assorted tips	
	Soldering iron, 100 W or higher, 3/8-in tip	

As the old adage says, every tool should have a place, and every tool should be in its place. If you must search the workbench, garage, attic and car to find the right screwdriver, you'll spend more time looking for tools than building projects.

### SHARPENING

Many cutting tools can be sharpened. Send a tool that has been seriously dulled to a professional sharpening service. These services can sharpen saw blades, some files, drill bits and most cutting blades. Touch up the edge of cutting tools with a whetstone to extend the time between sharpening.

Sharpen drill bits frequently to minimize the amount of material that must be removed each time. Frequent sharpening also makes it easier to maintain the critical surface angles required for best cutting with least wear. Most

inexpensive drill-bit sharpeners available for shop use do a poor job, either from the poor quality of the sharpening tool or inexperience of the operator. Also, drills should be sharpened at different angles for different applications. Commercial sharpening services do a much better job.

### INTENDED PURPOSE

Don't use tools for anything other than their intended purpose! If you use a pair of wire cutters to cut sheet metal, pliers as a vise or a screwdriver as a pry bar, you ruin a good tool and sometimes the work piece, as well. Although an experienced constructor can improvise with tools, most take pride in not abusing them. Having a wide variety of good tools at your disposal minimizes the problem of using the wrong tool for the job.

## 23.2.2 Tool Descriptions and Uses

Specific applications for tools are discussed throughout this chapter. Hand tools are used for so many different applications that they are discussed first, followed by some tips for proper use of power tools.

### SCREWDRIVERS AND NUTDRIVERS

For construction or repair, you need to have an assortment of screwdrivers. Each blade size is designed to fit a specific range of screw head sizes. Using the wrong size blade usually damages the blade, the screw head or both. You may also need stubby sizes to fit into tight spaces. Right-angle screwdrivers are inexpensive and can get into tight spaces that can't otherwise be reached.

Electric screwdrivers are relatively inexpensive and very useful, particularly for re-

petitive tasks. If you have a lot of screws to fasten, they can save a lot of time and effort. They come with a wide assortment of screwdriver and nutdriver bits. An electric drill can also function as an electric screwdriver, although it may be heavy and over-powered for many applications.

Keep screwdriver blades in good condition. If a blade becomes broken or worn out, replace the screwdriver. A screwdriver only costs a few dollars; do not use one that is not in perfect condition. Save old screwdrivers to use as pry bars and levers, but use only good ones on screws. Filing a worn blade seldom gives good results.

Nutdrivers, the complement to screwdrivers, are often much easier to use than a wrench, particularly for nuts smaller than 3/8 inch. They are also less damaging to the nut than any type of pliers, with a better grip on the nut. Nutdrivers also minimize the chances of damage to front panels when tightening the nuts on control shafts. A set of interchangeable nutdrivers with a shared handle is a very handy addition to the toolbox.

## PLIERS AND LOCKING-GRIP PLIERS

Pliers and locking-grip pliers are used to hold or bend things. They are not wrenches! If pliers are used to remove a nut or bolt, the nut or the pliers is usually damaged. To remove a nut, use a wrench or nutdriver. There is one exception to this rule of thumb: To remove a nut that is stripped too badly for a wrench, use a pair of pliers, locking-grip pliers, or a diagonal cutter to bite into the nut and start it turning. Reserve an old tool or one dedicated to just this purpose as it is not good for the tool.

Pliers are not intended for heavy-duty applications. Use a metal brake to bend heavy metal; use a vise to hold a heavy component. If the pliers' jaws or teeth become worn, replace the tool.

There are many different kinds of fine pliers, usually called "needle-nose" pliers or something similar, that are particularly useful in electronics work. These are intended for light jobs, such as bending or holding wires or small work pieces. Two or three of these tools with different sizes of jaws will suffice for most jobs.

## WIRE CUTTERS AND STRIPPERS

Wire cutters are primarily used to cut wires or component leads. The choice of blade style depends on the application. Diagonal blades or "dikes" are most often used to cut wire. Some delicate components can be damaged by cutting their leads with dikes because of the abrupt shock of the cut. Scissors or shears designed to cut wire should be used instead.

Specialized wire cutters are available to trim wires leads on circuit boards. These cut-

ters are often called "flush cutters". Their cutting end is *not* designed to cut thicker wires. Use them *only* to clip smaller gauge wires, such as that on components used in circuits.

Wire strippers are available in manual and automatic styles. The manual strippers have a series of holes designed to remove insulation from a specific gauge of wire. Using the holes that are too big or too small will create nicks in the wire, which usually leads to the wire breaking at the nick. Automatic strippers grab and hold the wire for a consistent strip — some even judge the wire thickness automatically. If you strip a lot of wires, an automatic stripper may be worth the extra expense.

Wire strippers are handy, but with a little practice you can usually strip wires using a diagonal cutter or a knife. This is not the only use for a knife, so keep an assortment handy. Do not use wire cutters or strippers on anything other than wire! If you use a cutter to trim a protruding screw head or cut a hardened-steel spring, you will usually damage the blades.

## FILES

Files are used for a wide range of tasks. In addition to enlarging holes and slots, they are used to remove burrs, shape metal, wood or plastic and clean some surfaces in preparation for soldering. Files are especially prone to damage from rust and moisture. Keep them in a dry place. The cutting edge of the blades can also become clogged with the material you are removing. Use file brushes (also called file cards) to keep files clean. Most files cannot be sharpened easily, so when the teeth become worn, the file must be replaced.

## DRILL BITS

Drill bits are made from carbon steel, high-speed steel or carbide. Carbon steel is more common and is usually supplied unless a specific request is made for high-speed bits. Carbon steel drill bits cost less than high-speed or carbide types; they are sufficient for most equipment construction work. Carbide drill bits last much longer under heavy use. One disadvantage of carbide bits is that they are brittle and break easily, especially if you are using a hand-held power drill. When drilling abrasive material, such as fiberglass, the carbide bits last much longer than the steel bits.

Twist drills are available in a number of sizes listed in **Table 23.3**. Those listed in bold type are the most commonly used in construction of amateur equipment. You may not use all of the drills in a standard set, but it is nice to have a complete set on hand. You should also buy several spares of the more common sizes. Although Table 23.3 lists drills down to #54, the series extends to number #80. While the smaller sizes cannot usually be

found in hardware stores or home improvement stores, they are commonly available through industrial tool suppliers and through various sources on the Internet.

A "step drill" consists of multiple drill diameters stacked as one bit, looking somewhat like a Christmas tree. These bits are very useful for drilling metal case material used in radio projects as the fluted edge of

the bit in between sizes removes most if not all burrs from the hole you are drilling. Use them carefully and slowly to take advantage of their ability to remove burrs. A step drill also has the advantage of being able to drill a number of different standard size holes without having to change the bit.

### SPECIALIZED TOOLS

Most constructors know how to use common tools, such as screwdrivers, wrenches and hammers. Although specialized tools usually do a job that can be done with other tools, once the specialty tool is used you will wonder how you ever did the job without it! Let's discuss other tools that are not so common.

A hand nibbling tool is shown in **Figure 23.1A**. Use this tool to remove small "nibbles" of metal. It is easy to use; position the tool where you want to remove metal and squeeze the handle. The tool takes a small bite out of the metal. When you use a nibbler, be careful that you don't remove too much metal, clip the edge of a component mounted to the sheet metal or grab a wire that is routed near the edge of a chassis. Fixing a broken wire is easy, but something to avoid if possible. It is easy to remove metal but nearly impossible to put it back. Do it right the first time!

### Deburring Tool

A deburring tool is just the thing to remove the sharp edges left on a hole after drilling or punching operations. See **Figure 23.1B**. Position the tool over the hole and rotate it around the edge of the hole to remove burrs or rough edges. As an alternative, select a drill bit that is somewhat larger than the hole, position it over the hole, and spin it lightly to remove the burr. Be sure to deburr both sides of the hole.

### Socket or Chassis Punches

Greenlee is the most widely known of the socket-punch manufacturers. Most socket punches are round, but they do come in other shapes. To use one, drill a pilot hole large enough to clear the bolt that runs through the punch. Then, mount the punch as shown in **Figure 23.1C**, with the cutter on one side of the sheet metal and the socket on the other. Tighten the nut with a wrench until the cutter cuts all the way through the sheet metal. These punches are often sold in sets at a significant discount to the same punches purchased separately. Hand-punches that operate by squeezing will also cut small holes by hand in light-gauge sheet metal, printed-circuit boards, and plastic.

### Crimping Tools

The use of crimped connectors is common in the electronics industry. In many com-

mercial and aerospace applications, soldered joints are no longer used. Hams have been reluctant to adapt crimped connections, largely due to mistrust of contacts that are not soldered, the use of cheap crimp connectors on consumer electronics, and the high cost of quality crimping tools or "crimpers." If high quality connectors and tools are used, the crimped connector will be as reliable a connection as a soldered one. The crimped

connection is easier to make than a soldered one in most cases.

Crimped coaxial connectors are the most common crimped connector. MIL-spec or equivalent crimp connectors are available for the UHF, BNC, F and N-series MIL-spec connectors. Power connectors, such as the Anderson PowerPoles and Molex connectors are probably the second most commonly used crimped connections.

When purchasing a crimper, look for a ratcheting model with dies that are intended for the connectors you will be using. The common pliers-type crimper designed for household electrical terminals will have trouble crimping power connectors and is unsuitable for coaxial connectors. A good ratcheting crimper can be obtained for \$50 to \$100 with the necessary interchangeable dies. Large ratcheting crimpers suitable for the larger coaxial connectors can cost several hundred dollars. A good crimper and set of dies is an excellent investment for a club or group of like-minded hams.

Compression tools are now the most common method of installing Type F connectors. (See the **Component Data and References** chapter.) BNC, TNC, and SMA connectors now can be installed using compression connectors and tools, as well. Quad-shielded RG-6 is the most common cable used for this purpose and a compression tool makes the job very easy. A compression crimp tool works differently as it presses an internal sleeve into the body of the connector to make contact with the shield. Most compression tools are lower in cost than conventional ratcheting tools, and are available at most home improvement stores. You will need to purchase compression connectors designed to work with the tool and cable type you selected. Installation instructions are usually provided on the tool's package and with packages of connectors.

### Useful Shop Materials

Small stocks of various materials are used when constructing electronics equipment. Most of these are available from hardware or radio supply stores. A representative list is shown at the end of Table 23.2.

Small parts, such as machine screws, nuts, washers and soldering lugs can be economically purchased in large quantities (it doesn't pay to buy more than a lifetime supply). For items you don't use often, many radio supply stores or hardware stores sell small quantities and assortments. Stainless steel hardware can be kept on hand for outdoor use.

### Tuning and Alignment Tools

It's helpful to have an assortment of special tools for adjusting variable capacitors, inductors, and potentiometers. See the section Tuning and Alignment later in this chapter.

**Figure 23.1** — At A, a nibbling tool is used to remove small sections of sheet metal. At B, a deburring tool is used to remove the burrs left after drilling a hole. At C, a socket punch is used to punch a clean, round hole in sheet metal.

# 23.3 Soldering Tools and Techniques

## 23.3.1 Soldering Tools

A soldering tool — we'll use the general term "iron" unless discussing a specific type of tool — must be hot enough to do the job and lightweight enough for agility and comfort. An assortment of soldering irons will help you do a wide variety of soldering tasks correctly. The powerful soldering tool you need for assembling wire antennas is too large for PC board work, for example, while a small fine-point tool works well for smaller jobs. The key is to be able to deliver the right amount of heat to do the job: Too much can damage the workpiece and too little can result in poor connections.

If you buy an iron for use on circuits that contain static-sensitive components, get one that has a grounded tip and use it on a static-dissipating workbench mat. Otherwise, you risk damage from static discharge. AC leakage current can also damage components. These irons are usually specified as having a grounded tip and will have a three-prong ac power plug. It is usually not necessary to have a grounded tip on a high-power iron or soldering gun as those are not normally used on sensitive components.

For PCB soldering, the ideal temperature is around 600 °F when using either 60/40 or 63/37 leaded solder and about 700 °F for lead-free solder. For use with solder wick when desoldering, a higher temperature setting may be necessary, depending on the size of connection being desoldered. These temperatures enable rapid melting of solder and heating of the component leads as well as the PCB pads or terminals being soldered. Using excessive heat or applying heat for too long can damage PCB pads, terminals, or the components themselves. A temperature that is too low will result in cold solder joints that don't conduct properly or that fail mechanically. See the Solder and Soldering sections for more discussion.

### SOLDERING IRONS

*Soldering pencils* and *soldering stations* (see **Figure 23.2A** and **B**) are by far the most common soldering tools for PCB and small component soldering. Pencil irons come in a variety of power ratings from 20 W to 40 W. The inexpensive pencil irons provided in soldering training kits will get you started but should be replaced with a higher quality iron for regular soldering of kits and projects.

Some pencil irons are available with a variable temperature control in the handle or on a cord-mounted module. Irons with accurate control of soldering temperature are a must for the best chances of successful soldering a variety of components. Without accurate control of the temperature, the tips can overheat and corrode, wearing much faster, and they may overheat or underheat your connections.

There are also small battery-powered pencil irons which that are useful away from the workbench. Battery-powered irons generally aren't powerful enough for larger connections and take time to recharge. Pencil irons powered by a 12 V dc cigarette lighter plug are useful for working on mobile stations and keeping in a kit for emergencies.

A soldering station is the most preferable soldering tool for most kits and projects. Soldering stations have a base that houses the controls, power supply, a tip cleaner, and includes a holder to safely place the iron between uses. Some soldering stations even have a holder for a roll of solder. The temperature controls range from a simple knob to calibrated controls that can keep the

iron's temperature set within 2 °C. Some soldering stations feature programmable temperature settings, allowing the user to specify different preset heat levels and idle cool-down timing. Features to look for include temperature memories, automatic idle cool-down, and automatic quick heating after idling when the handpiece is lifted for use.

The Metcal RF-powered soldering stations heat the tip with RF for rapid heating, very accurate temperature control and ease of use. This type of soldering station is most commonly found in commercial

## Temperature and Heat Capacity

If two different tips are both at 600 °F, why is the larger one able to solder a larger connection better than the other? Temperature is a measurement of how fast the molecules in the tip are moving and that can be the same regardless of tip size. But in the larger tip there are more moving molecules that can transfer their energy to the connection so it has more *heat capacity*. (*Thermal mass* is a similar concept.) Think of temperature as voltage and heat capacity as power. Tip temperature tells you the maximum temperature of the connection. Heat capacity tells you how fast the connection will heat and how big a connection can be heated to the maximum temperature.

manufacturing and product development but is often available used or reconditioned. If you do a lot of soldering, one of these might be worth the investment.

A *soldering gun* (Figure 23.2C) is used when a smaller soldering iron cannot supply the amount of heat needed for good solder flow. Typical power ratings are 100 to 250 W. Typical jobs for a gun include antenna wires, larger coax connectors, and heavy point-to-point wiring such as for vacuum-tube equipment. Soldering guns consist of an ac transformer with a low-voltage, high-current secondary formed by the copper wire tip. The high current heats the tip. The tips attach to terminals on the front of the soldering gun. Many soldering guns have a high and low power setting controlled by how far the trigger is pulled during operation. Soldering guns usually do not provide heat when not triggered.

Larger ac-powered soldering irons are also available with power ratings of 250 W or more. These irons are most often used for soldering very heavy connections or tubing and sheet metal. This type of iron is used where thorough heating is needed to allow solder to flow fully into the connection. If you plan on soldering a lot of PL-259 coax connectors, a large iron heats the connector body quickly to make a good connection without overheating the cable dielectric. Popular manufacturers include American Beauty, Weller, Hexacon, and others.

### TIPS FOR SOLDERING IRONS

Pencil irons and soldering stations are used with a variety of tip shapes and sizes. Several common types are shown in Figure 23.3. A *conical* tip comes to a small round point, the *chisel* tip or *mini-chisel* tip is also useful. Low-wattage pencil irons generally

have replaceable tips with several sizes and geometries available. For printed circuit board work, a good rule of thumb is to use a tip with a point of the same size as the component leads to be soldered. High-power irons of 100 W and larger usually have a non-interchangeable chisel tip.

Specialized tips are available for use with surface mount technology (SMT) components. These tips can take on the shape of the component being soldered, such as a square tip for working with square IC packages or a special tip for working with SMT resistors and capacitors. When working on SMT assemblies, a hot air gun or reflow oven is another common technique discussed in the section on Surface Mount Technology.

### FLAME-POWERED SOLDERING

When soldering outdoors and working with larger connections, a more powerful iron is needed. In addition, running a long extension cord outdoors can be a problem. Making antennas from copper tubing requires a lot of heat to allow the solder to flow completely into and through the connection. Soldered connections that are exposed to the weather should use a silver-bearing, high-temperature solder. All of these require a large amount of heat that is best supplied by combustion instead of resistance heating.

In this case, a *butane iron* or *butane torch* is ideal for work outdoors, especially for antenna wire or coaxial connectors. Wind will cool a conventional gun or pencil, but a butane iron can become hotter if the moving air enhances combustion. Butane irons use the same fuel canisters as refillable cigarette lighters. Fueling is quick and can supply heat for a useful amount of time. Most butane irons use a flint-type striker to ignite the fuel once the valve is opened. Butane irons generally come with a variety of different tips for soldering and cutting.

For really large jobs, a *propane torch* may be required. Propane torches can be found in most hardware stores and are most commonly used for household or commercial plumbing. A propane torch can deliver plenty of heat in a short amount of time, giving you enough time to flow the solder evenly with no gaps or irregularities in the connection. Be sure to follow the supplied directions carefully with a propane torch, including the correct amount of gas flow and the proper way to ignite the gas. A propane torch's open flame can overheat connectors, melt coaxial cable, and damage plastic components. (Some torches have a soldering style tip, but that limits the amount of heat they can deliver to the connection.) Use them with extreme caution and respect the amount of heat they can deliver.

The two types of gas most often used in larger torches include MAPP gas and propane. MAPP gas burns hotter than propane

Figure 23.3 —Typical soldering iron tips (this group is from Weller, [weller-tools.com](http://weller-tools.com)). Conical tips are shown at the upper left and chisel tips at the upper right. Larger connections require the heavier tips.

and is used with high-temperature solder. Propane or MAPP gas can be used for brazing or welding connections, depending on the type of metal involved. Information on brazing can be found at [www.thefabricator.com/thewelder/article/tubepipefabrication/6-steps-to-successful-brazing](http://www.thefabricator.com/thewelder/article/tubepipefabrication/6-steps-to-successful-brazing).

Finally, for the very large connections used in ground systems and ground rods, *thermite welding* is used. Known as “one-shots” by electrical contractors, they use an exothermic chemical reaction to melt copper wires and ground rods into a solid, welded connection that can be buried. The most common types used by amateurs are made by ERICO (“Cadweld”) and Harger (“Uni-Shot”).

### MAINTAINING SOLDERING TIPS

Keep soldering iron and gun tips in good condition by keeping them well-tinned with solder. Tinning is performed by melting solder directly onto the tip and letting it form a coating. Do not keep the tips at full temperature for long periods when not in use. Automatic cool-down is a great feature that reduces the need to tin the tip.

After moderate usage, remove the tip and clean off any scale that may have accumulated. There are “tip tinner” products available that can also be used for this function. A tip tinner often comes in a small can and is made up of a mixture of solder and flux and cleaner. Simply rolling the tip in the tinner makes it look and work like new again.

If a tip becomes oxidized during use, it can be restored to its shiny state by wiping the tip with a damp sponge or rag and then re-tinning. (Some tips are not supposed to be cleaned with water — check the manufacturer's recommendations.) A gentle scraping is also useful for stubborn cases. A copper or stainless-steel coil kitchen scrubber (do not use a scrubber that contains soap) works fine

for this. Swipe the iron through the scrubber to clean it. There are coiled brass tip cleaners available that perform at least as well as using a soldering sponge. A brass scrubber or sponge can be placed in a clean tuna can and placing it next to the solder station.

If a copper tip becomes pitted after repeated use, file it smooth and bright and then tin it immediately with solder. The solder prevents further oxidation of the tip. Most modern soldering iron tips are nickel or iron clad and should not be filed, as the cladding protects the tip from pitting.

### 23.3.2 Solder

Solders have different melting points, depending on the ratio of tin to lead. Tin melts at 450 °F and lead at 621 °F. Solder made from 63% tin and 37% lead melts at 361 °F, the lowest melting point for a tin and lead mixture. Called 63-37 (or eutectic), this type of solder also provides the most rapid solid-to-liquid transition and the best stress resistance. 63-37 solder also stays in the plastic state for the briefest time, thus making it ideal for hand soldering because it is a lot less likely to cool unevenly.

Solders made with different lead/tin ratios have a plastic state at some temperatures. If the solder is deformed while it is in the plastic state, the deformation remains when the solder freezes into the solid state. Any stress or motion applied to “plastic solder” causes a poor solder joint.

60-40 solder has the best wetting qualities. Wetting is the ability to spread rapidly, coat the surfaces to be joined, and bond materials uniformly. 60-40 solder also has a low melting point. These factors make it the most commonly used solder in electronics. However, 63-37 solder is the best-suited for manual construction techniques.

Some connections that carry high current can't be made with ordinary tin-lead solder because the heat generated by the current would melt the solder. Automotive starter brushes and transmitter tank circuits are two examples. Silver-bearing solders have higher melting points, and so prevent this problem. High-temperature silver alloys become liquid in the 1100 °F to 1200 °F range, and a silver-manganese (85-15) alloy requires almost 1800 °F.

Because silver dissolves easily in tin, tin-bearing solders can leach silver plating from components. This problem can be greatly reduced by partially saturating the tin in the solder with silver or by eliminating the tin. Commercial solders are available which incorporate these features. Tin-silver or tin-lead-silver alloys become liquid at temperatures from 430 °F for 96.5-3.5 (tin-silver), to 588 °F for 1.0-97.5-1.5 (tin-lead-silver). A 15.0-80.0-5.0 alloy of lead-indium-silver

melts at 314 °F.

Rosin-core wire-type solder is formed into a tube with a flux compound inside. The resin (usually called “rosin” in solder) in a solder is a *flux*. Flux melts at a lower temperature than solder, so it flows out onto the joint before the solder melts to coat the joint surfaces. The solder used for surface-mount soldering (discussed later) is a cream or paste and flux, if used, must be added to the joint separately.

Flux removes oxide by suspending it in solution and floating it to the top. Flux is not a cleaning agent! Always clean the surfaces to be soldered before soldering. Rubbing alcohol on a cotton swab is a good cleaning aid. Cleaning an entire board before beginning to install components is easy and prepares the surface for the best soldering. Flux is not a part of a soldered connection—it merely aids the soldering process. Don't touch the board with your fingers after cleaning.

After soldering, remove any remaining flux. Rosin flux can be removed with isopropyl or denatured alcohol. A cotton swab is a good tool for applying the alcohol and scrubbing the excess flux away. Commercial flux-removal sprays are available at most electronic-part distributors. Water-soluble fluxes are also available. Solder is now available with “no-clean” flux. This type of flux minimizes the amount of flux left on the board after soldering.

*Never* use acid flux or acid-core solder for electrical work. It should be used only for plumbing or chassis work. If used on electronics, the flux will corrode and damage the equipment. For circuit construction, only use fluxes or solder-flux combinations that are labeled for electronic soldering.

A basic tutorial on “Soldering 101” including a video demonstration is available from Sparkfun Electronics at [www.sparkfun.com/tutorials/213](http://www.sparkfun.com/tutorials/213).

### LEAD-FREE SOLDER

In 2006, the European Union Restriction of Hazardous Substances Directive (RoHS) went into effect. This directive prohibits manufacture and import of consumer electronics which incorporate lead, including the common tin-lead solder used in electronic assembly. California recently enacted a similar RoHS law. As a result of these directives there has been a move to lead-free solders in commercial use. They can contain two or more elements that are not as hazardous as lead, including tin, copper, silver, bismuth, indium, zinc, antimony and traces of other metals. Two lead-free solders commonly used for electronic use are SnAgCu alloy SAC305 and tin-copper alloy Sn100. SAC305 contains 96.5% tin, 3% silver, and 0.5% copper and melts at 217 °C. Sn100 contains 99.3% tin, 0.6% copper, as well as traces of nickel and silver and melts at 228 °C. Both of these melt-

ing points are higher than the 176 °C melting point of 60-40 and 63-37 lead-bearing solder, but conventional soldering stations will be able to reach the melting points of the new solders easily. Tin-lead solders are still available, but the move away from them by commercial manufacturers will probably lead to the day when they will be unavailable to hams who build their own gear. Be prepared.

The new RoHS solders can be used in much the same manner as conventional solders. The resulting solder joint appears somewhat duller than a conventional solder joint, and the lead-free solders tend to wick higher than the lead-tin solders. Due to the higher heat, it is important that the soldering iron tip be clean, shiny and freshly tinned so that heat is transferred to the joint to be soldered as quickly as possible to avoid excess heating of the parts being soldered. The soldering iron should be set to between 700 °F and 800 °F.

Solder and soldering equipment vendors provide numerous guides to hand soldering with lead-free solders. Weller's “Weller University” online presentation [www.elexp.com/Images/Weller\\_Coping\\_with\\_Lead\\_Free.pdf](http://www.elexp.com/Images/Weller_Coping_with_Lead_Free.pdf) provides a great deal of detail about how soldering iron tips work with lead-free solder. More information is available from Kester ([www.kester.com](http://www.kester.com)) in the Knowledge Base under the Hand Soldering link.

Most, if not all, RoHS-compliant components can be soldered with lead-tin solder. If the RoHS part has leads that are tinned or coated with an alloy to make soldering easier, it is necessary to use a hotter iron than would normally be required in lead-tin soldering. A soldering iron tip temperature of 315 °C (600 °F) or greater will be adequate for soldering RoHS parts with lead-tin solder. In contrast, a working tip temperature of 275 °C is generally adequate for working with conventional non-RoHS parts.

### 23.3.3 Soldering

The two key factors in quality soldering are time and temperature. Rapid heating is desired so that all parts of the joint are made hot enough for the solder to remain molten as it flows over the joint surfaces. Most unsuccessful solder jobs fail because insufficient heat has been applied. To achieve rapid heating, the soldering iron tip should be hotter than the melting point of solder and large enough that transferring heat to the cooler joint materials occurs quickly. A tip temperature about 100 °F (60 °C) above the solder melting point is right for mounting components on PC boards.

Use solder that is sized appropriately for the job. As the cross section of the solder decreases, so does the amount of heat required to melt it. Diameters from 0.025 to 0.040 inch are good for nearly all circuit wiring. The most common sizes suitable for amateur

projects are 0.031 or 0.025 inch. Sensitive and smaller components can be damaged or surfaces re-oxidized if heat is applied for too long a period. Solder that is too thick can cause shorts between close-by connections. (A heavier solder is useful for working on antennas, connectors, and light metal work, such as shields.)

If you are a beginner, you may want to start with one of the numerous “Learn to Solder” kits available from many electronics parts and kit vendors. The kits come with a printed-circuit board, a basic soldering iron, solder, and the components to complete a simple electronics project. Or, seek out a group kit building session, such as those put on by the QRP ARCI at the annual Dayton Hamvention or by a local or regional group at a hamfest or specialty convention. Robotics and maker groups often have learn-to-solder sessions, too.

You can also download the online article “The Art of Soldering” which provides an overview of guidelines on soldering ([www.arrl.org/files/file/Technology/tis/info/pdf/0102072.pdf](http://www.arrl.org/files/file/Technology/tis/info/pdf/0102072.pdf)).

Here’s how to make a good solder joint. This description assumes that solder with a flux core is used to solder a typical PC board connection such as an IC pin.

- Prepare the joint. Clean all conductors thoroughly with fine steel wool or a plastic scrubbing pad. Clean the circuit board at the beginning of assembly and individual parts such as resistors and capacitors immediately before soldering. Some parts (such as ICs and surface-mount components) cannot be cleaned easily; don’t worry unless they’re exceptionally dirty.

- Prepare the tool. It should be hot enough to melt solder applied to its tip quickly (half a second when dry, instantly when wet with solder). Apply a little solder directly to the tip so that the surface is shiny. This process is called “tinning” the tool. The solder coating helps conduct heat from the tip to the joint and prevents the tip from oxidizing.

- Place the tip in contact with one side of the joint. If you can place the tip on the underside of the joint, do so. With the tool below the joint, convection helps transfer heat to the joint.

- Place the solder against the joint directly opposite the soldering tool. It should melt within a second for normal PC connections, within two seconds for most other connections. If it takes longer to melt, there is not enough heat for the job at hand. If you have a variable heat soldering iron, adjust it so that the solder flows quickly for the size of wire and joints you are soldering. Much more heat can damage components and the board.

- Keep the tool against the joint until the solder flows freely throughout the joint.

When it flows freely, solder tends to form concave joints called “fillets” between the conductors. With insufficient heat solder does not flow freely; it forms convex shapes — blobs. Once the solder shape changes from convex to concave, remove the tool from the joint. If a fillet won’t form, the joint may need additional cleaning. Look for that “Hershey’s Kiss” shape to know if it is done correctly.

- Let the joint cool without movement at room temperature. It usually takes no more than a few seconds. If the joint is moved before it is cool, it may take on a dull, satin or grainy appearance that is characteristic of a “cold” solder joint. Reheat cold joints until the solder flows freely and hold them still until cool. Using 63-37 solder will help reduce the time until the solder is solid again.

- When the iron is set aside, or if it loses its shiny appearance, wipe away any dirt with a damp cloth or sponge. If it remains dull after cleaning, tin it again.

- Adafruit has published a good collection of photographs showing many common soldering problems and how to repair them. See [learn.adafruit.com/adafruit-guide-excellent-soldering/common-problems](http://learn.adafruit.com/adafruit-guide-excellent-soldering/common-problems).

Overheating a transistor or diode while soldering can cause permanent damage, although as you get better at soldering, you’ll be able to solder very quickly with little risk to the components. If the soldering iron will be applied for longer than a couple of seconds, use a small heat sink when you solder transistors, diodes or components with plastic parts that can melt. Grip the component lead with a pair of needle-nose pliers up close to the unit so that the heat is conducted away (be careful — it is easy to damage delicate component leads). A rubber-band wrapped around the pliers handles will hold the pliers on the wire. A small alligator clip or a flat spring type paper clip also makes a good heat sink.

Mechanical stress can damage components, too. Mount components so there is no appreciable mechanical strain on the leads. Be especially careful with small glass diodes and small disc capacitors as these components are easy to break when forming the leads.

Installing wire jumpers between connectors or modules and circuit boards can be straightforward or it can lead to a rat’s nest. For some excellent advice and guidance about this basic task, read “W8ZR’s Tips for Wiring Circuit Board Jumpers” at [w8zr.net/stationpro/images/download%20files/Tips%20for%20Wiring%20Circuit%20Board%20Jumpers.pdf](http://w8zr.net/stationpro/images/download%20files/Tips%20for%20Wiring%20Circuit%20Board%20Jumpers.pdf). This is a common task in building equipment so why not learn to do it well?

Soldering to hollow pins, such as found on connectors, can be difficult, particularly if the connector has been used previously or has oxidized. Use a suitable small twist drill to clean the inside of the pin and then tin

it. While the solder is still melted, clear the surplus solder from each pin with a whipping motion or by blowing through the pin from the inside of the connector. Watch out for flying hot solder — use safety goggles and protect the work surface and your arms and legs! A glass ashtray or small baking dish works great for catching the loose solder. Do not perform this operation near open electronic equipment as the loose solder can easily form short circuits. If the pin surface is plated, file the plating from the pin tip. Then insert the wire and solder it. After soldering, remove excess solder with a file, if necessary.

When soldering to the pins of plastic connectors or other assemblies, heat-sink the pin with needle-nose pliers at the base where it comes in contact with the plastic housing. Do not allow the pin to overheat; it will loosen and become misaligned. If you need to solder very quickly due to concerns about melting the housing, tin both the pin and wire first. Reheat the pin while inserting the wire. This melts the solder on both the pin and the wire, resulting in a solid connection without overheating the pin.

### 23.3.4 Desoldering

There are times when soldered components need to be removed. The parts may be bad, they may be installed incorrectly, or you may want to remove them for use in another project.

There are several techniques for desoldering. The easiest way is to use a desoldering braid. Desoldering braid is simply fine copper braid, often containing flux. It is available under a wide variety of trade names wherever soldering supplies are sold. A good rule of thumb is to choose a width and thickness of desoldering braid that matches the size of the connection being desoldered.

The soldering braid is placed against the joint to be desoldered. A hot iron is pressed onto the braid. If you have a variable temperature soldering station, you might get better results by turning up the temperature, as the combination of the wick and the connection absorbs more heat. As the solder melts, it is wicked into the braid and away from the joint. Copper is an excellent conductor of heat, and the braid can get quite hot, so watch your fingers when using braid for desoldering. After all the leads have been treated in this manner the part can be removed. (A thin film of solder may remain, but is easily broken loose through the use of needle-nose pliers.) The part of the braid that wicked up the solder is clipped off.

Do not allow the used portion of the braid get too long, as it will absorb too much heat and not do as good of a job removing solder. When desoldering connections that have been made by using lead-free or “RoHS” solder

it can sometimes be difficult to achieve the high temperature needed to use solder wick, even with the iron heat turned all of the way up. A good tip in this case is to add a small amount of conventional leaded solder to the joint first, allowing it to mix. That lowers the melting point to a level that allows for much easier desoldering using solder wick, or other methods.

A desoldering vacuum pump can also be used. There are two types of desoldering vacuum tools, a simple rubber syringe bulb with a high temperature plastic tip and a desoldering pump. The desoldering pump is a simple manual vacuum pump consisting of a cylinder that contains a spring-loaded plunger attached to a metal rod inside a tip of high temperature plastic on the end of the pump. To desolder a joint, the plunger is pushed down, and locked in place. The tip is placed against the joint to be desoldered along with a soldering iron. When the solder melts, a button on the pump releases the plunger, which pulls the rod back, creating a vacuum that sucks the molten solder through the tip. The part being desoldered can then be removed. Pushing the plunger again ejects the solder from the desoldering tip.

The desoldering bulb employs a similar concept: heat the joint to be desoldered, squeeze the bulb, place the tip on the joint and release it to suck up the solder. Remove the part that was desoldered. If the first application of the desoldering pump doesn't suck up all the solder, reheat the joint and suck up the rest.

If the desoldering tool doesn't seem to be sucking up solder, the tip may be clogged with solder. The tip can be unclogged by pushing the solder through. You may have to clear the tip several times when doing a job that requires desoldering many joints. One can purchase small desoldering irons that contain a bulb on the handle that leads to a tip adjacent to the iron tip. This desoldering iron combination is somewhat easier to handle than the separate bulb and iron and does an effective job. Use a glass ashtray for a container to blow out the excess solder from this tool before using it again, as an ashtray is usually designed to handle heat.

Desoldering stations are also available. One type contains a vacuum pump in a console much like a soldering station. A vacuum line is connected to the tip of the soldering iron. There is a valve trigger on the iron that is used to open the tip to the vacuum when the solder is melted. The solder is sucked up

the line into a receptacle in the station or in the hand piece.

## DESOLDERING SURFACE-MOUNT DEVICES

Special tools are available for desoldering and replacing surface-mount parts. (See the previous section on Tools for Soldering Surface-Mount Devices.) The two most common are "hot tweezers" which is really a special dual-tipped soldering iron that is squeezed to match the size of the component. Hot tweezers can be used to not only remove, but to replace surface-mount parts. Another tool for this purpose is a hot-air tool with a small tip that focuses the hot air on a single component. This tool can be used to remove a surface mount part as well as to replace one. The hot-air tool heats the joint with hot air so the component can be lifted off with tweezers or needle-nose pliers.

Use surplus circuit boards to practice soldering and desoldering techniques. Old boards from all kinds of electronic items are often at very low cost or free at many flea markets. Use these surplus boards to practice different soldering and desoldering techniques without having to worry about damaging a project. Computer boards are often made with lead-free solder, and are ideal for practicing desoldering methods by adding leaded solder to the connections before desoldering.

### 23.3.5 Soldering Safety

Soldering requires a certain degree of practice and, of course, the right tools. What potential hazards are involved?

Since the solder used for virtually all electronic components is a lead-tin alloy, the first thing in most people's minds is lead, a well-known health hazard. There are two primary ways lead might enter our bodies when soldering: we could breathe lead fumes into our lungs or we could ingest (swallow) lead or lead-contaminated food. Inhalation of lead fumes is extremely unlikely because the temperatures ordinarily used in electronic soldering are far below those needed to vaporize lead. Nevertheless, since lead is soft and we may tend to handle it with our fingers, contaminating our food is a real possibility. For this reason, wash your hands carefully after any soldering (or touching of solder connections).

Using a small fan can keep the fumes away from your eyes and reduce your exposure to solder smoke. A small computer chipset fan, often only an inch or two wide, can be used. By reducing the voltage that feeds the fan,

the speed and noise can be reduced, allowing the fumes to be blown away, yet not creating another problem with the airflow. Look in old computers for these little fans, often attached to video cards or to the bus chips on the motherboard. The CPU or case fans can be also used, but the voltage supplying them will definitely need to be reduced to create the desired level of airflow. There are also commercially available specialized fans with built-in filters designed for this purpose — look for a soldering "fume extractor".

Soldering equipment gets *hot!* Be careful. Treat a soldering iron as you would any other hot object. A soldering iron stand is helpful, preferably one that has a cage that surrounds the hot tip of the iron. Here's a helpful tip — if the soldering iron gets knocked off the bench, train yourself not to grab for it because the chances are good that you'll grab the hot end!

When heated, the flux in solder gives off a vapor in the form of a light gray smoke-like plume. This flux vapor, which often contains aldehydes, is a strong irritant and can cause potentially serious problems to persons who suffer from respiratory sensitivity conditions such as asthma. In most cases it is relatively easy to use a small fan, like the small computer fans described previously to move the flux vapor away from your eyes and face. Opening a window provides additional air exchange.

Solvents are often used to remove excess flux after the parts have cooled to room temperature. Minimize skin contact with solvents by wearing molded gloves resistant to the solvent. If you use a solvent to remove flux, it is best to use the mildest one that does the job. Isopropyl alcohol, or rubbing alcohol, is often sufficient. You can purchase alcohol ranging from 70% to 92% concentration at local drug stores that works well in removing most types of fluxes. Some water-soluble solder fluxes can be removed with water.

Observe these precautions to protect yourself and others:

- Properly ventilate the work area. If you can smell fumes, you are breathing them.
- Wash your hands after soldering, especially before handling food.
- Minimize direct contact with flux and flux solvents. Wear disposable surgical gloves when handling solvents.

For more information about soldering hazards and the ways to make soldering safer, see "Making Soldering Safer," by Brian P. Bergeron, MD, NU1N (Mar 1991 *QST*, pp 28-30) and "More on Safer Soldering," by Gary E. Meyers, K9CZB (Aug 1991 *QST*, p 42).

# 23.4 Surface Mount Technology (SMT)

Today, nearly all consumer electronic devices are made with surface mount technology. Hams have lagged behind in adopting this technology largely due to the misconception that it is difficult, requires extensive practice and requires special equipment. In fact, surface mount devices can be soldered easily with commonly available equipment. There is no more practice required to become proficient enough to produce a circuit with surface-mount (SM) devices than there is with soldering through-hole (lead) components.

There are several advantages to working with SMT:

- Projects are much more compact than if through-hole components are used
- SM parts are available that are not available in through-hole packages
- Fewer and fewer through-hole parts are being produced
- Equivalent SM components are often cheaper than through-hole parts, and
- SM parts have less self-inductance, less self-capacitance and better thermal properties.

There are several techniques that can be used effectively to work with SM components: conventional soldering iron, hot air reflow and hot plate/hot air reflow. This section describes the soldering iron technique. On-line descriptions of reflow techniques are available for the advanced builder that wants to try them. As is the case for through-hole soldering, kits are available to teach the beginner how to solder SMT components.

The following material on working with surface-mount technology contains excerpts from a series of *QST* articles, "Surface Mount Technology — You Can Work with It! Part 1" by Sam Ulbing, N4UAU, published in the April 1999 issue. (The entire series of four articles is available with the online supplemental content. Additional information on SMT is available at [www.arrl.org/surface-mount-technology](http://www.arrl.org/surface-mount-technology).) Additional information and illustrations were contributed by George Heron, N2APB.

## 23.4.1 Equipment Needed

You do not need lots of expensive equipment to work with SM devices.

- A fundamental piece of equipment for SM work is an illuminated magnifying glass. You can use an inexpensive one with a 5 inch diameter lens, and it's convenient to use the magnifier for all soldering work, not just for SM use. Such magnifiers are widely available from about \$25. Most offer a 3x magnification and have a built-in circular light. Be sure to use a light that is fluorescent or LED-based.

Incandescent lights are much hotter and make it difficult to ascertain the correct color of component markings.

- A low-power, temperature-controlled soldering iron is necessary. Use a soldering iron with a grounded tip as most SM parts are CMOS devices and are subject to possible ESD (static) failure.
- Use of thin (0.020 inch diameter) rosin-core solder is preferred because the parts are so small that regular 0.031 inch diameter solder will flood a solder pad and cause bridging. Solder paste or cream can also be used.
- A flux pen comes in handy for applying just a little flux at a needed spot.
- Good desoldering braid is necessary to remove excess solder if you get too much on a pad. 0.100 inch wide braid works well.
- ESD protective devices such as wrist straps may be necessary if you live in a dry area and static is a problem.
- Tweezers help pick up parts and position them. Nonmagnetic, stainless-steel drafting dividers also work well. The nonmagnetic property of stainless steel means the chip

doesn't get attracted to the dividers.

- Some hams prefer to hold components in place with a temporary adhesive such as DAP Blue-Stik while soldering rather than holding the part with tweezers.

## 23.4.2 Surface-Mount Parts

Figure 23.4 shows some common SM parts. (The **Component Data and References** chapter has more information on component packages.) Resistors and ceramic capacitors come in many different sizes, and it is important to know the part size for two reasons: Working with SM devices by hand is easier if you use the larger parts; and it is important that the PC-board pad size is larger than the part.

Discrete component packaging has shrunk to 0.12 × 0.06 inch, as shown in the "1206" capacitor in Figure 23.5 compared to a penny. Even smaller packages are common today, requiring much less PC board area for the same equivalent circuits. Integrated circuit packaging has also been miniaturized to cre-

Figure 23.4 — Size comparisons of some surface-mount devices and their dimensions. See the **Component Data and References** chapter for more information about component packages and labeling.

**Figure 23.5** — SMT components are small. Clockwise from left: MMIC RF amp, 1206 resistor, SOIC integrated circuit, 1206 capacitor and ferrite inductor.

the 10 × 5 mm SOIC packages with lead separations of 0.025 inch.

Tantalum capacitors are one of the larger SMT parts. Their case code, which is usually a letter, often varies from manufacturer to manufacturer because of different thicknesses. The EIA code for ceramic capacitors and resistors is a measurement of the length and width in inches, but for tantalum parts, those measurements are in millimeters times 10! Keep in mind that tantalum capacitors are polarized; the case usually has a mark or stripe to indicate the positive end. Nearly any part that is used in through-hole technology is available in an SMT package.

If you are a beginner, it is probably best to start with the larger sizes — 1206 for resistors and capacitors, SOT-23 for transistors, and SO-8 for ICs. When you get proficient with these parts you can move to smaller ones.

## PREPARING FOR SMT WORK

The key to success with any construction project is selecting and using the proper tools. A magnifying lamp is essential for well-lit, close-up work on the components. **Figure 23.6** shows a convenient magnifying visor. Tweezers or fine-tipped pliers allow you to grab the small chip components with dexterity.

A clean work surface is of paramount importance because SMT components have a tendency to slip from pliers or tweezers and fly off even when held with the utmost care. You'll have the best chance of recovering your wayward part if your table is clear. When the inevitable happens, you'll have lots of trouble finding it if the part falls onto a rug. It's best to have your work area in a room without carpeting, for this reason as well as to protect static-sensitive parts. Using a cookie sheet with a raised lip helps to contain stray SMT parts.

**Figure 23.6** — A magnifying visor is great for close-up work on a circuit board. These headsets are often available for less than \$10 at hamfests and some even come with superbright LEDs mounted on the side to illuminate the components being soldered.

## 23.4.3 SMT Soldering Basics

If the project contains both SMT parts and conventional through-hole parts and you intend to use a heat-gun or oven for reflow soldering, always mount the SMT parts first, as through-hole components are not always designed to handle the higher reflow heat levels. Use junk PC boards to practice your soldering and desoldering techniques for SMT parts until you are comfortable beginning your own project.

SMT soldering techniques are covered in the March 2019 *QST* article “Soldering Surface-Mount Devices” by Dino Papas, KLØS. Reflow soldering is explained in the *QST* and *QEX* articles “Reflow Soldering for the Radio Amateur” (Jan 2011 *QST*) and “Reflow Soldering for the Radio Amateur — Revisited” (Mar 2019 *QEX*) by Jim Koehler, VE5FP. All three are included in the downloadable supplemental information for this chapter.

### USING A SOLDERING IRON

Let's look at how to solder a surface-mount IC with a soldering iron. Use a little solder to pre-tin the PC board pads if the board is not already pre-tinned. The trick is to add just enough solder so that when you reheat it, it flows to the IC, but not so much that you wind up with a solder bridge. Putting a (very) little flux on the board and the IC legs makes for better solder flow, providing a smooth layer. You can tell if you have the proper soldering-iron tip temperature if the solder melts within 1.5 to 3.5 seconds.

Place the part on the board and then use dividers (or fingers) to push and prod the chip into position. Because the IC is so small and light, it tends to stick to the soldering iron and pull away from the PC board. To prevent this, use the dividers to hold the chip down while tack-soldering two IC legs at diagonally opposite corners. After each tack, check that

the part is still aligned. With a dry and clean soldering iron, heat the PC board near the leg. If you do it right, when the solder melts, it will flow to the IC.

The legs of the IC must lie flat on the board. The legs bend easily, so don't press down too hard. Check each connection with a continuity checker placing one tip on the board the other on the IC leg. Check all adjacent pins to ensure there's no bridging. It is easier to correct errors early on, so perform this check often.

If you find that you did not have enough solder on the board for it to flow to the part, add a little solder. It's best to put a drop on the trace near the part, then heat the trace and slide the iron and melted solder toward the part. This reduces the chance of creating a bridge. Soldering resistors and capacitors is similar to soldering an IC's leads, except the resistors and capacitors don't have exposed leads. The reflow method works well for these parts, too.

Attaching wires that connect to points off the board can be a bit of a challenge because even #24 AWG stranded wire is large in comparison to the SMT parts. First, make sure all the wire strands are close together, then pre-tin the wire. Pre-tin the pad, carefully place the wire on the pad, then heat it with the soldering iron until the solder melts.

## USING REFLOW TECHNIQUES

While SMT projects can be built with conventional solder and a fine-point soldering iron, if you move on to reflow techniques you will need to use solder paste. Solder paste is a grayish looking paste made of a blend of flux and solder. A small dot of solder paste is put on the board at each location a component will need to be soldered. The components are then carefully placed on the board, with the paste loosely holding the parts in position. The whole board is then heated in an oven, or the area of the board being assembled is heated with a heat gun. With sufficient heat, the solder paste melts and flows onto the pad and component contacts, then the board is cooled leaving all of the components soldered in place.

A toaster oven can also be modified to perform reflow soldering as described in the article “Reflow Soldering for the Radio Amateur” by Jim Koehler, VE5FP, in the January 2011 issue of *QST* (this article is included with the online supplemental content). There are many on-line tutorials for adapting and using a toaster oven such as [www.instructables.com/id/Hack-a-Toaster-Oven-for-Reflow-Soldering/](http://www.instructables.com/id/Hack-a-Toaster-Oven-for-Reflow-Soldering/) and [www.youtube.com/watch?v=vduU4WWbpbM](http://www.youtube.com/watch?v=vduU4WWbpbM). SparkFun also shows how to add a temperature control to a toaster oven at [www.sparkfun.com/tutorials/60](http://www.sparkfun.com/tutorials/60). If you plan on doing a lot of SMT assembly, learning

reflow techniques is well worth the effort.

For occasional SMT use, a heat gun is a better choice. Many hobby/crafts stores sell a special heat tool that is used for melting embossing inks used in scrapbooking. Look for an embossing heat tool in the scrapbooking department of these stores. Do not get the heat gun too close to the board, as the airflow may move your components out of place. Hold the tool steady a couple of inches above the board until you see the solder paste turn silver and you see the component appear to be soldered in place, then gradually remove the heat gun. Never use a heat gun designed for paint stripping as the airflow is way too strong for this purpose and will blow the SM parts off the board.

Only a small amount of solder paste is required. Kester Easy Profile 256 is a good solder paste to start with. It is available at reasonable cost in a small syringe with a fine needle-point applicator. As only a small amount is needed for each solder joint, this small amount will last through several medium sized projects. Solder paste must be kept cold or it deteriorates. Kept in a household refrigerator or freezer it has a shelf life of at least a year.

*Hot tweezers* are a dual-tipped soldering iron used to solder and remove SMT parts. Hot tweezers can make very quick work of removing and replacing most common two- and three-terminal surface mount devices with a lot lower risk of board damage.

### 23.4.4 Removing SMT Components

The surface-mount ICs used in commercial equipment are not easy for experimenters to replace. They have tiny pins designed for precision PC boards. Sooner or later, you may need to replace one, though. If you do, don't try to get the old IC out in one piece! This will damage the IC beyond use anyway, and will probably damage the PC board in the process.

Although it requires a delicate touch and small tools, it's possible to change a surface mount IC at home. To remove the old one, use small, sharp wire cutters to cut the IC pins flush with the IC. This usually leaves just enough of the old pin to grab with tweezers. Heat the soldered connection with a small

iron and use the pliers to gently pull the pin from the PC board. Use desoldering braid to remove excess solder from the pads and remove and flux with rubbing alcohol. Solder in the new component using the techniques discussed above.

You can also use the embossing heat gun previously described to remove SM parts, especially ICs. Keep in mind that not only the desired component, but some adjacent parts as well may be loosened by this process, so be sure to not move the board during reheating to allow the other components to stay in place. Use a long-handled tweezers to remove a component once you see the solder become silvery again. Be careful to not disturb any adjacent components. Allow the board to thoroughly cool before moving it to prevent inadvertently allowing other components to shift before the solder solidifies again.

To remove individual components without a heat gun, first remove excess solder from the pads by using desoldering braid. Then the component will generally come loose from the pads if gently lifted with a hobby knife or dental tool. If the component remains attached to the pad, touch the pad with the soldering iron and lift the component off the pad. It may take one or two attempts to free the component from all pads. In extreme cases, it may be necessary to add solder to the pad to completely loosen the component. A product called CHIPQUIK ([www.chipquik.com](http://www.chipquik.com)) reduces the melting point of the existing solder by mixing in a very low temperature solder. Using the flux and solder that comes with a CHIPQUIK kit lets you desolder an SMD easily without a hot-air tool.

### 23.4.5 SMT Construction Examples

The first project example is the DDS Daughtercard — a small module that generates precision RF signals for a variety of projects. This kit has become immensely popular in homebrew circles and is supplied with the chip components contained in color-coded packaging that makes an easy job of identifying the little parts, a nice touch by a kit supplier.

**Figure 23.7A** shows the DDS PC board, a typical layout for SMT components. All traces are on one side, since the component

leads are not “through-hole.” The little square pads are the places where the 1206 package-style chips will eventually be soldered. This project demonstrates the reflow technique using a soldering iron. **Figure 23.7B** illustrates how to use this technique.

(a) Pre-solder (“tin”) one of the pads on the board where the component will ultimately go by placing a small blob of solder there.

(b) Carefully hold the component in place with small needle-nose pliers or sharp tweezers on the tinned pad.

(c) Reheat the tinned pad and component to reflow the solder onto the component lead, thus temporarily holding the component in place.

(d) Solder the other end of the component to its pad.

(e) Finally, check all connections to make sure there are no bridges or shorts.

**Figure 23.7C** shows the completed DDS board.

The second project example is the K8IQY Audio Amp — a discrete component audio amplifier that is homebrew-constructed “Manhattan-style” as described later in the chapter in which small pads are glued or soldered to the copper-clad base board wherever you need to attach component leads or wires. See **Figure 23.7D**.

Instead of using little squares or dots of PC board material for pads, you might decide to create isolated connection points by cutting an “island” in the copper using an end mill or pad cutter. No matter how the pads are created, SMT components may be easily soldered from pad-to-pad, or from pad-to-ground plane to build up the circuit. **Figure 23.7E** shows the completed board, combining SMT and leaded components.

Homebrewing with SOIC-packaged integrated circuits is a little trickier and typically requires the use of an “SOIC carrier board” such as the one shown in **Figure 23.7F**, onto which you solder your surface-mount integrated circuit. You can then wire the carrier board onto your base board or whatever you're using to hold your other circuit components.

Full details on the DDS Daughtercard, the K8IQY Islander Audio Amp, and the Islander Pad Cutter may be found online at [www.njqrp.org](http://www.njqrp.org).

**Figure 23.7A** — This DDS Daughtercard has all interconnections on the top side. Connections to the ground plane on the backside of the board are made by the use of “vias,” wires through the PC board. Pin 28 of the SMT IC is shown being tack-soldered to hold it to the board, keeping all other pins carefully aligned on their pads. Then the other pins are carefully soldered, starting with pin 14 (opposite pin 28). Finally, pin 28 is reheated to ensure a good connection there. If you bridge solder across adjacent pads or pins, use solder wick or a vacuum solder sucker to draw off the excess solder.

**Figure 23.7C** — The fully-populated DDS Daughtercard PC board contains a mix of SMT and through-hole parts, showing how both packaging technologies can be used together.

**Figure 23.7B** — Attaching an SMT part. It is a lot easier attaching capacitors, resistors and other discrete components compared to multi-pin ICs. Carefully hold the component in place and properly aligned using needle-nose pliers or tweezers and then solder one end of the component. Then reheat the joint while gently pushing down on the component with the pliers or a Q-tip stick to ensure it is lying flat on the board. Finally, solder the other side of the component.

**Figure 23.7D** — SMT resistors soldered to base board of the Audio Amp in the beginning stages of assembly.

**Figure 23.7F** — Surface mount ICs can be mounted to general-purpose carrier boards, then attached as a submodule with wires to the base board of the homebrew project.

**Figure 23.7E** — The completed homebrew Audio Amp assembly shows simple, effective use of SMT components used together with conventional leaded components when constructed “Manhattan-style.”

## 23.5 Constructing Electronic Circuits

Most of the construction projects undertaken by the average amateur involve electronic circuitry. The circuit is the “heart” of most amateur equipment. It might seem obvious, but in order for you to build it, the circuit must work! Don’t always assume that a “cookbook” circuit that appears in an applications note or electronics magazine is flawless. These are sometimes design examples that have not always been thoroughly debugged. Many home-construction projects are one-time deals; the author has put one together and it worked. In some cases, component tolerances or minor layout changes might make it difficult to get a second unit working. Using a solderless breadboard can make it easier to test this type of circuit design. For RF circuits above a few MHz, a solderless breadboard is not always practical due to long lead lengths that result.

Take steps to protect the electronic and mechanical components you use in circuit construction. Some components can be damaged by rough handling. Dropping a  $\frac{1}{4}$  W resistor causes no harm, but dropping a vacuum tube or other delicate subassemblies usually causes damage.

Some components are easily damaged by heat. Some of the chemicals used to clean electronic components (such as flux removers, degreasers or control-lubrication sprays) can damage plastic. Check them for suitability before you use them.

### 23.5.1 Electrostatic Discharge (ESD)

Some components, especially high-impedance components such as FETs and CMOS gates, can be damaged by electrostatic discharge (ESD). Protect these parts from static charges. Most people are familiar with the static charge that builds up when one walks across a carpet then touches a metal object; the resultant spark can be quite lively. Walking across a carpet on a dry day can generate 35 kV! A worker sitting at a bench can generate voltages up to 6 kV, depending on conditions, such as when relative humidity is less than 20%.

You don’t need this much voltage to damage a sensitive electronic component; damage can occur with as little as 30 V. The damage is not always catastrophic. A MOSFET can become noisy, or lose gain; an IC can suffer damage that causes early failure. To prevent this kind of damage, you need to take some precautions.

The energy from a spark can travel inside a piece of equipment to affect internal components. Protection of sensitive electronic components involves the prevention of static

build-up together with the removal of any existing charges by dissipating any energy that does build up.

#### MINIMIZING STATIC BUILD-UP

Several techniques can be used to minimize static build-up. Start by removing any carpet in your work areas. You can replace it with special antistatic carpet, but this is expensive. It’s less expensive to treat the carpet with antistatic spray, which is available from electronics wholesalers. Adding humidity to the air can help reduce the presence of static charges as well.

Even the choice of clothing you wear can affect the amount of ESD. Polyester has a much greater ESD potential than cotton.

Many builders who have their workbench on a concrete floor use a rubber mat to minimize the risk of electric shocks from the ac line. Unfortunately, the rubber mat increases the risk of ESD. An antistatic rubber mat can serve both purposes.

Many components are shipped in anti-static packaging. Leave components in their conductive packaging. Other components, notably MOSFETs, are shipped with a small metal ring that temporarily shorts all of the leads together. Leave this ring in place until the device is fully installed in the circuit.

Use antistatic bags to transport susceptible components or equipment. Keep your workbench free of objects such as paper, plastic and other static-generating items. Use con-

ductive containers with a dissipative surface coating for equipment storage. Storing partially assembled projects in antistatic bags is also a good idea.

These precautions help reduce the build-up of electrostatic charges. Other techniques offer a slow discharge path for the charges or keep the components and the operator handling them at the same ground potential.

#### DISSIPATING STATIC

One of the best techniques is to connect the operator and the devices being handled to earth ground, or to a common reference point. It is not a good idea to directly ground an operator working on electronic equipment, though; the risk of shock is too great. If the operator is grounded through a high-value resistor such as 100 k $\Omega$  to 1 M $\Omega$ , ESD protection is still offered but there is no risk of shock.

The operator is usually grounded through a conductive wrist strap. This wrist band is equipped with a snap-on ground lead. A 1 M $\Omega$  resistor is built into the snap of the strap to protect the user should a live circuit be contacted. Build a similar resistor into any homemade ground strap.

The devices and equipment being handled are also grounded, by working on a charge-dissipating mat that is connected to ground. The mat should be an insulator that has been impregnated with a resistance material. Suitable mats and wrist straps are available from most electronics supply houses. **Figure 23.8** shows

**Figure 23.8** — A work station that has been set up to minimize ESD features (1) a grounded dissipative work mat and (2) a wrist strap that (3) grounds the worker through high resistance.

a typical ESD-safe work station.

The work area should also be grounded, directly or through a conductive mat. Use a soldering iron with a grounded tip to solder sensitive components. Most irons that have three-wire power cords are properly grounded. When soldering static-sensitive devices, use two or three jumpers: one to ground you, one to ground the work, and one to ground the iron. If the iron does not have a ground wire in the power cord, clip a jumper from the metal part of the iron near the handle to the metal box that houses the temperature

control. Another jumper connects the box to the work. Finally, a jumper goes from the box to an elastic wrist band for static grounding.

### 23.5.2 Sorting Parts

When building a project, especially one packaged as a kit, finding the appropriate container to sort your components can be a problem. There are a number of things that make this task a lot easier and at a low cost.

Using a plastic egg carton or poking com-

ponent leads into Styrofoam works quite well for sorting parts, but both methods can lead to ESD damage of sensitive components. Use this method for components such as resistors, capacitors and inductors that are relatively immune to ESD.

Metal cupcake trays are ideal, as the tray itself can be grounded through a 1 M $\Omega$  resistor to prevent static buildup. Cupcake trays typically come in three sizes: 6, 12 and 16 cups. The best sorting technique is to place the most common or first-used components in the cups closest to the builder (usually resistors),

## Common Standard Parts

When building a project or repairing equipment, it is helpful to have an assortment of standard and common parts on hand for use in modifying circuit designs and fine-tuning performance. Making repairs or completing a kit that is missing a part are also good reasons to keep an assortment of parts on hand. It is not possible to have every possible needed part, but the majority of components in any project are usually one of the common standard values.

Assortments of new parts such as resistors, capacitors, and semiconductors are available from electronic distributors, such as DigiKey, Mouser, Newark, and Jameco, and from parts companies such as Velleman. These are often available with a storage container or cabinet, as well. When taking into account the cost of the parts cabinet and the parts themselves, it is very economical to buy standard parts in this manner. If parts cabinets are not available, craft stores as well as fishing supply stores often have low-cost compartmentalized containers ideal for sorting and storing small parts. Tackle boxes are also useful for storing components and materials, particularly if purchased during the end-of-season sales.

Another recommendation is to buy in quantity when ordering

parts for a project. Not only can you often get a price break on the individual components but you will be building up your store of components along the way.

Many vendors also have bags of one or more values of surplus parts from electronic manufacturing. It is often less expensive to buy an entire bag of surplus parts than it is to buy even one or two of them elsewhere. Some come as truly random assortments, often called "grab bags," and others may be sold as "tapes" that were prepared for a parts-placement machine. You will have to sort out the components but the price makes it worthwhile!

You can accumulate a good selection of parts at ham radio flea markets. It is common to see parts cabinets available with entire collections of components and hardware! Grab bags and parts junk boxes are also common here and generally a very good value if you are willing to sort through the components.

The tables in this sidebar list common parts used in many projects. It is a good idea to accumulate these parts and keep them on hand. Keep in mind that you do not have to have every one of these parts, but have the list in mind as you shop for parts. (See the **Component Data and References** chapter for more information on part types.)

Another great idea for parts sorting is to use a fishing tackle box with removable trays. Inexpensive tackle boxes are available at outdoor supply houses and department stores, and you can often find them on sale. The tackle box has a distinct advantage of allowing you to sort your parts into different compartments within each movable tray, and some trays have pieces that allow you to resize the compartments to better fit the parts for your project. Many tackle boxes have a larger open space in the top which allows you to store your partially finished boards, with the remaining components in the closeable trays below it. This arrangement is ideal to protect your project from damage and can be securely stored between work sessions.

### 23.5.3 Construction Order

When building a kit or DIY project, the question often arises as to what order the parts need to be mounted. In a kit, the manual often is very explicit, requiring the builder to construct the project stage by stage. Other kit manuals offer only a minimum of directions, leaving it up to the builder. Have the manual handy, either printed or on a laptop or tablet nearby for reference.

In stage by stage construction, each stage in the project is completed in order to allow the builder to test and troubleshoot that area of the project without having a more complex problem to solve with all components mounted. This method also allows the builder to learn the principles involved in the project and how each part of the circuit works from the power supply to the output. This is a great aid to future modification and repair.

When building a kit in stages, it is often better to sort the parts by stages as well, placing the parts from each stage in their own space. That way, when each stage is completed, there should be no extra parts left over in that stage's container. Number the stages, if they are not already numbered in the manual, and place a small piece of paper with that number in each compartment, indicating the stage that those parts belong to.

When given a minimum of assembly instructions, the best approach is to mount the resistors first, then the capacitors, and then the semiconductors, followed by the more unique components. This way, the majority of parts are mounted early in the process, so finding the remaining part locations is a lot easier. This technique also allows the builder to double check the usage of parts. Try to mount large parts after the smaller surrounding parts so as not to possibly block your ability to properly mount all of them.

Inventory the parts before commencing construction. In kits or DIY projects, if a

change is introduced after a number of kits have been assembled, there is a chance of errors so that the parts list or board layouts do not reflect changes in the design of the circuit. Sometimes, a number of extra parts are supplied with a kit to facilitate different options, such as the choice of bands covered. Sometimes parts are eliminated or substituted with a change of other components in the circuit. Be sure to ask the kit supplier if you are not sure as to why you have an empty space or surplus parts. Sometimes new parts values are added to substitute for old values already packed in the kit, making the old values surplus. Resolve questions about component placement before powering up a completed project.

### 23.5.4 Component Mounting

When working with a large number of components, there are a few techniques that can be helpful should troubleshooting be required. Although resistors are not polarized, it is a good idea to mount them with the color codes reading the same direction to make it easier to spot a part that is not in its correct position. Polarity-sensitive parts, such as diodes, electrolytic capacitors and ICs, must be placed in their specified direction. In general, mount components so their values are readable without having to remove the component from the board or bending it, causing possible damage.

Axial-lead components such as resistors are mounted in one of two methods, upright and flat. To save space on a PC board, resistors are often mounted upright with one lead bent double in a manner resembling a hairpin. The best practice is to make this bend so that the color stripes denoting the resistor value begin at the top and the precision stripe (often silver or gold) is at the bottom, making it easier to read the values once mounted. Components with alphanumeric markings, such as diodes, should be mounted with the markings visible.

Non-polarized capacitors are best placed with markings facing in the same direction, unless the markings would be blocked by another component.

For polarized parts, always double-check its positioning before soldering. A commercially-prepared PC board often has stripes on the diode labels, indicating which end to place the cathode stripe on the diode. A "+" sign on the board inside or next to the circle for a capacitor denotes the positive lead which will often be longer. LEDs will have a flat spot on or a notch on a lead to identify the cathode. See the **Component Data and References** chapter and manufacturers' data sheets for more information on component body styles.

When mounting ICs, using a pin straightener helps align the leads for insertion. If one is not available, use a flat surface to align

them at once. Be sure a pin does not get bent inward and that all pins go into the socket or PC board holes.

Straight-pin "header" connectors are commonly used in projects and kits. Unless you have a specialized jig for this purpose, soldering this type of connector can appear to be difficult. An easy technique is to simply solder one pin to hold the part on the board, without regard to how exactly straight the connector is. Using a finger, apply pressure on an unsoldered pin or pins, and reheat the solo pin that was previously soldered. You can feel when the connector is moved into place, straight and vertical. Be sure to only touch a pin that is not being heated as it can become very hot! (KØNEB has contributed photos that are available in the book's online supplemental material as additional guidance.)

Once the connector is in the correct position with only one pin soldered, the other pins can be soldered, completing the connector. This same process can also be used for soldering things like plugs and jacks to a PC board. Temporarily or "tack" solder one pin, then reheat it while adjusting its position, followed by completing the other pins on the connector.

### 23.5.5 Electronics Construction Techniques

Several different point-to-point wiring techniques or printed-circuit boards (PC boards) can be used to construct electronic circuits. Most circuit projects use a combination of techniques. The selection of techniques depends on many different factors and builder preferences.

For one-time construction, PC boards are really not necessary. It takes time to lay out, drill and etch a PC board. Alterations are difficult to make if you change your ideas or make a mistake.

The simple audio amplifier shown in **Figure 23.9** will be built using various point-to-point or PC-board techniques. This shows

**Figure 23.9** — Schematic diagram of the audio amplifier used as a design example of various construction techniques.

how the different construction methods are applied to a typical circuit. (Surface-mount techniques are discussed in the previous section.)

### POINT-TO-POINT TECHNIQUES

Point-to-point techniques include all circuit construction techniques that rely on tie points and wiring, or component leads, to build a circuit. This is the technique used in most home-brew construction projects. It is sometimes used in commercial construction, such as old vacuum-tube receivers and modern tube amplifiers.

Point-to-point wiring is also used to connect the “off-board” components used in a printed-circuit project. It can be used to interconnect the various modules and printed-circuit boards used in more complex electronic systems. Most pieces of electronic equipment have at least some point-to-point wiring.

### GROUND-PLANE CONSTRUCTION

A point-to-point construction technique that uses the leads of the components as tie points for electrical connections is known as “ground-plane,” “dead-bug” or “ugly” construction. “Dead-bug construction” gets its name from the appearance of an IC with its leads sticking up in the air. In most cases, this technique uses copper-clad circuit-board material as a foundation and ground plane on which to build a circuit using point-to-point wiring, so in this chapter it is called “ground-plane construction.” An example is shown in Figure 23.10.

Ground-plane construction is quick and simple: You build the circuit on an unetched piece of copper-clad circuit board. Whenever a component connects to ground, you solder it to the copper board. Ungrounded connections between components are made point-to-point. Once you learn how to build with a ground-plane board, you can grab a piece of circuit board and start building any time you see an interesting circuit.

A PC board has strict size limits; the components must fit in the space allotted. Ground-plane construction is more flexible; it allows you to use the parts on hand. The circuit can be changed easily — a big help when you are experimenting. The greatest virtue of ground-plane construction is that it is fast.

Ground-plane construction is something like model building, connecting parts using solder almost — but not exactly — like glue. In ground-plane construction you build the circuit directly from the schematic, so it can help you get familiar with a circuit and how it works. You can build subsections of a large circuit on small ground-plane modules and string them together into a larger design.

Circuit connections are made directly, minimizing component lead length. Short lead lengths and a low-impedance ground conductor help prevent circuit instability. There is usually less inter-component capacitive coupling than would be found between PC-board traces, so it is often better than PC-board construction for RF, high-gain or sensitive circuits.

Use circuit components to support other

circuit components. Start by mounting one component onto the ground plane, building from there. There is really only one two-handed technique to mount a component to the ground plane. Bend one of the component leads at a 90° angle, and then trim off the excess. Solder a blob of solder to the board surface, perhaps about 0.1 inch in diameter, leaving a small dome of solder. Using one hand, hold the component in place on top of the soldered spot and reheat the component and the solder. It should flow nicely, soldering the component securely. Remove the iron tip and hold the component perfectly still until the solder cools. You can then make connections to the first part.

Connections should be mechanically secure before soldering. Bend a small hook in the lead of a component, then “crimp” it to the next component(s). Do not rely only on the solder connections to provide mechanical strength; sooner or later one of these connections will fail, resulting in a dead circuit.

In most cases, each circuit has enough grounded components to support all of the components in the circuit. This is not always

Figure 23.10 — The example audio amplifier of Figure 23.9 built using ground-plane construction.

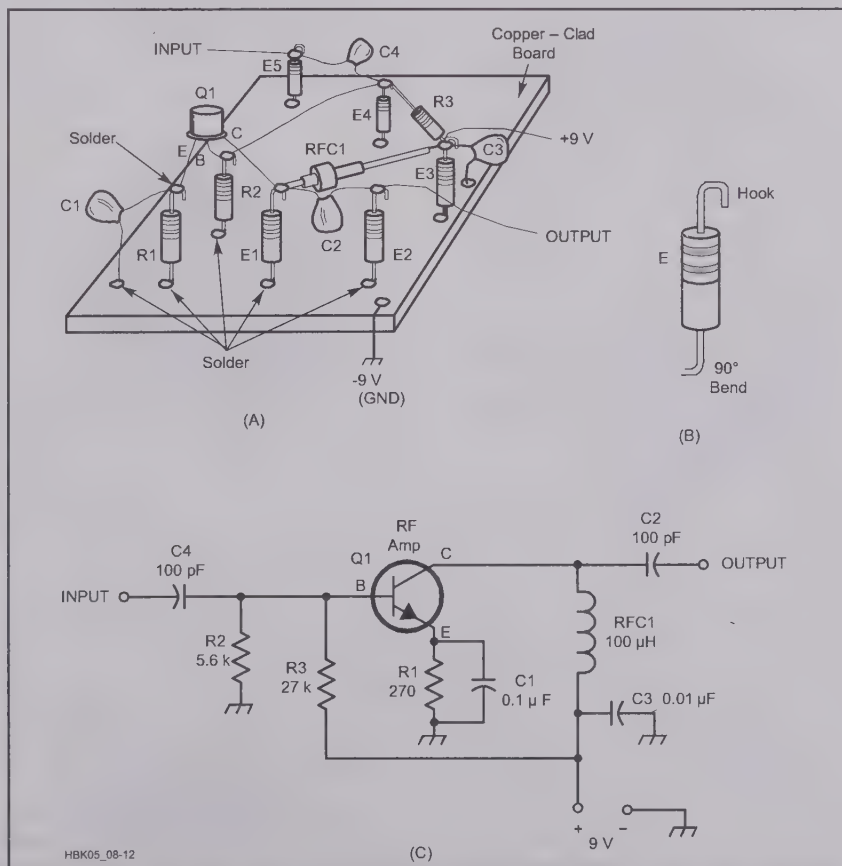

Figure 23.11 — Pictorial view of a circuit board that uses ground-plane construction is shown at A. A close-up view of one of the standoff resistors is shown at B. Note how the leads are bent. The schematic diagram at C shows the circuit displayed at A.

possible, however. In some circuits, high-value resistors can be used as standoff insulators. One resistor lead is soldered to the copper ground plane; the other lead is used as a circuit connection point. You can use  $\frac{1}{4}$  or  $\frac{1}{2}$  W resistors in values from 1 to 10 M $\Omega$ . Such high-value resistors permit almost no current to flow, and in low-impedance circuits they act more like insulators than resistors. As a rule of thumb, resistors used as standoff insulators should have a value that is at least 10 times the circuit impedance at that point in the circuit.

Figure 23.11A shows how to use the standoff technique to wire the circuit shown at Figure 23.11C. Figure 23.11B shows how the resistor leads are bent before the standoff component is soldered to the ground plane. Components E1 through E5 are resistors that are used as standoff insulators. They do not appear in the schematic diagram. The base circuitry at Q1 of Figure 23.11A has been stretched out to reduce clutter in the drawing. In a practical circuit, all of the signal leads should be kept as short as possible. E4 would, therefore, be placed much closer to Q1 than the drawing indicates.

No standoff posts are required near R1 and R2 of Figure 23.11. These two resistors serve two purposes: They are not only the normal circuit resistances, but function as standoff posts as well. Follow this practice wherever a capacitor or resistor can be employed in the dual role.

### "MANHATTAN" CONSTRUCTION

Another solution to building up a circuit is called "Manhattan" construction, shown previously in the Surface-Mount Components section as Figure 23.7E. This method got its name from the appearance of the finished product, resembling the tall buildings in a city. Manhattan construction uses plain, unetched copper clad PC board material to make both the main board and the component connection points. The PC board material used may be single or double-sided.

After cutting the desired size and shape of the board required for the project, use the scraps left over to make the insulated contact pads. These pads can be made a number of ways, the most common being cutting the material into tiny squares—about  $\frac{1}{4}$  or  $\frac{3}{8}$  inch across. Another method to create the pads is to use a heavy-duty hole punch. This kind of punch often has changeable dies to create various sizes of round holes in materials such as sheet metal, and is available at many tool dealers. Once cut, the pads can be glued to the board in a pattern that accommodates the lead lengths of the parts to be connected.

Pads can be glued to the base board or soldered if the pads are double-sided PC board material. Use a tiny drop of instant glue, such as a cyanoacrylate "super glue" to mount the pads to the board. When soldering to the pads,

use the minimum amount of heat required to avoid loosening the pads.

Component leads are soldered to the pads, and additional leads can be added to a pad by simply reheating the connection already there. The main board is used as the ground plane with all ground leads soldered to the board. This method of construction works well with RF circuits up to UHF.

### WIRED TRACES — THE LAZY PC BOARD

If you already have a PC-board design, but don't want to copy the entire circuit—or you don't want to make a double-sided PC board—then the easiest construction technique is to use a bare board or perfboard and hard-wire the traces.

Drill the necessary holes in a piece of single-sided board, remove the copper ground plane from around the holes, and then wire up the back using component leads and bits of wire instead of etched traces (Figure 23.12).

To transfer an existing board layout, make a 1:1 photocopy and tape it to your piece of PC board. Prick through the holes with an automatic (one-handed) center punch or by firm pressure with a sharp scribe, remove the photocopy and drill all the holes. Holes for ground leads are optional—you generally get

a better RF ground by bending the component lead flat to the board and soldering it down. Remove the copper around the rest of the holes by pressing a drill bit lightly against the hole and twisting it between your fingers. A drill press can also be used, but either way, don't remove too much board material. Then wire up the circuit beneath the board. The results look very neat and tidy—from the top, at least!

Circuits that contain components originally designed for PC-board mounting are good candidates for this technique. Wired traces would also be suitable for circuits involving multi-pin RF ICs, double-balanced mixers and similar components. To bypass the pins of these components to ground, connect a miniature ceramic capacitor on the bottom of the board directly from the bypassed pin to the ground plane.

A wired-trace board is fairly sturdy, even though many of the components are only held in by their bent leads and blobs of solder. A drop of cyanoacrylate "super glue" can hold down any larger components, components with fragile leads or any long leads or wires that might move.

### PERFORATED CONSTRUCTION BOARD

A simple approach to circuit building uses

Figure 23.12 — The audio amplifier built using wired-traces construction.

Figure 23.13 — The audio amplifier built on perforated board. Top view at left; bottom view at right.

a perforated phenolic or epoxy resin board known as perfboard. Perfboard is available with many different hole patterns. Choose the one that suits your needs. Perfboard is usually unclad, although it is made with pads that facilitate soldering.

Circuit construction on perforated board is easy. Start by placing the components loosely on the board and moving them around until a satisfactory layout is obtained. Most of the construction techniques described in this chapter can be applied to perfboard. The audio amplifier of Figure 23.9 is shown constructed with this technique in **Figure 23.13**.

Perfboard and accessories are widely available. Accessories include mounting hardware and a variety of connection terminals for solder and solderless construction.

### TERMINAL AND WIRE

A perfboard is usually used for this technique. Push terminals are inserted into the hole in a perfboard. Components can then be easily soldered to the terminals. As an alternative, drill holes into a bare or copper-clad board wherever they are needed (**Figure 23.14**). The components are usually mounted on one side of the board and wires are soldered to the bottom of the board, acting as wired PC-board "traces." If a component has a reasonably rigid lead to which you can attach other components, use that instead of a push terminal — a modification of the ground-plane construction technique.

If you are using a bare board to provide a ground plane, drill holes for your terminals with a high-speed PC-board drill and drill press. Mark the position of the hole with a center punch to prevent the drill from skidding. The hole should provide a snug fit for the push terminal.

Mount RF components on top of the board, keeping the dc components and much of the interconnecting wiring underneath. Make dc feed-through connections with terminals having bypass capacitors on top of the board. Use small solder-in feedthrough capacitors for more critical applications.

### SOLDERLESS PROTOTYPE BOARD

One construction alternative that works well for audio and digital circuits is the solderless prototype board (protoboard), shown in **Figure 23.15**. It is usually not suitable for RF circuits above a few MHz.

A protoboard has rows of holes with spring-loaded metal strips inside the board. Circuit components and hookup wire are inserted into the holes, making contact with the metal strips. Components that are inserted into the same row are connected together. Component and interconnection changes are easy to make. Pre-made and color-coded jumpers make wiring these boards easier. (A length of phone system cable with four solid-

**Figure 23.15** — The audio amplifier built on a solderless prototyping board.

conductor wires makes an excellent source of colored jumper wire.) Look for a protoboard that has power supply terminals already mounted on them for easier connection.

Protoboards have some minor disadvantages. The metal strips add stray capacitance to the circuit and jumper lengths can be long. Large-diameter component leads can deform the metal contacts of the strips — be sure to insert wire no larger than the manufacturer recommends.

### WIRE-WRAP CONSTRUCTION

Wire-wrap techniques can be used to quickly construct a circuit without solder. Low- and medium-speed digital circuits are often assembled on a wire-wrap board. The technique is not limited to digital circuits, however. **Figure 23.16** shows the audio amplifier built using wire wrap. Circuit changes are easy to make, yet the method is suitable for permanent assemblies.

Wire wrap is done by wrapping a wire around a small square post to make each connection. A wrapping tool resembles a thick pencil. Electric wire-wrap guns are convenient when many connections must be made. The wire is almost always #30 AWG wire

**Figure 23.16** — The audio amplifier built using wire-wrap techniques.

**Figure 23.17** — Wire-wrap connections. Standard wrap is shown at A; modified wrap at B.

with thin insulation. Two wire-wrap methods are used: the standard and the modified wrap (Figure 23.17). The modified wrap adds a turn of insulated wire which provides a bit of stress relief to the connection. The wrap-post terminals are square (wire wrap works only on posts with sharp corners). They should be long enough for at least two connections. Figure 23.17 and Figure 23.18 show proper and improper wire-wrap techniques. Mount small components on an IC header plug. Insert the header into a wire-wrap IC socket as shown in Figure 23.16. The large capacitor in that figure has its leads soldered directly to wire-wrap posts.

### “READY-MADE” UTILITY PC BOARDS

“Utility” PC boards are an alternative to custom-designed etched PC boards. They offer the flexibility of perforated board construction and the mechanical and electrical advantages of etched circuit connection pads. Utility PC boards can be used to build anything from simple passive filter circuits to computers.

Circuits can be built on boards on which the copper cladding has been divided into connection pads. Power supply voltages can be distributed on bus strips. Boards like those shown in Figure 23.19 are commercially available.

An audio amplifier constructed on a utility PC board is shown in Figure 23.20. Component leads are inserted into the board and soldered to the etched pads. Wire jumpers connect the pads together to complete the circuit.

Utility boards with one or more etched plugs for use in computer-bus, interface and general purpose applications are widely available. Connectors, mounting hardware and other accessories are also available. Check with your parts supplier for details.

### 23.5.6 Printed-Circuit (PC) Boards

PC boards are everywhere — in all kinds of consumer electronics, in most of your Amateur Radio equipment. They are also used in most kits and construction projects. A newcomer to electronics might think that there is some unwritten law against building equipment in any other way!

The misconception that everything needs to be built on a printed-circuit board is often a stumbling block to easy project construction. In fact, a PC board is probably the worst choice for a one-time project. In actuality, a moderately complex project (such as a QRP transmitter) can be built in much less time using other techniques such as those described in the preceding section. The additional design, layout and manufacturing is usually much more work than it would take

to build the project by hand.

So why does everyone use PC boards? The most important reason is that they are reproducible. They allow many units to be mass-produced with exactly the same layout, reducing the time and work of conventional wiring and minimizing the possibilities of wiring errors. If you can buy a ready-made PC board or kit for your project, it can save a lot of construction time. This is true because someone else has done most of the real work involved — designing the PC board layout and fixing any “bugs” caused by inter-trace capacitive coupling, ground loops and similar problems. In most cases, if a ready-made board is not available, ground-plane construction is a lot less work than designing, debug-

Figure 23.18 — Improper wire-wrap connections. Insufficient insulation for modified wrap is shown at A; a spiral wrap at B, where there is too much space between turns; an open wrap at C, where one or more turns are improperly spaced and an overwrap at D, where the turns overlap on one or more turns.

ging and then making a PC board.

Using a PC board usually makes project construction easier by minimizing the risk of wiring errors or other construction blunders. Inexperienced constructors usually feel more confident when construction has been simplified to the assembly of components onto a PC board. One of the best ways to get started with home construction (to some the best part of Amateur Radio) is to start by assembling a few kits using PC boards. A list of kit manufacturers can be found on the QRP ARCI website, [www.qrparci.org](http://www.qrparci.org), under “Links.” Then click on “QRP Kits Bits and Supplies”. Another web page listing kits is at [www.w0ch.net/kits/kits.htm](http://www.w0ch.net/kits/kits.htm).

### ON-LINE PC BOARD FABRICATION SERVICES

In the past few years, on-line PC board fabrication services have become popular among hobbyists and professional designers. See the CAD for PCB Design section of this chapter for a discussion of PCB design software and services. These services specialize in fast turnaround (two or three days, typically) of small boards in low quantities. Some accept artwork files in standard interchange formats and others have proprietary software packages. The cost per board is quite reason-

Figure 23.20 — The audio amplifier built on a multipurpose PC breadboard. Top view at A; bottom view at B.

able, considering the expense of maintaining the tools and techniques needed to construct boards in a home shop. The results are professional and high-quality.

## PC-BOARD ASSEMBLY TECHNIQUES

### Cleanliness

Make sure your PC board and component leads are clean. Clean the entire PC board before assembly; clean each component before you install it. Corrosion looks dark instead of bright and shiny. Don't use sandpaper to clean your board. Use a piece of fine steel wool or a Scotchbrite cleaning pad to clean component leads or PC board before you solder them together.

### Installing Components

In a construction project that uses a PC board, most of the components are installed on the board. Installing components is easy — stick the components in the right board holes, solder the leads, and cut off the extra lead length. Most construction projects have a parts-placement diagram that shows you where each component is installed.

Getting the components in the right holes is called "stuffing" the circuit board. Inserting and soldering one component at a time takes too long. Some people like to put the components in all at once, and then turn the board over and solder all the leads. If you bend the leads a bit (about 20°) from the bottom side after you push them through the board, the components are not likely to fall out when you turn the board over.

Start with the shortest components — horizontally mounted diodes and resistors. Larger components sometimes cover smaller components, so these smaller parts must be installed first. If building a kit, follow the suggested order of mounting your parts if provided. Use adhesive tape to temporarily hold difficult components in place while you solder.

### PC-Board Soldering

To solder components to a PC board, bend the leads at a slight angle; apply the soldering iron to one side of the lead, and flow the solder in from the other side of the lead. See **Figure 23.21A**. Too little heat causes a bad or "cold" solder joint; too much heat can damage the PC board. Practice a bit on some spare copper stock before you tackle your first PC board project. After the connection is soldered properly, clip the lead flush with the solder.

Make sure you have the components in the right holes before you solder them. Components that have polarity, such as diodes, ICs and some capacitors must be oriented as shown on the parts-placement diagram.

**Figure 23.21** — The top photo shows how to solder a component to a PC board. Make sure that the component is flush with the board on the other side. Below is a solder bridge that has formed a short circuit between PC board traces.

Inspect solder connections. A bad solder joint is much easier to find before the PC board is mounted to a chassis. Look for any damage caused to the PC board by soldering. Look for solder "bridges" between adjacent circuit-board traces. Solder bridges (**Figure 23.21B**) occur when solder accidentally connects two or more conductors that are supposed to be isolated. It is often difficult to distinguish a solder bridge from a conductive trace on a tin-plated board. If you find a bridge, re-melt it and the adjacent trace or traces to allow the solder's surface tension to absorb it. Double check that each component is installed in the proper holes on the board and that the orientation is correct. Make sure that no component leads or transistor tabs are touching other components or PC board connections. Check the circuit voltages before installing ICs in their sockets. Ensure that the ICs are oriented properly and installed in the correct sockets.

### 23.5.7 From Schematic to Working Circuit

Turning a schematic into a working circuit is more than just copying the schematic with components. One thing is usually true — you can't build it the way it looks on the schematic. The schematic describes the electrical connections, but it does not describe the mechanical layout of the circuit. Many

design and layout considerations that apply in the real world of practical electronics don't appear on the schematic.

## HOW TO DESIGN A GOOD CIRCUIT LAYOUT

A circuit diagram is a poor guide toward a proper layout. Circuit diagrams are drawn to be readable and to describe the electrical connections. They follow drafting conventions that have very little to do with the way the circuit works. On a schematic, ground and supply voltage symbols are scattered all over the place. The first rule of RF layout is — *do not layout RF circuits as their schematics are drawn!* How a circuit works in practice depends on the layout. Poor layout can ruin the performance of even a well-designed circuit.

The easiest way to explain good layout practices is to take you through an example. **Figure 23.22** is the circuit diagram of a two-stage receiver IF amplifier using dual-gate MOSFETs. It is only a design example, so the values are only typical. To analyze which things are important to the layout of this circuit, ask these questions:

- Which are the RF components, and which are only involved with AF or dc?
- Which components are in the main RF signal path?
- Which components are in the ground return paths?

Use the answers to these questions to plan the layout. The RF components that are in the main RF signal path are usually the most critical. The AF or dc components can usually be placed anywhere. The components in the ground return path should be positioned so they are easily connected to the circuit ground. Answer the questions, apply the answers to the layout and then follow these guidelines:

- Avoid laying out circuits so their inputs and outputs are close together. If a stage's output is too near a previous stage's input, the output signal can feedback into the input and cause problems.
- Keep component leads as short as practical. This doesn't necessarily mean as short as possible, just consider lead length as part of your design.
- Remember that metal transistor cases conduct, and that a transistor's metal case is usually connected to one of its leads. Prevent cases from touching ground or other components, unless called for in the design.

In our design example, the RF components are shown in heavy lines, though not all of these components are in the main RF signal path. The RF signal path consists of T1/C1, Q1, T2/C4, C7, Q2, T3/C11. These need to be positioned in almost a straight line, to avoid feedback from output to input. They form the backbone of the layout, as shown in **Figure 23.23A**.

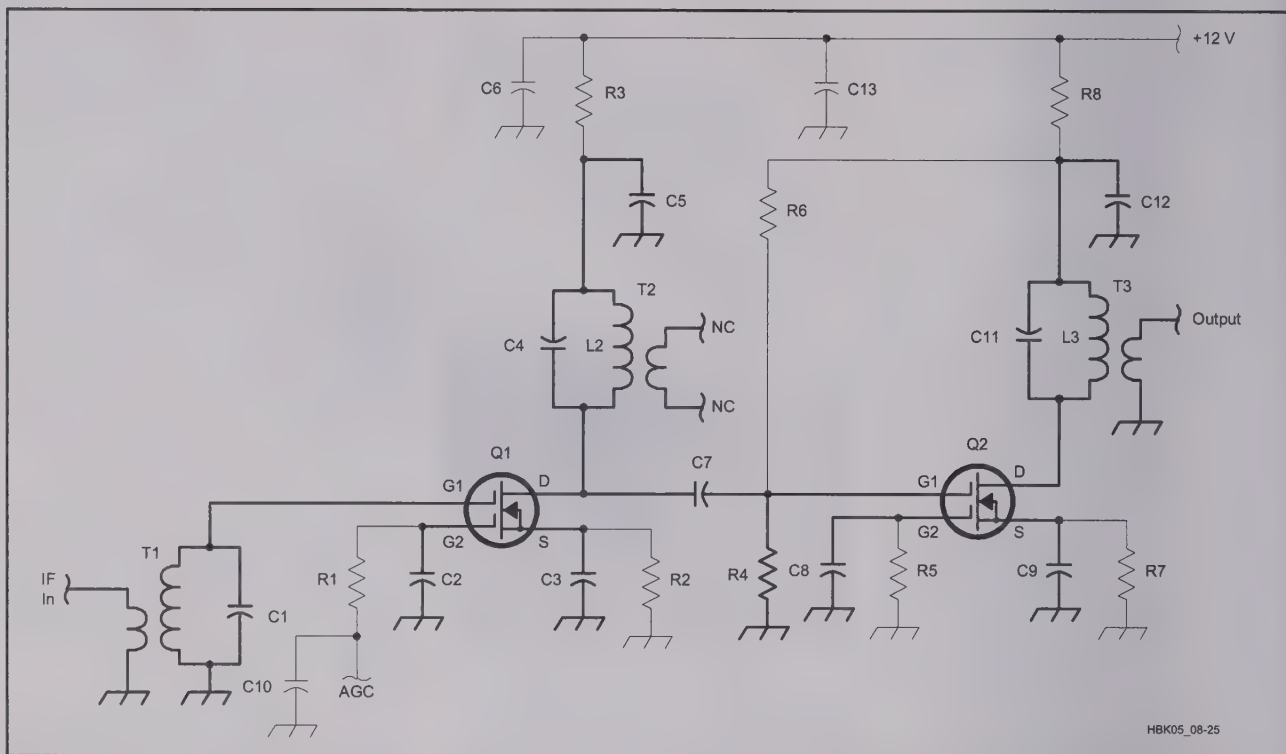

Figure 23.22 — The IF amplifier used in the design example. C1, C4 and C11 are not specified because they are internal to the IF transformers.

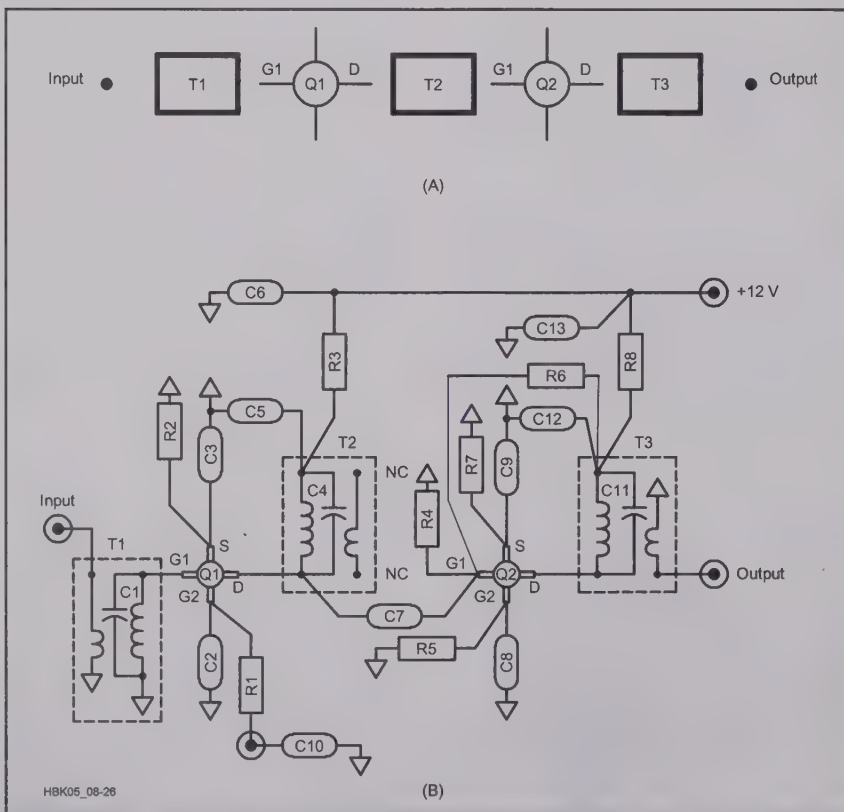

Figure 23.23 — Layout sketches. The preliminary line-up is shown in A; the final layout in B.

The question about ground paths requires some further thought — what is really meant by “ground” and “ground-return paths”? Some points in the circuit need to be kept at RF ground potential. The best RF ground potential on a PC board is a copper ground plane covering one entire side. Points in the circuit that cannot be connected directly to ground for dc reasons must be bypassed (“decoupled”) to ground by capacitors that provide ground-return paths for RF.

In Figure 23.23, the components in the ground-return paths are the RF bypass capacitors C2, C3, C5, C8, C9 and C12. R4 is primarily a dc biasing component, but it is also a ground return for RF so its location is important. The values of RF bypass capacitors are chosen to have a low reactance at the frequency in use; typical values would be 0.1  $\mu\text{F}$  at LF, 0.01  $\mu\text{F}$  at HF and 0.001  $\mu\text{F}$  or less at VHF. Not all capacitors are suitable for RF decoupling; the most common are disc ceramic capacitors. RF decoupling capacitors should always have short leads. Surface mount capacitors with no leads are ideal for bypassing.

Almost every RF circuit has an input, an output and a common ground connection. Many circuits also have additional ground connections, both at the input side and at the output side. Maintain a low-impedance path between input and output ground connections. The input ground connections for Q1

are the grounded ends of C1 and the two windings of T1. The two ends of an IF transformer winding are generally not interchangeable; one is designated as the “hot” end, and the other must be connected or bypassed to RF ground.) The capacitor that resonates with the adjustable coil is often mounted inside the can of the IF transformer, leaving only two component leads to be grounded as shown in Figure 23.22B.

The RF ground for Q1 is its source connection via C3. Since Q1 is in a plastic package that can be mounted in any orientation, you can make the common ground either above or below the signal path in Figure 23.23B, although the circuit diagram shows the source at the bottom. The practical circuit works much better with the source at the top, because of the connections to T2.

It’s a good idea to locate the hot end of the main winding close to the drain lead of the transistor package, so the other end is toward the top of Figure 23.23B. If the source of Q1 is also toward the top of the layout, there is a common ground point for C3 (the source bypass capacitor) and the output bypass capacitor C5. Gate 2 of Q1 can safely be bypassed toward the bottom of the layout.

C7 couples the signal from the output of Q1 to the input of Q2. The source of Q2 should be bypassed toward the top of the layout, in exactly the same way as the source of Q1. R4 is not critical, but it should be connected on the same side as the other components. Note how the pinout of T3 has placed the output connection as far as possible from the input. With this layout for the signal path and the critical RF components, the circuit has an excellent chance of working properly.

### DC Components

The rest of the components carry dc, so their layout is much less critical. Even so, try to keep everything well separated from the main RF signal path. One good choice is to put the 12 V connections along the top of the layout, and the AGC connection at the bottom. The source bias resistors R2 and R7 can be placed alongside C3 and C9. The gate-2 bias resistors for Q2, R5 and R6 are not RF components so their locations aren’t too critical. R7 has to cross the signal path in order to reach C12, however, and the best way to avoid signal pickup would be to mount R7 on the opposite side of the copper ground plane from the signal wiring. Generally speaking, 1/8 W or 1/4 W metal-film or carbon-film resistors are best for low-level RF circuits.

Actually, it is not quite accurate to say that resistors such as R3 and R8 are not “RF” components. They provide a high impedance to RF in the positive supply lead. Because of R8, for example, the RF signal in T2 is conducted to ground through C5 rather than ending up on the 12 V line, possibly causing

unwanted RF feedback. Just to be sure, C6 bypasses R3 and C13 serves the same function for R8. Note that the gate-1 bias resistor R6 is connected to C12 rather than directly to the 12 V supply, to take advantage of the extra decoupling provided by R8 and C13.

If you build something, you want it to work the first time, so don’t cut corners! Some commercial PC boards take liberties with layout, bypassing and decoupling. Don’t assume that you can do the same. Don’t try to eliminate “extra” decoupling components such as R3, C6, R8 and C13, even though they might not all be absolutely necessary. If other people’s designs have left them out, put them in again. In the long run it’s far easier to take a little more time and use a few extra components, to build in some insurance that your circuit will work. For a one-time project, the few extra parts won’t hurt your pocket too badly; they may save untold hours in debugging time.

A real capacitor does not work well over a large frequency range. A 10- $\mu$ F electrolytic capacitor cannot be used to bypass or decouple RF signals. A 0.1- $\mu$ F capacitor will not bypass UHF or microwave signals. Choose component values to fit the range. The upper frequency limit is limited by the series inductance,  $L_s$ . In fact, at frequencies higher than the frequency at which the capacitor and its

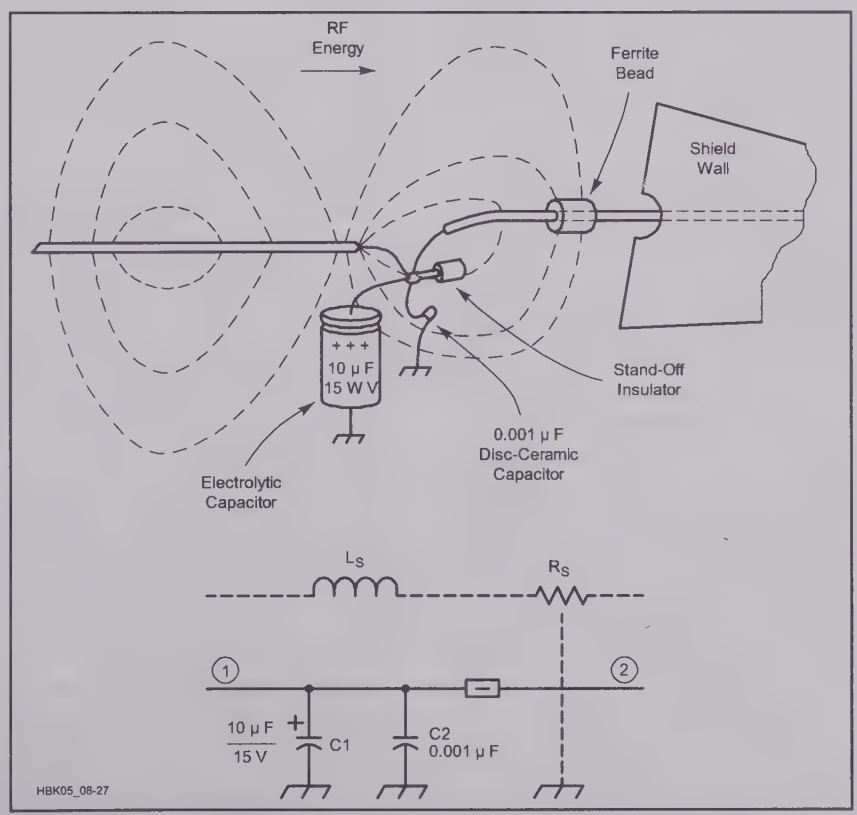

series inductance form a resonant circuit, the capacitor actually functions as an inductor. This is why it is a common practice to use two capacitors in parallel for bypassing, as shown in Figure 23.24. At first glance, this might appear to be unnecessary. However, the self-resonant frequency of C1 is usually 1 MHz or less; it cannot supply any bypassing above that frequency. However, C2 is able to bypass signals up into the lower VHF range. (This technique should not be applied under all circumstances as discussed in the section on Bypassing in the **RF Techniques** chapter.)

Let’s summarize how we got from Figure 23.22 to Figure 23.23B:

- Lay out the signal path in a straight line.
- By experimenting with the placement and orientation of the components in the RF signal path, group the RF ground connections for each stage close together, without mixing up the input and output grounds.
- Place the non-RF components well clear of the signal path, freely using decoupling components for extra measure.

### Practical Construction Hints

Now it’s time to actually construct a project. The layout concepts discussed earlier can be applied to nearly any construction technique. Although you’ll eventually learn from your own experience, the following

**Figure 23.24** — Two capacitors in parallel afford better bypassing across a wide frequency range.

guidelines give a good start:

- Divide the unit into modules built into separate shielded enclosures—RF, IF, VFO, for example. Modular construction improves RF stability, and makes the individual modules easier to build and test. It also means that you can make major changes without rebuilding the whole unit. RF signals between the modules can usually be connected using small coaxial cable.

- Use a full copper ground plane. This is your largest single assurance of RF stability and good performance.

- Keep inputs and outputs well separated for each stage, and for the whole unit. If possible, lay out all stages in a straight line. If an RF signal path doubles back or re-crosses itself it usually results in instability.

- Keep the stages at different frequencies well-separated to minimize interstage coupling and spurious signals.

- Use interstage shields where necessary, but don't rely on them to cure a bad layout.

- Make all connections to the ground plane short and direct. Locate the common ground for each stage between the input and the output ground. Single-point grounding may work for a single stage, but it is rarely effective in a complex RF system.

- Locate frequency-determining components away from heat sources and mount them so as to maximize mechanical strength.

- Avoid unwanted coupling between tuned circuits. Use shielded inductors or toroids rather than open coils. Keep the RF high-voltage points close to the ground plane. Orient air-wound coils at right angles to minimize mutual coupling.

- Use lots of extra RF bypassing, especially on dc supply lines.

- Try to keep RF and dc wiring on opposite sides of the board, so the dc wiring is well away from RF fields.

- Compact designs are convenient, but don't overdo it! If the guidelines cited above mean that a unit needs to be bigger, make it bigger.

## COMBINING TECHNIQUES

You can use a mixture of construction techniques on the same board and in most cases you probably should. Even though you choose one style for most of the wiring, there will probably be places where other techniques would be better. If so, do whatever is best for that part of the circuit. The resulting hybrid may not be pretty (these techniques aren't called "ugly construction" for nothing), but it will work!

Mount dual-in-line package (DIP) ICs in an array of drilled holes, then connect them using wired traces as described earlier. It is okay to mount some of the components using a ground-plane method, push pins or even wire wrap. On any one board, you may use

a combination of these techniques, drilling holes for some ICs, or gluing others upside down, then surface mounting some of the pins, and other techniques to connect the rest. These combination techniques are often found in a project that combines audio, RF and digital circuitry.

## A Final Check

No matter what construction technique is chosen, do a final check before applying power to the circuit! Things do go wrong, and a careful inspection minimizes the risk of a project beginning and ending its life as a puff of smoke! Check wiring carefully. Make a photocopy of the schematic and mark each connection and lead on the schematic with a red X or use highlighter to mark the circuit when you've verified that it's connected properly.

## 23.5.8 Tuning and Alignment

The task of performing adjustment or alignment can be difficult unless you are using the proper tools. There are variable inductors of various sizes and types and different types of variable capacitors as well as specialized potentiometers to adjust. Each different type of adjustable component requires its own specialized tool for making the adjustment. Failure to use the proper tool in the proper manner can result in damage to the component.

In RF circuits, the proximity of your hand or a metal object can greatly influence the apparent value of the variable component and make it difficult, if not impossible to adjust. For this reason, a number of plastic or ceramic tools are available to make this task as easy as possible and at a very low cost. An example is the Velleman "Plastic Tuning Needle Set" which can be found online ([www.velleman.eu](http://www.velleman.eu)) and is widely available for a few dollars. Sources such as Mouser, Digi-Key, Newark, and Allied sell both individual tools and assortments of tools. Specialized tools, if required, are usually available from the same vendor selling the adjustable component.

When choosing a tuning tool, use the tool that best fits the adjustment hole or slot. Tips that are too small can end up damaging the inside of the adjustment slot or hole, and tools that are too large can also damage these small components or their adjustment mechanism. Choose a tuning tool with a tip that exactly matches the component.

## VARIABLE INDUCTORS

Most variable inductors used in low-power RF circuits are a tiny coil of wire wound around a plastic form, with a threaded ferrite (or sometimes brass) slug in the center. For ferrite slug coils, inserting the slug into to coil increases the inductance and vice versa. (Brass slugs work oppositely and are

uncommon.) Some variable inductors are inside metal cans, which act as a shield to reduce coupling to nearby components. The slug either has a hexagonal hole or a slot for a tuning tool to adjust the position of the slug like turning a screw.

Do not use small metal screwdrivers or hex keys (Allen wrenches) to adjust these coils. The metal tool will alter the inductance when inserted, making adjustment unpredictable and frustrating. A metal tool can also damage the slug by cracking it as ferrite slugs are quite brittle, ruining the inductor. Plastic or plastic-tipped tools allow you to make the adjustment while keeping your hand far away and not damaging the slug. Most tuning tools also have a mark on them in the form of a dimple, a logo/identification or a stripe to help you count the number of times you rotate the tool.

## VARIABLE CAPACITORS

Variable capacitors not tuned with a shaft and knob usually have a screw-slot for adjustment. These include ceramic and mica trimmers, piston trimmers, and small air variables. Try using a plastic tool first but these adjustments are sometimes too stiff to use a plastic tool. Ceramic and plastic-tipped tools are available but not common in most electronics stores. Metal screwdrivers introduce enough capacitance to alter the value of these small capacitors but may be used in a series of small adjustments.

## POTENTIOMETERS

Multi-turn miniature potentiometers (a.k.a. "trim pots") usually have small metal adjusting screws. Resistance values are rarely sensitive to metal tools and so a miniature jeweler's screwdriver can be used. For RF circuits, however, use a plastic or ceramic screwdriver to avoid any possible interactions with the signals.

Larger potentiometers that are found inside equipment and that do not have a shaft are designed to be adjusted with a screwdriver-style tool. While a metal screwdriver can be used, a plastic tool eliminates any chance that the metal screwdriver could slip and come in contact with nearby components or leads. The metal screwdriver's shaft can also make accidental contact with wiring inside equipment.

## ADJUSTING HIGH VOLTAGE CIRCUITS

If high voltages are involved, such as during tube neutralization or bias voltage adjustment, safety precautions are important. If the adjustable component is located near an RF stage, the presence of your hand can influence the circuit, as well. Use plastic or ceramic screwdrivers for both slotted and Phillips-type screws. Be sure to use a tool that is long enough to keep your hands well away from any high voltage source! There

are extra long tools available for use in high voltage areas. Shops that repair vacuum tube musical instrument amplifiers may be able to help locate suitable tools — safety first!

## RESPECT ADJUSTMENT LIMITS

When making adjustments on any variable component, be sure not to force an adjustment beyond its range as that can cause permanent damage. For example, turning a slug all the way into or out of an adjustable inductor can begin to strip the tiny threads that hold the slug, making it difficult to perform future adjustments. If you feel resistance, stop, then look to see if the adjustment is at a limit. When an adjustment reaches a component's limit, that is usually an indication of a problem somewhere else in the circuit or, less frequently, that the component value has changed. Determine whether either is the case before proceeding.

In some circuits, adjustment is quite smooth and easy while others can be quite touchy, requiring patience and a steady hand to get the circuit adjusted properly. Take your time and watch your meter or oscilloscope for the desired changes. Use the dimples or marks on the tool to give a visual indication of how the adjustment is set or to count turns of a multi-turn adjustment. Keep notes if you are making multiple adjustments or if different adjustments interact.

Finally, don't be a "screwdriver technician" who adjusts components seemingly at random, hoping to get lucky and correct a problem. That usually results in more problems and even a completely non-functional piece of equipment requiring professional realignment or repair. Make small adjustments and if you don't see the results you were expecting, stop and figure out why before proceeding.

## 23.5.9 Other Construction Techniques

### WIRING

Select the wire used in connecting amateur equipment by considering: the maximum current it must carry, the voltage its insulation must withstand and its use.

To minimize leakage of RF that causes EMI, the power wiring and low-level signal wiring of all transmitters should use shielded wire or coaxial cable. Receiver and audio circuits may also require the use of shielded wire at some points for stability or the elimination of coupling to adjacent circuits. Coaxial cable is recommended for all 50  $\Omega$  circuits. It can also be used for *short* runs of high-impedance audio wiring.

When choosing wire, consider how much current it will carry. (See the Copper Wire Specifications table in the **Component Data and References** chapter for maximum cur-

rent-carrying capability, called *ampacity*.) Stranded wire is usually preferred over solid wire because stranded wire better withstands the inevitable bending that is part of building and troubleshooting a circuit. Solid wire is more rigid than stranded wire; use it where mechanical rigidity is needed or desired.

Wire with typical plastic insulation is good for voltages up to about 500 V. Use Teflon-insulated or other high-voltage wire for higher voltages. Teflon insulation does not melt when a soldering iron is applied. This makes it particularly helpful in tight places or large wiring harnesses. Although Teflon-insulated wire is more expensive, it is often available from industrial surplus houses.

Solid wire is often used to wire RF circuits in both receivers and transmitters. Bare soft-drawn tinned wire, #22 to #12 AWG (depending on mechanical requirements) is suitable. Avoid kinks by stretching a piece 10 or 15 feet long and then cutting it into short, convenient lengths. Run RF wiring directly from point to point with a minimum of sharp bends and keep the wire well-spaced from the chassis or other grounded metal surfaces. Where the wiring must pass through a chassis wall or shield, cut a clearance hole and line it with a rubber grommet. If insulation is necessary, slip spaghetti insulation or heat-shrink tubing over the wire. For power-supply leads, bring the wire through walls or barriers via a feedthrough capacitor.

In transmitters where the peak voltage does not exceed 500 V, shielded wire is satisfactory for power circuits. Shielded wire is not readily available for higher voltages — use point-to-point wiring instead. In the case of filament circuits carrying heavy current, it is necessary to use #10 or #12 AWG bare or enameled wire. Slip the bare wire through spaghetti then cover it with copper braid pulled tightly over the spaghetti. Slide the shielding back over the insulation and flow solder into the end of the braid; the braid will stay in place, making it unnecessary to cut it back or secure it in place. Clean the braid first so solder will flow into the braid with a minimum of heat.

### ENAMELED WIRE

When connecting enameled wire leads, care must be taken to be sure a good connection is made. There are two methods that can be used to remove the insulation. With Thermaleze-type enamel, the heat from a soldering iron can be used to remove the insulation. You will first need to turn up the heat on your soldering iron for best results. After adding some melted solder to your soldering tip, move the drop slowly along the desired length of the wire lead. Moving it slowly gives the insulation time to melt and the solder a chance to tin the now-exposed wire. The tinned leads will then easily solder to a PC board or other mounting system.

If using other kinds of enameled wire, an emery board or small file can be used to remove the insulation. (Using a knife to scrape off the enamel usually nicks the wire which will eventually break at that point.) Be sure you have removed it completely from the desired lead. Follow that up with your soldering iron and solder to tin the wire using a thin coating of solder. Be sure to not make the tinned surface so thick that the lead cannot fit through the PC board holes. Preparing the leads in this manner will give the best possibility for a clean and secure connection.

## HIGH-VOLTAGE TECHNIQUES

High-voltage wiring and construction requires special care. Read and follow the guidelines for high-voltage construction in the **Power Sources** chapter. You must use wire with insulation rated for the voltage it is carrying. Most standard hookup wire is inadequate above 300 or 600 V. High-voltage wire is usually insulated with Teflon or special multilayer plastic. Some coaxial cable is rated at 3700  $V_{RMS}$  (or more) *internally* between the center conductor and shield but the outer jacket rating is usually considerably lower.

### CABLE ROUTING

Where power or control leads run together for more than a few inches, they present a better appearance when bound together in a single cable. Plastic cable ties or tubing cut into a spiral are used to restrain and group wiring. Check with your local electronic parts supplier for items that are in stock.

To give a commercial look to the wiring of any unit, route any dc leads and shielded signal leads along the edge of the chassis. If this isn't possible, the cabled leads should then run parallel to an edge of the chassis. Further, the generous use of the tie points mounted parallel to an edge of the chassis, for the support of one or both ends of a resistor or fixed capacitor, adds to the appearance of the finished unit. In a similar manner, arrange the small components so that they are parallel to the panel or sides of the chassis.

### Tie Points

When power leads have several branches in the chassis, it is convenient to use fiber-insulated terminal strips as anchors for junction points. Strips of this kind are also useful as insulated supports for resistors, RF chokes and capacitors. Hold exposed points of high-voltage wiring to a minimum; otherwise, make them inaccessible to accidental contact.

### WINDING COILS

A detailed tutorial for winding coils by Robert Johns, W3JJP, titled "Homebrew Your Own Inductors!" from August 1997 *QST* can be found in the Radio Technology section of the ARRL TIS at [www.arrl.org/](http://www.arrl.org/)

**radio-technology-topics** under Circuit Construction. Understanding these techniques greatly simplifies coil construction.

Close-wound coils are readily wound on the specified form by anchoring one end of the length of wire (in a vise or to a doorknob) and the other end to the coil form. Straighten any kinks in the wire and then pull to keep the wire under slight tension. Wind the coil to the required number of turns while walking toward the anchor, always maintaining a slight tension on the wire.

To space-wind the coil, wind the coil simultaneously with a suitable spacing medium (heavy thread, string or wire) in the manner described above. When the winding is complete, secure the end of the coil to the coil-form terminal and then carefully unwind the spacing material. If the coil is wound under suitable tension, the spacing material can be easily removed without disturbing the winding. Finish space-wound coils by judicious applications of RTV sealant or hot-melt glue to hold the turns in place.

The “cold” end of a coil is the end at (or close to) chassis or ground potential. Wind coupling links on the cold end of a coil to minimize capacitive coupling.

### Winding Toroidal Inductors

Toroidal inductors and transformers are specified for many projects in this *Handbook*. The advantages of these cores include compactness and a self-shielding property. **Figures 23.25** and **23.26** illustrate the proper way to wind and count turns on a toroidal core.

The task of winding a toroidal core, when more than just a few turns are required, can be greatly simplified by the use of a homemade bobbin upon which the wire is first wound. A simple yet effective bobbin can be fashioned from a wooden popsicle stick. Cut a “V” notch at each end and first wind the wire coil on the popsicle stick lengthwise through the notches. Once this is done, the wound bobbin can be easily passed through the toroid’s inside diameter. While firmly grasping one of the wire ends against the toroidal core, the bobbin can be moved up, around, and through the toroidal core repeatedly until the wire has been completely transferred from the bobbin. The choice of bobbin used is somewhat dependent on the inside diameter of the toroid, the wire size, and the number of turns required.

Another method is to create a holder that allows you to grip the core, yet thread the wire easily around it. When winding toroids, be sure to seat the wire so it hugs the shape of the core and do not allow turns to overlap unless part of a twisted group of wires as in bifilar or trifilar windings. Do not pull the wire too tight as the thin wire used in some toroids can break if pulled too tightly.

When you wind a toroid inductor, count each pass of the wire through the toroid center

as a turn. You can count the number of turns by counting the number of times the wire passes through the center of the core. See **Figure 23.26A**.

### Multiwire Windings

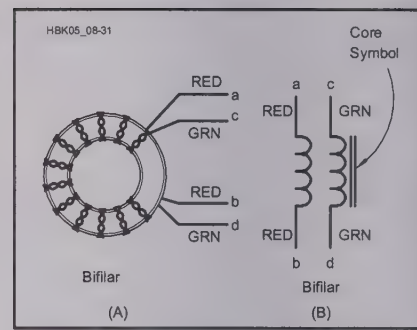

A bifilar winding is one that has two identical lengths of wire, which when placed on the core result in the same number of turns for each wire. The two wires are wound on the core side by side at the same time, just as if a single winding were being applied. An easier

**Figure 23.25** — The maximum-Q method for winding a single-layer toroid is shown at **A**. A 30° gap is best. Methods at **B** and **C** have greater distributed capacitance. **D** shows how to place a tap on a toroidal coil winding.

**Figure 23.26** — **A** shows a toroidal core with two turns of wire (see text). Large black dots, like those at **T1** in **B**, indicate winding polarity (see text).

**Figure 23.27** — Schematic and pictorial presentation of a bifilar-wound toroidal transformer.

and more popular method is to twist the two wires (8 to 15 turns per inch is adequate), then wind the twisted pair on the core. The wires can be twisted handily by placing one end of each in a bench vise. Tighten the remaining ends in the chuck of a small hand drill and turn the drill to twist the pair.

A trifilar winding has three wires, and a quadrifilar winding has four. The procedure for preparation and winding is otherwise the same as for a bifilar winding. **Figure 23.27** shows a bifilar toroid in schematic and pictorial form. The wires have been twisted together prior to placing them on the core. It is helpful, though by no means essential, to use wires of different color for multifilar windings. It is more difficult to identify multiple windings on a core after it has been wound. Various colors of enamel insulation are available, but it is not easy for amateurs to find this wire locally or in small-quantity lots. This problem can be solved by taking lengths of wire (enameled magnet wire), cleaning the ends to remove dirt and grease, then spray painting them. Ordinary aerosol-can spray enamel works fine. Spray lacquer is not as satisfactory because it is brittle when dry and tends to flake off the wire.

You may also identify bifilar and trifilar toroid lead pairs of identical colors by using a continuity checker. It is a good idea to check all toroids with an ohmmeter or continuity tester to be sure there are no shorts between different windings and that there is a good connection on the ends of each winding. Testing the leads after mounting can be difficult due to the circuit layouts, so be sure to test all toroids before mounting.

The winding sense of a multifilar toroidal transformer is important in most circuits. **Figure 23.26B** illustrates this principle. The black dots (called phasing dots) at the top of the **T1** windings indicate polarity. That is, points **a** and **c** are both start or finish ends of their respective windings. In this example, points **a** and **d** are of opposite polarity to provide push-pull voltage output from **Q1** and **Q2**.

## 23.6 CAD for PCB Design

[With numerous PCB design software packages available and low quantity, low cost PCB manufacturing services accepting orders electronically, the development of PCBs has never been easier for the amateur. As with any assembly or manufacturing process, it is important to understand the vocabulary and technology in order to achieve the desired result. Thus, this section provides a detailed description of the entire process of PCB design. — *Ed.*]

The primary goal of using software for printed circuit board (PCB) design is the production of so-called PCB artwork — the graphic design used to create the patterns of traces that establish connectivity on the PCB. Historically, PCB artwork was created by hand on clear film using black tape and special decals which were then photographically reduced. However, free and low cost programs specifically for the PCB design process are now widely available. These programs not only allow the creation of artwork efficiently and accurately, but produce the required ancillary files for commercial production, exchange information with schematic capture software, produce Bills of Materials (parts lists), and even include such features as three dimensional visualization of the finished board. While artwork files can be shared with other people for PCB production, the “source” files used by the CAD program can typically only be used by other people who share the same program.

The decision to produce a PCB must take into account the nature of the circuit itself (for example, high frequency, low noise and high current circuits require additional care). Other considerations are time available, expense, available alternatives, quantity required, ability to share and replicate the design, and non-electrical characteristics such as thermal and mechanical, as well as desired robustness.

### 23.6.1 Overview of the PCB Design Process

The PCB design process begins with establishing the list of components in the circuit, the connections between the components, the physical outline/size of the board, and any other physical, thermal and electrical

constraints or design goals. Much of the connectivity and component information is reflected in the schematic for a circuit, so in many cases the PCB layout process begins by entering the schematic in a schematic capture program which may be integrated with the PCB CAD program or standalone. (Schematic capture is not required for PCB layout.) Once the schematic is entered, there may be other options possible such as simulating the circuit as described in the preceding sections. A clean, well organized schematic that is easily modified is an asset regardless of the circuit production and construction methods.

With input from the schematic and other information, the board outline is created, mounting and other holes placed, the components positioned, and the pattern of traces created. Once the layout is complete, in many cases it is possible to run a design rules check — the equivalent of a “spell checker.” Design rules include component connections and other information to check for problems related to connectivity and manufacturability. This step can save a great deal of time and expense by catching errors that could be fixed by hand, but would otherwise negate some of the benefits of a PCB.

The final step in the PCB layout program is to produce the collection of up to a dozen or so different files required for PCB production. In brief, the list includes the artwork for the pattern of traces, files for producing the board outline, solder masks, silk screens and holes.

The user then uploads the set of files to a PCB manufacturer. As quickly as two to three days later an envelope will be delivered with the freshly minted boards ready for assembly! Alternatively, the user may create the board “in house” using photomechanical or other processes based on the output files from the software.

### 23.6.2 Types of PCB Design Software

PCB software varies in features, function and cost, but for the radio amateur, the most interesting software for introductory use fall into the following categories: (See **Table 23.4**)

1) Open Source: PCB design software such as *GNU PCB* ([pcb.gpleda.org](http://pcb.gpleda.org) for *Linux*, *Mac OS X*) and *KiCad* ([kicad.sourceforge.net/wiki/index.php/Main\\_Page](http://kicad.sourceforge.net/wiki/index.php/Main_Page), for *Linux*, *Mac OS X*, and *Windows*), includes schematic capture) are free to use and have no artificial restrictions. Support is through user forums. Source code is available for the user to modify. *gschem* is a schematic capture sister program to *GNU PCB*.

2) Free, restricted use/restricted feature commercial: At least one company makes a version of their PCB and schematic software that is free to use for noncommercial purposes. Though it is restricted in number of layers (two) and maximum board size (4 × 3.2 inches), *Eagle PCB* is very popular among hobbyists. Files can be shared with others; the resulting industry standard files can be sent to nearly any PCB manufacturer. *Eagle* also contains a schematic entry program.

3) Free, restricted output commercial: Several PCB manufacturers offer schematic and PCB software with a proprietary output format tied to their PCB manufacturing service. *PCB123* from Sunstone Circuits ([www.sunstone.com](http://www.sunstone.com), for *Windows*) is one such offering, including schematic capture and layout software with up to four layers and board sizes up to 12 × 18 inches (double sided). For an additional fee (per design), industry standard files can be exported. Schematic entry is included. *Express PCB* ([www.expresspcb.com](http://www.expresspcb.com), for *Windows*) also provides schematic capture and PCB layout capability, tied to the Express PCB board fabrication services, including the fixed size (3.8 × 2.5 inches) Mini-board service. Advanced Circuit’s proprietary *PCB Artist* software ([www.4pcb.com](http://www.4pcb.com), for *Windows*) includes the ability to import netlists.

4. Low cost commercial: Many companies offer PCB and schematic software at a range of prices from \$50 to many thousands of dollars. Several versions are typically offered from each company, usually based on limitations on board size, schematic size/complexity and features such as auto-routing. Schematic entry may be included in some packages, or be a separate purchase.

keystrokes and other shortcuts that make operations such as routing traces much more efficient.

The first time designing and ordering a PCB can be daunting, so keep the initial job simple and pay attention to details (and read the instructions). When starting to use a specific software package, join a user's support group or forum if one is available. Request sample designs from other users and experiment with them to see how they are constructed and what files are required in the output data set. Once you are comfortable with the tools, you can begin on a design of your own.

### 23.6.3 Schematic Capture

The first step in PCB design is to create a schematic. It is possible to design a layout directly from a paper schematic, but it is much easier if the schematic is entered (or "captured") in electronic form. Schematic capture software has two outputs — the visual schematic and the component and connectivity data for subsequent PCB layout. These two separate requirements can make some operations during schematic entry more complicated than what would seem at first glance necessary. Bear in mind however, that the user is creating not only a clear graphic representation of the circuit, but of the underlying electrical connectivity.

Schematics are generally entered on a (virtual) page usually corresponding to common paper sizes — for example, 11 × 17 inches. More complicated schematics can span multiple pages, using special labels or components to indicate both visual and electrical connectivity. Often one can group logically related elements into a module that can then be referenced as a "black box" on a higher level schematic. For complex circuits, these features are extremely useful and make the difference between a jumbled diagram that is difficult to use and an organized, compact diagram that efficiently communicates the function and operation of the circuit.

## COMPONENTS

The components (resistors, capacitors, etc) on a schematic are either selected from an existing library or created by the user and stored in a custom library. It is also possible to find components and/or additional libraries on the Internet, although each program has its own specific format.

Each component includes a great deal more than shape and pin numbers. A typical component library entry includes:

**Symbol** — This is the graphic representation shown on the schematic. Many components may have the same symbol (eg, the op amp symbol may be shared by many different types of op amps)

**Pins** — For each pin or point of electrical connection, the component model may specify the pin number, label (eg, "V<sub>DD</sub>"), pin type (inverting, noninverting) or pin functions (common).

**PCB footprint** — A given component may be available in a number of different packages (eg, DIP or surface mount). Many components may have the same physical footprint (eg, op amps, comparators and optoisolators could all map to the same eight-pin DIP footprint). Footprints include the electrical connections (pins) as well as mechanical mounting holes and pad sizes, and the component outline.

**Value** — Many components such as resistors and capacitors will have identical information except for a difference in value. All ¼ W resistors may be instances of the same component, differing only in value and designator.

**Designator** — The unique reference to the component, such as R1, C7, D3. This is assigned when the component is used (often automatically and in sequence).

**Source information** — Part number, vendor, cost, etc. This information is for the Bill of Materials.

Components are typically placed on the schematic by opening a library and searching for the desired component. It may be tempting for the beginner to select a component that looks "about right" when faced by a long list of components in some libraries. However, even at this early stage, the physical PCB often must be taken into account. For example, either "1/8W Resistor, Axial" or "1W Resistor, Upright" will result in the same neatly drawn resistor symbol on the schematic but in the subsequent step of using the component data to create a PCB, the footprints will be dramatically different.

It is not at all uncommon to add new components to the library in the course of creating a schematic. Since many components are closely related to existing devices, the process often consists of selecting an existing schematic symbol, editing the shape and/or component data, creating a new label, and associating the part with an existing footprint. Adding a specific type of op amp is an example. This usually only needs to be done once since symbols can be saved in a personal library (and shared with others). It is usually easier to modify a part that is close to what is desired than to "build" a new part from scratch.

Component symbols can generally be rotated and flipped when placing the component instance on the schematic. Designators (R1, T34, etc) can be assigned and modified by the user although the default designators are usually selected sequentially.

## CONNECTIONS

The schematic software will have a mode for making electrical connections, called "nets." For example, one might click on the "draw net" symbol then draw a line using the mouse from one pin to another pin, using intermediate mouse clicks to route the line neatly with 90° turns on a uniform grid. Internally, the software must not only draw the visual line, but recognize what electrical connectivity that connection represents. So one must click (exactly) on a component pin to start or end a line or when making a connection between two lines that intersect, explicitly indicate a net-to-net connection (often with a special "dot" component). The connections on a schematic can often be assigned additional information, such as the desired width of the trace for this connection on the PCB or a name assigned by the user, such as "input signal."

Not all connections on a schematic are drawn. To make any schematic — electronic or hand drawn — more readable, conventions are often employed such as ground or power symbols or grouping similar connections into busses. Schematic capture software often supports these conventions. In some cases, components may be created with implicit power connections; in these cases the connections may not even be noted on the schematic but will be exported to the PCB software. However, as a general rule, software aimed at beginning PCB designers will not require the use of these advanced features.

Since it is often possible for component pins to be assigned attributes such as "power input", "output," "input," and so on, some schematic entry programs allow one to do an early design check. The program can then flag connections between two outputs, inputs that are missing connections, and so on. This is not nearly as helpful or complete as the Design Rule Check discussed below.

Free text can be placed on the schematic and there will be a text block in a corner for date, designer, version, title and the other information that identifies the schematic.

## NETLISTS

Once the components are placed and connections made, the schematic may be printed and any output files for the PCB layout software produced. The connectivity and component information needed for PCB layout is captured in a *netlist* file. The flow from schematic entry to PCB may be tightly integrated, in which case the user may switch between schematic and PCB like two views of the same design (which they are). However, most schematic software will generate a separate netlist to be used by PCB layout software, whether integrated or a separate program. The netlist can also be exported to an exter-

HBK0631

nal circuit simulation program or be used by an integrated simulator program. (See the **Computer-Aided Circuit Design** chapter for more information on circuit simulation.)

Netlists are often human readable text files and in most cases it is possible to create a netlist file manually. In the absence of a schematic entry program, this allows the user to take a hand drawn schematic, extract the connectivity information, and create the netlist for the PCB program to perform design rule checks. However, a netlist is generally not required for the PCB layout software; the user will also have the option to create a PCB on-the-fly, adding components and connections as they wish.

### ANNOTATION AND BILL OF MATERIALS

The important features of *forward* and *backward annotation* enter at the interface between schematic entry and PCB layout. It is not uncommon during the PCB layout process to either come across some design deficiency or realize that a change to the schematic could produce a design that would be easier to lay out. Likewise, a review of the schematic partway through the PCB layout process could reveal some needed design change. In the case of changes to the PCB (perhaps changing some pins on a connector to make routing easier), back annotation can propagate the changes “backward” to the schematic. The connectivity data will be updated; however the user may need to manually route the connection lines to neaten up the schematic. Likewise, changes to the schematic when the PCB is already (partially) routed are known as forward annotations and like the schematic, while the connectivity is updated the user will likely need to manually

route the traces. Neither forward nor back annotation is necessary, but is useful in keeping the schematic and PCB consistent. In their absence, the user is strongly urged to keep the schematic and PCB up to date manually to avoid time consuming problems later on.

Finally, the underlying data in the schematic can be used to produce a *Bill of Materials* (BOM). A BOM lists all the components of the schematic, typically ordered by reference designator(s), and may even be exportable for online ordering.

### 23.6.4 PCB Characteristics

#### PCB CONSTRUCTION

It is useful to know a little bit about PCB construction in order to make sense of the PCB design process. Figure 23.28 shows the basic structure of a PCB and some of its design elements (discussed in later sections). The laminate material provides a stable, insulating substrate with other known characteristics (thermal, dielectric, etc). Copper is bonded to one or both sides and selectively removed (usually chemically) to leave traces and pads. The pads provide points of connection for components. Though electrical connectivity is crucial, it is important to remember that the solder and pads provide mechanical and thermal connectivity as well. Pads may be drilled for mounting *through-hole* components or left undrilled for *surface-mount* components.

A separate electrochemical process plates the inside surface of *plated-through holes* to provide connectivity between upper and lower pads. Plated-through holes whose sole purpose is to provide electrical connectivity between layers of a PCB are known as *vias*,

Figure 23.29 — *Via* refers to a plated-through hole that connects one board layer to another. Vias are used for signal, power, or ground connections and even for ventilation. Different via types include through-hole (1); blind (2), and buried (3).

shown in Figure 23.29. Since they do not need to accommodate a component lead, their hole and pad size are smaller.

While two layer boards can mount components on either side, most PCBs will have a primary side called the *component side* upon which most of the components will be placed, and a *solder side* dominated by soldered pins and traces. Where high density is required, surface mount (and sometimes through-hole) devices are mounted on both sides, but this is considerably more complex.

Multi-layer boards are essentially a stack of two or more two-layer boards, with an insulating layer between each board. Plated-through holes make connections possible on every layer, and the laminate material is proportionally thinner so the entire multi-layer board is roughly the same thickness as a regular two-layer board. Vias that join selected, adjacent copper layers without connecting the entire stack of layers are called “buried” or “blind” vias and are typically only needed for very

dense designs. Multi-layer boards provide much more flexibility in routing signals and some other benefits such as dedicated layers for power distribution and grounding, but at often substantial additional cost.

## PCB MANUFACTURING SPECIFICATIONS

Unless the board is manufactured by the hobbyist, the PCB files are sent out to be manufactured by a *board house*. The most important issue for the amateur may be the pricing policies of the board house. Board size, quantity, delivery time, number of layers, number and/or density of holes, presence of solder masks and silk screens, minimum trace/separation width, type of board material, and thickness of copper will all influence pricing. One cost saving option of the past, a single-layer board, may not be offered with low-cost, low-volume services — two layers may be the simplest option and it results in a more robust board. [Note that most ordering specifications use English units of inches and ounces. Offshore board houses may use both English and metric units, or be metric-only. English units are used here because they are the most common encountered by hobbyists. — *Ed.*]

The second issue to consider is manufacturing capabilities and ordering options. These will vary with pricing and delivery times, but include the following:

**Board material and thickness** — FR-4 is the most popular board material for low volume PCBs; it consists of flame-resistant woven fiberglass with epoxy binder. Typical thickness is 0.062 inch ( $\frac{1}{16}$  inch), but thinner material is sometimes available. Flexible laminates are also available at greater cost and longer delivery time. Special board laminates for microwave use or high-temperature applications are also available.

**Copper thickness** — Expressed in ounces per square foot, typical values are 1-2 oz (1 oz corresponds to 0.0014 inch of thickness.) Other values may not be available inexpensively for small volumes. Inner layers on multi-layer boards may be thinner — check if this is important. Most board designs can assume at least 1 oz copper for double-sided boards; trace width is then varied to accommodate any high current requirements.

**Layers** — Two-layer boards are the most common. Because of the way PCBs are manufactured, the number of copper layers will be multiples of two. For quick-turn board houses, usually only two or four layer boards are available. PCBs with more than two layers will always be more expensive and often take longer to manufacture.

**Minimum hole size, number, and density of holes** — Minimum hole size will rarely be an issue, but unusual board designs with high hole density or many different hole sizes may

incur additional costs. Be sure to include vias when specifying minimum hole size. Some board houses may have a specific list of drill sizes they support. Note that you can often just edit the drill file to reduce the number of different drill sizes.

**Minimum trace width and clearance** — Often these two numbers are close in value. Most board houses are comfortable with traces at least 0.010 inch in width, but 0.008 and 0.006 inch are often available, sometimes at a higher cost.

**Minimum annular ring** — A minimum amount of copper is required around each plated-through hole, since the PCB manufacturing process has variations. This may be expressed as the ratio of the pad size to hole size, but more commonly as the width of the ring.

**Edge clearances** — Holes, pads, and traces may not be too close to the edge of the board.

**Board outline and copies** — There may be options to route the outline of the board in other shapes than a rectangle, perhaps to accommodate a specific enclosure or optimize space. If multiple copies of a board are ordered, some board houses can *panelize* a PCB, duplicating it multiple times on a single larger PCB (with a reduction in cost per board). These copies may be cut apart at the board house or small tabs left to connect the boards so assembly of multiple boards can be done as a single unit.

**Tin plating** — Once the traces and pads have been etched and drilled, tin plating is usually applied to the exposed copper surfaces for good soldering.

**Solder mask** — This is a solder-resistant coating applied after tin plating to both sides of the board covering everything except the component mounting pads. It prevents molten solder from bridging the gaps between pads and traces. Solder mask is offered except by the quickest turn services. Green is the most common color, but other colors may be available.

**Silkscreen** — This is the ink layer, usually white, on top of the solder mask that lays out component shapes and designators and other symbols or text. A minimum line width may be specified — if not specified, try to avoid thin lines. All but the quickest turn services typically offer silk screening on one or both sides of the PCB.

### 23.6.5 PCB Design Elements

The schematic may not note the specific package of a part, nor the width or length of a connection. The PCB, being a physical object, is composed of specific instances of components (not just “a resistor,” but a “ $\frac{1}{4}$ W, axial-lead resistor mounted horizontally,” for example) plus traces — connections between pins of components with a specific width

and separation from other conductors. Before discussing the process of layout, we briefly discuss the nature of components and connections in a PCB.

## COMPONENTS

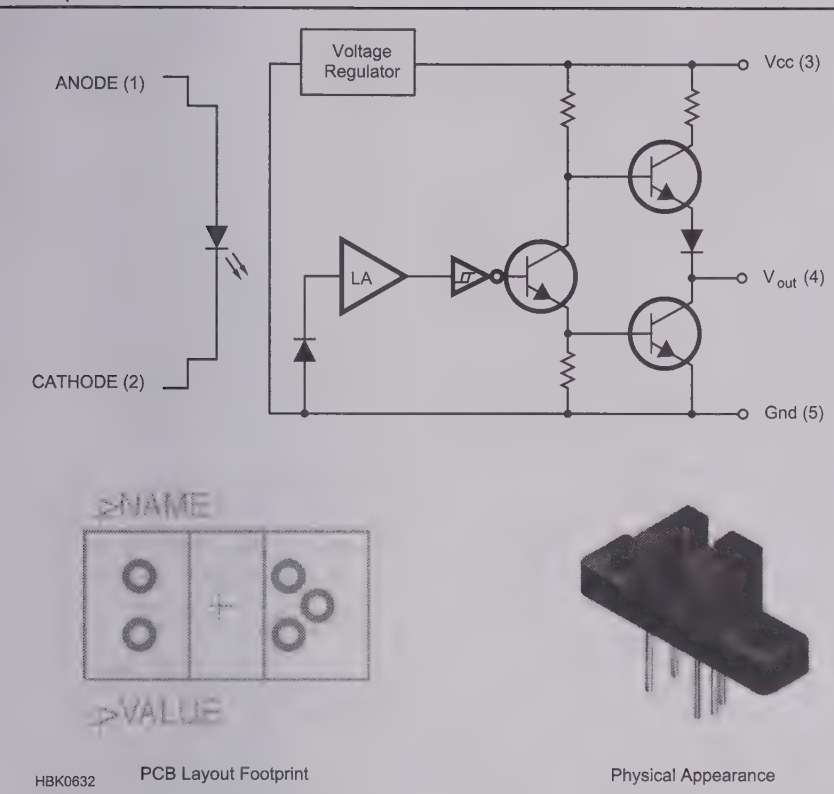

A component in a PCB design is very similar to its counterpart on the schematic. **Figure 23.30** shows the PCB footprint of an opto-interrupter, including graphics and connectivity information. The footprint of a component needs to specify what the footprint is like on all applicable copper layers, any necessary holes including non-electrical mounting holes or slots, and any additional graphics such as a silkscreen layer.

Take a common  $\frac{1}{4}$  W axial-lead resistor as an example. This footprint will have two pins, each associated with a pad, corresponding to the resistor’s two leads. This pad will appear on both the top and bottom layers of the board, but will also have a smaller pad associated with inner layers, should there be any. The hole’s size will be based on the nominal lead diameter, plus some allowance (typically 0.006 inch). The pad size will be big enough to provide a reasonable annular ring, but is usually much larger so as to allow good quality soldering. The pins will be labeled in a way that corresponds to the pin numbering on the schematic symbol (even though for this component, there is no polarity). A silkscreen layer will be defined, usually a box within which the value or designator will appear. The silkscreen layer is particularly useful for indicating orientation of parts with polarity.

More complicated parts may require additional holes which will not be associated with a schematic pin (mounting hole, for example). These are usually added to the part differently than adding a hole with a pad — in this case, the hole is desired without any annular ring or plating. The silkscreen layer may be used to outline the part above and

## PCB Design and EMC

While amateur projects are rarely subject to electromagnetic compatibility (EMC) standards, using good engineering practices when designing the board still reduces unwanted RF emissions and susceptibility to RF interference. For example, proper layout of a microprocessor circuit’s power and ground traces can reduce RF emissions substantially. Proper application of ground planes, bypass capacitors and especially shield connections can have a dramatic effect on RFI performance. (See the **RF Interference** chapter for more on RFI.) A good reference on RFI and PCB design is *Electromagnetic Compatibility Engineering*, by Henry Ott, WA2IRQ.

**Figure 23.30** — The PCB footprint for a component, such as the opto-interrupter shown here, combines electrical connectivity as defined in the part's schematic and the part's physical attributes.

beyond what is obvious from the pads, for example, a TO-220 power transistor laying on its back, or the plastic packaging around the opto-interrupter in Figure 23.30.

As with schematic entry, it is not uncommon to have to modify or create a new PCB footprint. Good technical drawings are often available for electronic parts; when possible the user should verify these dimensions against a real part with an inexpensive dial caliper. It is also useful to print out the finished circuit board artwork at actual size and do a quick check against any new or unusual parts.

## TRACES

Traces are the other main element of PCB construction — the copper pathways that connect components electrically. PCB traces are merely planar, flat wires — they have no magical properties when compared to an equivalent thickness of copper wire. At VHF/UHF/microwave frequencies and for high-speed digital signals, PCB traces act as transmission lines and these properties need to be accounted for, and can be used to advantage, in the design.

There are few constraints on traces apart from those such as minimum width and clearance imposed by the board house. They are created by chemical etching and can take arbitrary shapes. In fact, text and symbols may be

created on copper layers which may be handy if a silkscreen is not included. Traces may be of any length, vary in width, incorporate turns or curves, and so on. However, most traces will be a uniform width their entire length (a width they will likely share with other traces carrying similar signals), make neat 45° or 90° corners, and on two-layer boards have a general preference for either horizontal travel on the component side or vertical travel on the solder side.

The same considerations when building a circuit in other methods applies to PCB design, including current capacity (width of trace, thickness of copper), voltage (clearance to other signals), noise (shielding, guarding, proximity to other signals), impedance of ground and power supplies, and so on.

### 23.6.6 PCB Layout

With a schematic and netlist ready and all of the PCB characteristics defined, the actual layout of the PCB can begin.

## BOARD SIZE AND LAYERS

The first step in PCB layout is to create the board outline to contain not only the circuit itself and any additional features such as mounting holes. For prototype or one-off designs, the board is often best made a bit

larger to allow more space between components for ease in testing and debugging. (Some low cost or freeware commercial PCB software imposes limits on board size and number of components.) The board outline may be provided in a default size that the user can modify, or the user may need to enter the outline from scratch.

As discussed above, rectangular board shapes are generally acceptable, but many board houses can accommodate more complex outlines, including curves. These outlines will be routed with reasonable accuracy and may save an assembly step if the PCB needs a cutout or odd shape to fit in a specific location.

While the software may not require deciding at the start how many layers the PCB will use, this is a decision the user should make as early as possible, since the jump from two to four or more will have a big impact on routing the traces as well as cost!

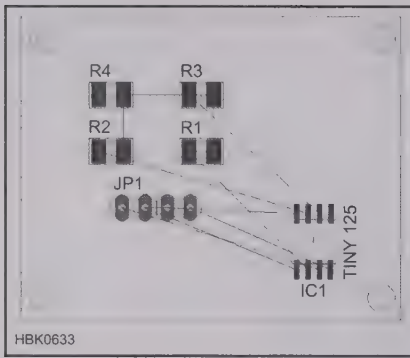

For your initial design, start with a two layer board for a simple circuit that you have already built and tested. This will reduce the number of decisions you have to make and remove some of the unknowns from the design process.

## COMPONENT PLACEMENT

Good component placement is more than half the battle of PCB layout. Poor placement will require complicated routing of traces and make assembly difficult, while good placement can lead to clean, easy-to-assemble designs.

The first elements placed should be mounting holes or other fixed location features. These are often placed using a special option selected from a palette of tools in the software rather than as parts from a library. Holes sufficient for a #4 or #6 screw are usually fine; be sure to leave room around them for the heads of the screws and nut driver or standoff below. These will be non-plated-through holes with no pad (though the board house may plate all the holes in a board, regardless).

Depending on the software and whether schematic capture was performed, the board outline may already contain the footprints of all the circuit components (sometimes stacked in a heap in one corner of the board) and the netlist will already be loaded. In this case, components may be placed by clicking and dragging the components to the desired location on the board. Most PCB programs have a “rat’s nest” option that draws a straight line for each netlist connection of a component, and this is a great aid in placement as the connections between components are apparent as the components are moved around. (See Figure 23.31) However, connections are shown to the nearest pin sharing that electrical connection; thus, components such as decoupling capacitors (which are often meant

**Figure 23.31** — The rat's nest view during PCB layout shows the direct connections between component pins. This helps the designer with component placement and orientation for the most convenient routing.

to be near a specific component) will show rats nest connections to the nearest power and ground pins and not the pins the designer may have intended. These will have to be manually edited.

The PCB layout software may offer *auto-placement* in which the components are initially arranged automatically. The beginner should certainly feel free to experiment and see how well this tool performs, but it is likely not useful for the majority of designs.

PCBs need not be arranged to precisely mimic the schematic, but it is appropriate to place components in a logical flow when possible so as to minimize the length of traces in the signal path. Sensitive components may need to be isolated or shielded from other components, and grounding and decoupling attended to, just as one would do with a point-to-point soldered version.

If the PCB is being designed “on-the-fly” or using an imported netlist, components may need to be selected and placed on the board manually using the libraries of parts in the PCB software. Not all design software makes this task simple or fast — in particular, the description of component footprints may be confusing. The use of highly condensed industry standard or non-uniform naming conventions often means the user needs to browse through the component library to see the different types of components. Resistors, diodes and capacitors seem particularly prone to a propagation of perplexing options. One solution is to open an example PCB layout and see what library element that designer used for resistors, LEDs and so on. Here, the PCB layout software directed at hobbyists may be superior in that there are fewer options than in professional programs.

During placement the user will find that different orientations of components simplify routing (for example, minimizing the number of traces that have to cross over each other

or reducing the trace lengths). Components are generally rotated in increments of 90°, although free rotation may be an option. The user is strongly urged to maintain the same orientation on like devices as much as possible. Mixing the position of pin 1 on IC packages, or placing capacitors, diodes, and LEDs with random orientation invites time consuming problems during assembly and testing that can be minimized by consistent, logical layout.

Placement and orientation of components can also affect how easily the final PCB can be assembled. Allow plenty of space for sockets, for example, and for ICs to be inserted and removed. Components with a mechanical interface such as potentiometers and switches should be positioned to allow access for adjustment. Any components such as connectors, switches, or indicators (eg, LEDs) should be positioned carefully, especially if they are to protrude through a panel. Often this will involve having the component overhang the edge of the PCB. (Beware of the required clearance between copper traces and pads to the edge of the PCB.)

Components should include a silkscreen outline that shows the size of the whole component — for example, a transistor in a TO-220 package mounted flat against the PCB should have an outline that shows the mounting hole and the extent of the mounting tab. The user should also consider the clearance required by any additional hardware for mounting a component, such as nuts and bolts or heatsinks — including clearance for nut drivers or other assembly tools.

Take care to minimize the mechanical stress on the PCB, since this can result in cracked traces, separated pads, or other problems. Utilize mounting holes or tabs when possible for components such as connectors, switches, pots. Use two-layer boards with plated-through holes even if the design can be single-layer. Component leads soldered to plated-through holes produce much stronger mechanical connections than single-layer boards in which the soldered pad is held only by the bond between copper and laminate and is easily lifted if too much heat or stress is imposed.

When prototyping a new design, add a few unconnected pads on the circuit board for extra components (eg, a 16 pin DIP, 0.4 inch spaced pads for resistors and other discrete components). Include test points and ground connections. These can be simply pads to which cut off leads can be soldered to provide convenient test points for ground clips or to monitor signals.

Wires or cables can be directly soldered to the PCB, but this is inconvenient when swapping out boards, and is not very robust. Connectors are much preferred when possible and often provide strain relief for the wire or cable. However, if a wire is directly

soldered to the PCB, the user should consider adding an unplated hole nearby just large enough to pass the wire including insulation. The wire can then be passed from the solder side through the unplated hole, then soldered into the regular plated-through hole. This provides some measure of strain relief which can be augmented with a dollop of glue if desired.

## ROUTING TRACES

After placing components, mounting holes and other fixed location features that limit component or trace placement, traces can be *routed*. That is, to complete all the connections between pins without producing short circuits.

Most PCB design programs allow components and traces to be placed on a regular grid, similarly to drawing programs. There may be two grids — a visible coarse pitch grid, and a “snap” fine pitch grid, to which components and other objects will be aligned when placed. It is good practice to use a 0.1 or 0.050 inch grid for component placement and to route traces on a 0.025 inch grid. While the “snap to grid” feature can usually be turned off to allow fine adjustment of placement, a board routed on a grid is likely to look cleaner and be easier to route.

The trace starts at a component pin and wends its way to any other pins to which it should be connected. Traces should start and end at the center of pads, not at the edge of a pad, so that the connection is properly recorded in the program's database. If a netlist has been loaded, most PCB software will display a rat's nest line showing a direct connection between pads. Once the route is completed, the rat's nest line for that connection disappears. The rat's nest line is rarely the desired path for the trace and often not the correct destination. For example, when routing power traces, the user should use good design sense rather than blindly constructing a Byzantine route linking pins together in random order. For this reason, routing the power and ground early is a good practice.

High speed, high frequency, and low noise circuits will require additional care in routing. In general, traces connecting digital circuits such as microprocessors and memories should not cross or be in close proximity to traces carrying analog or RF signals. Please refer to the **RF Techniques** chapter and earlier sections of this chapter, and the references listed at the end of this section.

Manual routing is a core skill of PCB design, whether or not auto-routing is used. The process is generally made as simple as possible in the software, since routing will take up most of the PCB design time. A trace will be routed on the copper layer currently selected. For a single-sided board, there is only one layer for routing; for a two-layer board

the component side and solder side can have traces; and for multi-layer boards additional inner layers can have traces. Often a single keystroke can change the active copper layer (sometimes automatically inserting a via if a route is in progress). The trace is drawn in straight segments and ends at the destination pin. When routing, 90° corners are normally avoided — a pair of 45° angles is the norm. **Figure 23.32** shows some sample traces.

It is good practice on a double-sided board to have one side of the board laid out with mostly horizontal traces, and the other side laid out with mostly vertical traces. A trace that needs to travel primarily vertically can do so on the side with vertical traces and use a via to move to the other side to complete the horizontal part of the route.

It is easiest during testing and debugging to route most traces on the bottom (solder) side of the board — traces on the component side often run under ICs or other components, making them hard to access or follow. It is often much clearer to connect adjacent IC or connector pins by routing a trace that leaves one pad, moves away from the IC or connector, then heads back in to the adjacent pad to connect. This makes it clear the connection on the assembled board is not a solder bridge, which a direct connection between the two pads would resemble.

It may be the case that no amount of vias or winding paths can complete a route. The one remaining tool for the PCB designer is a jumper — a wire added as a component during assembly just for the purpose of making a connection between two points on the board. Jumpers are most often required for single-sided boards; when the “jump” is rather small, uninsulated wire can be used. Jumpers are usually straight lines, and can be horizontal or vertical. Professional production PCBs use machine-insertable zero-ohm resistors as jumpers. Jumpers on double-sided boards are usually not viewed very favorably, but this is an aesthetic and efficiency issue, not a functional one.

Multi-layer boards clearly offer additional routing options, but again having some dominant routing direction (vertical or horizontal) on each layer is recommended, since mixing directions tends to cause routing problems. However, it is not uncommon to devote one or two inner layers to power and ground, rather than merely be additional layers for routing signals. This allows power and ground to be routed with minimal resistance and exposes the traces carrying interesting signals on the component and solder sides where they are available to be probed or modified. It is very difficult to modify traces on inner layers, needless to say!

Before routing too many traces, it is helpful to run the *Design Rule Check (DRC)* on the board. (See the section on Design Rule

Checking below.) Applied early and often, DRC can identify areas of concern when it is easiest to correct. For example, a given trace width may provide insufficient clearance when passing between two IC pads.

Some PCB design packages offer *auto-router* capability in which the software uses the component and connectivity data of the netlist and attempts to route the traces automatically. There are some circumstances when they save time, but view these tools with some caution. Auto-routers are good at solving the routing puzzle for a given board, but merely connecting all the pins correctly does not produce a good PCB design. Traces carrying critical signals may take “noisy” routes; components that should have short, low resistance connections to each other may have lengthy traces instead, and so on. More sophisticated auto-routers can be provided with extensive lists of “hints” to minimize these problems. For the beginner, the time spent conveying this design information to the auto-router is likely better spent manually routing the traces.

If an auto-router is used, at a minimum, critical connections should be first routed manually. These include sensitive signals, connections whose length should be minimized, and often power and ground (for both RFI and trace width reasons). Better still is to develop a sense of what a good layout looks like (which will come with practice and analyzing well designed boards), and learn at what stage the auto-router can be “turned loose” to finish the routing puzzle.

## TRACE WIDTH AND SPACING

All traces will have some width — the width may be the default width, the last width selected, or a width provided from data in the netlist. It may be tempting to route all but the power traces using the smallest trace width available from the board house (0.008 inch or smaller), since this allows the highest density of traces and eases routing. A better design practice is to use wider traces to avoid hard-to-detect trace cracking and improve board reliability. The more common traces 0.012 inch wide can be run in parallel on a 0.025 inch grid and can pass between many pads on 0.1 inch centers. Even wider traces will make the board easier to produce “in house,” though the exact process used (CNC routing, chemical etching, etc) will limit the resolution. Note that it is possible to “neck down” traces where they pass between IC or connector pads — that is, the regular, thick trace is run up close to the narrow gap between the pads, passes between the pads with a narrow width, then expands back to the original width. There is little reason to use traces wider than 0.030 inch or so for most signals (see **Table 23.5**) but power and ground trace widths should be appropriate for the current.

All traces have resistance, and this resistance is a function of the cross section of the trace (width times thickness) and the length. This resistance will convert electrical power to heat. If the heat exceeds a relatively high threshold, the trace becomes a fairly expensive and difficult-to-replace fuse. The

**Figure 23.32** — This example shows traces on the side of the PCB for horizontal routing. Traces are routed between pins of ICs. The smaller pads are for vias to a different layer of the PCB.

trace width should be selected such that for the worst case expected current, heat rise is limited to some threshold, often 10 °C. In practice, power traces (especially grounds) are often made as wide as practical to reduce resistance, and they greatly exceed the width required by heat rise limits alone.

Table 23.5 summarizes maximum currents for external (component and solder side) and internal traces for some common trace widths. Internal traces (on inner layers of multi-layer boards) can carry only about half the current of external traces for the same width since the internal layers do not dissipate heat to the ambient air like external traces can. (Note that trace widths are also sometimes expressed in “mils.” 1 mil = 0.001 inch; it is shorthand for “milli-inch”, not millimeter!)

There is no upper bound on the effective trace width. It is common to have large areas of the board left as solid copper. These *copper fill* areas can serve as grounds, heat sinks, or may just simplify board production (especially homemade boards). It is not a good idea to place a component hole in the middle of a copper fill — the copper is a very efficient heat sink when soldering. Instead, a “wagon wheel” pattern known as a thermal relief is placed (sometimes automatically) around the solder pad, providing good electrical connectivity but reducing the heat sinking. Often, copper fill areas can be specified using a polygon and the fill will automatically flow around pads and traces in that area, but can lead to isolated pads of copper.

In practice, most boards will have only two or perhaps three different trace widths; narrow widths for signals, and a thicker width for power (usually with a healthy margin).

One final note on trace width — vias are typically one size (ie, small), but multiple vias can be used to create low resistance connections between layers. Spacing the vias so their pads do not touch works well; the pads are then shorted on both top and bottom layers.

Voltage also figures into the routing equation, but instead of trace width, higher voltages should be met with an increased clearance between the trace and other copper. The IPC-2221 standard calls for a clearance of 0.024 inch for traces carrying 31-150 V (peak) and 0.050 inch for traces carrying 151-300 V (peak); these are external traces with no coating. (With the appropriate polymer solder mask coating, the clearances are 0.006 inch for 31-100 V and 0.016 inch for 101-300 V. Internal traces also have reduced clearance requirements.) Fully addressing the safety (and regulatory) issues around high voltage wiring is outside the scope of this brief review, however, and the reader is urged to consult UL or IPC standards.

## SILKSCREEN AND SOLDER MASK

The silkscreen (or “silk”) layer contains the

text and graphics that will be silkscreened on the top of the board, shown in **Figure 23.33**. Components will generally have elements on the silkscreen layer that will automatically appear, such as designators and values, but other elements must be created and placed manually. Common silkscreen elements include: Circuit name, date, version, designer (and call sign), company name, power requirements (voltage, current, and fusing), labels for connections (eg, “Mic input”), warnings and cautions, labels for adjustments and switches. A solid white rectangle on the silkscreen layer can provide a good space to write a serial number or test information.

The board house will specify the minimum width for silkscreen lines, including the width of text. Text and graphics can be placed anywhere on the solder mask, but not on solder pads and holes.

Many quick-turn board houses omit the silkscreen for prototype boards. As noted earlier, many of the text elements above can be placed on the external copper layers. Component outlines are not possible since the resulting copper would short out traces, but component polarization can be noted with symbols such as a hand-made “+” made from two short traces, or a “1” from a single short trace. (Note that some component footprints follow a practice of marking the pad for pin 1 with a square pad while others are round or oval.)

The solder mask is a polymer coating that is screened onto the board before the silkscreen graphics. As shown in **Figure 23.34**, it covers the entire surface of the board except for pads and vias. Solder masking prevents solder bridges between pads and from pads to traces during assembly and is particularly important for production processes that use wave soldering or reflow soldering. There is one solder mask layer for the top layer and another for the bottom layer. Internal layers do not need a solder mask. Solder masking may be omitted for a prototype board, but care must be taken to keep solder from creating unwanted bridges or short circuits.

**Figure 23.33** — The relationship between the layout’s top copper layer with traces and pads, the solder mask that covers the copper (a separate solder mask is required for the top and bottom layers of the PCB) and the silkscreen information that shows component outlines and designators.

During the PCB layout process, solder mask layers are generally not shown because they do not affect connectivity. **Figure 23.34** shows a typical PCB as it appears when the PCB layout process is complete.

## DESIGN RULE CHECK

If a netlist has been provided from the schematic capture program, a *design rule check (DRC)* can be made of the board's layout. The PCB software will apply a list of rules to the PCB, verifying that all the connections in the netlist are made, that there is sufficient clearance between all the traces, and so on. These rules can be modified based on the specific board house requirements. As stated above, it is useful to run the DRC even before all the traces have been routed — this can identify clearance or other issues that might require substantial re-routing or a different approach.

If the user has waited until all the routing is done before running the DRC, the list of violations can be daunting. However, it is often the case that many if not all of the violations represent issues that may prevent the board from operating as wished. Whenever possible, all DRC violations should be rectified before fabrication.

## 23.6.7 Preparation for Fabrication

### LAYOUT REVIEW

Once the board has passed DRC, the electrical connectivity and basic requirements for manufacturability have likely been satisfied. However, the design may benefit from an additional review pass. Turn off all the layers but the copper layer and examine the traces — often simplifications in routing will be apparent

without the distractions of the other copper layers. For example, a trace can be moved to avoid going between two closely spaced pins. Densely spaced traces could be spaced farther apart. There may be opportunities to reduce vias by routing traces primarily on one layer even if that now means both vertical and horizontal travel. Repeat the exercise for all the copper layers.

Review the mechanical aspects of the board as well, including the proximity of traces to hardware. If your prototype PCB does not have a solder mask, traces that run underneath components such as crystals in a conductive case or too close to mounting hardware can form a short circuit. An insulator must be provided or the trace can be re-routed.

### GENERATING OUTPUT FILES

Once the PCB design is complete, the complete set of design description files can be generated for producing the PCB. These are:

**Copper layers** — One file per copper layer. These are known as *Gerber files* and were text files of commands originally intended to drive a *photoplotter*. Gerber was the primary manufacturer of photoplotters, machines that moved a light source of variable width (apertures) from one location to another to draw patterns on photographic film. While photoplotters have been replaced by digital technology, the format used by Gerber has been standardized as RS-274X and is universally used except by PCB software tied to a specific manufacturer. RS-274X is related to RS-274D (“G-Code”) used by machinists to program CNC machinery but is an *additive* description (essentially saying “put copper here”), rather than describing the movements of a tool to remove material. A program is thus required to translate between Gerber and

G-Code if a CNC machine is used to make a PCB by mechanically removing copper.

**Drill file** — The file containing the coordinates and drill sizes for all the holes, plated or not. Also called the *NC* or *Excellon* file, some board houses may require a specific format for the coordinates, but these are usually available to be set as options in the PCB program. There is only one drill file for a PCB, since the holes are drilled from one side. (Exotic options such as buried vias will require more information.) Like RS-274X apertures, the drill file will generally contain a drill table.

**Silkscreen** — Also in RS-274 format. Some board houses can provide silkscreen on both sides of the board, which will require two files.

**Solder mask** — The solder mask file is used by the board house to create the solder mask. One file per side is required.

A Gerber preview program such as *Gerby* ([gerbv.gpleda.org](http://gerbv.gpleda.org), open source, Linux, Mac OS X) or *GC-Prevue* ([www.graphic-code.com](http://www.graphic-code.com), Windows) can be used to review the trace layout Gerber files. This is a good test — the board house will make the boards from the Gerber files, not the PCB design file. Gerber previewers can import the copper layers, silkscreen and drill files to verify they correspond and make sense.

Any of the layers can usually be printed out within the PCB program (and/or Gerber preview program) for reference and further inspection.

In addition to files for PCB production, PCB layout programs can also generate assembly diagrams, and in some cases can provide 3D views of what the assembled board will look like. These can be useful for documentation as well as verification of mechanical issues such as height clearance.

Sending the files to the PCB manufacturer or board house and ordering PCBs is explained on the manufacturing website or a customer service representative can walk you through the process. Some firms accept sets of files on CD-ROM and may also offer a design review service for first-time customers or on a fee basis.

## 23.7 Microwave Construction

Paul Wade, W1GHZ, updated this short tutorial to construction practices suitable for microwave frequency operation originally written by ARRL Laboratory Engineer, Zack Lau, W1VT. For more information on microwave equipment, read Paul's series of columns, "Microwavelengths," in *QST*.

Microwave construction is not only fun, but within the capabilities of most amateurs. To get on the air requires some degree of construction, since you can't buy a ready to go box. At a minimum, a few modules must be connected together with coax and power cables. At the other extreme, the whole station may be homebrewed from scratch, or from a kit.

The growth of mobile phones and wireless networking has caused a proliferation of microwave integrated circuits offering high performance at low cost. Some of these are also useful for ham applications, so that microwave construction has evolved from traditional waveguide "plumbing" to printed circuitry requiring surface-mount assembly of tiny components. Waveguide techniques are still valuable for some components, such as filters and antennas, so proficiency in both types of construction is valuable.

A problem we all face when building new microwave equipment is finding a nearby station to try it out. One solution is to convince a buddy to build a similar system, so that you will both have someone to work. If you have complementary skills, say one with metal and the other with surface-mount soldering, you can help each other. A larger group or club effort can be even better — someone with experience and test equipment can be an Elmer for the group.

### 23.7.1 Lead Lengths

Microwave construction is becoming more popular, but at these frequencies the size of physical component leads and PC-board traces cannot be neglected. Microwave construction techniques either minimize these stray values or make them part of the circuit design.

The basic consideration in microwave circuitry is short lead lengths, particularly

**Figure 23.35**— Current must always flow in a complete loop. This is particularly important at microwave frequencies where wavelengths are very short.

for ground returns. Current always flows in a complete loop with a return path through the "ground". (See **Figure 23.35**) The loop must be much smaller than a wavelength for a circuit to work properly — as the frequency gets higher, dimensions must get smaller. One area that requires particular care to ensure good ground return continuity is the transition from coax cable outside a cabinet to a PC board inside the cabinet.

At microwave frequencies, the mechanical aspects and physical size of circuits become very much a part of the design. A few millimeters of conductor has significant reactance at these frequencies. This even affects VHF and HF designs in which the traces and conductors resonate on microwave frequencies. If a high-performance FET has lots of gain in this region, a VHF preamplifier might also function as a 10 GHz oscillator if the circuit stray reactances were just right (or wrong!). You can prevent this by using shields between the input and output or by adding microwave absorptive material to the lid of the shielded module. (SHF Microwave sells absorptive materials.)

### 23.7.2 Metalworking

Waveguide construction requires some basic metalworking skills, which are also useful for assembly and packaging of microwave systems. Some minimal tools would be a hacksaw, drills, files, and layout tools. While a hand drill can suffice, an inexpensive drill press will make work more precise as well as safer. In metals, Dewalt Pilot Point drill bits make clean, accurate holes. Files and nibbling tools can make rectangular or odd-shaped holes.

Solder has a poor reputation for microwave losses — but, of course, it is essential. It does have higher resistance than copper or aluminum, but that only matters in locations of high

**Figure 23.36** — Larger assemblies may be soldered with a heat gun. A torch is better for high-temperature brazing.

current, for instance, the ground end of a high-Q quarter-wave resonator. Horn antennas and most waveguide structures have low Q so a clean solder joint, without excess blobs, has no effect. Traditional tin-lead solder works well; the silver solder with 1% silver has no performance advantage but looks pretty.

For things like waveguide and antennas that are too large for a soldering iron, a hot air gun does an excellent job. **Figure 23.36** shows the backshort of a waveguide transition as it is being soldered with a hot air gun. A small amount of paste flux (Kester SP-44) was applied to the waveguide end, and a ring of solder placed along the joint. Then heat is applied to the whole area until the solder melts and flows into the joint.

A torch can also be used for soldering, but tends to cause more oxidation of the metal. However, when a high-temperature brazed joint is desired, a torch is required. A MAPP gas torch and Silvaloy 15 (or Harris Stay-silv 15) silver brazing material, which requires no flux, are suitable for small and medium-sized components.

Many hams seem to think that silver plating is desirable, but it rarely makes a differ-

ence — it just looks much prettier. The only application in which silver plating has been shown to make a significant difference is in UHF cavities with sliding contacts. In most other places, copper losses are low enough so that little improvement is possible, and aluminum is fine for most uses.

### 23.7.3 Circuit Construction

Modular construction is a useful technique for microwave circuits. Often, circuits are tested by connecting their inputs and output to known 50  $\Omega$  sources and loads. Modules are typically kept small to prevent the chassis and PC board from acting as a waveguide, providing a feedback path between the input and output of a circuit, resulting in instability.

### PRINTED-CIRCUIT BOARDS AT MICROWAVES

A microwave printed circuit board (PCB) is typically double-sided, with transmission-line circuitry printed on one side and a ground plane on the far side. The ground return path is best provided by plated-thru holes (PTH) connecting the two sides with minimum length. Surface-mount components — integrated circuits, chip capacitors, and chip resistors — are soldered directly to printed pads and transmission lines, and to ground pads with embedded PTH. Many of the microwave integrated circuits come in really tiny packages, with lead pitch as small as 25 mils. See the section on Surface-Mount Technology earlier in this chapter for more information on this type of construction.

When using glass-epoxy PC board at microwave frequencies, the crucial board parameter is the thickness of the dielectric. It can vary quite a bit, in excess of 10%. This is not surprising; digital and lower-frequency analog circuits work just fine if the board is a little thinner or thicker than usual. Some of the board types used in microwave-circuit construction are a generic Teflon PC board, Duroid 5870 and 5880.

### TRANSMISSION LINES AND CONNECTORS

From a mechanical accuracy point of view, the most tolerant type of construction is based on waveguide. Tuning is usually accomplished via one or more screws threaded into the waveguide. It becomes unwieldy to use waveguide on the amateur bands below 10 GHz because the dimensions get too large.

Proper connectors are a necessary expense at microwaves. At 10 GHz, the use of the proper connectors is essential for repeatable performance. Do not connect microwave circuits with coax and pigtailed. It might work but it probably can't be duplicated. SMA connectors are common because they are small and work well. SMA jacks are sometimes

soldered in place, although 2-56 hardware is more common.

At 24 GHz and above, even waveguide becomes small and difficult to work with. At these frequencies, most readily available coax connectors work unreliably, so these higher bands are really a challenge. Special SMA connectors are available for use at 24 GHz.

### DEVICE SUBSTITUTION

It is important to copy microwave circuits exactly, unless you really know what you are doing. "Improvements," such as better shielding or grounding can sometimes cause poor performance. It isn't usually attractive to substitute components, particularly with the active devices. It may look possible to substitute different grades of the same wafer, such as the ATF13135 and the ATF13335, but these are really the same transistor with different performance measurements. While two transistors may have exactly the same gain and noise figure at the desired operating frequency, often the impedances needed to maintain stability at other frequencies can be different. Thus, the "substitute" may oscillate, while the proper transistor would work just fine.

You can often substitute MMICs (monolithic microwave integrated circuits) for one another because they are designed to be stable and operate with the same input and output impedances (50  $\Omega$ ).

The size of components used at microwaves can be critical — in some cases, a chip resistor 80 mils across is not a good substitute for one 60 mils across. Hopefully, the author of a construction project tells you which dimensions are critical, but you can't always count on this; the author may not know. It's not unusual for a person to spend years building just one prototype, so it's not surprising that the author might not have built a dozen different samples to try possible substitutions.

Figure 23.37 — Printed comb-line filter uses two chip capacitors in parallel to reduce loss.

### 23.7.4 Capacitors for Microwave Construction

Ordinary ceramic chip capacitors cost a few cents while microwave chip capacitors are more than a dollar each. All have them have parasitic resistance and inductance, but the microwave versions use lower-loss materials which make a difference at higher microwave frequencies. Ordinary ceramic capacitors work fine in non-critical applications like blocking and bypass capacitors, even up to 10 GHz. In critical areas, like low-noise or power amplifiers, microwave capacitors are preferred.

For applications requiring high-Q for low loss, like the printed comb-line filter in Figure 23.37, two ordinary capacitors in parallel as shown have lower loss than one expensive microwave capacitor. By paralleling, the parasitic resistances are also paralleled, cutting the resistance in half. An additional advantage is that combinations can be chosen to yield non-standard capacitance values. We might apply this trick to really demanding applications, like high-power solid-state amplifiers, by paralleling microwave capacitors to reduce losses.

### 23.7.5 Tuning and "No-Tune" Designs

Microwave construction does not always require tight tolerances and precision construction. A fair amount of error can often be tolerated if you are willing to tune your circuits, as you do at MF/HF. This usually requires the use of variable components that can be expensive and tricky to adjust.

Proper design and construction techniques, using high precision, can result in a "no-tune" microwave design. To build one of these no-tune projects, all you need do is buy the parts and install them on the board. The circuit tuning has been precisely controlled by the board and component dimensions so the project should work.

One tuning technique you can use with a microwave design, if you have the suitable test equipment, is to use bits of copper foil or EMI shielding tape as "stubs" to tune circuits. Solder these small bits of conductor into place at various points in the circuit to make reactances that can actually tune a circuit. After their position has been determined as part of the design, tuning is accomplished by removing or adding small amounts of conductor, or slightly changing the placement of the tuning stub. The size of the foil needed depends on your ability to determine changes in circuit performance, as well as the frequency of operation and the circuit board parameters. A precision setup that lets you see tiny changes allows you to use very small pieces of foil to get the best tuning possible.

## 23.8 Mechanical Fabrication

Most projects end up in some sort of an enclosure, and most hams choose to purchase a ready-made chassis for small projects, but some projects require a custom enclosure. Even a ready-made chassis may require a fabricated sheet-metal shield or bracket, so it's good to learn something about sheet-metal and metal-fabrication techniques.

Most often, you can buy a suitable enclosure. These are sold by most electronics distributors. Select an enclosure that has plenty of room. A removable cover or front panel can make any future troubleshooting or modifications easy. A project enclosure should be strong enough to hold all of the components without bending or sagging; it should also be strong enough to stand up to expected use and abuse.

### 23.8.1 Cutting and Bending Sheet Metal

Enclosures, mounting brackets and shields are usually made of sheet metal. Most sheet metal is sold in large sheets, 4 to 8 feet or larger. It must be cut to the size needed.

Most sheet metal is thin enough to cut with metal shears or a hacksaw. A jigsaw or band saw makes the task easier. If you use any kind of saw, select a blade that has teeth fine enough so that at least two teeth are in contact with the metal at all times.

If a metal sheet is too large to cut conveniently with a hacksaw, it can be scored and broken. Make scratches as deep as possible along the line of the cut on both sides of the sheet. Then, clamp it in a vise and work it back and forth until the sheet breaks at the line. Do not bend it too far before the break begins to weaken, or the edge of the sheet might bend. A pair of flat bars, slightly longer than the sheet being bent, make it easier to hold a sheet firmly in a vise. Use "C" clamps to keep the bars from spreading at the ends.

Smooth rough edges with a file or by sanding with a large piece of emery cloth or sandpaper wrapped around a flat block.

### 23.8.2 Finishing Aluminum

Give aluminum chassis, panels and parts a sheen finish by treating them in a caustic bath. (See the information on chemical safety at the beginning of this chapter.) Use a plastic container to hold the solution and wear both safety goggles and protective clothing while treating aluminum. Ordinary household lye can be dissolved in water to make a bath solution. Follow the directions on the container. A strong solution will do the job more rapidly.

Stir the solution with a non-metal utensil until the lye crystals are completely dissolved. If the lye solution gets on your skin,

wash with plenty of water. If you get any in your eyes, immediately rinse with plenty of clean, room-temperature water and seek medical help. It can also damage your clothing, so wear something old. Prepare sufficient solution to cover the piece completely. When the aluminum is immersed, a very pronounced bubbling takes place. Provide ventilation to disperse the escaping gas. A half hour to two hours in the bath is sufficient, depending on the strength of the solution and the desired surface characteristics.

### 23.8.3 Chassis Working

With a few essential tools and proper procedure, building radio gear on a metal chassis is a relatively simple matter. Aluminum is better than steel, not only because it is a superior shielding material, but also because it is much easier to work and provides good chassis contact when used with secure fasteners.

Spend sufficient time planning a project to save trouble and energy later. The actual construction is much simpler when all details are worked out beforehand. Here we discuss a large chassis-and-cabinet project, such as a high-power amplifier. The techniques are applicable to small projects as well.

Cover the top of the chassis with a piece of wrapping paper or graph paper. Fold the edges down over the sides of the chassis and fasten them with adhesive tape. Place the front panel against the chassis front and draw a line there to indicate the chassis top edge.

Assemble the parts to be mounted on the chassis top and move them about to find a satisfactory arrangement. Consider that some will be mounted underneath the chassis and ensure that the two groups of components won't interfere with each other.

Place controls with shafts that extend through the cabinet first, and arrange them so that the knobs will form the desired pattern on the panel. Position the shafts perpendicular to the front chassis edge. Locate any partition shields and panel brackets next, then sockets and any other parts. Mark the mounting-hole centers of each part accurately on the paper. Watch out for capacitors with off-center shafts that do not line up with the mounting holes. Do not forget to mark the centers of socket holes and holes for wiring leads. Make the large center hole for a socket *before* the small mounting holes. Then use the socket itself as a template to mark the centers of the mounting holes. With all chassis holes marked, center-punch and drill each hole.

Next, mount on the chassis the capacitors and any other parts with shafts extending to the panel. Fasten the front panel to the chassis temporarily. Use a machinist's square to extend the line (vertical axis) of any control

## Repurposing Obsolete Equipment Cabinets

One of the best deals at a hamfest or flea market might not be anything having to do with radio — yet! Obsolete industrial and commercial equipment may not be useable in the ham station but their metal enclosures are top-quality. Purchasing one of these cabinets new would cost hundreds of dollars but the surplus equipment is often sold very cheaply. Reusing the cabinets is easy and stripping the electronics often results in a large collection of hardware and electronic components that can be re-used in ham equipment. The overall process is illustrated in a January/February 2017 *QEX* article by Scott Roleson, KC7CJ included with this book's online supplemental material. Keep an eye out for these bargains everywhere, even at garage sales!

shaft to the chassis front and mark the location on the front panel at the chassis line. If the layout is complex, label each mark with an identifier. Also mark the back of the front panel with the locations of any holes in the chassis front that must go through the front panel. Remove the front panel.

### MAKING ENCLOSURES WITH PC BOARD MATERIAL

Much tedious sheet-metal work can be eliminated by fabricating chassis and enclosures from copper-clad printed-circuit-board material. While it is manufactured in large sheets for industrial use, some hobby electronics stores and surplus outlets market usable scraps at reasonable prices. PC-board stock cuts easily with a small hacksaw. The nonmetallic base material isn't malleable, so it can't be bent. Corners are easily formed by holding two pieces at right angles and soldering the seam. This technique makes excellent RF-tight enclosures. If mechanical rigidity is required of a large copper-clad surface, solder stiffening ribs at right angles to the sheet.

Figure 23.38 shows the use of PC-board stock to make a project enclosure. This enclosure was made by cutting the pieces to size then soldering them together. Start by laying the bottom piece on a workbench, then placing one of the sides in place at right angles. Tack-solder the second piece in two or three places, then start at one end and run a bead of solder down the entire seam. Use plenty of solder and plenty of heat. Continue with the rest of the pieces until all but the top cover is in place.

In most cases, it is better to drill all needed

les in advance. It can sometimes be difficult to drill holes after the enclosure is soldered together.

You can use this technique to build enclosures, subassemblies or shields. This technique is easy with practice; hone your skills on a few scrap pieces of PC-board stock.

### 23.8.4 Drilling Techniques

Before drilling holes in metal with a hand drill, indent the hole centers with a center punch. This prevents the drill bit from “walking” away from the center when starting the hole. Pre-drill holes greater than 1/2 inch in diameter with a smaller bit that is large enough to maintain the flat spot at the large bit’s tip. When the metal being drilled is thinner than the depth of the drill-bit tip, back up the metal with a wood block to smooth the drilling process. The chuck on the common hand drill is limited to 3/8 inch bits. Some bits are much larger, with a 3/8 inch shank. If necessary, enlarge holes with a reamer or round file. For very large or odd-shaped holes, drill a series of closely spaced small holes just inside of the desired opening. Cut the metal remaining between the holes with a cold chisel and file or grind the hole to its finished shape. A deburring tool also works well for such holes. Use socket-hole punches to make socket holes and other large holes in an aluminum chassis. Drill a guide hole for the punch center bolt, assemble the punch with the bolt through the guide hole and tighten the bolt to cut the desired hole. Oil the threads of the bolt occasionally.

Cut large circular holes in steel panels or chassis with an adjustable circle cutter (“fly cutter”) in a drill press at low speed. Occasionally apply machine oil to the cutting groove to speed the job. Test the cutter’s diameter setting by cutting a block of wood or scrap material first.

Remove burrs or rough edges that result from drilling or cutting with a burr-remover, round or half-round file, a sharp knife or chisel. Keep an old chisel sharpened and available for this purpose.

### 23.8.5 Construction Notes

If a control shaft must be extended or insulated, a flexible shaft coupling with adequate insulation should be used. Satisfactory support for the shaft extension, as well as electrical contact for safety, can be provided by means of a metal panel bushing made for the purpose. These can be obtained singly for use with existing shafts, or they can be bought with a captive extension shaft included. In either case the panel bushing gives a solid feel to the control. The use of fiber washers between ceramic insulation and metal brackets, screws or nuts will prevent the ceramic parts from breaking.

### PAINTING

Painting is an art, but, like most arts, successful techniques are based on skills that can be learned. The surfaces to be painted must be clean to ensure that the paint will adhere properly. In most cases, you can wash the item to be painted with soap, water and a mild scrub brush, then rinse thoroughly. When it is dry, it is ready for painting. Avoid touching it with your bare hands after it has been cleaned. Your skin oils will interfere with paint adhesion. Wear rubber or clean cotton gloves.

Sheet metal can be prepared for painting by abrading the surface with medium-grade sandpaper, making certain the strokes are applied in the same direction (not circular or random). This process will create tiny grooves on the otherwise smooth surface. As a result, paint or lacquer will adhere well. On aluminum, one or two coats of zinc chromate primer applied before the finish paint will ensure good adhesion.

Keep work areas clean and the air free of dust. Any loose dirt or dust particles will probably find their way onto a freshly painted project. Even water-based paints produce some fumes, so properly ventilate work areas.

Select paint suitable to the task. Some paints are best for metal, others for wood and so on. Some dry quickly, with no fumes; others dry slowly and need to be thoroughly ventilated. You may want to select rust-preventative paint for metal surfaces that might be subjected to high moisture or salts.

Most metal surfaces are painted with some sort of spray, either from a spray gun or from spray cans of paint. Either way, follow the manufacturer’s instructions for a high-quality job.

### PANEL LAYOUT AND LABELING

There are many ways to layout and label a panel. Some builders don’t label any controls or jacks, relying on memory to figure what does what. Others use a marking pen to label controls and inputs. Decals and dry transfers have long been a staple of home brewing. Label makers that print on clear or colored tape are used by many.

With modern computers and available software, it is not hard to lay out professional looking panels. One can use a standard drawing program for the layout. The grids available on these drawing programs are sufficient to make sure that everything is lined up squarely. If the panel label is laid out before the panel is drilled for controls, a copy of the label can be used as a drill template.

Computer-aided design (CAD) programs can also be used to lay out and label panels, although they can have a steep learning curve and may be overkill for many applications.

Surplus meters often find their way into projects. Unfortunately the meter faces usually do not have an appropriate scale for the project at hand. Relabeling meters has long been a mainstay to make home brew gear look professional. With the advent of computers this job has been made very easy. A software package, *MeterBasic*, by Jim Tonne, W4ENE, available with the downloadable supplemental content, is very easy to use and results in professional looking meters that indicate exactly what you want them to indicate.

# Assembling a Station

Although many hams might not build a major project, such as a transmitter, receiver or amplifier, they do have to assemble the various components into a working station. There are many benefits to be derived from assembling a safe, comfortable, easy-to-operate collection of radio gear, whether the station is at home, in the car or in the field. Configuring and operating a remote-control station is becoming very common. Ken Norris, KK9N, maintains the material on remote control that was originally contributed by K6VVA. Such topics as station location, grounding and bonding, power sources, station layout, and cable routing are also covered.

## 24.1 Fixed Stations

Regardless of the type of installation you are attempting, good planning greatly increases your chances of success. Take the time to think the project all the way through, consider alternatives, and make rough measurements and sketches during your planning and along the way. You will save headaches and time by avoiding "shortcuts." What might seem to save time now may come back to haunt you with extra work when you could be enjoying your shack.

One of the first considerations should be to determine what type of operating you intend to do. While you do not want to strictly limit your options later, you need to consider what you want to do, how much you have to spend and what room you have to work with. There is a big difference between a casual operating position and a "big gun" contest station, for example.

### 24.1.1 Selecting a Location

Selecting the right location for your station is the first and perhaps the most important step in assembling a safe, comfortable, convenient station. The exact location will depend on the type of home you have and how much space can be devoted to your station. Fortunate amateurs will have a spare room to devote to housing the station; some may even have a separate building for their exclusive use. Most must make do with a spot in the cellar or attic, or a corner of the living room is pressed into service.

Examine the possibilities from several angles. A station should be comfortable; odds are good that you'll be spending a lot of time there over the years. Some unfinished basements are damp and drafty — not an ideal environment for several hours of leisurely hamming. Attics have their drawbacks, too; they can be stifling during warmer months. If possible, locate your station away from the heavy traffic areas of your home. Operation of your station should not interfere with family life. A night of chasing DX on 80 meters may be exciting to you, but the other members of your household may not share your enthusiasm.

Keep in mind that you must connect your station to the outside world. The location you choose should be convenient to a good power source and an adequate ground. If you use a computer, you may need access to the Internet. There should be a fairly direct route to the outside for running antenna feed lines, rotator control cables and the like.

Although most homes will not have an "ideal" space meeting all requirements, the

right location for you will be obvious after you scout around. The amateurs whose stations are depicted in **Figures 24.1** through **24.3** all found the right spot for them. Weigh the trade-offs and decide which features you can do without and which are necessary for your style of operation. If possible pick an area large enough for future expansion.

### 24.1.2 Station Grounding and Bonding

As discussed in the **Safety** chapter, the station's ground system is very important and serves three purposes: ac safety, lightning protection, and RF management. With some attention to detail and planning, your station can be designed to satisfy all three needs from the start. This section is limited to providing general guidelines for grounding and bonding. Additional information is available from the ARRL's website in the Technology section under the Radio Technology Topics page's group of Safety articles and resources. The ARRL's *Grounding and Bonding for the Radio Amateur* collects a great deal of information into a single book for convenient reference with guidelines for station builders.

#### AC SAFETY

The **Safety** chapter covers the basic elements of how ac power is configured in residences, including the requirements for grounding and bonding of equipment and earth connections. Make sure your station wiring complies with all ac wiring requirements.

Before building a station or modifying an existing station, start by making sure your existing ac wiring is in good shape. Before you begin, if you are new to ac wiring or uncomfortable around it, get a professional to do the job or have an experienced person

show you how to do it. Treated with respect and following simple safety rules, working on ac wiring is safe. This is a good time to read the safety section of any wiring handbook or guide, even if you *think* you know what you're doing.

All branch circuits must have a ground conductor that runs back to the service panel. The ground conductor should be at least as large as the current-carrying conductors so it can handle the same current overloads without causing a fire hazard. The branch circuit ground conductor is almost always one wire in a multi-conductor non-metallic (NM) cable, usually referred to by its trade name, Romex. Inside the cable sheath, the wire is usually bare copper but it can also be have insulation that is green or green-with-yellow-stripes. Make sure the ac service entry ground rod or other earth connection is present and that all wiring to it is sufficiently heavy and that all connecting hardware is in good condition.

Along with the residence's ac service entry ground rod, additional ground rods are often installed for panels where feed lines enter a building, for antennas and towers, and a direct connection to the station's bonding bus. All of these external earth connections must be bonded together using heavy wire or strap.

Although it has been long recommended in Amateur Radio articles and books, do not use a metal cold water pipe as a ground electrode. Those recommendations were made in an era when copper and galvanized pipe were used for all water service plumbing. Plastic pipe is now the standard and mixed systems of copper and plastic pipe are common. Your local building codes will specify how the pipes inside your home should or shouldn't be connected together for electrical grounding purposes.

A bonding bus is a good way for connecting equipment together and also provides a good way to make ac safety grounding connections. Installed behind or under your equipment, the bus can be any heavy metal conductor — copper or aluminum are both available and relatively inexpensive. Strap, pipe, or even heavy wire will do. Connect the bus to the ac safety ground conductor at a power outlet. Only one connection is needed. Then connect the enclosure of each piece of equipment to the bus using a piece of #14 AWG wire, strap, or flat-weave grounding braid.

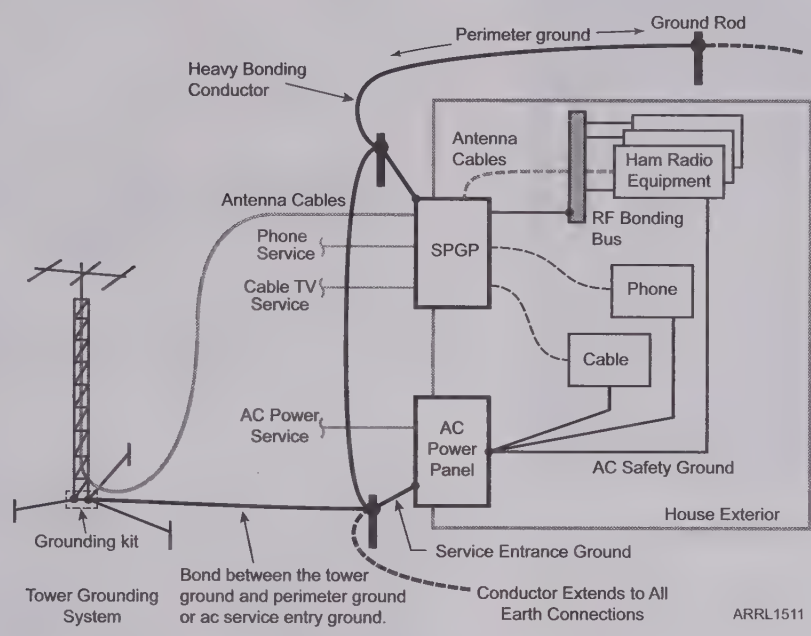

The typical amateur station includes a lot of accessory equipment that is itself unpowered but which connects to equipment that is connected to the ac line. Your goal in station building should be to insure that any exposed metal will not present a shock hazard. This requires you to provide a safety ground connection for any unpowered equipment with a metal enclosure, such as an SWR bridge, antenna tuner, or antenna switch. Most large pieces of this type of equipment will have a ground terminal for you to use. If not, add a screw to the enclosure or use a mounting screw for the connection.

#### LIGHTNING PROTECTION

Begin by reading about and understanding what lightning is and what protection against its effect consists of. Information about lightning and protection plans are available in the 2002 series of *QST* articles by Ron Block, KB2UYT. (The complete set of articles are posted online at [www.arrl.org/lightning-protection](http://www.arrl.org/lightning-protection).) Once you have a plan, you can implement it using standard grounding and bonding techniques. The **Safety** chapter covers the basic elements of lightning protection.

**Figure 24.4** shows an overview of how

**Figure 24.4 —** Overview of a station grounding system that incorporates ac safety, lightning protection, and RF management. A single-point ground-panel (SPGP) is used to provide a common bonding connection to equalize voltage during a lightning transient. All ground connections must be bonded together.

**Figure 24.5 —** A single-point ground-panel (SPGP) for an active HF station. Mounted on an exterior wall under the station, all filters, switches, and protectors are attached to the aluminum sheet. A heavy ground conductor connects the panel to a ground rod outside. [Kirk Pickering, K4RO, photo]

ation grounding and bonding works together provide lightning protection. All earth connections such as ground rods and buried conductors are connected together. Inside the station, all equipment is bonded together either directly or through a bonding bus.

Devise a lightning protection plan as instructed in the articles by Block. Remember that every conductor entering or leaving your protected zone must have some means of protection against lightning or lightning-induced transients. **Figure 24.5** shows a

single-point ground-panel (SPGP) installed on an exterior wall below the station. **Figure 24.6** shows an example of how to mount lightning protectors on an SPGP. Your circumstances are unique and the exact solution is up to you to design and build.

Don't depend on power strips with simple MOV surge protectors to protect your equipment. You can protect one or two branch circuits with a professional/industrial-quality ac surge protector (see **Figure 24.7**), mounted on your ground panel, and connect your ac power distribution system to that. Whole-house surge protectors will not protect your station equipment from lightning since they are only connected to the residence's incoming ac service. You will still need to create an effective ground system in your station.

Make sure all of your equipment is bonded together so that voltage is equalized between pieces of equipment. Bonding can be done directly between pieces of equipment if you do not have too many individual radios and accessories. An alternative is to use the bonding bus approach as illustrated by **Figure 24.8**. Bonding will also serve to provide ac safety if the bonding includes a connection to the ac safety ground.

**RF MANAGEMENT**

It is typical for a station to begin with one or two radios, a power supply, and some feed lines to antennas outside. Eventually, more accessories are added, along with a computer, possibly and amplifier, and so on. This eventually leads to "RF in the shack" or RFI to various pieces of equipment. The problem is

**Figure 24.6** — Lightning protectors mounted on a SPGP using an aluminum angle bracket. Some protectors can be mounted directly to panels or as a through-hole using the threaded bulkhead-style connectors. [Ward Silver, NØAX, photo]

**Figure 24.7** — An in-line ac power protector suitable for lightning protection and designed to be mounted on a grounded panel.

caused by the numerous interconnections between pieces of equipment. These pick up transmitted signals as common-mode RF current that can affect amateur equipment, just as it can cause RFI to consumer equipment. (See the **RF Interference** chapter for more information.)

By starting your station with a plan to manage the RF that will be present, you can reduce or eliminate the effects. You will probably not be able to shield your station against RF being picked up by the various cables and enclosures. Instead, use bonding to minimize RF voltage between pieces of equipment so that RF current doesn't flow between them.

**Figure 24.8** — A typical bonding bus for a station with equipment on a table or desk. Connections between the equipment and the bonding bus should be made with heavy wire or strap (#14 AWG is suitable).

**Figure 24.9** — A simple RF ground plane made of aluminum roof flashing with a copper pipe bonding bus attached at the rear of the table. Equipment is placed on the flashing and attached to the pipe with short jumpers. The ground plane and bus are attached to the station ground system with a heavy wire. [Ward Silver, NØAX, photo]

Bonding can be done by direct connection or by using a bonding bus.

As an added bonus, good bonding between pieces of equipment also minimizes the small audio buzz and hum voltages caused by leakage current and stray magnetic fields. Many stations use low-level audio signals for digital operation. Bonding helps keep unwanted hum and buzz from contaminating these signal paths. Bonding for RF management can satisfy the requirements for ac safety and lightning protection, too.

One technique for helping to equalize RF voltage around your station is the use of an *RF ground plane* or *reference plane*. **Figure 24.9** shows a simple ground plane made from a sheet of aluminum roof flashing attached to a table top. A bonding bus of copper pipe

is clamped to the flashing at the back of the table. Sheet metal screws in the pipe are provided for attaching bonding jumpers to each piece of equipment. The ground plane and bonding bus are then connected to the station ground system. A metal desk or table can serve as the RF ground plane, as well. (The RF ground plane is different than a set of ground radials that provide a return path for RF to the feed point of a vertical antenna.) RF voltage differences are kept low by the ground plane. Extra cable length can be coiled up and placed directly on the ground plane to help keep them from picking up common-mode RF.

Portable and temporary stations pose a challenge for RF management. Station configuration usually has to work around various

ARRL 1529

**Figure 24.10** — For equipment on shelves, create a ground plane on each shelf. Bond each ground plane segment together (heavy lines) and route cables between the segments along the bonding strap or wire. Several possible examples are shown.

constraints and physical obstacles. Installing a comprehensive ground and bonding system is usually not possible. Under these circumstances, a roll of strap or flexible braid may serve as an effective bonding bus. Screen or even aluminum foil will work as a ground plane. Have plenty of short jumpers and clip leads to connect the equipment enclosures to whatever common connection you can manage.

Many stations have shelving to hold equipment above a desk or table. **Figure 24.10** shows several possible techniques for adding metal sheet or strap to the shelves and connecting it together. You can use metal sheet, screen, or even surplus PC board material as the ground plane. The important thing is to get some metal under the various pieces of equipment to help the bonding connections work at RF.

### 24.1.3 Station Power

Power supply design and use is covered in the **Power Sources** chapter, and safety issues and station wiring are covered in the **Safety** chapter. A single 20 A, 120 V circuit will provide sufficient power for all of the radio and computer equipment in almost any single-operator amateur station, including most 500 W power amplifiers. A single 20 A, 240 V circuit will provide sufficient power for two legal limit amplifiers that do not transmit simultaneously. A generous number of 120 V outlets should be provided. The 120 V and 240 V outlets should have their equipment grounds bonded together. This

simple power arrangement has the major advantage of minimizing problems with audio hum and buzz caused by power system leakage current. Install good quality 20 A outlets and 20 A breakers.

**Figure 24.11** shows how you can build your own heavy-duty, high-quality power distribution box. Use metal “back boxes” with high-quality outlets and heavy #12 or #14 AWG wiring. Multiple boxes can be mechanically attached together to support as many outlets as needed. If more than one multi-outlet box is used on the same circuit, use rigid EMT or flexible metal BX conduit between them with all of the metalwork solidly assembled and connected to the ground conductor. A heavy switch can be included

**Figure 24.11** — A heavy-duty homemade power distribution box. Several gangable “back boxes” are assembled into a larger box that can hold several duplex outlets. A light switch or GFCI-protected outlet can be included for power control and shock protection. [Jim Brown, K9YC, photo]

to turn the entire package on and off. A GFCI outlet can be included in the box if the branch circuit is not already protected by a GFCI.

Wherever commercial power strips are used in your station, use industrial-quality products with a metal enclosure, heavy wiring, good quality outlets and a built-in switch and circuit breaker (typically rated at 15 A). Avoid inexpensive plastic power strips which cost much less but are of far lower quality.

Using ground fault circuit interrupter (GFCI) circuit breakers or outlets to supply power is not required by the NEC. However, given the many opportunities for stray current in an amateur station and antenna system, GFCI protection is not a bad idea. You can install GFCI breakers in the ac service panel or install GFCI outlets at the station.

### 24.1.4 Station Layout

Station layout is largely a matter of personal taste and needs. It will depend mostly on the amount of space available, the equipment involved and the types of operating to be done. With these factors in mind, some basic design considerations apply to all stations.

#### THE OPERATING TABLE

The operating table may be an office or computer desk, a kitchen table or a custom-made bench. What you use will depend on space, materials at hand and cost. The two most important considerations are height and size of the top. Most commercial desks are about 29 inches above the floor. Computer tables are usually a couple inches lower for a more comfortable keyboard and mouse placement. This is a comfortable height for most adults. Heights much lower or higher than this may cause an awkward operating position.

The dimensions of the top are an important consideration. A deep (36 inches or more)

top will allow plenty of room for equipment interconnections along the back, equipment about midway and room for writing or a keyboard and mouse toward the front. The length of the top will depend on the amount of equipment being used. An office or computer desk makes a good operating table. These are often about 36 inches deep and 60 inches wide. Drawers can be used for storage of logbooks, headphones, writing materials, and so on. Desks specifically designed for computer use often have built-in shelves that can be used for equipment stacking. Desks of this type are available ready-to-assemble at most discount and home improvement stores. The low price and adaptable design of these desks make them an attractive option for an operating position. An example is shown in **Figure 24.12**.

If possible, arrange your operating desk or table so that it is easy to access the rear of the equipment. You may be able to provide a walkway behind the equipment or the desk or table might be moveable. Either way, you will appreciate being able to work behind the equipment without having to get under a table or work in uncomfortable positions. It also helps avoid wiring errors caused by not having a clear view of the equipment. Equipment can also be left in place while connections are made.

### ARRANGING THE EQUIPMENT

No matter how large your operating table, some vertical stacking of equipment may be necessary to allow you to reach everything from your chair. Stacking pieces of equipment directly on top of one another is not a good idea because most amateur equipment needs airflow around it for cooling. A shelf like that shown in **Figure 24.13** can improve equipment layout in many situations. Dimensions of the shelf can be adjusted to fit the size of your operating table.

When you have acquired the operating table and shelving for your station, the next task is arranging the equipment in a convenient, orderly manner. The first step is to provide power outlets and a good ground as described in a previous section. Be generous in estimating the number of power outlets for your installation; radio equipment has a habit of multiplying with time, so plan for the future at the outset. Try to obtain power distribution strips or install some outlets with enough space between them to accommodate multiple plug-in "wall-wart" power supplies.

Every station is different and each operator has different preferences so giving "cookbook" instructions for station layout is unrealistic. Even so, there are some general principles that make a station layout effective. Start by looking at the photographs of stations in this chapter, in *QST*, and online. Visit

**Figure 24.12** — Mike Adams, N1EN makes the most of his desktop to operate on the HF and VHF+ bands. His laptop and tablet computers are an alternative to the larger desktop systems. He uses a full-size keyboard with the laptop. [Mike Adams, N1EN, photo]

stations of other operators to get ideas and try different arrangements. Think about what equipment you use most while operating and make that easy to reach and use. Consider making a temporary arrangement to try out different configurations before you settle on a final layout. Make it easy to update your layout as your habits, tastes, and body change. Configure the station to suit your interests, and keep thinking of ways to refine the layout.

Portable stations have the additional requirement to be lightweight and sturdy, often part of a "go-kit" for emergency

communication or other public service. **Figures 24.14** and **24.15** show two different solutions for very different sets of circumstances but both are well-considered and appropriate to the need.

You may find yourself taking advantage of non-traditional materials for your station. **Figure 24.16** shows equipment supported by open metal wire shelving used as commercial or industrial shelving. Not only is the shelving strong, since it is metallic, it serves as an RF ground plane and is open to airflow that provides ventilation to the equipment.

## ERGONOMICS

Ergonomics is a term that loosely means “fitting the work to the person.” If tools and equipment are designed around what people can accommodate, the results will be much more satisfactory. For example, in the 1930s research was done in telephone equipment manufacturing plants because use of long-nosed pliers for wiring switchboards required considerable force at the end of the hand’s range of motion. A simple tool redesign resolved this issue.

Considerable attention has been focused on ergonomics in recent years because we have come to realize that long periods of time spent in unnatural positions can lead to repetitive-motion injuries. Much of this attention has been focused on people whose job tasks have required them to operate computers and other office equipment. While most Amateur Radio operators do not devote as much time to their hobby as they might in a full-time job, it does make sense to consider comfort and flexibility when choosing furniture and arranging it in the shack or workshop. Adjustable height chairs are available with air cylinders to serve as a shock absorber. Footrests might come in handy if the chair is so high that your feet cannot support your lower leg weight. The height of tables and keyboards often is not adjustable.

Placement of computer screens should take into consideration the reflected light coming from windows. It is always wise to build into

your sitting sessions time to walk around and stimulate blood circulation. Your muscles are less likely to stiffen, while the flexibility in your joints can be enhanced by moving around.

Selection of hand tools is another area where there are choices to make that may affect how comfortable you will be while working in your shack. Look for screwdrivers with pliable grips. Take into account how heavy things are before picking them up — your back will thank you.

## FIRE EXTINGUISHERS

Fires in well-designed electronic equipment are not common but are known to occur. Proper use of a suitable fire extinguisher can make the difference between a small fire with limited damage and loss of an entire home. Make sure you know the limitations of your extinguisher and the importance of reporting the fire to your local fire department immediately.

Several types of extinguishers are suitable for electrical fires. The multipurpose dry chemical or “ABC” type units are relatively inexpensive and contain a solid powder that is nonconductive. Avoid buying the smallest size; a 5-pound capacity will meet most requirements in the home. ABC extinguishers are also the best choice for kitchen fires (the most common location of home fires). One disadvantage of this type is the residue left behind that might cause corrosion in electrical connectors. Another type of fire extinguisher suitable for energized electrical equipment is the carbon dioxide unit. CO<sub>2</sub> extinguishers require the user to be much closer to the fire, are heavy and difficult to handle, and are relatively expensive. For obvious reasons, water extinguishers are not suitable for fires in or near electronic equipment.

## AIDS FOR HAMS WITH DISABILITIES

A station used by an amateur with physical disabilities or sensory impairments may require adapted equipment or particular layout considerations. The station may be highly customized to meet the operator’s needs or just require a bit of “tweaking.”

The myriad of individual needs makes describing all of the possible adaptive methods impractical. Each situation must be approached individually, with consideration to the operator’s particular needs. However, many types of situations have already been encountered and worked through by others, eliminating the need to start from scratch in every case.

An excellent resource is the Courage Handi-Ham System. The Courage Handi-Ham System, a part of the Courage Center, provides a number of services to hams (and aspiring hams) with disabilities. These include study materials and a wealth of useful infor-

mation on their comprehensive website. Visit [www.handiham.org](http://www.handiham.org) for more information.

## 24.1.5 Interconnecting Your Equipment

Once you have your equipment and get it arranged, you will have to interconnect it all. No matter how simple the station, you will at least have antenna, power and microphone or key connections. Equipment such as amplifiers, computers, TNCs and so on add complexity. By keeping your equipment interconnections well organized and of high quality, you will avoid problems later on.

Often, ready-made cables will be available. But in many cases you will have to make your own cables. A big advantage of making your own cables is that you can customize the length. This allows more flexibility in arranging your equipment and avoids unsightly extra cable all over the place. Many manufacturers supply connectors with their equipment along with pinout information in the manual. This allows you to make the neces-

**Figure 24.17** — Labels on the cables make it much easier to rearrange things in the station. Labeling ideas include masking tape, cardboard labels attached with string and labels attached to fasteners found on plastic bags (such as bread bags).

sary cables in the lengths you need for your particular installation.

Always use high quality wire, cables and connectors in your shack. Take your time and make good mechanical and electrical connections on your cable ends. Sloppy cables are often a source of trouble. Often the problems they cause are intermittent and difficult to track down. You can bet that they will crop up right in the middle of a contest or during a rare DX QSO! Even worse, a poor quality connection could cause RFI or even create a fire hazard. A cable with a poor mechanical connection could come loose and short a power supply to ground or apply a voltage where it should not be. Wire and cables should have good quality insulation that is rated high enough to prevent shock hazards.

Interconnections should be neatly bundled and labeled. Wire ties, masking tape or paper labels with string work well. See **Figure 24.17**. Whatever method you use, proper labeling makes disconnecting and reconnecting equipment much easier. **Figure 24.18** illustrates the number of potential interconnections in a modern, full-featured transceiver.

## WIRE AND CABLE

The type of wire or cable to use depends on the job at hand. The wire must be of sufficient size to carry the necessary current. Use the tables in the **Component Data and References** chapter to find this information. Never use underrated wire; it will be a fire hazard. Be sure to check the insulation too. For high-voltage applications, the insulation must be rated at least a bit higher than the intended voltage. A good rule of thumb is to use a rating at least twice what is needed.

Use good quality coaxial cable of sufficient size for connecting transmitters, transceivers, antenna switches, antenna tuners and so on. RG-58 might be fine for a short patch between your transceiver and SWR bridge, but is too

small to use between your legal-limit amplifier and antenna tuner. For more information, see the **Transmission Lines** chapter.

Hookup wire may be stranded or solid. Generally, stranded is a better choice since it is less prone to break under repeated flexing. Many applications require shielded wire to reduce the chances of RF getting into the equipment. RG-174 is a good choice for control, audio and some low-power RF applications. Shielded microphone or computer cable can be used where more conductors are necessary.

For RF connections, #12–#16 AWG solid or stranded wire or solid strap are preferred. For indoor connections not exposed to the weather, flat-weave tinned braid strap is acceptable. Do not use braid salvaged from coaxial cable for RF connections.

### CONNECTORS

Connectors are a convenient way to make an electrical connection by using mating electrical contacts. There are quite a few connector styles, but common terms apply to all of them. Pins are contacts that extend out of the connector body, and connectors in which pins make the electrical contact are called “male” connectors. Sockets are hollow, recessed contacts, and connectors with sockets are called “female.” Connectors designed to attach to each other are called “mating connectors.” Connectors with specially shaped bodies or inserts that require a complementary shape on a mating connector are called “keyed connectors.” Keyed connectors ensure that the connectors can only go together one way, reducing the possibility of damage from incorrect mating.

*Plugs* are connectors installed on the end of cables and *jacks* are installed on equipment. *Adapters* make connections between two different styles of connector, such as between two different families of RF connectors. Other adapters join connectors of the same family, such as double-male, double-female and gender changers. *Splitters* divide signal between two connectors.

While the number of different types of connectors is mind-boggling, many manufacturers of amateur equipment use a few standard types. If you are involved in any group activities such as public service or emergency-preparedness work, check to see what kinds of connectors others in the group use and standardize connectors wherever possible. Assume connectors are not waterproof, unless you specifically buy one clearly marked for outdoor use (and assemble it correctly).

### Power Connectors

Amateur Radio equipment uses a variety of power connectors. Some examples are shown in **Figure 24.19**. Most low power ama-

The proper orientation for paired Powerpole connectors is with the red connector on the right and its tongue on top — “red-right-up”. teur equipment uses coaxial power connectors. These are the same type found on consumer electronic equipment that is supplied by a wall transformer power supply. Transceivers and other equipment that requires high current in excess of a few

amperes often use Molex connectors ([www.molex.com](http://www.molex.com) — enter “MLX” in the search window) with a white, nylon body housing pins and sockets crimped on to the end of wires.

An emerging standard, particularly among

Figure 24.21 — Audio and data signals are carried by a variety of different connectors. Individual cable conductors are either crimped or soldered to the connector contacts. [Ward Silver, NØAX, photo]

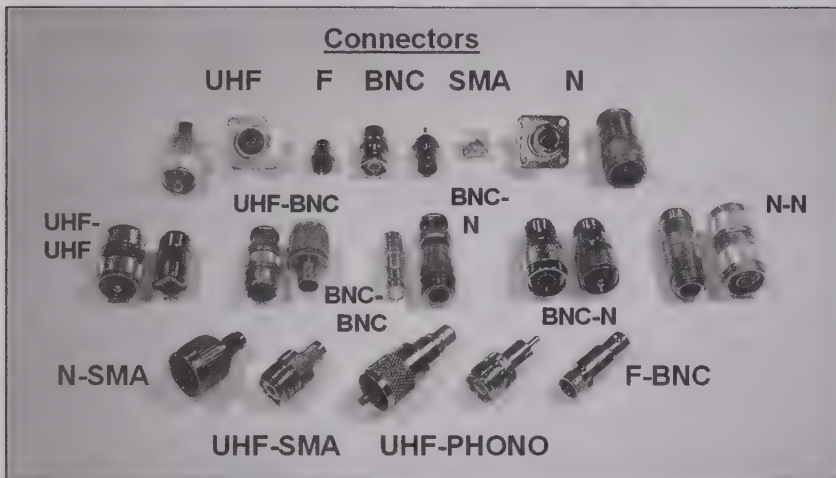

Figure 24.22 — Each type of RF connector is specially made to carry RF signals and preserve the shielding of coaxial cable. Adapters are available to connect one style of connector to another. [Ward Silver, NØAX, photo]

ARES and other emergency communications groups, is the use of Anderson Powerpole connectors ([www.andersonpower.com](http://www.andersonpower.com)). These connectors are “sexless” meaning that any two connectors of the same series can be mated — there are no male or female connectors. By standardizing on a single connector style, equipment can be shared and replaced easily in the field. The standard orientation for pairs of these connectors is shown in Figure 24.19. Using this orientation increases the compatibility of your wiring with that of other hams.

Molex and Powerpole connectors use crimp terminals (both male and female) installed on the end of wires. A special crimping tool is used to attach the wire to the terminal and the terminal is then inserted into

the body of the connector. Making a solid connection requires the use of an appropriate tool — do not use pliers or some other tool to make a crimp connection.

Some equipment uses terminal strips for direct connection to wires or crimp terminals, often with screws. Other equipment uses spring-loaded terminals or binding posts to connect to bare wire ends. Figure 24.20 shows some common crimp terminals that are installed on the ends of wires using special tools.

### Audio and Control Connectors

Consumer audio equipment and Amateur Radio equipment share many of the same connectors for the same uses. Phone plugs and jacks are used for mono and stereo

audio circuits. These connectors, shown in Figure 24.21 come in ¼ inch, ½ inch (miniature) and subminiature varieties. The contact at the end of the plug is called the tip and the connector at the base of the plug is the sleeve. If there is a third contact between the tip and sleeve, it is the ring (these are “stereo” phone connectors). Stereo phone connectors are often called TRS (for tip-ring-sleeve) connectors by audio equipment manufacturers.

Phono plugs and jacks (sometimes called RCA connectors since they were first used on RCA brand equipment) are used for audio, video and low-level RF signals. They are also widely used for control signals.

The most common microphone connector on mobile and base station equipment is an 8-pin round connector. On older transceivers you may see 4-pin round connectors used for microphones. RJ-45 modular connectors (see the section on telephone connectors below) are often used in mobile and smaller radios.

### RF Connectors

Feed lines used for radio signals require special connectors for use at RF frequencies. The connectors must have approximately the same characteristic impedance as the feed line they are attached to or some of the RF signal will be reflected by the connector. Inexpensive audio and control connectors cannot meet that requirement, nor can they handle the high power levels often encountered in RF equipment. Occasionally, phono connectors are used for HF receiving and low-power transmitting equipment.

By far, the most common connector for RF in amateur equipment is the UHF family shown in Figure 24.22. (The UHF designator has nothing to do with frequency.) A PL-259 is the plug that goes on the end of feed lines, and the SO-239 is the jack mounted on equipment. A “barrel” (PL-258) is a double-female adapter that allows two feed lines to be connected together. UHF connectors are typically used up to 150 MHz and can handle legal-limit transmitter power at HF.

UHF connectors have several drawbacks including lack of weatherproofing, poor performance above the 2 meter band and limited power handling at higher frequencies. The Type-N series of RF connectors addresses all of those needs. Type-N connectors are somewhat more expensive than UHF connectors, but they require less soldering and perform better in outdoor use since they are moisture resistant. Type-N connectors can be used to 10 GHz.

For low-power uses, BNC connectors are often used. BNC connectors are the standard for laboratory equipment, as well, and they are often used for dc and audio connections. BNC connectors are common on handheld

## Coax Connectors — Not as Simple as They Appear

by Hal Kennedy, N4GG

"You get what you pay for" was never more true than when it comes to common UHF connectors, including PL-259s, SO-239s, adapters, and related parts. Every hamfest seems to have at least one vendor selling "mystery" UHF connectors, sometimes for as little as a dollar each. What are you buying when you buy the cheapest PL-259? It's pretty much a guess. For the difference of a dollar or two, "mystery" UHF connectors are a very poor investment.

PL-259s have four parts: the outer sleeve called the "knurled nut," the connector body, the insulator/dielectric and the center pin. All four components can be compromised to the point of making a bargain connector useless.

Problems frequently encountered:

- **Finish:** Bargain connectors sometimes have a finish you can't solder to! They may have a chrome-like appearance, but the plating may not take solder well and has to be filed down for a good connection.
  - **Threading:** The internal threads at the rear of the body are there to accept a UG-style insert that narrows the connector barrel to accept smaller diameter coax such as RG-8X or RG-58. The threads may be metric! UG inserts also sometimes appear in the US market with metric threads. Either way, the insert will not screw into the body.
  - **Dielectric:** Good connectors use quality phenolic or Teflon insulation between the center pin and the body. Bargain connectors might use anything, including materials such as polystyrene, which will melt when the center pin is soldered.
  - **Center pin diameter:** This is one of the most common and insidious problems in mystery PL-259s. The center pin outer diameter (OD) is almost always slightly smaller than it should be and it's hard to notice. The center pin connection between a PL-259 and an SO-239 or barrel connector depends on the male side pin OD being correct and the matching fingers on the female side being the correct diameter and made of the proper spring material.
  - **Center socket spring tension:** If the SO-239 socket metal relaxes over time and/or temperature, an intermittent connection will be created that can be very hard to track down.
  - **Mating indentions:** The indentations on the end of the SO-239 that mate to a PL-259 (the annulus flange) may only have four indentations to match up with the short prongs on the body of the male connector. A quality SO-239 or barrel connector has indentations all the way around. If the PL-259 and SO-239 don't seat completely, an intermittent connection is likely to develop.
  - **Tee and right-angle (elbow) UHF adapters:** The center conductor has to make a right-angle turn inside the shell. In poor-quality adapters the right-angle connection is done with a spring contact — these do not hold up. Quality tee and right-angle adapters are reliable because the internal conductors are tapped and threaded — the conductors are screwed together within the body at the right angle junction.
- How can we tell the good connectors? If the price is too good to be true — well, it is. PL-259s with good silver plating have a dull appearance. Good connectors have a part number and manufacturer's name stamped into them. You can look up the connector's specifications if it's marked. An example is the connectors made by Amphenol — all of which have parts numbers such as 83-1SP (PL-259) or 83-1R (SO-239) stamped into or onto the connector body.

radios for antenna connections. The newest handheld transceivers often use small, screw-on SMA type connectors for their antennas, though.

The type of connector used for a specific job depends on the size of the cable, the frequency of operation and the power levels involved. More information on RF connectors may be found in the **Component Data and References** chapter.

### Data Connectors

Digital data is exchanged between computers and pieces of radio equipment more than ever before in the amateur station. The con-

nectors follow those found on computer equipment.

D-type connectors are used for RS-232 (COM ports) and parallel (LPT port) interfaces. A typical D-type connector has a model number of "DB" followed by the number of connections and a "P" or "S" depending on whether the connector uses pins or sockets. For example, the DB-9P is used for PC COM1 serial ports.

USB connectors are becoming more popular in amateur equipment as the computer industry has eliminated the bulkier and slower RS-232 interface. A number of manufacturers make USB-to-serial converters that allow

devices with RS-232 interfaces to be used with computers that only have USB interfaces.

*Null modem* or *crossover* adapters or cables have the same type of connector on each end. The internal connections between signal pins are swapped between ends so that inputs and outputs are connected together. This allows interfaces to be connected together directly without any intermediary equipment, such as an Ethernet switch or an RS-232 modem.

Pinouts for various common computer connectors are shown in the **Component Data and References** chapter. Several practical data interface projects are shown in the **Station Accessories** and **Digital Communications** chapters in the downloadable supplemental content.

### Telephone and Computer Network Connectors

Modular connectors are used for telephone and computer network connections. Connector part numbers begin with "RJ." The connectors are crimped on to multiconductor cables with special tools. The RJ11 connector is used for single- and double-line telephone system connection with 4 or 6 contacts. The RJ10 is a 4-contact connector for telephone handset connections. Ethernet computer network connections are made using RJ45 connectors with 8 contacts.

### 24.1.6 Documenting Your Station

An often neglected but very important part of putting together your station is properly documenting your work. Ideally, you should diagram your entire station from the ac power lines to the antenna on paper and keep the information in a special notebook with sections for the various facets of your installation. Having the station well documented is an invaluable aid when tracking down a problem or planning a modification. Rather than having to search your memory for information on what you did a long time ago, you'll have the facts on hand.

Besides recording the interconnections and hardware around your station, you should also keep track of the performance of your equipment. Each time you install a new antenna, measure the SWR at different points in the band and make a table or plot a curve. Later, if you suspect a problem, you'll be able to look in your records and compare your SWR with the original performance.

In your shack, you can measure the power output from your transmitter(s) and amplifier(s) on each band. These measurements will be helpful if you later suspect you have a problem. If you have access to a signal generator, you can measure receiver performance for future reference.

## 24.2 Mobile Installations

Solid-state electronics and miniaturization have allowed mobile operators to equip their vehicles with stations rivaling base stations. Indeed, it is possible to operate from 160 meters through 70 cm with one compact transceiver. Adding versatility, most designed-for-mobile transceivers are set up so that the main body of the radio can be safely tucked under a seat, with the operating “head” conveniently placed for ease of use as shown in **Figure 24.23**.

Common power levels reach 100-150 W on HF, and 50-75 W on VHF. With proper antenna selection and placement (see the **Antennas** chapter), mobile stations can work the world, just like their base station counterparts. The only real difference between them is that you’re trying to drive at the same time you are operating, and safe operating requires attention to the details.

For some of us living in antenna-restricted areas, mobile operating may offer the best solution for getting on the air. For others it is an enjoyable alternative to home-station operation. No matter which category you’re in, you can enjoy success if you plan your installation with safety and convenience in mind.

There is a considerable amount of information about mobile operation, both HF and VHF+, online. Many contributions to this section have come from the website of Alan Applegate, KØBG, at [www.k0bg.com](http://www.k0bg.com). Specialty groups, such as RVers and off-road groups will have additional perspectives. Your vehicle dealer also has service bulletins regarding the installation of radio equipment. Although the bulletins mainly apply to VHF equipment, they are a valuable source of information about convenient routes and access points for power and other wiring.

### 24.2.1 Installation

Installing Amateur Radio equipment in modern vehicles can be quite challenging, yet rewarding, if basic safety rules are followed. All gear must be securely attached to the vehicle. Unsecured cup holder mounts, mounts wedged between cushions, elastic cords, hook-and-loop tape, magnets, or any other temporary mounting scheme *must be avoided!* Remember, if it isn’t bolted down, it will become a missile in the event of a crash. The radio mounting location must avoid SRS (airbag) deployment zones — virtually eliminating the top of the dash in most modern vehicles — as well as vehicle controls (see the sidebar “Air Bags and Mobile Installations”).

If you’re not into building a specific mount for your vehicle, there are many no-holes-needed mounts available from Amateur Radio dealers. Some mounts are even designed for a specific transceiver make and model. **Table 24.1** lists some suppliers.

Two other points to keep in mind when choosing a mounting location are convenience and lack of distraction. Microphone and power cabling should be placed out of the way and properly secured. The transceiver’s controls should be convenient to use and to view. See **Figure 24.24** for examples.

Mounting radios inside unvented center

consoles and overhead bins should also be avoided. Modern mobile transceivers designed for remote mounting allow the main body to be located under a seat, in the trunk, or in another out-of-the-way place (**Figure 24.25**) but be sure there is plenty of ventilation.

If you drive off-road or on rough roads, you may also wish to consider using shock mounts, also known as “Lord Mounts” for their original manufacturer. For more information, see the product information on “Platform Mounts” from the Astrotex Company at [www.astrotex.com/lord.htm](http://www.astrotex.com/lord.htm).

### 24.2.2 Coaxial Cable

Cable lengths in mobile installations seldom exceed 15 feet, so coax losses are not a major factor except on the 70 cm and higher-frequency bands. Good quality RG-58A or RG-8X size coax is more than adequate for HF and VHF. While there is nothing wrong with using RG-8 size coax (0.405 inch), it is stiffer and has a larger bending radius, making it harder to work with in most mobile applications.

There are some caveats when selecting coax. Avoid solid center conductors such as in standard RG-58. It has a propensity to kink, is susceptible to failure from vibration and can be difficult to solder properly. Both RG-58A and RG-8X use foam dielectric, and care is needed when soldering PL-259 connectors — especially when reducers are being used. The **Component Data and References** chapter illustrates the correct installation procedure.

### 24.2.3 Wiring

Proper wiring is an essential part of any mobile installation. Consider the following points when selecting materials and planning the cable routing.

- Wire needs to be correctly sized and fused stranded wire.
- All cables need to be protected from abrasion, heat, and chemicals.
- Wiring needs to be shortened and/or bundled with appropriate wire ties to avoid interaction with passengers and mechanical devices. **Figure 24.26** shows a typical vehicle wiring tray.

**Figure 24.23** — In this mobile installation, the transceiver control head is mounted in the center console, next to a box with switches for adjusting the antenna.

Mounts are typically highly adjustable, allowing the control head or radio to be positioned close to the operator. An antenna controller is mounted below the microphone. At B, HF and VHF transceiver control heads and the microphone are all mounted to the dashboard, within easy reach.

(B)

Figure 24.25 — The main body of the radio may be mounted in the vehicle's trunk or other out-of-the-way spot. Allow for plenty of ventilation.

Power cables should be connected directly to the battery following manufacturers' recommendations, with the requisite positive and negative lead fuses located close to the battery. Figure 24.27 shows a typical fuse block. Accessory (cigarette lighter) sockets and power taps shouldn't be used except for very low current loads (<5 A), and then only with care. It pays to remember that a vehicle fire is both costly and dangerous! More information may be found at [www.fordemc.com/docs/download/Mobile\\_Radio\\_Guide.pdf](http://www.fordemc.com/docs/download/Mobile_Radio_Guide.pdf) and [service.gm.com/techlineinfo/radio.html](http://service.gm.com/techlineinfo/radio.html).

## Marine Grounding and Equipment Installation

Marine vessels, either fresh- or salt-water, pose challenges to radio and electrical systems. Luckily, there are many online and print references explaining how to do things right, whether the vessel is power or sail, wooden, fiberglass, or metal-hulled. Each type requires certain practices be followed to avoid corrosion and maintain good electrical connections at dc and RF. Your best sources of information can be found through marine outfitters and communication shops that install marine HF and VHF radios.

The fuses supplied with most mobile transceivers are ATC style. Most automotive fuses are ATO. The ATC fuse element is completely sealed in plastic and the ATO is not. Since the power cable fuse holders are not waterproof, only an ATC fuse should be used if the fuse holder is exposed to the weather or located anywhere in the engine compartment. If an ATO is used, and water gets into the fuse, the fuse element corrodes and eventually fails.

Proper wiring also minimizes voltage drops and helps prevent ground loops. Modern solid-state transceivers will operate effectively down to 12.0 V dc (engine off). If the voltage drops below 11.6 V under load, some transceivers will reduce power, shut down or operate incorrectly. The vehicle chassis should not be used for ground returns; paint or other insulation can isolate different chassis sections and using a chassis return can create a ground loop.

Running cables through the engine firewall can be easy in some vehicles and nearly impossible in others. Using factory wiring grommets should be avoided unless they're not being used. In some cases, the only alternative is to drill your own hole. If you have any questions or concerns, have your local mobile sound shop or two-way radio dealer install the wiring for you.

Power for ancillary equipment (wattmeters, remotely tuned antennas and so on) should follow the same wiring rules. The use of a multiple outlet power distribution panel such as a RigRunner ([www.westmountainradio.com](http://www.westmountainradio.com)) is also recommended. They're convenient, and offer a second level of protection.

### WIRE SIZE

The **Component Data and References** chapter lists the current-handling capabilities of various gauges of wire and cable. The correct wiring size is one that provides a low voltage drop (less than 0.5 V under full load). Don't use wire at its maximum current-current carrying capacity.

Figure 24.26 — Most vehicles have wiring troughs hidden behind interior body panels.

Figure 24.27 — Wiring attached to a fuse block.

Here's the formula for calculating the cable assembly voltage drop ( $V_d$ ):

$$V_d = [(R_w \times 2 \ell \times 0.001) + 2 k] \times I$$

where

$R_w$  = resistance value ( $\Omega$  per 1000 feet) from the **Component Data and References** chapter.

$\ell$  = overall length of the cable assembly including connectors, in feet.

$k$  = nominal resistive value for one fuse and its holder. Note: Most power cables have two fuses. If yours doesn't, use 1 k in the formula. If you don't know the fuse and holder resistance, use a conservative value of 0.002  $\Omega$ .

$I$  = peak current draw in amperes for a SSB transceiver, or steady state for an FM radio.

For example, the peak current draw for a 100 W transceiver is about 22 A, and a typical power cable length is 10 feet. Using the resistive values for 1000 feet of #10 AWG wire (0.9987  $\Omega$ ), and a conservative value for the fuse resistances (0.002  $\Omega$  each), the calculated drop will be 0.527 V.

It's important to reiterate that the wire size should be selected for minimum voltage drop, not maximum power handling capability. The voltage drop is often referred to as "I-squared-R loss" — the current in amperes, squared, times the resistance — and should be held to a minimum whenever possible. In cabling, excessive  $I^2R$  losses can cause the wire to overheat with predictable results.

The insulation material of wire used in mobile installations should have a temperature rating of at least 90 °C, and preferably 105 °C. It should be protected with split-loom covering whenever possible, especially under-hood wiring.

## Battery Connections

For many years, connecting mobile station power leads directly to the battery (or to the battery positive and ground tie-point) has been the standard recommendation. In vehicles equipped with EIS (Engine Idle Shutoff), however, additional sensing modules in the vehicle electrical system may require alternate connections.

With EIS, as soon as the vehicle stops for a short time, the engine shuts off and the battery voltage drops. To support the additional starting cycles, starters and batteries are more robust, but so are the sophistication of the electrical devices supporting them. The most important device is the ELD (Electronic Load Detector), typically located within the main fuse panel.

ELDs have been in use for many years to measure the current drawn by the accessories (air conditioning, lights, and so on), which allow the engine CPU to more accurately adjust the air/fuel mixture. However, on vehicles equipped with EIS, the ELD is located in battery's negative lead or its connector. (See your vehicle's service manual for the exact location of the ELD.) The ELD is used for *coulomb-counting* to estimate the battery's State of Charge (SoC). Measuring current during starting provides an estimate of the battery's Reserve Capacity (RC). This ensures the battery has enough reserves to restart the engine when the engine has to start again. (See the **Power Sources** chapter for more information on vehicle batteries.)

During engine shutdown, most EIS systems use a dc-to-dc converter to assure that the accessories have a constant voltage source for electric motors that power brakes, air conditioning, transmission servo pressure, fuel pumps, and engine cooling systems. A second trunk-mounted battery may be used, or even super-capacitors (low-voltage capacitors with many farads of capacitance). The converter and accessory operation is under the control of the Battery Monitoring System (BMS) and amateur transceiver wiring must avoid circumventing its operation.

Connecting the transceiver directly to the battery would bypass the BMS which is not recommended, nor is connecting the radio to the dc-to-dc converter, to the trunk-mounted accessory-power battery, or to existing vehicle wiring. In vehicles equipped with a BMS and/or ELD the correct method of connecting the radio is to connect the positive lead directly to the battery, and the negative lead to the battery's chassis grounding point. The negative lead fuse should not be removed! This avoids damage caused by a loose or broken battery connection, which could cause a Load Dump Transient (LDT) to occur. Should an LDT occur, the fuse might blow depending on the location of the battery lead failure. Without the fuse, damage to the transceiver could be the result.

If there is any doubt, check with your dealer about how the Battery Monitoring System (BMS) is connected and the recommended connection points for your radio's power leads. Be sure the connections you make are to points adequately rated for the load your radio presents. More information on batteries, alternators, and the newer vehicle power systems is available online at [www.k0bg.com](http://www.k0bg.com). —

Alan Applegate, K0BG

**Figure 24.28** — Chart of opening delay versus current for five common sizes of Maxi fuses, the plastic-body high-current fuses common in vehicles. [Based on a chart from Littelfuse Corp]

Selecting the correct size fuse is also important. The average current draw for any given fuse should not exceed 60% of its rating. Thus, the correct fuse rating for a 22-A load is 30 A. That same 30-A fuse will handle a 40-A load for about 120 seconds, and a 100-A load for about 2 seconds. Therefore, it pays to be conservative when selecting the carrying capacities of both wire and fuses. **Figure 24.28** shows the characteristics of several sizes of automotive fuses.

#### 24.2.4 Amplifiers

Mobile HF amplifiers have been around for many years, and with the advent of high-power solid state devices they are common. However, running high power in a mobile environment requires careful planning. Considerations include, but are not limited to:

- alternator current ratings and battery capacity

- wiring (in addition to safe current ratings, excessive voltage drop will create distortion of the output signal)
  - antenna and feed line power ratings
  - placement and secure mounting in the vehicle
  - wiring and placing of remote controls
- See [www.k0bg.com/amplifiers.html](http://www.k0bg.com/amplifiers.html) for more information on these topics.

Before purchasing an amplifier, take a close look at your antenna installation and make sure it is operating efficiently. Using an amplifier with a poor antenna installation is counterproductive. Here's a rule of thumb applicable to any type of antenna: If the *unmatched* input SWR is less than 1.7:1 on 17-meters or any lower frequency band, then it isn't mounted correctly, and/or you need a better antenna. Whatever antenna you use, it must be capable of handling the amplifier power level—500 W or more. More information on HF mobile antennas and installation

techniques may be found in the **Antennas** chapter.

Mobile amplifiers for VHF/UHF operation are not as popular as they once were because most mobile transceivers have adequate output power (about 50 W). Boosting this to 150-300 W or more should be done with caution. Mobile VHF/UHF antennas for high power (>100 W) are rare, so check antenna ratings carefully. Those that are available need to be permanently mounted, and preferably on the roof to avoid inadvertent contact.

With any high-power mobile installation, pay careful attention to RF safety. More information on RF exposure can be found in the **Safety** chapter.

#### 24.2.5 Interference Issues

In a mobile installation, radio frequency interference falls under two basic categories: *egress* (interference from the vehicle to your amateur station) and *ingress* (from your amateur gear to the vehicle). Most hams are familiar with ignition interference as it is the most common form of egress. RF interference to an auto sound system is a common form of ingress.

Both types of interference have unique solutions but they have at least one in common and that is *chassis bonding*. Chassis bonding refers to connecting accessory equipment or assemblies to the frame or chassis of the vehicle. For example, the exhaust system is isolated from the structure of the vehicle and acts like an antenna for the RFI generated by the ignition system. It should be bonded to the chassis in at least three places. **Figure 22.29** shows an example of bonding. More on these techniques is available at [www.k0bg.com/bonding.html](http://www.k0bg.com/bonding.html).

Other RFI egress problems are related to fuel pumps, HVAC fans and engine cooling fans, ABS sensors, data distribution systems and control system CPUs. These are best cured at the source by liberal use of snap-on ferrite cores on the wiring harnesses of the offending devices. Snap-on cores come in a variety of sizes and formulations called mixes. The best all-around ferrite core material for mobile RFI issues is Mix 31. Suitable cores are available from most Amateur Radio dealers. Unknown surplus units typically offer little HF attenuation and should be avoided. See the **RF Interference**, **RF Techniques**, and **Component Data and References** chapters for more information on ferrite cores.

Alternator whine can be another form of RFI egress. It is typically caused by an incorrectly mounted antenna resulting in a ground loop, rather than a defective alternator diode or inadequate dc power filtering as has been the traditional solution. Attempting to solve alternator whine with a dc filter can mask the problem and increases I<sup>2</sup>R losses. Additional

information on proper antenna mounting is in the **Antennas** chapter.

RFI ingress to the various on-board electronic devices is less common. The major causes are unchecked RF flowing on the control wires and common mode currents flowing on the coax cable of remotely-tuned HF antennas. Again, this points out the need to properly mount mobile antennas.

For more information on RFI issues, see the **RF Interference** chapter, *The ARRL RFI Handbook*, and the ARRL Technical Information Service ([www.arrl.org/tis](http://www.arrl.org/tis)).

## Air Bags and Mobile Installation

Since 1998 all passenger vehicles are required to have Supplemental Restraint Systems (SRS), better known as *airbags*. Side airbags and airbags for rear seat passengers have become commonplace. When used in conjunction with seat belts, they've become a great life saving device, but they do have a drawback — they literally explode when they deploy!

Airbags deploy within 200 ms, expanding at about 200 mph, driven by gas from a controlled explosion.

**Figure 24.A** drawing shows a typical vehicle with several air bags deployed in the passenger compartment. Any radio gear within range of an airbag will be ripped free with great force and flung about the interior. This should eliminate from consideration any dash-top mounting scheme including windshield suction cup (mobile phone) mounts, so often employed.

**Figure 24.B** shows the passenger compartment of a vehicle with airbags deployed after a minor collision that caused less than \$300 damage to the bumper. Note the loose piece of dashboard on top of the deflated air bag and the broken windshield. These are typical effects of a deploying airbag, whether from the top or center of the dash. Knowing how airbags deploy, avoid mounting radio gear anywhere near them.

It is always a difficult task finding a suitable mounting location for a transceiver and/or control head that is out of airbag range yet easily seen and operated. One workaround is a gooseneck mount (see **Table 24.1** for a list of suppliers). These attach via a seat bolt (no hole needed). They're a good alternative as long as they're placed away from the passenger airbag deployment area (the whole right side of the dashboard). The dealer for your make and model may have additional guidelines for mounting radios and control heads in the car.

**Figure 24.B — Airbag deployment following a minor collision caused significant disruption inside the passenger compartment.**

## 24.2.6 Operating

The most important consideration while operating mobile-in-motion is safety! Driver distraction is a familiar cause of vehicle crashes. While Amateur Radio use is far less distracting than mobile phones or texting, there are times when driving requires all of our attention. When bad weather, excessive traffic, or a construction zone require extra care, play it safe — hang up the microphone and turn off the radio!

In addition to properly installing gear, a few operating hints can make your journey less distracting. One of those is familiarization with your transceiver's menu functions and its microphone keys (if so equipped). Even then, complicated programming or adjustments are not something to do while underway.

Logging mobile contacts has always been difficult. Compact digital voice recorders have made that function easy and inexpensive. Units with up to 24 hours of recording time are available for less than \$50.

## 24.3 Portable Installations

Many amateurs experience the joys of portable operation once each year in the annual emergency exercise known as ARRL Field Day. Setting up an effective portable station requires organization, planning and some experience. For example, some knowledge of propagation is essential to picking the right band or bands for the intended communications link(s). Portable operation is difficult enough without dragging along excess equipment and antennas that will never be used.

Some problems encountered in portable operation that are not normally experienced in fixed-station operation include finding an appropriate power source and erecting an effective antenna. The equipment used should be as compact and lightweight as possible. A good portable setup is simple. Although you may bring lots of gear to Field Day and set it up the day before, during a real emergency speed is of the essence. The less equipment to set up, the faster it will be operational.

### 24.3.1 Portable AC Power Sources

There are three popular sources of ac power for use in the field: batteries, dc-to-ac inverters, and gasoline powered generators. Batteries and inverters are covered in detail in the **Power Sources** chapter. This section will focus on gasoline powered generators. The book *Emergency Power for Radio Communications* by Mike Bryce, WB8VGE

For maximum intelligibility at the other end, avoid excessive speech processing and too much microphone gain. Don't shout into the microphone! It's human nature to increase your speaking level when excited or when the background level increases. In the closed cabin of a vehicle, your brain interprets the reflected sound from your own voice as an increase in background level. Add in a little traffic noise and by the end of your transmission you're in full shout mode! One solution is to use a headset and the transceiver's built-in monitor function. Doing so gives you direct feedback (not a time-delayed echo), and your brain won't get confused. Note that headset use is not legal in some jurisdictions and never legal if both ears are covered.

Overcoming vehicle ambient noise levels often requires the use of an external speaker and all too often it is an afterthought. Selecting a speaker that is too small accentuates high frequency noise which makes reception tiresome. Using adapters to interface with vehicle stereo systems isn't productive for the

same reason. For speakers that are too large, mounting becomes a safety issue.

For best results, use at least a 4-inch speaker. Rather than mount it out in the open, mount it out of the way, under the driver's seat. This attenuates the high frequency noise, and enhances the mid-range response which increases intelligibility.

Many vehicle audio systems now support audio input from external sources including analog (headphone audio), USB, and Bluetooth. You may be able to route your mobile rig's audio through the vehicle audio system using one of these methods. The audio sounds far better than through a small speaker!

Most modern transceivers contain some form of DSP (digital signal processing) noise reduction as covered in the **DSP and SDR Fundamentals** chapter. Some are audio based and some are IF based, with the latter being preferred. But both types do a decent job of reducing high-frequency hiss, static spikes, and even ignition hash.

is another good resource for generator application information.

Essentially, a generator is a motor that's operating "backward." When you apply electricity to a motor, it turns the motor's shaft (allowing it to do useful work). If you need more rotational power, add more electricity or wind a bigger motor. Take the same motor and physically rotate its shaft and it generates electricity across the same terminals used to supply power when using the motor as a motor. Turn the shaft faster and the voltage and frequency increase. Turn it slower and they decrease. To some degree, all motors are generators and all generators are motors. The differences are in the details and in the optimization for specific functions.

A "motor" that is optimized for generating electricity is an alternator — just like the one in your car. The most basic generators use a small gas engine to power an ac alternator, the voltage and frequency of which depends on rotational speed. Because the generator is directly coupled to the engine, the generator's rotational speed is determined by the speed of the engine. If the engine is running too fast or too slow, the voltage and frequency of the output will be off. If everything is running at or near the correct speed, the voltage and frequency of the output will be a close approximation of the power supplied by the ac mains — a 120 V ac sine wave with a frequency of 60 Hz. These are referred to as *constant-speed generators*. Most consumer models use two pole armatures that run at 3600 RPM to pro-

duce a 60 Hz sine wave.

*Inverter generators* produce high-voltage, multiphase ac that is rectified to dc — similar to an automobile alternator. The dc power is then converted back to very clean and consistent ac power by a solid state power inverter controlled by a microprocessor. Unlike the constant-speed generators, inverters can run at idle while still providing power, increasing speed to meet additional demand. This improves economy and reduces emissions. The most common models are available with capacities to approximately 2000 W output and some can be paralleled with special cables for higher capacity. The June 2012 *QST* Product Review "A Look at Gasoline Powered Inverter Generators" compares several popular models available at that time and is provided on the CD-ROM accompanying this book.

### VOLTAGE REGULATION

There are several electronic and mechanical methods used to "regulate" the ac output — to keep the voltage and frequency values as stable as possible as generator and engine speeds vary because of current loads or other factors. Remember, a standard generator *must* turn at a specific speed to maintain output regulation, so when more power is drawn from the generator, the engine must supply more torque to overcome the increased physical/magnetic resistance in the generator's core — the generator *can't* simply spin faster to supply the extra power.

Most generators have engines that use mechanical or vacuum “governors” to keep the generator shaft turning at the correct speed. If the shaft slows down because of increasing generator demand, the governor “hits the gas” and draws energy stored in a heavy rotating flywheel, for example, to bring (or keep) the shaft speed up to par. The opposite happens if the generator is spinning too fast.

In addition to mechanical and vacuum speed regulating systems, generators that are a step up in sophistication additionally have electronic automatic voltage regulation (AVR) systems that use special windings in the generator core (and a microprocessor or circuit to monitor and control them) to help keep things steady near 120 V and 60 Hz. AVR systems can respond to short term load changes much more quickly than mechanical or vacuum governors alone. A decade ago AVR generators were the cream of the crop. Today, they’re mostly used in medium to large units that can’t practically employ inverters to maintain the best level of output regulation. You’ll find them in higher quality 5 to 15 kW “home backup systems” and in many recreational vehicles.

### Isolate Source and Load

Basic, inexpensive generators are intended to power lights, saws, drills, ac motors, electric frying pans and other devices that are not dependent on clean sine-wave power. If you want the highest margin of safety when powering computers, transceivers and other sensitive electronics, a portable *inverter generator* is the best way to go. Some popular examples are shown in **Figure 24.30**, and their key specifications are shown in **Table 24.2**. Available in outputs ranging from 1 to 5 kW, these generators use one or more of the mechanical regulation systems mentioned previously, but their ultimate benefit comes from the use of a built-in ac-dc-ac inverter system that produces beautiful — if not perfect — 60 Hz sine waves at 120 V ac, with a 1% to 2% tolerance, even under varying load conditions.

Instead of using two windings in the generator core, an inverter generator uses 24 or more windings to produce a high frequency ac waveform of up to 20 kHz: A solid state inverter module converts the high frequency

ac to smooth dc, which is in turn converted to clean, tightly regulated 120 V ac power. And that’s not all. Most inverter generators are compact, lightweight and quiet.

### GENERATOR CONSIDERATIONS

In addition to capacity and output regulation, other factors such as engine type, noise level, fuel options, fuel capacity, run time, size, weight, cost or connector type, may factor in your decision. Consider additional uses for your new generator beyond Field Day or other portable operation.

### Power Rating

Your generator must be able to safely power all of the devices that will be attached to it. Simply add up the power requirements of *all* the devices, add a reasonable safety

margin (25 to 30%) and choose a suitably powerful generator that meets your other requirements.

Some devices — especially electric motors — take a lot more power to start up than they do to keep running. A motor that takes 1000 W to run may take 2000 to 3000 W to start. Many items don’t require extra start-up power, but be sure to plan accordingly.

Always plan to have more capacity than you require or, conversely, plan to use less gear than you have capacity for. Running on the ragged edge is bad for your generator *and* your gear. Some generators are somewhat overrated, probably for marketing purposes. Give yourself a margin of safety and don’t rely on built-in circuit breakers to save your gear during overloads. When operating at or beyond capacity, a generator’s frequency and voltage can vary widely before the current breaker trips.

### Size and Weight

Size and weight vary according to power output — low power units are lightweight and physically small, while beefier models are larger, weigh more and probably last longer. Watt for watt, however, most modern units are smaller and lighter than their predecessors. Models suitable for ham radio typically weigh between 25 and 125 pounds.

### Engines and Fuel

Low end generators are typically powered by low-tolerance, side valve engines of the type found in discount store lawnmowers. They’re noisy, need frequent servicing and often die quickly. Better models have overhead valve (OHV) or overhead cam (OHC) engines, pressure lubrication, low oil shutdown, cast iron cylinder sleeves, oil filters, electronic ignition systems and even fuel injection. These features may be overkill for occasional use but desirable for more consistent power needs.

Generators used for emergency power are frequently left idle for long periods of time. Running the generator up to 30 minutes every so often — six months is frequently suggested — is a good way to keep it ready. After you use the generator for an emergency or to keep it in good condition, run it until the gas tank and carburetor are completely dry. Another option is to close the fuel shut-off valve and

**Figure 24.30** — Modern inverter generators from Honda and Yamaha. See **Table 24.2** for a partial list of specifications.

run the generator until the carburetor is dry.

If you store the generator with fuel in the tank, use a fuel stabilizer additive to prevent varnish build up and to absorb any condensation that may occur. In addition, ethanol-free gasoline, if available, holds up better for long storage periods. Generator shops, powersports dealers, power equipment dealers, and RV websites are good sources of recommendations for additives and sources of ethanol-free gas. Gasoline stored in a container should also be regularly rotated out by using it in a vehicle and refilling the container or an additive for storing gasoline should be added.

## Run Time

Smaller generators usually have smaller gas tanks, but that doesn't necessarily mean they need more frequent refueling. Some small generators are significantly more efficient than their larger counterparts and may run for half a day while powering small loads. As with output power, run times for many units are somewhat exaggerated and are usually specified for 50% loads. If you're running closer to max capacity, your run times may be seriously degraded. The opposite is also true. Typical generators run from three to nine hours on a full tank of gas at a 50% load.

## Noise

Except for ham-friendly inverter units — which are eerily quiet thanks to their high tech, sound dampening designs — standard generators are almost always too loud. Noise levels for many models are stated on the box, but try to test them yourself or talk to someone who owns the model you're interested in before buying. Environmental conditions, distance to the generator and the unit's physical orientation can affect perceived noise levels.

Generators housed in special sound dampened compartments in large boats and RVs can be much quieter than typical "outside" models. However, they are expensive and heavy, use more fuel than compact models, and most don't have regulation specs comparable to inverter models.

## Regulation

For hams, voltage and frequency regulation are the biggies. AVR units with electronic output regulation (at a minimum) and inverter generators are highly desirable and should be used exclusively, if only for peace of mind.

Unloaded standard generators can put out as much as 160 V ac at 64 Hz. As loads increase, frequency and voltage decrease. Under full load, output values may fall as low as 105 V at 56 Hz. Normal operating conditions are somewhere in between.

Some hams have tried inserting uninterruptible power supplies (UPSs) between the

generator and their sensitive gear. These devices are often used to maintain steady, clean ac power for computers and telecommunication equipment. As the mains voltage moves up and down, the UPS's Automatic Voltage Regulation (AVR) system bucks or boosts accordingly. The unit's internal batteries provide power to the loads if the ac mains (or your generator) go down.

In practice, however, most UPSs can't handle the variation in frequency and voltage of a generator powered system. When fed by a standard generator, most UPSs constantly switch in and out of battery power mode — or don't *ever* switch back to ac power. When the UPS battery goes flat, the unit shuts off. Not *every* UPS and *every* generator lock horns like this, but an inverter generator is a better solution.

## RF Noise

Some generators create RF noise in the HF bands as common-mode current on connected power cords. Glen Brown, W6GJB, built and Jim Brown, K9YC, designed the choke in **Figure 24.31** to suppress the noise. The assembly consists of a pair of chokes in

**Figure 24.31** — A heavy-duty common-mode RF choke wound on Type 31 ferrite cores for ac generators. K9YC and W6GJB use this choke during portable operating. See the text for construction details.

series, each consisting of 8 turns of #14 AWG Romex-type cable wound on Type 31, 2.4-inch OD ferrite toroids. One choke is wound on two cores for 80- and 40-meter coverage. The second choke is wound on one core for 10 MHz and above. (Figure 24.31A) The chokes are attached directly to a duplex outlet installed in an electrical enclosure (Figure 24.31B). A heavy-duty extension cord connects the choke to the generator.

## DC Output

Some generators have 12 V dc outputs for charging batteries. These range from 2 A trickle chargers to 100 A powerhouses. Typical outputs run about 10 to 15 A. As with the ac outputs, be sure to test the dc outputs for voltage stability (under load if possible) and ripple. Car batteries aren't too fussy about a little ripple in the charging circuit, but your radio might not like it at all!

## Miscellaneous

Other considerations include outlets (120 V, 240 V and dc output), circuit breakers (standard or ground fault interrupter type), fuel level gauges, handles (one or two), favorite brands, warranties, starters (pull or electric), wheels, handles or whatever you require.

## SETUP, SAFETY AND TESTING

Before starting the engine, read the user manual. Carefully follow the instructions regarding engine oil, throttle and choke settings (if any). Be sure you understand how the unit operates and how to use the receptacles, circuit breakers and connectors.

Make sure the area is clean, dry and unobstructed. Generators should *always* be set up outdoors. Do not operate gas powered engines in closed spaces, inside passenger vans, inside covered pickup beds, etc. If rain is a possibility, set up an appropriate canopy or other outdoor protective structure. Operating generators and electrical devices in the rain or snow can be dangerous. Keep the generator and any attached cords dry!

Exhaust systems can get hot enough to ignite certain materials. Keep the unit several feet away from buildings, and keep the gas can (and other flammable stuff) at a safe distance. Don't touch hot engines or mufflers!

When refueling, shut down the generator and let things cool off for a few minutes. Don't smoke, and don't spill gasoline onto hot engine parts. A flash fire or explosion may result. Keep a small fire extinguisher nearby. If you refuel at night, use a light source that isn't powered by the generator and can't ignite the gasoline.

## Testing

Before starting (or restarting) the engine, disconnect all electrical loads. Starting the

unit while loads are connected may not damage the generator, but your solid state devices may not be so lucky. After the engine has warmed up and stabilized, test the output voltage (and frequency), if possible, *before* connecting loads.

Because unloaded values may differ from loaded values, be sure to test your generator under load (using high wattage quartz lights or an electric heater as appropriate). Notice that when you turn on a hefty load, your generator will “hunt” a bit as the engine stabilizes. Measure ac voltage and frequency again to see what the power conditions will be like under load. See your unit’s user manual or contact the manufacturer if adjustments are required.

### Safety Grounds and Field Operation

The NEC addresses safety grounding for this type of generators in section 250.34. The NEC considers “portable” to describe a generator that is easily carried from one location to another by a person. “Mobile” applies to generators that are capable of being moved on wheels or rollers and includes generators mounted in a vehicle.

A ground rod or other direct earth connection is not required for portable generators as long as the generator has receptacles mounted on the generator panel and the receptacles have equipment grounding terminals (i.e. the third ground pin of an ac receptacle) that are bonded to the frame of the generator. Equipment must be connected to the generator through a suitable cord and plug, such as the usual extension cord. Any exposed metal surface of the equipment must be connected through the ground wire of the power cord to the receptacle ground terminal, as well. If the generator is mounted in a vehicle the same rules apply as long as the equipment supplied by the generator is mounted on the vehicle and the frame of the generator is bonded to the frame of the vehicle. In both cases, it is OK to use a ground rod connected to the generator frame but you don’t have to.

Ground rods may be used if desired. If the generator is more than a short distance from the station or if more than one separate station is powered by the same generator, a ground rod at the generator and at each station may be prudent (with all ground rods bonded together).

Regardless of the grounding method you choose, a few electrical safety rules remain the same. Your extension cords *must* have intact, waterproof insulation, three “prongs” and three wires, and must be sized according to loads and cable runs. Use #14 to #16 AWG, three wire extension cords for low wattage runs of 100 feet or less. For high wattage loads, use heavier #12 AWG, three-wire cords designed for air compressors, air

conditioners or RV service feeds. If you use long extension cords to power heavy loads, you may damage your generator or your radio gear. When it comes to power cords, think *big*. Try to position extension cords so they won’t be tripped over or run over by vehicles. And don’t run electrical cords through standing water or over wet, sloppy terrain.

During portable operations, try to let all operators know when the generator will be shut down for refueling so radio and computer gear can be shut down in an orderly manner. Keep the loads disconnected at the generator

until the generator has been refueled and restarted.

### 24.3.2 Portable DC Power Sources

If a generator is not available to supply ac voltage for portable operation, starter or marine deep-cycle batteries are often used for portable or Field Day operation. Battery-only dc operation has its own unique set of problems, not the least of which is voltage stability.

**Figure 24.33** — Telescoping fiberglass poles can be used to support a variety of wire antennas or small VHF/UHF Yagis. The one shown in A is 40 feet long, yet collapses to 8 feet for storage. At B, a typical twist-lock mechanism secures the sliding sections in place.

Most solid-state transceivers are designed to operate at a nominal 13.8 V from a battery being charged by a vehicle's engine. Depending on the battery type, resting voltage may be as low as 12.2 V (lead-acid in this case). As the battery's state of charge (SoC) is reduced, so is the voltage, especially under load. (See the **Power Sources** chapter for complete information on batteries, including charging.) As voltage falls, transmit signal quality begins to drop, sometimes drastically, and output power drops off as well. Further, most transceivers will simply shut themselves off once their input voltage drops to approximately 11.6 V. There are two

popular workarounds to the problem.

First, multiple batteries wired in parallel may be used to extend operating time. But their terminal voltage when not being charged is still around 12 – 12.2 V, well below what the radio wants to see. Several manufacturers and distributors sell “battery boosters” that provide a regulated output of 13.8 V as battery voltage varies. Booster efficiency varies with the input voltage and current draw, but hovers around 80%.

Another workaround in some cases is a dc-to-dc converter which runs from a nominal input of 24 or 48 V, providing a regulated output of 13.8 V. In this case, two (or more) 12 V batteries are wired in series or in series-parallel to extend operating time. Converter efficiency is typically greater than 88%. Both ground-isolated and non-isolated models are available. The latter units use a common bus for the negative connection between power source batteries and output connections.

Whichever method is used, battery voltage should be monitored to assure long battery charge-cycle life. For example, a nominal 12 V lead-acid battery is considered 100% discharged when the voltage under load reaches 10.5 V. Below this level the charge-cycle life is reduced. Other battery types have similar SoC (discharge) level ratings.

### 24.3.3 Portable Antennas

An effective antenna system is essential to all types of operation. Effective portable antennas, however, are more difficult to devise than their fixed-station counterparts. A portable antenna must be light, compact

and easy to assemble. It is also important to remember that the portable antenna may be erected at a variety of sites, not all of which will offer ready-made supports. Strive for the best antenna system possible because operations in the field are often restricted to low power by power supply and equipment considerations. Some antennas suitable for portable operation are described in the **Antennas** chapter.

### ANTENNA SUPPORTS

While some amateurs have access to a truck or trailer with a portable tower, most are limited to what nature supplies, along with simple push-up masts. Select a portable site that is as high and clear as possible. Elevation is especially important if your operation involves VHF. Trees, buildings, flagpoles, telephone poles and the like can be pressed into service to support wire antennas. Drooping dipoles are often chosen over horizontal dipoles because they require only one support.

An aluminum extension ladder makes an effective antenna support, as shown in **Figure 24.32**. In this installation, a mast, rotator and beam are attached to the top of the second ladder section with the ladder near the ground. The ladder is then pushed vertical and the lower set of guy wires attached to the guy anchors. When the first set of guy wires is secured, the ladder may be extended and the top guy wires attached to the anchors. Do not attempt to climb a guyed ladder.

Telescoping fiberglass poles (**Figure 24.33**) are popular for supporting wire verticals, inverted Vs and small VHF/UHF antennas. These poles can extend up to 40 feet in length, yet retract to 4 to 8 feet for easy trans-

port. They typically weigh less than 20 pounds, and some are much lighter.

Figures 24.34 and 24.35 illustrate two methods for mounting portable antennas described by Terry Wilkinson, WA7LYI. Although the antennas shown are used for VHF work, the same principles can be applied to small HF beams as well.

In Figure 24.34A, a 3 foot section of Rohn 25 tower is welded to a pair of large hinges, which in turn are welded to a steel plate measuring approximately 18 x 30 inches. One of the rear wheels of a pickup truck is “parked” on the plate, ensuring that it will not move. In Figure 24.34B, quad array antennas for 144 and 222 MHz are mounted on a Rohn 25 top section, complete with rotator and feed lines. The tower is then pushed up into place using the hinges, and guy ropes, anchored to heavy-duty stakes driven into the ground, complete the installation. This method of portable tower installation offers an exceptionally easy-to-erect, yet sturdy, antenna support. Towers installed in this manner may be 30 or 40 feet high; the limiting factor is the number of “pushers” and “rope pullers” needed to get into the air. A portable station located in the bed of the

pickup truck completes the installation.

The second method of mounting portable beams described by WA7LYI is shown in Figure 24.35. This support is intended for use with small or medium-sized VHF and UHF arrays. The tripod is available from any dealer selling television antennas; tripods of this type are usually mounted on the roof of a house. Open the tripod to its full size and drive a pipe into the ground at each leg. Use a hose clamp or small U-bolt to anchor each leg to its pipe.

The rotator mount is made from a 6-inch-long section of 1.5-inch-diameter pipe welded to the center of an “X” made from two 2-foot-long pieces of concrete reinforcing rod (rebar). The rotator clamps onto the pipe, and the whole assembly is placed in the center of the tripod. Large rocks placed on the rebar hold the rotator in place, and the antennas are mounted on a 10 or 15 foot tall mast section. This system is easy to make and set up.

#### TIPS FOR PORTABLE ANTENNAS

Any of the antennas described in the **Antennas** chapter or available from commercial manufacturers may be used for por-

table operation. Generally, though, big or heavy antennas should be passed over in favor of smaller arrays. The couple of decibels of gain a 5-element, 20 meter beam may have over a 3-element version is insignificant compared to the mechanical considerations. Stick with arrays of reasonable size that are easily assembled.

Wire antennas should be cut to size and tuned prior to their use in the field. Be careful when coiling these antennas for transport, or you may end up with a tangled mess when you need an antenna in a hurry. The coaxial cable should be attached to the center insulator with a connector for speed in assembly. Use RG-58 for the low bands and RG-8X for higher-band antennas. Although these cables exhibit higher loss than standard RG-8, they are far more compact and weigh much less for a given length.

Beam antennas should be assembled and tested before taking them afield. Break the beam into as few pieces as necessary for transportation and mark each joint for speed in reassembly. Hex nuts can be replaced with wing nuts to reduce the number of tools necessary.

## 24.4 Remote Stations

The following section was updated by Ken Norris, KK9N, from material originally contributed by Rick Hilding, K6VVA. Although this section focuses on “remoting” HF equipment, the same considerations apply to most remotely-operated stations, with the exception of repeater installations.

### 24.4.1 Introduction to Remote Stations

Remote stations (stations operated by remote control) have been a part of Amateur Radio for decades, but usually in the form of VHF/UHF repeaters. In the past, a few remote stations operating on HF have been developed in impressive locations with significantly more land, equipment and expense than for a repeater installation. Prior to the expansion of Internet technologies, some of these remote pioneers utilized VHF/UHF links, dialup, or commercial microwave equipment for connectivity between the remote and home stations. There has been a significant increase in the number of remote stations over the last 10 years and the trend is accelerating rapidly.

Since this section was originally written, there have been several new developments and refinements of the technology available to access your home or remote station. As latency across the Internet has been reduced, operating in fast-paced contests over very long links — even between continents — is now commonplace.

You may want to monitor your home station while you’re away, avoid homeowner restrictions on outdoor antennas, or fight interference issues from electrical power lines, plasma TVs, network routers, and the like. With today’s technology your home station or a remote HF station may be as simple as a 100-W HF radio and all-band dipole or vertical, or a fully automated contest station, with connectivity to the operator via the Internet. There is a flavor of remote station to meet almost every taste and budget.

This overview of remote station operation looks at different methods of remote operation and how they are each unique in equipment and technologies. There is no cookbook approach to creating a remote station. This discussion is intended to introduce topics to be considered in the circumstances encountered by each station builder.

Two important definitions that will be used throughout this chapter are the naming of the locations of equipment. The location for your radio, host computer, amplifier and antennas is your *station site* whether this is at your house or at a distant site. The other end of the connection is the *remote client* location. This location consist of the computer in front of

you with the remote computer running client software and possibly a remote radio head (front panel) connected to the station site.

### LICENSING AND REMOTE OPERATION

Before discussing the technical details, it must be emphasized that operating a remote station also carries with it an extra responsibility to be properly licensed and to identify your station correctly. Because the transmissions are made from the location of the remote station, you must follow the regulations that apply at the remote location. This is particularly important when the station is outside the jurisdiction of the regulatory authority that granted your license, such as a US ham operating a station in South America or a European ham operating a station in the US. You must be properly licensed to transmit from the remote station! This may require a separate license or reciprocal operating permission from the country where the remote station is located. FCC rules require the control operator of a remotely-controlled station to have a US license, regardless of where the operator is located.

Don’t assume that because you have a US license, you automatically have a corresponding license to operate a remote station outside the US. For instance, CEPT agreements generally do not apply to operators who are not physically present in the country of the transmitter and you may be required to be physically present at the transmitter, as well. There may also be contest or award rules that apply to remote stations — be sure to know and follow all rules that apply.

### 24.4.2 Types of Remote Operation

#### REMOTE RECEIVERS

There are several different options for remote operation today. The most basic is the many remote receivers that are available online. These receivers are maintained by other amateurs and communication hobbyists and can be used by anyone with a computer, web browser, and the Internet. Websdr and GlobalTuner are just two examples of remote monitoring sites and there are many more. (See this section’s Resources list for URLs of these and other websites.) These websites give you the opportunity to be able to monitor radio activities in other countries or your own signal from another location.

Amateurs are also using the Raspberry Pi microcomputers, USB SDR receivers, and a long wire to build remote radio servers. The technologies available on these micro-

computers allow remote access through a WiFi or cellular modem, connectivity by VPN (Virtual Private Network) or VNC (Virtual Network Computing) software and RDP (Remote Desktop Protocol), or use the operating system’s built-in web publisher to produce the screen of the radio software. The best part is that all the components are low-powered enough to be powered by a solar cell on top of a mountain or at a friend’s farm.

### REMOTING YOUR HOME STATION

With the availability of high speed internet through cell phones or hotel room and office WiFi, operating your Amateur Radio station while at work, traveling, vacationing, or just visiting the family has become an enjoyable part of the hobby. Your remote connection, referred to as “remoting,” can be as simple as a computer or cell phone monitoring the audio from your radio for the frequency you left it on, to full automated control and a remote radio control head so you can catch that last needed DX country to fulfill your DXCC award. Some Amateur Radio operators have removed their HF equipment from their vehicles and installed remote connections to their home stations.

### DEDICATED REMOTE STATION

There are many Amateur Radio operators who are handicapped by homeowners’ association requirements or living in a temporary location, apartment, or retirement home that restricts the installation of outdoor antennas. Other operators live in areas where noise from electrical utilities and electronic devices render an HF receiver almost useless. For these reasons, setting up a station away for the restrictions and noise can be very appealing.

Some contesters build a remote station in another country in order to be the DX while operating from home. Setting up a remote station in another country does not add any more equipment than a station a few miles out of town. It does add different rules and regulations to your operating that must be followed.

Maintenance is also more difficult. If you want to find out why the amplifier is alarming when operating on 40 meters, a 6-hour flight to a remote site is no trivial matter. Technology is available for remote monitoring the remote site. As long as you have Internet connectivity to the remote site, there are ways of troubleshooting your problems.

### 24.4.3 Remote Networking Basics

Today, the Internet has become the preferred source for connectivity of your

remote station. Landline telephones can still be used for remote DTMF control of your equipment or as a source for transferring the audio to and from your remote radio.

With the availability of high-speed Internet at your home, at the office, or on the road from WiFi and mobile phones, reliable connectivity to your remote station has become easier. This ease of connectivity does come with the need to understand more about networking and how computers and other TCP devices communicate with each other. This section has been included to expose you to terminologies and technology that will aid in getting your Internet equipment connected and operational. (See this section's Glossary for definitions of terms, abbreviations, and acronyms.)

## ROUTER AND PORT FORWARDING

When you turn on your computer at home to browse the Internet, it does not connect directly to the Internet. As seen in **Figure 24.36** the computer first connects to a gateway most commonly known as a *router*. The router then allows the computer to connect to it and awaits to see what the computer wants to do with the connection. When you open your Internet browser on the computer, the router then assigns a numeric *port* within the router for the computer's IP address to route data to the IP address your Internet Service Provider (ISP) has assigned to the router.

This is basically how computers in your private home or work network communicate with the World Wide Web, public computer servers and devices throughout the world. The router is the guardian that controls what

information comes in and goes out of your private network.

*Port forwarding* is an option in most routers that enables you to create a permanent translation table that maps an incoming protocol port from your ISP to a specific IP address on your private network. It is a transparent process, meaning Internet clients cannot see that port forwarding is being performed. This process enables you to remotely connect to TCP/IP-enabled equipment and TCP servers on a computer on your private network that are otherwise hidden from the Internet by your router.

## STATIC OR DDNS IP ADDRESSING

When you sign up with an Internet service, the ISP provides you with a modem to connect their network with the network in your house. Normally when the modem is activated, it will request an IP from the ISP's *Dynamic Host Configuration Protocol* (DHCP) servers. Even though you can find out what the IP address is, you have no control over what IP address is assigned and how often it changes. Because it can be changed, this is a *dynamic IP address*.

For the best connection to the Internet to provide access to your station remotely, a *static IP address* from your ISP is the preferred option. With a static IP address you will be able to easily connect remotely to your remote station without the IP address changing periodically. ISPs are currently assigning more static IP addresses due to better management of active IP addresses and larger companies moving to the new IPv6 routing which has more addresses available. This means the old static IPv4 IP addresses

they were using must be changed, as well.

If you are unable to get a static IP address, there are avenues for finding out what your assigned dynamic IP address is. WhatIsMyIPAddress, MyIPAddress and other websites can tell you the current dynamic IP address you have been assigned from the ISP.

A better way to manage the ISP dynamic IP address is to use a service known as *Dynamic Domain Name System* (DDNS). This service will maintain an external connection to your computer through the modem/router and *firewall*, providing a named address for you to connect to your equipment at home. This requires a small piece of software to run on your computer at home and an external DDNS service provider. Most DDNS service providers charge a fee to maintain and support this connection.

## INTERNET BANDWIDTH

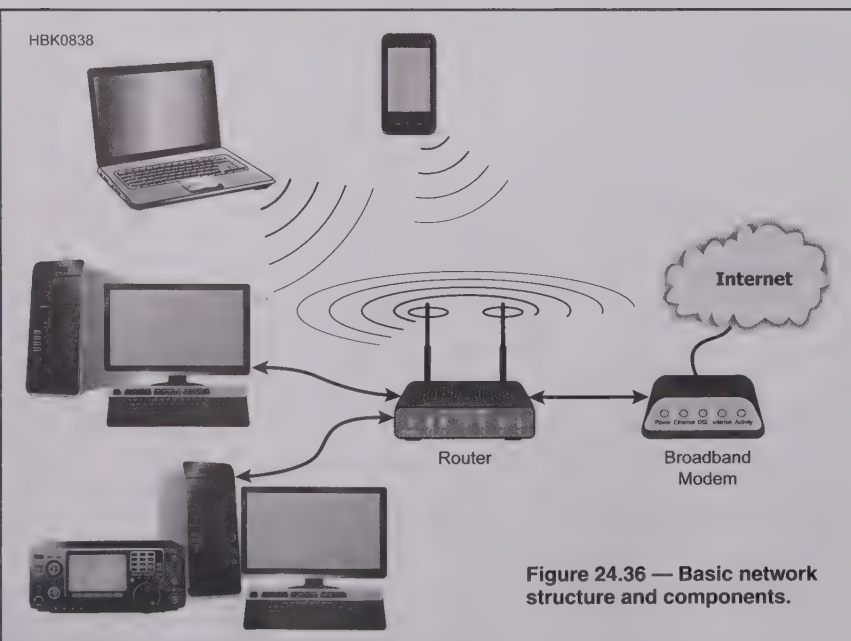

How much Internet bandwidth do you need? How you set up your station, what devices and protocols you use, and what means you use for connecting to the Internet determine if you get a reliable connection or one that freezes or delays when you are copying the call of a DX station.

If you are using a mobile connection for your roaming client station, you need *high-speed* or *high-bandwidth* service, the same as required for a streaming music service. 3G cellular service is the minimum service you can use at 144 kbits/s transfer rate. Mobile network services such as 4G or LTE vary in most areas, but will give you network speeds and reliability closer to what most ISP networks can provide.

Speed is advertised by download speed (the bit rate from the ISP to your computer). *Upload speed* (from your computer to the ISP) may be only 1/2 of the download speed, but is important for getting your audio and control to the transmitter. Using Internet sites such as Speakeasy can give you a good indication of the download and upload speeds on your computer.

It is important to realize that sharing an Internet connection can also cause reduction in bandwidth. If others in your home are online at the same time, their activity will consume some of the bandwidth available to your network devices. A dedicated line or service upgrade to support remote station operation may be required unless you can account for all the concurrent household bandwidth requirements and determine that your service is capable of handling it all. A router with *quality of service* (QoS) prioritizing capabilities might solve or at least minimize multi-user problems on a single-line Internet connection.

Rural ISPs usually consist of a wireless network over large areas. Network speeds can vary depending on the time of day or day

**Figure 24.36 — Basic network structure and components.**

Figure 24.37 — N6RK’s method for testing latency.

of the week. This can be important, especially when you are trying to operate in a contest over a weekend when everyone is home streaming a movie. If you plan to use a webcam for monitoring and security purposes, or stream a panadapter/waterfall type display, you must account for that bandwidth in your overall connectivity needs as well.

Hotels are known to vary network speeds depending on how many guests are in the hotel that night. You can check with the hotel staff to see if there is a secondary WiFi system that can give you more bandwidth.

**INTERNET LATENCY**

You need *low delay* (latency) to operate remote, the same as any online game player. For casual operating, you may be able to tolerate a latency of 250 ms or 300 ms. Serious contesters and DXers will most likely find this much delay frustrating, especially on CW. If you are a high-speed CW contest operator, very low latency is required to be competitive. Below 200 ms is adequate, below 100 ms is better. Otherwise, tuning “lags” and you will experience poor timing in the pileups. Voice and digital operating are more tolerant of delay.

You can easily evaluate basic Internet latency yourself using the computer. In a Windows 7 (PC) environment, under START |

ALL PROGRAMS | ACCESSORIES you will find COMMAND PROMPT, or in a Windows 8 and newer system, select START and type CMD. From within this DOS-like window you can run the *ping*, *tracert* and or *pathping* commands to access a particular IP address at the station site and average the response times to measure the latency. By adding the -t command to the ping command (for example, “ping 192.168.0.1 -t”), you will get continuous ping results until you use the

CTRL-C keys to stop the ping process. This critical to know in advance or to troubleshoot connectivity issues once you are operational.

For the purposes of conducting Internet system audio latency tests, N6RK’s method illustrated in Figure 24.37 is very effective. Using a receiver at the remote site and one at the control point, the recorded latency can easily be determined. Figure 24.38 shows a latency of 40 ms for the return audio over K6VVVA’s private control link using

Figure 24.38 — K6VVVA’s latency test results.

RemoteRig audio interface that requires a network speed of about 180 kbps. The audio is crystal clear and at 40 ms, little difference is noticed from the remote site than from having the radio control head connected directly to the radio at home.

### 24.4.4 Connecting to Your Remote Station

There are many ways to connect, control, and monitor a remote station. What equipment, communications medium to connect them, and how you use your remote station is only limited by time, money, and resources available. The following methods are to be used as guidance as you plan and build your remote Amateur Radio station.

#### BASIC MONITORING

The basic remote monitoring station shown in **Figure 24.39** can consist of very few components. If you just want to set your HF radio on a specific frequency, let's say a 40 meter net, and monitor it from work during your lunch break, then all you need is an audio cable connected from the headphone/speaker

jack on your radio to the microphone jack on your computer. On your computer you will need audio software to provide a connection to your mobile phone or work computer. Using the *Autoanswer* function on the host computer will give you unmanned audio connect. Simply connect the computer/handheld device to the audio software account on your home computer and listen in on the net.

Many remote station operators have found *Skype* to be a workable solution for remote audio routing as well as *IP-Sound*. Another way to completely avoid Internet latency and bandwidth issues for audio is to use a POTS (Plain Old Telephone System) connection with a dedicated analog phone line that might also be shared with a DSL data service for control.

One of the newest technologies available to give you basic remote monitoring is the ability to use a Raspberry Pi as a TCP server for a SDR receiver. There are a few different versions of RTL-SDR TCP servers available that makes it possible for programs like Airspy's *SDR#* to remotely connect to a Raspberry Pi/SDR receiver through the internet.

#### VNC CONNECTIONS

If you enjoy listening to your HF radio and would like to be able to tune remotely through the bands for different conversations, start with an audio cable from your radio's headphone /speaker jack to the microphone input on the computer. Your radio will need to have *computer aided transceiver* (CAT) control capabilities. Radios with CAT control will have a serial, USB, or Ethernet port available for the computer to be able to connect and send control data to the radio. Icom radios have a CI-V control port which require an COM-to-CI-V or USB-to-CI-V interface.

You will then need radio control software installed on the computer. Several radio manufacturers have radio control software available. There are several software companies that have software to control just about any radio with CAT control. Two examples are *Ham Radio Deluxe* and *TRX-Manager*.

Once you have installed the radio control software and connected the computer to the radio, you will need remote access to the host computer. A simple scenario, shown in **Figure 24.40**, uses *Virtual Network*

Figure 24.39 — Basic remote monitoring.

Figure 24.40 — VNC software connection.

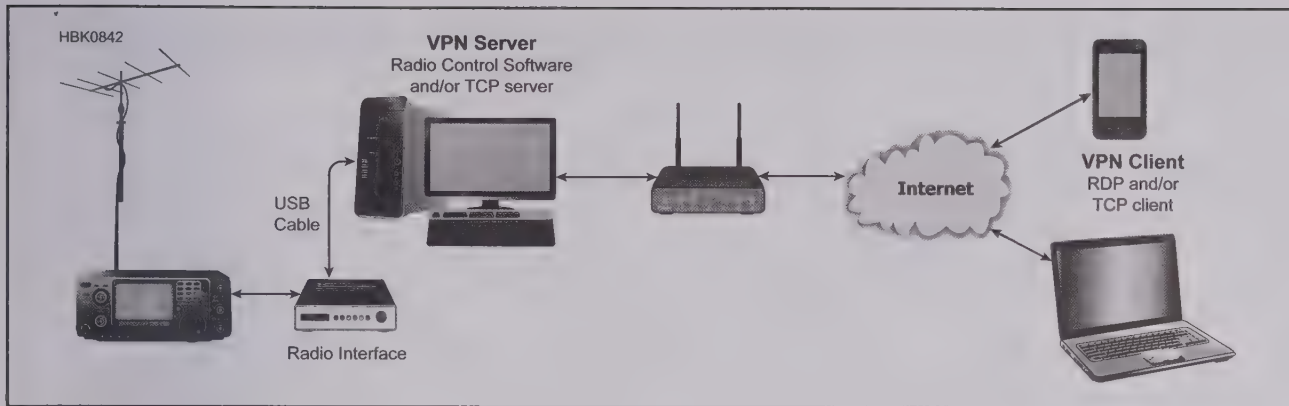

Figure 24.41 — VPN software connection.

Computing (VNC) software, such as *Chrome Remote Desktop*, *TightVNC*, *TeamViewer* or *LogMeIn*, that allows users to take remote control of the host computer running the radio software. VNC software allows full control of the host computer, with some software including the sound interface and others requiring additional software for monitoring for the audio. Audio server software like *Skype* and *IP-Sound* can also be used. Be aware that some VNC software packages charge extra for access to the remote sound. This software does take a lot of bandwidth to pass the screens and control between the connected computers/handheld devices.

All of the VNC software options mentioned here can be accessed with an iPhone, iPad, Android phone or tablet. Once you have connected to your station with the VNC software, you will be able to change frequency and bands using the radio control software on the host computer.

### VPN CONNECTIONS

A virtual private network (VPN) is like a tunnel through public Internet access to connect to a private network, such as your station network. There are a number of VPN software packages and hardware options that enable you to create the Internet connection for transporting data between the computer in front of you and the computer/devices at your home or remote station. A VPN uses encryption and other security mechanisms to ensure that only authorized users can access the network and that the data cannot be intercepted.

The VPN server at the station end can be either on the host computer or in the network router. It depends on if you need connectivity to only the host computer or the whole station network. Microsoft has included VPN servers and clients in recent versions of their operating systems and some network routers include VPN servers. Other VPN software packages include *OpenVPN* and *LogMeIn Hamachi*.

Once you have established a VPN connection to the host computer or router from your client computer, shown in **Figure 24.41**, you will be able to connect your TCP client software to the radio control TCP server software and/or accessories at your station. Another option is connecting to the radio control software on the host computer with a *Remote Desktop Protocol* (RDP) connection to view your radio control software on the screen and use *Skype* or *IP-Sound* for the audio connection. This will give you a secure connection to your station.

Using a VPN connection can be combined with a remote radio head. This will give you secure access to the equipment connected to your radio, and allow you to operate the radio from the remote radio head.

### TCP SERVER/CLIENT

TCP server/client software is two programs that provide a connection over the Internet between your host computer and the client

computer you have in front of you. Each piece of equipment can have its own TCP server/client software installed at both ends.

The TCP server software is installed on a computer that will be connected to your radio, tuner, rotator, or other station equipment, where it communicates with the station equipment by serial, Ethernet, or USB connections. Most of the TCP server software allows you to be able to control the equipment locally on this computer when you are at the station, as well as through a remote Internet connection.

The TCP client software is installed on the computer that will connect to the TCP server software through your Internet connection. This provides you access to the station equipment with a dedicated TCP network connection to each device you connected to a TCP server computer.

There are advantages to using dedicated TCP server/client connections to your station. They use very small data packets, multiple

Figure 24.42 — Ham Radio Deluxe.

TCP servers can be run in parallel for each device, and they can be connected only when you really need to see the data from the remote piece of equipment.

There are several radio manufacturers that have radio control software available utilizing TCP server/client technology. There are also software companies that provide software to control just about any radio with a CAT interface. Examples of this software are *Ham Radio Deluxe* (shown in **Figure 24.42**) and *TRX-Manager*.

### REMOTE RADIO HEADS

Operating remotely from a computer or tablet can be fun and exciting, but it is not the same as turning a VFO or tweaking a bandpass filter knob to dig out the weak DX station. Manufacturers have developed Internet-based interfaces to remotely connect a detachable radio head to the base section of the radio, hundreds of miles away.

One company to advance this idea is Microbit. Their RemoteRig standalone interfaces use separate *Session Initiation Protocol* (SIP), VoIP, and control channels to connect the two parts of the radio over Ethernet. Passing of the audio and control signals, along with CW paddle signals is transparent to the remote radio head. Elecraft even makes the K3/0 remote head for the K3 transceiver that is identical to the front of the radio, giving you full functionality of your K3 station wherever you have Internet access. The W4AAW multi-multi contest station uses the K3/RemoteRig combination at one of the operating positions for off-site operators during contests.

These remote radio interfaces work with several other radios. Remoting the Icom IC-706 and Kenwood TS-480 transceivers is very popular among amateurs. There are groups that have installed the base part of the Icom IC-706 in different locations and have the ability to connect to any one of them from the radio head. They have the capability to change the profile in the RemoteRig at the

radio head for it to connect to the different remote site base units.

**Figure 24.43** shows the Elecraft K3/0 remote head with the RemoteRig interface installed in a tool case for easy transport and setup. One major advantage to using these interfaces with the remote radio heads is the audio and control signals have been streamlined and optimized to best performance between the two interfaces. This makes operating over low bandwidth and weak cellular network possible.

### HAM RADIO ONLINE

If you are unable to invest in the equipment to be able to operate remotely and really want to experience the rush of operating a contest or DX from a station with large antennas and lots of power, there are options available online.

The websites for RemoteHams and RemoteHamRadio offers you a chance to operate world-class Amateur Radio stations around the world from your home. You can either lease a K3/0 remote head or install a TCP client software on your computer, then connect a microphone and/or paddle. Now you have access to a community of stations accessible through the Internet, offering an experience not available through most stations.

The VY1JA remotely controlled contest station in the Yukon Territory is an ongoing work in progress. When the station becomes fully operational, guest operators will be allowed to remotely operate in contests from this unique station in the Canadian north.

### 24.4.5 Station Automation

Automation is key to having a fully functional remote station. The ability to control your rotator, antennas, and amplifier from your computer has been around for some time. Now several manufactures have added remote TCP server/client software to control your station from off-site. The following

section describes software and hardware to enable automation and remote control of your station.

### SWITCHING ANTENNAS

To automate your antenna system, one of the first pieces of hardware you will need is a band decoder. A band decoder detects what band your radio is on and passes this information to the antenna switching network. The band decoders can detect the band either by a binary coded decimal (BCD) output from the radio, through a CI-V interface on an Icom radio, or reading the frequency data from the radio. Band decoding can be accomplished with standalone units, such as the Array Solutions BandMaster or Elecraft KRC2, or a decoder built into an antenna switching controller, as with the Ameritron RCS-12, EA4TX RemoteBox, or Hamation integrated controllers.

An alternative to using a band decoder takes advantage of station control or logging software with the capability to send band data to antenna switching units via Ethernet or serial connections. The Green Heron Engineering antenna switches can be controlled by local software, as well as through TCP server/client software. Snaptek offers a 4-port antenna switch with WiFi and a TCP server built in.

Additional advantages of Hamation antenna switches and EA4TX RemoteBox is the availability of USB connections to the host computer and TCP server/client software. With this software you can reconfigure your automatic antenna selection remotely or manually control what antenna you want to use.

You can simplify your remote station by using one antenna for all the bands. Using a multiband dipole or vertical antenna will eliminate the need for antenna switching. Using the SteppIR BigIR vertical antenna with its controller, for example, gives you a versatile antenna that follows the frequency from your radio.

Figure 24.43 — Remote Station Go Box.

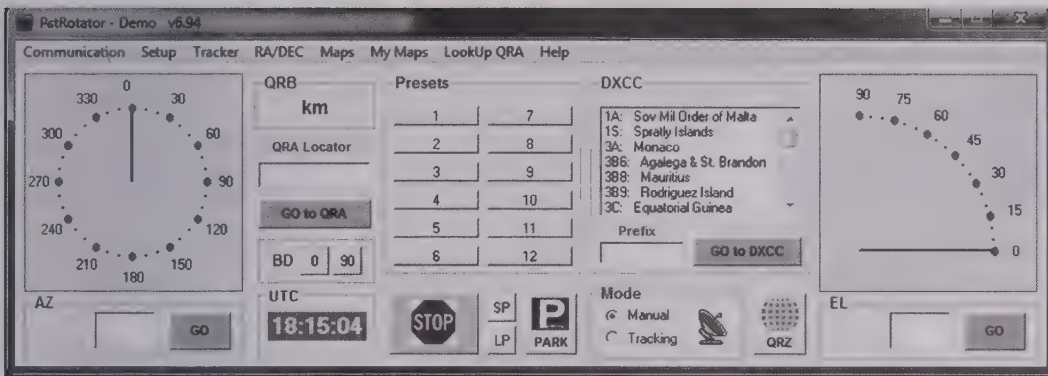

Figure 24.44 — PSTRotator software.

## ROTATORS

Automating your rotator system usually starts with installing an interface in the rotator control box to give your computer control of the rotator. Electronic Rotator Control (ERC) interface kits from Vibroplex or EA4TX give you the capability of connecting to your computer via USB or serial connections.

Most logging and contesting software, either directly or indirectly, gives you control of your rotator as you enter a call sign into the call field of your logging software. *PSTRotator* control software (see **Figure 24.44**) can interface with several logging software packages. It also has built-in TCP server/client software to tie it into your logging software on your remote client computer for automated rotator control from an offsite operating location.

## RF AMPLIFIERS

Several modern amplifiers have the capability of full automation by detecting and following the frequency the radio's output signal. Add this to the automatic antenna switching and tuners found in some of today's high end amplifiers, such as the SPE Expert series, automation of your station has become

much easier. Connecting these amplifiers to your host computer only takes a single USB or serial cable, giving you monitoring and control of half your station.

A remote VPN connection and an RDP session will give you remote access to configure and monitor the amplifier. Combine this with the RemoteRig RC-1216H interface and you will have the ability to remotely configure and operate ACOM and SPE Expert amplifiers.

Another option is to use separate amplifier and tuner/antenna switches. Equipment such as the Elecraft K3 line can be combined to read the frequency data from the K3 transceiver, set the band on the amp, set the tuner to a preset memory location, and select the appropriate antenna. The Elecraft KPA500 amplifier and KAT500 tuner both have serial connections for the host computer, as well as TCP server/client software for control and monitoring from the remote client computer as seen in **Figure 24.45**. Combine this with a remote head radio connection and you have no need for a VPN or VNC connection to your station, providing you with a clean, low bandwidth connection.

## STATION MONITORING

It's important to know that a remote station is operating correctly when in a contest or trying to snag that rare DX station. There are a few manufacturers of power and SWR meters that include serial ports and software to monitor the meter on the host computer. The TelePost LP-100A power meter includes an RS-232 serial port for connection to the host computer. This software can be monitored via a VPN or VNC connection. TCP server/client software from Wizkers will allow remote access to the LP-100A through your host computer.

Several other RF power meters have built-in Ethernet connections and TCP server/client software for direct connection to the meter from a remote site without going through a host computer. The SM $\Omega$ RF meter from MicroHAM shown in **Figure 24.46** is one such example that gives the operator a full range of information about how the station is operating and evaluates the antenna system in the event of a problem.

## POWER AND RELAY CONTROL

There are a lot of ways to remotely turn devices on and off in your shack. If you want

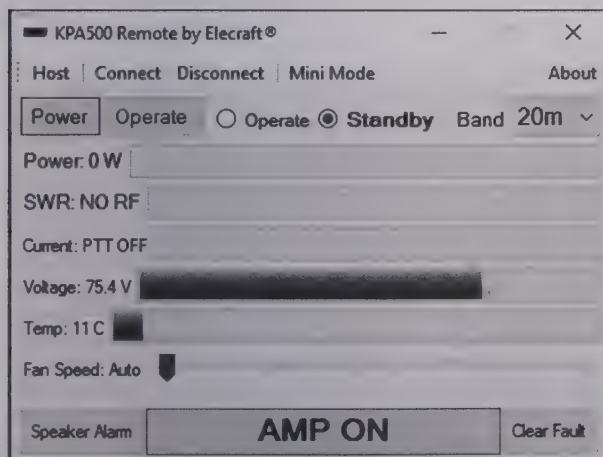

Figure 24.45 — Elecraft KPA500 TCP server/client.

Figure 24.46 — MicroHAM SM $\Omega$ RF power meter.

Figure 24.47 — Belken WiFi switches.

Figure 24.48 — MicroHAM microKEYER II interface.

to turn your radio, amplifier, and computer on and off, or switch between antennas, there is equipment available to do this.

Using your phone line to control devices is as simple as using the DTMF keypad on a phone. Several manufactures produce equipment to connect to the phone line with onboard relays that are turned on and off by DTMF tones. You can buy units with 1 to 8 relays from Velleman and Viking Electronics.

Using the Internet to control relays is also possible. Digital Loggers and Belken produce Ethernet-enabled power strips that can be turned on and off by an app on your Android or iPhone. Figure 24.47 shows how G4IRN uses a pair of WiFi units to turn his amplifier and 12 V power supply on and off. This works great for turning on a power supply or

switching between two antennas. For a lower cost option, Velleman makes a relay kit that connects to your host computer by USB and provides software that runs on the computer with an app to control the relays from your phone.

### RADIO INTERFACES

Connecting the radio to the computer can be as simple as running serial cables and audio cables from the radio to the computer, but serial connections can be difficult to configure and the audio connections can allow noise to get into the receive and transmit audio. It is recommended that an interface between the radio and the computer be installed. Several manufactures make interface for most radio models that have CAT control in them, such

as the ones offered from MicroHAM (see Figure 24.48), Tigertronics, and West Mountain Radio. Using interfaces simplifies connections and configurations. They also provide higher quality analog-to-digital audio converters than what most computers come with.

Several newer radios have the interface built in. A USB cable is all that's required for audio and CAT between the radio and the computer.

### SERIAL PORT SERVERS

Serial port servers, such as the Moxa Nport or Digi Connect series, are interfaces that connect a RS-232/422/485 device to an Ethernet port. These port servers can act as a gateway between two protocols or pass

encapsulated serial traffic between a serial device and a remote computer over Ethernet networks. Unless your software on the client computer is designed to communicate with the serial device over Ethernet, redirect software such as the Digi RealPort is required to manage the encapsulated serial traffic. Serial port servers are used when you do not want to use a computer at the station to connect the serial port on a piece of remote station equipment.

## 24.4.6 Remote Site Requirements

### PURCHASE VS RENT OR LEASE

Although having direct control over every aspect of what you want to do is most desirable, you may want to consider a rental or lease with a cooperative land owner. In either case, having a detailed agreement or contract prepared by a competent attorney is a must. Be sure to include every contingency you can think of, and especially what happens if the land owner decides to sell. Leasing or renting with an option to purchase allows you to fully evaluate the site before making a long-term commitment to it.

### RELIABLE ACCESS BY ROAD

If your remote site is not on developed property, will you be able to get there safely, rain or shine? What happens if any problems develop that require immediate attention at the remote site? Pavement or a good all-weather, well-maintained gravel road should be available. Having more than one means of getting in or out should emergencies arise while you are at the site is also an important consideration. These concerns must be addressed before agreeing to purchase, rent, or lease a remote site.

### GEOLOGICAL AND OTHER HAZARDS

Evaluate the geological factors involved. In a hilltop or mountaintop site, is there evidence of soil movement that could affect access or damage your equipment shelter or tower installations? Does the property sit near an earthquake fault? Is there a significant risk of fire during fire season? Is the site exposed to high wind or storms? In flat-land sites, is there a risk of flooding or drainage problems? Remember, you won't be there to rescue your equipment! In consideration of both your initial construction activities and ongoing maintenance tasks, are there any wildlife hazards from animals or insects? What about allergies or reactions to plants such as poison ivy or poison oak? Diligently investigate all aspects of a potential remote site *before* you end up with bad surprises down the line. For

a reasonable fee, there are companies from which you can secure a Geological and Property Hazards report to aid in your assessment.

### RAW SITE PREPARATION

If you are fortunate enough to locate suitable property, be sure to evaluate the site preparation needs. How much time and money will be necessary to develop the remote site to meet your specific needs? Is there brush and vegetation to be dispensed with? Will trees need to be cut down? Will bulldozers, excavators, and trenchers need access to the site? Concrete trucks? Service vehicles? Diligent evaluation of all costs involved will reduce unnecessary stress.

### SITES WITH EXISTING FACILITIES

Finding a site with a self-supporting tower or two in place that can accommodate your needs, along with a building large enough for your equipment and operational needs can be like finding a pot of remote gold. However, unless you are experienced with towers and construction, hire professionals to evaluate everything. If you are considering co-locating at a remote site with existing antennas and equipment in use, consider hiring a professional to help you evaluate the likelihood of problems. Birdies and intermodulation could end up being a source of potential conflict and stress if problems can't be resolved.

### TERRAIN CONSIDERATIONS

Evaluate the terrain on the bands you wish to operate. For HF, Dean Straw, N6BV, has developed a very useful program called *HFTA* — *High Frequency Terrain Assessment*. (See the *ARRL Antenna Book*.) Use *HFTA* to assist you in placement of your antennas. Don't expect excellent ground/soil conductivity if your remote site is on top of a rocky mountaintop.

If you plan to use vertical antennas, make sure there is sufficient room on the property to place the radials, whether on a mountain-top or flat area. Placing verticals near water, especially saltwater, is the most desirable way to achieve the low takeoff angles for long-haul DX. Remember that exposure to salt air or spray will create significant maintenance issues.

### NOISE LEVELS

Since one of the reasons for building a dedicated remote station away from your home is to lower noise levels, you'll want to carefully evaluate existing and potential noise sources. Start by visiting the site with a receiver in several different types of weather and listening on all the bands you intend to use with a full-size dipole antenna. If noise levels are low, this is no guarantee that

problems won't crop up in different seasons or from hardware failures. You should avoid nearby substations or high-voltage and power distribution lines. If you will be sharing a site with other users, coordinate with them to test intermodulation and adjacent channel interference before you go into full operation.

### ELECTRICAL POWER

Having electrical power already available at your remote site can certainly save a lot of money. The most ideal situation is to have underground power to the remote site. Be sure to evaluate the full costs of installing ac power if it is not already present at the site or on the property. Truly remote sites may require wind, solar, or generator power systems like that shown in **Figure 24.49**.

If your remote site will require solar/wind/battery power, it is critical that you properly assess sunlight path and duration, wind patterns, and provide sufficient battery storage to meet your intended operating needs during lengthy periods of inclement weather. The article "Designing Solar Power System for FM Translators" is a valuable resource for planning of remote HF station off-grid power. (See the Resources section below.) You must thoroughly account for the power requirements of each and every piece of equipment.

There are various estimates for the duty cycle of transceivers. A conservative duty cycle of 50% for CW/SSB is recommended for power capacity evaluation. (RTTY/digital/AM/FM duty cycles will likely be higher.) Internet switches, routers, rotators, computers and anything electrical will also consume power. A supplementary diesel or propane remote-start generator to a basic off-grid system may be an appropriate option, particularly if you plan on using an amplifier. If your remote site is in a rugged terrain rural area, make sure a diesel or propane service provider vehicle can get to the location *before* you make final plans! It may be possible to use smaller propane tanks you can haul in a truck, but any manifold-type system necessitates insuring that the proper BTU requirements can be met based upon the propane generator manufacturer's ratings. Installing a solar and wind remote battery monitor system is advisable.

When you have made an accurate assessment of your complete system needs, add a generous additional contingency factor. It is also advisable to get quotes on your proposed system from at least two different "green power" equipment suppliers, and to make sure they fully understand your requirements and intended use *before* you purchase anything.

**Figure 24.49** — Solar panels can be used to charge a bank of batteries to supply power. Effective off-grid power requires an accurate and conservative estimate of power needs and available energy sources. [Rick Hilding, K6VVA, photo]

### INTERNET ACCESS

If you are planning to operate your remote station via the Internet, be sure that broadband service such as cellular, rural wireless, DSL or cable TV can reach your site by asking the local service provider to do a site evaluation. Satellite Internet downlink speed may be fast, but uplink speed is often quite a bit slower. Be sure the minimum link speed is adequate in both directions.

If your control point is close enough to the remote site, another option is to implement your own private wireless “bridge” system. Even if multiple “hops” are involved, with the right equipment you can potentially have better results than using even broadband Internet. Hamnet technologies (see the **Digital Modes and Protocols** chapter) may be an option to connect a remote station that’s not too far away.

### INSURANCE AND SECURITY

You’ve heard the expression “Stuff Happens.” Unless you have blanket coverage in an existing homeowner’s insurance policy that includes your remote site equipment, look into the ARRL “All-Risk” Ham Radio Equipment Insurance Plan. If you will be hiring others to do work at your remote site, be sure that liability coverage issues are addressed. The same applies to any guests or visitors such as fellow hams. Have a competent attorney draw up a “Liability Release” agreement with strong “Hold

Harmless” language.

If your remote site is yours alone and not a co-habitation arrangement with other services, be sure and evaluate all security needs (a necessity even if co-located). You might need one or more security gates, webcam surveillance and auto-remote notification of security breaches.

### PERSONAL SAFETY

Regardless of your age, it is prudent to have someone with you at the site. You could severely cut yourself, or fall and break a leg. If there are wildlife hazards in the area, take

appropriate steps to protect yourself.

Carry a first aid kit and have one readily available at your remote site. Keep some emergency supplies such as various sealed food items in a varmint-proof container and a case of bottled water in the event you find yourself stranded.

If your remote site is within the coverage area of a local repeater, take along a handheld radio (with batteries charged) as part of your SOP (Standard Operating Procedure). This is especially important for rural and remote operating sites.

### 24.4.7 Station in Your Hand

Operating or just monitoring band conditions from your mobile phone or tablet is almost as easy as from your computer. With today’s smartphone technologies, Skype, VPN, RDP, and VNC connections to your station are quite possible.

There are several apps available or being developed for connections directly to your radio or radio interface. *RRC-Nano* is an app for Android devices from RemoteRig (see **Figure 24.50**), which makes it possible to remote your station. It uses the RemoteRig interface at the station site to provide remote access to the radio through your phone. Another option available is the *SmartSDR* app for the iPhone or iPad to remotely connect to the FlexRadio Systems 6000-series SDR radios.

### 24.4.8 Future of Remote Operating

The Future is Boundless! With upcoming advancements in hardware technologies and software development, operating remotely will soon become second nature. Several Amateur Radio equipment manufacturers have turned their attention to providing remote access to their equipment.

**Figure 24.50** — RemoteRig RRC-Nano phone app

Figure 24.51 — FlexRadio Maestro.

Someday in the not too distant future you will be able to make changes to the amplifier, select a different antenna, or test an antenna to see if severe weather has affected it. All this through the screen on the Maestro-like control console as seen in **Figure 24.51**, while sitting in a coffee shop.

The Raspberry Pi has become a versatile and powerful microcomputer for the radio amateur. There are projects available for band decoding for control of antennas, VPN server interfaces for radios, and USB SDR's for remote monitoring. For more information on project with the Raspberry Pi, view the presentation by Ed James, KA8JMW and Mike Pendley, K5ATM on "Raspberry Pi: A Low Cost Platform for Amateur Radio Projects." The ARRL's *Raspberry Pi Projects for Dummies* is a great book to start with if you have not played with one yet and want to learn how to use them.

### 24.4.9 Special Events and Demonstrations

Remote stations come in very handy during special events. If you are putting on a demonstration of Amateur Radio, setting up an effective antenna may not always be viable, and you may not be able to communicate very far. Local noise levels or RFI problems may present significant challenges.

Setting up a remote link to your home or dedicated remote station will give you a definite advantage and make the experience more enjoyable for the audience. For example, a remote client station was used at a Boy Scout Jamboree-On-The-Air event. Young scouts were given the chance to communicate with other scouts around the world with the help of a capable station without the usual compromises associated with portable stations. This makes for a more effective demonstration of what Amateur Radio can do.

### 24.4.10 Remote Station Glossary

**App** — An application (program) installed on a cellular smartphone.

**Band decoder** — An interface device that reads frequency data from a modern transceiver and facilitates automatic control switching of other equipment such as a bandpass filter.

**Bandwidth** — Typically expressed in Mbps or kbps, this is used to represent both the capability of an Internet connection for data transfer as well as the amount of data that can be transferred.

**CAT** — Computer Aided Transceiver. Used for interface between modern Amateur Radio transceiver and computer. Provides radio control and audio interfacing.

**Cellular Modem** — Also known as a "hot spot", allows an Internet connection through the cellular phone network.

**CEPT** — European Conference of Postal and Telecommunications Administrators. US amateurs are permitted to operate from member nations without the requirement of obtaining additional licenses or permits.

**CI-V** — Proprietary communications medium for interfacing Icom transceivers to computers and associated equipment.

**DDNS** — Dynamic Domain Name System. Internet services provided to associate domain names with Dynamic IP addresses.

**DHCP** — Dynamic Host Configuration Protocol. This functionality is incorporated into most routers and provides automatic assignment of IP addresses to computer devices on a LAN where fixed or static IP addresses are not required.

**DSL** — Digital Subscriber Line. A technology for bringing high-bandwidth data to homes and small businesses over ordinary copper telephone lines.

**DTMF** — Dual-Tone Multi-Frequency signaling. Keypad signaling system using the voice-frequency band over telephone lines between telephone equipment and other communications devices. Also known by the trade name Touch-Tone.

**Duty cycle** — A device which is constantly "on" would normally be considered to have a 100% duty cycle. Morse code keying has spaces between the elements and the characters, therefore the duty cycle would be less.

**ERC** — Easy Rotator Control. Electronic interfaces for controlling rotators from a computer.

**Firewall** — Firmware or software capabilities in computers and routers that can be configured to minimize or completely block unauthorized users from access.

**HAMNET** — Broadband-Hamnet (BBHN). A high speed wireless computer network using commercial WiFi equipment with custom firmware on Amateur Radio frequencies.

**Internet Service Provider (ISP)** — An organization that provides services for accessing and using the Internet.

**IP** — Internet Protocol. The communications protocol used to route packets of information between devices on the Internet. (see also *TCP*)

**IPv4** — The fourth version of the Internet Protocol (IP), based on 32-bit (four-byte) decimal addressing.

**IPv6** — The sixth and most recent version of the Internet Protocol (IP), based on 128-bit addressing, using eight groups of four hexadecimal digits.

**IP Address** — Every computer or device accessible via the Internet or a LAN has a unique numeric address, such as 192.168.1.1 assigned to it. The IP address is associated to the fixed MAC address of the device.

**kbps** — Kilobits per second (one thousand bits per second). Typically used as a reference to bandwidth data rate capability or actual usage.

**LAN** — Local Area Network. A home LAN enables multiple computers to connect to a single Internet service.

**Latency** — The delays involved in data routing from one point to another, but also a factor in A/D conversion processes.

**MAC address** — Media Access Control address. A unique address given to network interface devices such as Ethernet or WiFi interface cards.

**Mbps** — Megabits per second (one million bits per second). Typically used as a reference to bandwidth data rate capability or actual usage.

**ms** — Milliseconds. The unit of time typically used for measuring latency.

**Netbook** — A portable computer smaller than a traditional laptop or notebook. Many netbooks now use solid-state instead of rotating hard drives.

**Packet** — A formatted set of digital information. All information sent via the Internet is first converted into packets for transmission.

**Panadapter** — A device similar to a spectrum analyzer that allows you to visually see the RF spectrum received by the radio.

**Pathping** — A hybrid utility of the *path* and *tracert* functions which requires more time for analysis between two Internet connection points, but results in a more detailed analysis.

**Ping** — A utility used to ascertain the availability of another computer device over the Internet or LAN and also measure the round trip time required for the connection.

**Port forwarding** — Functionality most commonly used in routers to direct or re-direct incoming Internet traffic to specific destinations on a local network.

**POTS** — Plain Old Telephone Service. This generally refers to the use of a regular analog telephone system for purposes of remote audio and control signal routing in lieu of the Internet.

**QoS** — Quality of Service. The overall performance of a telephony or computer network. Performance can be enhanced by prioritizing services on the network.

**RDP** — Remote Desktop Protocol. A proprietary protocol developed by Microsoft, which provides a user with a graphical interface to connect to another computer over a network connection.

**Remote Client** — The remote location from which the operator will be controlling the host station site. This could be a home location or hotel room, but can be anywhere connectivity to the host station site is available.

**Router** — A device that allows traffic on a single Internet service line to be selectively distributed to multiple computer devices on a LAN. Many routers provide for assignment of local IP addresses as well as automatically via DHCP.

**SDR** — Software Defined Radio. A radio communication system where components that have been typically implemented in hardware (e.g. mixers, filters, amplifiers, modulators/demodulators, detectors, etc.) are instead implemented by means of software on a personal computer or embedded system.

**Serial Port Server** — A device that transfers data between a computer or device serial port (COM port) and an Ethernet local area network (LAN).

**Smartphone** — A generic term for portable cellular phones with integrated computer capabilities.

**Static IP** — A fixed IP address in a computer or device.

**Station site** — The actual physical location of the transmitter, host computer, antennas and related equipment necessary to generate an RF signal on the HF bands. Some have used the term *Remote Base*.

**Switch** — A network device that allows multiple computers or devices to share the same Internet or LAN connection.

**TCP** — Transport Control Protocol. An Internet protocol, usually combined with IP (see *Internet Protocol*) to transfer data between devices over networks.

**TCP Client** — Software designed for remotely connecting to and processing data from equipment through a TCP Server over a home network or the Internet.

**TCP Server** — Host software used for providing TCP Client software remote access to a computer or device.

**Tracert** — A utility for tracing the path taken by packets across the Internet and latency assessing analysis along the route.

**VNC** — Virtual Network Computing. A graphical desktop sharing system that uses the Remote Frame Buffer protocol (RFB) to remotely control another computer.

**VPN** — Virtual Private Network. Allows you to create a secure connection to another network over the Internet.

**Waterfall** — A graphical display that shows a continually updating sequence of RF spectra.

**WiFi** — A form of network connectivity without a physical wired connection, although with limited range. Also known by its controlling standard, IEEE 802.11.

**Wireless bridge** — Low powered transmitter-receiver devices for providing point-to-point digital communications, usually Ethernet, such as for interfacing Internet services to areas without traditional means.

# Test Equipment and Measurements

This chapter, originally written by Alan Bloom, N1AL, covers test equipment and measurement techniques common to Amateur Radio.

The initial sections discuss ac, dc, and RF measurements and describe what to look for in commercially available test equipment. The concluding sections discuss transmitter and receiver performance testing, including the standard tests performed by the ARRL Lab. A selection of simple test equipment construction projects is presented as well.

## 25.1 Introduction

According to the great physicist Sir William Thomson, Lord Kelvin, (1824-1907) “When you can measure what you are speaking about, and express it in numbers, you know something about it; but when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind.” This is the purpose of electronic test and measurement, to express the characteristics and performance of electronic devices in numbers that can be observed, recorded and compared.

The amateur should undertake to master basic electronic and test instruments: the multimeter, oscilloscope, signal generator, RF power meter and SWR and impedance analyzers. This chapter, written by Alan Bloom, N1AL is the reader’s guide to these instruments and the physical parameters they measure. The chapter goes beyond basic instrumentation to advanced instruments and measurements that are often encountered by amateurs. The material does not attempt to be complete in covering all available instruments and measurements. The goal of the chapter is to instruct and educate, present useful projects, and encourage the reader to understand more about these important facets of the radio art.

### 25.1.1 Measurement Standards

The measurement process involves evaluating the characteristic being tested using a *standard*, which is a rule for determining the proper numbers to assign to the measurement. In the past, instruments were calibrated to standards represented by physical objects. For example, the reference standard for length was a platinum bar, exactly 1.0 meters long, stored in an environmentally-controlled vault in Paris, France. In the latter part of the 20th century, most measurements were redefined based on fundamental physical constants. In 1983 the meter was defined as the distance traveled by light in free space in  $1/299,792,458$  second.

While most common everyday measurements in the United States still use the old Imperial system (feet, inches, pounds, gallons, and so on), electronic measurements are based on the international system of units, called *SI* after the French name *Système International d’Unités*, which is the modern, revised version of the metric system. The SI defines seven base units, which are length (meter, m), time (second, s), mass (kilogram, kg), temperature (kelvin, K), amount of substance (mole, mol), current (ampere, A), and light intensity (candela, cd). All other units are derived from those seven. For example, the unit of electric charge, the coulomb, is proportional to  $s \times A$  and the volt has the dimensions  $m^2 \times kg \times s^{-3} \times A^{-1}$ .

In the United States, measurement standards are managed by the *National Institute of Standards and Technology* (NIST), a non-regulatory agency of the federal government which until 1988 was called the National Bureau of Standards (NBS).<sup>1</sup> (Notes may be found in the References section.) NIST’s services include calibration of *transfer standards*. The transfer standards in turn are used to calibrate *working standards* which are used by companies to calibrate and measure their products. Such products are said to be *NIST traceable* if the rules and procedures specified by NIST have been followed. Most low-cost instruments used by hobbyists are another level down in accuracy, being calibrated by instruments that themselves may or may not be NIST traceable.

## 25.1.2 Measurement Accuracy

Accuracy and resolution are different specifications that are often confused. *Resolution* is the smallest distinguishable difference in a measured value. *Accuracy* is the maximum expected error in the measurement. For example an 8-digit frequency counter can measure the frequency of a 100 MHz signal to a resolution of 1 Hz, which is 0.01 ppm (parts per million). However, accuracy is determined by the time-base oscillator used as a reference, which typically would be significantly less accurate than 0.01 ppm in a low-cost instrument. Similarly, many digital voltmeters can display measurements to more digits of resolution than their accuracy permits. The extra resolution can be useful when comparing two or more values that differ only slightly because closely-spaced measurements tend to have nearly the same error. The difference can then be measured more accurately than the individual values.

An instrument's accuracy can be specified

in absolute or relative terms or sometimes in both. An example of an absolute specification is an RF power meter with an accuracy of "5% of full scale." If the full-scale reading is 100 W, then the accuracy is plus or minus 5 W at all power levels. Theoretically a reading of 10 W could represent an actual power of 5 W to 15 W.

An example of a relative accuracy specification is an analog voltmeter with an accuracy of 3%. That means a voltage of 1.000 V can be measured to an accuracy of plus or minus 0.030 V. A voltage of 10.000 V can be measured to an accuracy of plus or minus 0.3 V. An example of a combined absolute and relative accuracy specification is a frequency counter with an accuracy of "1 ppm plus one count." When measuring a 100 kHz signal with 1 Hz resolution, one count is 10 ppm of the 100 kHz signal. The total accuracy is  $1 + 10 = 11$  ppm, or  $\pm 1.1$  Hz.

An important point is that measurement error is not a mistake but rather a natural result of the imperfections inherent in any measurement. The sources of error can be sorted into several general classes. *Systematic*

*error* is repeatable; it is always the same when the measurement is taken in the same way. An example is the inaccuracy of the voltage reference in a digital voltmeter that causes all measurements to be off by the same percentage in the same direction. *Random error* is caused by noise and results in a different measured value each time it is measured. Receiver sensitivity measurements involve measuring the signal-to-noise ratio of the audio output, which varies due to the random fluctuations of the noise level.

*Dynamic error* results when the value being measured changes with time. The peak-envelope power (PEP) of a single-sideband transmitter varies with the modulation that is present at the particular time the measurement is taken. *Instrument insertion error* (also called *loading error*) is an often-overlooked factor. For example, a voltmeter must draw at least a little current from the circuit under test in order to perform the measurement, which can affect circuit operation. When performing high-frequency measurements, the capacitance of the measurement probe often can be significant.

## 25.2 DC Measurements

In discussions of instruments and measurements, the abbreviation *dc* generally refers to currents and voltages that remain stable during the measurement. If the dc current or voltage changes rapidly, it is said to have an *ac component* that may be measured separately.

### 25.2.1 Basic Vocabulary and Units

The **Electrical Fundamentals** chapter introduces basic electrical units of measurement and how they relate to circuit operation. The following material discusses additional points of particular relevance to test and measurement.

#### VOLTAGE

Another name for voltage is *potential difference*, because it is a measure of the difference in electrical potential between two points in a circuit. That is a very important point that is widely misunderstood among radio amateurs, technicians and even many engineers. It makes no sense to speak of the voltage "at" a particular point in a circuit unless you specify the reference point to which you are measuring the difference in potential. Normally the reference point is understood to be the chassis or circuit common. However, it is worth remembering that if the other lead of your voltmeter is connected to some other

point in the circuit the readings will likely be different. Voltage is not a property of only a single circuit node, but rather is a measure of the *difference* in potential between two points. This is why voltmeters have two leads.

Unfortunately, the circuit common connection is conventionally called the "ground" which leads people to believe that it must be connected to the Earth for proper operation. In fact, the voltage with respect to Earth has no effect on the circuit as long as all the differences of potential within the circuit are correct. For example, a low-pass filter may need to be "grounded" to the chassis or circuit common connection for proper operation but it does not need to be "grounded" to the Earth.

The simplest way to calibrate an inexpensive meter is simply to use a more accurate meter. For example, when constructing a home-built power supply, the analog panel meter may be calibrated with a digital voltmeter (DVM) because most DVMs have better accuracy than an analog meter. Perhaps the most practical voltage reference for the home workshop is an integrated circuit voltage reference. Special circuit techniques in the IC are used to generate a very stable, low-temperature-coefficient reference based on the band-gap voltage of silicon, approximately 1.25 V, on the chip. Inexpensive devices with specified accuracy of 0.1% and better are available from companies such as

Analog Devices, Linear Technology, Maxim and National Semiconductor.

#### CURRENT

*Conventional current* is the flow of positive charge and is considered to flow in the direction of positive to negative voltage, or from the higher voltage point in a circuit toward the lower voltage point. The flow of negatively-charged electrons in the opposite direction from negative to positive voltage is sometimes called *electronic current*. Electronic and conventional current are equivalent, but flow in opposite directions. Conventional current is used in most circuit design and is reflected in the direction of the arrow in the symbol for diodes and bipolar transistors. An *ammeter* is an instrument for measuring current. An ammeter may be calibrated by measuring the attractive force between two electromagnets carrying the current to be tested, but in practice it is easier to place a known resistor in series, measure the voltage drop across the resistor, and calculate the current using Ohm's law. Resistance and voltage can both be calibrated accurately, so that method gives good accuracy.

The most common analog ammeter type is the *D'Arsonval galvanometer* in which the pointer is attached to a rotating electromagnet mounted between the poles of a fixed permanent magnet. The modern form of this meter

was invented by Edward Weston and uses two spiral springs to provide the restoring force for the pointer, providing good scale linearity and accuracy. Most commonly-available meter movements of this type have a full-scale deflection between about 50  $\mu\text{A}$  and several mA.

Digital ammeters use an analog-to-digital converter to measure the voltage drop across a low-value resistor and scale the result to display as a value of current. They are generally more accurate than analog meters and are more rugged due to the lack of delicate moving parts.

## RESISTANCE

Measuring resistance requires one or more precision resistors to use as a reference, either in a bridge circuit or as part of an ohmmeter as described below. Resistors with a 1% rating cost only a few pennies and are readily available in a wide variety of values from many suppliers. Precision resistors are generally considered to be those with a tolerance of 0.1% or less and are typically available for less than a dollar or so in small quantities. Expect to pay a few dollars each for parts with a 0.01% tolerance.

An *ohmmeter* is a meter designed for measuring resistance. Various circuits can be used, but most are variations of the simplified schematics in Figure 25.1. In the circuit at A, the battery is in series with the resistor under test. If the resistance is zero (the test leads are shorted) then the battery is in parallel with the voltmeter and it reads a maximum value. If

the resistance is infinite (test leads not connected) the meter reads zero. If the resistor equals  $R$ , the internal reference resistance, the meter reads half-scale.

In the circuit at B, the resistor under test is in parallel with the voltmeter. The meter indication is reversed from the series-connected circuit, that is, the meter reads zero for zero resistance, full-scale for infinite resistance, and mid-scale when the resistor equals  $R$ . In both circuits, an adjustment is normally provided to set the meter to full scale with the test leads shorted or open, as appropriate. In addition, a switch selects different values of the internal resistance  $R$  for measuring high or low-valued resistances.

A *Wheatstone bridge* is a method of measuring resistance that does not depend on the accuracy of the meter. Each arm of the bridge ( $R_1 - R_S$  and  $R_2 - R_X$ ) forms a voltage divider. In Figure 25.2, the meter is a zero-center type so that it can read both positive and negative voltages between the center connections of the two voltage dividers. When variable resistor  $R_S$  in Figure 25.2B is adjusted for a zero reading on the meter, then the two arms of the bridge have the same ratio,

$$\frac{R_1}{R_S} = \frac{R_2}{R_X}$$

The resistor under test,  $R_X$ , can be calculated from

$$R_X = R_S \frac{R_2}{R_1}$$

Nowadays, the Wheatstone bridge is rarely used for measuring resistance since it is not as convenient as an ohmmeter, but the concept is important for several other types of measurement circuits that will be covered later.

## 25.2.2 Multimeters

A *multimeter* is probably the single most useful test equipment for an electronics experimenter. Besides measuring dc voltage and current, most also measure resistance and low-frequency ac voltage as well. Another common feature is a tone that sounds whenever the test leads are shorted, which is useful as a quick continuity tester. With most modern multimeters, the voltage they use for the resistance measurement is too low to forward-bias the junction of a silicon diode or transistor, which is a desirable characteristic for measuring in-circuit resistance. Many multimeters also have a special "diode" mode with a higher test voltage so that diodes and transistors can be tested as well. It is increasingly common for even low-cost digital multimeters to include functions such as frequency and capacitance measurement.

## ANALOG MULTIMETERS

Nearly all analog multimeters use a D'Arsonval meter for the display. Compared to a digital display, analog meters have the advantage that it is easier to see whether the reading is increasing or decreasing as adjustments are made to the circuit under test. The experimenter may want to consider owning an inexpensive analog multimeter for that kind of testing as well as a higher-quality digital instrument for more precise measurements.

A *volt-ohm meter* (VOM) is a basic analog instrument that includes no electronic circuitry other than a switch and resistors to set the scale, a battery for the resistance-measuring circuit, and perhaps a diode to convert ac voltage to dc. Despite the name, most can also measure current as well as voltage and resistance.

A disadvantage of the VOM is that, when measuring voltage, the current to operate the meter must be drawn from the circuit under test. A figure of merit for a VOM is its *ohms-per-volt* ( $\Omega/\text{V}$ ) rating, which is just the reciprocal of the full-scale current of the meter movement. For example, if the VOM uses a meter that reads 50  $\mu\text{A}$  full-scale then it has  $1 / 50 \times 10^{-6} = 20,000$  ohms per volt. On the 1-V scale the meter has a resistance of 20 k $\Omega$  and on the 10-V scale, it is 200 k $\Omega$ .

Depending on the circuit being tested, drawing 50  $\mu\text{A}$  may be enough to disrupt the measurement or the operation of the circuit. To solve that problem, some analog meters include a built-in amplifier with high input impedance. In the days of vacuum tubes, such meters were called *vacuum-tube voltmeters*

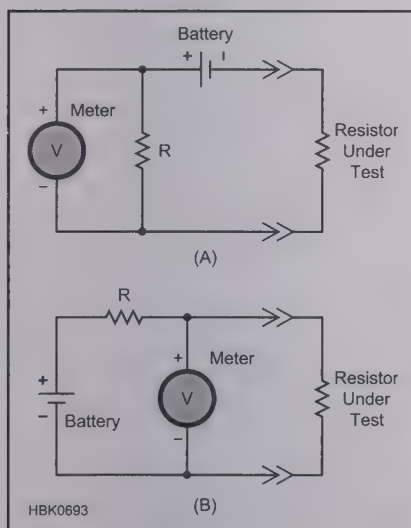

Figure 25.1 — Two ohmmeter circuits. At A, the meter reads full scale with a zero-ohm resistor and reads zero with no resistor connected. The circuit at B is the opposite; the meter reads full scale with no resistor connected (infinite resistance) and reads zero with zero resistance.

Figure 25.3 — This classic Hewlett-Packard HP412A vacuum-tube voltmeter (VTVM) has specifications that put many modern solid-state multimeters to shame.

Figure 25.4 — A modern digital multimeter typically has a liquid crystal display readout.

(VTVM). An example is shown in **Figure 25.3**. The modern equivalent is called an *electronic voltmeter* and generally uses an amplifier with field-effect transistors at the input. Again, despite the name, VTVMs and electronic voltmeters usually can measure current and resistance as well.

### DIGITAL MULTIMETERS

Instead of using an analog meter to display its measurements, a *digital multimeter* (DMM) has a digital readout, usually an LCD display. A microprocessor controls the measurement process and the display. (See **Figure 25.4**.) To convert the analog voltage or current being measured to a digital number requires an analog-to-digital converter (ADC) controlled by a microprocessor. Most use a dual-slope type of ADC, which trades off a relatively slow measuring speed for excellent accuracy and low cost. (Analog-to-digital conversion is discussed in the **Analog Basics** chapter.)

A digital voltmeter is constructed as shown in **Figure 25.5**. The input section is the same as in an analog electronic voltmeter. A range

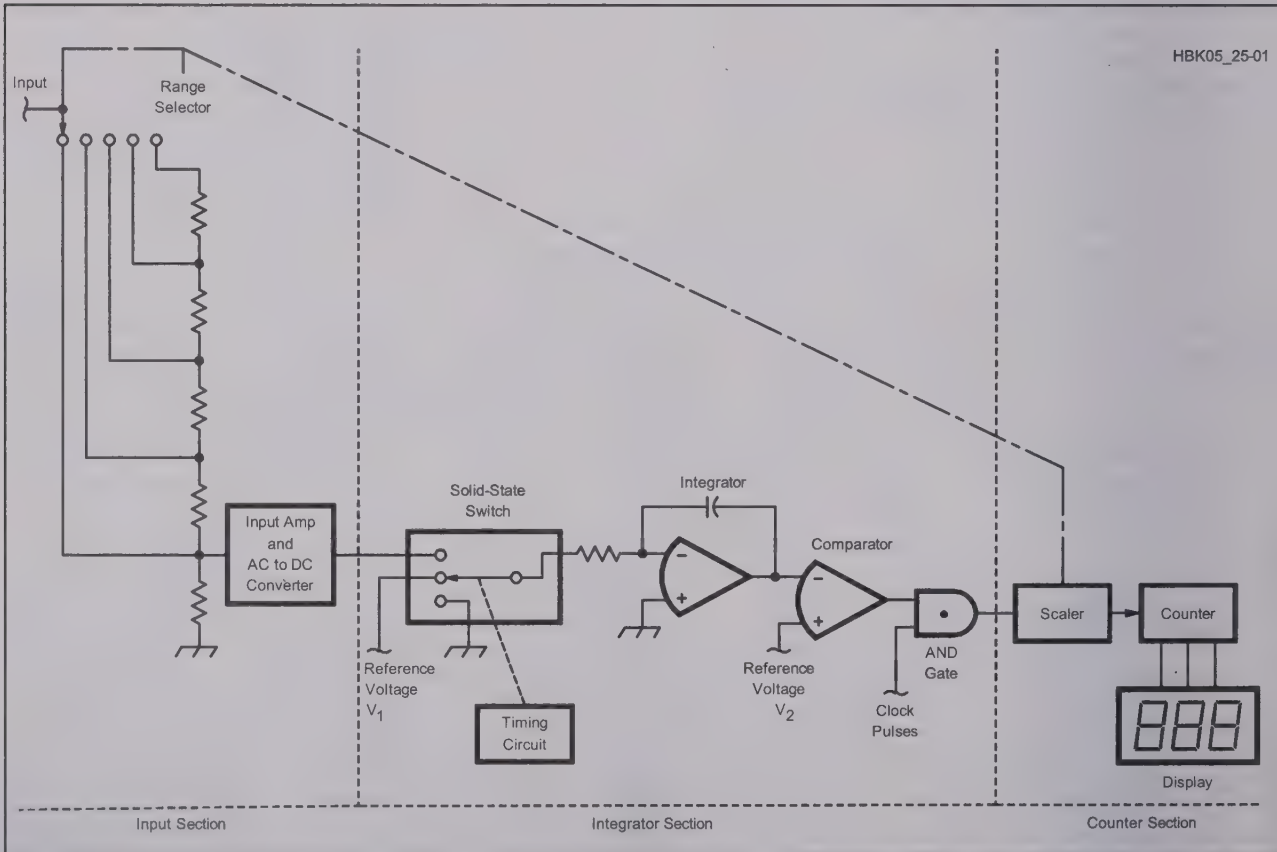

Figure 25.5 — A typical digital voltmeter consists of three parts: an input section for scaling, an integrator to convert voltage to a pulse whose width varies with voltage, and a counter to measure the width of the pulse and display the measured voltage.

selector switch scales the input signal appropriately for amplification by an input preamplifier, which also includes a rectifier circuit that is used when in ac mode to convert the ac signal into dc, suitable for conversion by the ADC.

An additional feature that becomes possible with digital multimeters is *autoranging*. The selector switch is used only to choose between voltage, current, resistance and any other available functions. The scale or range is selected automatically based on the amplitude of the signal being measured, which is a nice convenience. If the signal is fluctuating such that it causes frequent range changes, there is usually a way to turn off auto-ranging and select the range manually.

Digital multimeters that feature a serial data interface can also act as a *data logger*, taking and storing measurements for use by a PC or under the control of a PC.<sup>2</sup> This is a very useful feature for experimenters.

## HOW TO USE A MULTIMETER

When preparing to make a measurement, the first thing to do is to select the proper function on the multimeter — voltage, current, resistance or some other function. If the meter is not an auto-ranging type, set the range to the lowest value that does not over-range the meter. If you're not sure of the voltage or current being measured, start with a high range, connect the test probes then switch the range down until a good reading can be obtained. Choosing the correct function and range may involve connecting the test leads to specific connectors on the meter.

When measuring high voltage, special precautions must be taken. As little as 35 V should be considered dangerous because it can produce lethal current in the human body under some conditions. Grasp the test probes by the insulated handles, being careful to keep fingers away from the metal probe tips. Pay attention to the multimeter manufacturer's maximum voltage ratings. Special test probes are generally available for measuring high voltage. Do not exceed the meter's rated maximum voltage.

High current can be dangerous as well. If a probe accidentally shorts a power supply to ground, sparks can fly, damaging the equipment and endangering the operator. Be careful of metal jewelry such as rings and bracelets. If connected across a high-current circuit you could get a nasty burn. Most meters have a fuse to protect the instrument from an over-current condition in current-measuring mode. If the multimeter turns on but always reads zero, consult the manual on how to replace the fuse.

To measure a current, the meter must be inserted in series with the circuit. In a series-connected circuit, all components carry the same current, so it doesn't matter which component is disconnected to allow insert-

**Figure 25.6 — The four-wire technique for measuring low-value resistors. By connecting the current source and the meter separately to the leads of the device under test, the error due to lead resistance is reduced.**

ing the ammeter. Select the one that is most convenient, or the one that is at a low-voltage point if you're measuring a high-voltage circuit. For measuring ac power circuits without disconnecting them, clamp-on current probes are used.

It can be difficult to measure low-value resistors accurately because of the resistance of the meter leads, typically one or two tenths of an ohm. With the series-connected ohmmeter circuit described in the previous section, the calibration procedure compensates for that and some digital meters may have a means to compensate as well. However, accurate low-resistance measurement requires the *four-wire* technique, as illustrated in **Figure 25.6**. Two wires are connected to each end of the resistor, one to carry the test current and one to read the voltage with a high-input impedance voltmeter. In that way the resistance of the wires does not affect the measurement.

A similar technique can be used to measure high currents. Most inexpensive meters do not have a high-enough current range to measure the 20 A or so that is drawn from a 12-V power supply by a typical 100 W transistor. The solution is to use an external *meter shunt*, which is a low value resistor placed in series with the current. See **Figure 25.7**. The multimeter reads the voltage,  $E$ , across the shunt, and then the current is calculated from Ohm's Law,  $I = E/R_s$ , where  $R_s$  is the

**Figure 25.7 — This 50-A, 50-mV current shunt has a resistance of  $0.05 / 50 = 0.001 \Omega$ . The two large terminals are for connecting to the circuit under test and the two small terminals are for connecting to a voltmeter.**

resistance of the shunt. Resistors designed for this service may have four leads rather than two to allow a true four-wire measurement. The clamp-on current probes mentioned earlier may also be used.

There are several issues that apply specifically to analog multimeters. An analog meter movement is a rather delicate device. It can be damaged if the case is dropped or mechanically shocked. When transporting the instrument, it is a good idea to place a low resistance or short in parallel with the terminals of the meter movement, which increases damping and reduces the amount of pointer movement as the case is bounced around. Some multimeters have a special OFF position on the selector switch for that purpose. On others, switching to the highest current range accomplishes the same thing.

Most D'Arsonval meters have an adjustment screw located near the pointer's pivot point that may be accessed from the front of the meter. It should be adjusted so that the meter reads zero with no signal applied.

Some older VOMs include a high-voltage battery that is used on the highest resistance ranges. When testing solid-state devices, that voltage can be high enough to cause damage. If there is any doubt, use another high-impedance multimeter to test the voltage on the test leads of the VOM when it is set to the highest resistance ranges.

## MULTIMETER CRITICAL SPECIFICATIONS

The first decision when selecting a multimeter is whether you want an analog or digital type. That is largely a matter of personal taste. Digital meters are generally more accurate but analog meters may make it easier to tune a circuit for a specific voltage or current. The next decision is between a hand-held or bench-type instrument. The latter tend to have more features and better specifications, but obviously are less portable and usually are more expensive.

The most obvious selection criteria are the features provided. Nearly all multimeters measure dc voltage, current and resistance and most also measure low-frequency ac voltage. Other common features on digital meters include autoranging and automatic turn-off to

## Probe Adapters for Multimeters

Multimeters come with test probes intended for precise contact with terminals, components, wires, and so forth. They work well if the item to be probed is easily exposed or otherwise available to the probe. Measuring signals on connector pins, however, is often a challenge. Inserting a probe into the miniature sockets on many connectors is often not possible and if the connector has exposed pins, trying to insure the probe does not slip to or between adjacent pins is nearly

impossible. The solution is to build an adapter as shown in Figure 25.A's three examples.

**Figure 25.A1** provides a convenient way to hold probes steady in a spring-loaded, push-button, two-wire speaker connector connected to a pair of Powerpole connectors. Keep the colors of the wires, buttons, and connectors consistent to prevent confusion. An enclosure such as an inexpensive plastic box protects the exposed terminals.

Figure 25.A1 — A convenient way to hold probes steady

Figure 25.A2 — Adapting an automotive-style fuse to make a current-measuring adapter.

**Figure 25.A2** shows how to adapt an automotive-style fuse to make a current-measuring adapter for your multimeter. First, remove the back of the fuseholder and the fuse element and pry the fuseholder open. Solder leads to the exposed terminals then glue or snap the fuseholder back together. Be sure to include the external in-line fuseholder — available in auto parts stores — so that the circuit is protected and you don't blow an expensive multimeter fuse. (Note — multimeter fuses are rated at the full voltage limits of the meter for your safety. Do not replace them with low-voltage fuses.)

**Figure 25.A3** is a typical adapter for a multi-pin connector using a terminal strip. Take care to arrange the terminals in order of pin number and label them so you don't have to guess when using the adapter. Make an adapter for the common connectors in your station and you'll never regret it!

These are just three types of adapters — you will no doubt think of many more that will help you with your particular needs. Remember to protect yourself against exposed voltages and short-circuits when constructing and using the adapters. (Thanks to W4QO and KG4VHV and the *QRP Quarterly* for the suggestions.)

Figure 25.A3 — A typical adapter for a multi-pin connector.

save the battery. More capable meters include features such as data hold, peak voltage, true RMS voltage, 4-wire resistance, capacitor tester, inductor tester, diode and transistor tester, logic tester, frequency counter, computer data logging and a graphical display.

One important feature that is often not specified is over-voltage and over-current protection. On analog meters, there may be internal back-to-back diodes across the meter movement to protect it from over-voltage. Most digital meters include autoranging which should prevent damage from any voltage below the specified maximum. The current-measuring input on both types is normally protected with a fuse.

The next most critical specification is the available measurement ranges of the voltage, current, resistance and any other functions provided. Analog meters tend to space the voltage and current ranges by a factor of three. For example, the full-scale voltage readings might be 3 V, 10 V, 30 V, 100 V, 300 V or perhaps 5 V, 15 V, 50 V, 150 V, 500 V. The latter is a particularly good choice since two voltages that are commonly measured, 12 V dc and 120 V ac, are near the top of a range where accuracy is best. The more range selections provided, the greater the span of values that can be measured. With auto-ranging instruments the measurement minimum and maximum range may not be obvious without consulting the manual.

The input impedance is important in minimizing the effect of the multimeter on the circuit under test. Impedance should be high for voltage measurements and low for current measurements. For VOMs the figure of merit for voltage measurements is the ohms-per-volt rating. Multiply the full-scale voltage range by ohms-per-volt to get the input resistance. Both digital and analog electronic voltmeters usually have the same input impedance on all voltage ranges, typically between 1 and 11 M $\Omega$ . The input resistance for current measurements is often specified by the *burden voltage*, which is the voltage drop across the test leads with a full-scale signal. Typical values vary widely, from a few millivolts to more than a volt. The voltage drop can often be reduced by switching to a higher current range, at the expense of measurement resolution.

Measurement accuracy can be an important specification for some applications. An inexpensive analog meter may have voltage and current accuracy of 3% or so. The best analog meters have accuracy specifications in the range of 1%. At that level, accuracy may be limited by *parallax*, which causes the meter reading to appear to change as you change the angle of view. To mitigate that, some high-end analog meters have a *mirror scale*. The reflection of the pointer in the mirror has a parallax error equal and opposite

to the unreflected pointer so that the correct reading is half way between the two.

You can't necessarily tell the accuracy of a digital meter from the number of digits in the display. Usually the accuracy is limited by the analog circuitry. However, the number of digits defines the resolution, which can be important when comparing two nearly-equal readings or when tuning a circuit for a peak or minimum value. A typical DMM might have a specified accuracy of 0.1% to 1% for dc measurements and perhaps 1% to 3% for ac voltage. (See the section on ac measurements.) Many inexpensive digital multimeters do not have published specifications and may not be very accurate.

Many bench-type multimeters and some hand-held units can be connected to a computer. That allows the computer to control the instrument to take automated readings and store the results in a computer file. Some older test equipment may have a GPIB (general purpose interface bus) interface, also known as IEEE-488 (HP-IB on Hewlett-Packard equipment). GPIB-to-USB converters are available to allow connection to a PC.<sup>3</sup> Modern instruments typically have a USB or RS-232 interface.

## USED AND SURPLUS MULTIMETERS

Figure 25.3 shows a typical multimeter that might show up at a ham flea market or on the Internet, a Hewlett-Packard model 412A VTVM. While obsolete, it is still a very useful instrument with capabilities that are rare in modern units. For example, it can measure dc voltage down to 1 mV (0.001 V) full scale and the burden voltage for current measurements is only 1 mV for currents up to 10 mA, rising to 100 mV at 1 A. The highest resistance range is 100 M $\Omega$  center scale, which allows reasonably-accurate resistance measurements up to about 1 G $\Omega$ . Don't overlook surplus equipment just because it is old. Some of it is a real bargain.

When buying a used analog multimeter, the most important thing to check is the meter movement itself. D'Arsonval meters are rather delicate and easy to damage. For a VOM or battery-operated multimeter, put the instrument in resistance-measuring mode then short and un-short the test leads. The needle should move smoothly between zero and full scale. If you can't do that test, at least make sure that the needle rests close to zero. Rotate the instrument back and forth to make the needle move and observe whether it appears to bind. It is difficult or impossible to repair a damaged meter movement.

Digital multimeters are less delicate than analog meters and many of their failures are electronic in nature so they sometimes can be repaired using normal troubleshooting techniques. Of course it is always a good

idea to test used equipment before buying, if possible. If at all possible, measure voltage and resistance with the meter to be sure it is fundamentally sound.

## 25.2.3 Panel Meters

Analog panel meters are quite expensive to buy new so many experimenters keep an eye open for flea-market bargains. You often can find old "boat anchor" equipment with good salvageable panel meters selling for less than the value of the meters.

The scale markings on surplus meters often represent what the meter was measuring in the equipment rather than the actual current flowing through the meter itself. Sometimes the full-scale current of the meter movement will be shown in small text at the bottom of the scale. However, that may not be the same as the current measured at the meter terminals because some meters include an internal shunt.

The only sure way to know the full-scale current and resistance of a surplus meter is to measure it. The resistance can be measured with the ohmmeter function of a multimeter, but be careful. On the lowest resistance ranges, the multimeter may output enough voltage and current to damage the meter under test. If the multimeter is an auto-ranging type you have no way to control test current unless you can turn auto-ranging off. With a non-autoranging ohmmeter, start the measurement at the highest resistance scale and then reduce the scale one step at a time until a valid reading is obtained, while keeping an eye on the meter under test to be sure it is not over-ranged.

A safer way to measure both the full-scale current and resistance of a panel meter is to place a high-value resistor in series with it and connect the combination to a dc power supply, perhaps a battery. A 1.5-V battery in series with a 100 k $\Omega$  resistor (15  $\mu$ A of current) is a good starting point. Keep trying smaller and smaller resistance values until a good reading is obtained on the meter. Assuming the scale that is marked on the meter's scale face is linear, the full-scale current is

$$I_{FS} = I_{TEST} \frac{D_{FS}}{D_{TEST}}$$

where  $I_{FS}$  is the full-scale meter current,  $D_{FS}$  is the scale's full-scale marking,  $D_{TEST}$  is the needle indication measured with the test current, and  $I_{TEST}$  is the test current, which is equal to the voltage across the resistor divided by the resistance. The meter's resistance is the voltage across the meter divided by  $I_{TEST}$ .

## USING PANEL METERS

Whether surplus or new, it is rare that a panel meter measures exactly what you need

for a particular application. Usually you must change the current or voltage sensitivity.

To increase the full-scale current, place a *current shunt* in parallel with the meter. This is simply a resistor whose value is

$$R_{\text{SHUNT}} = R_M \frac{I_M}{I_{\text{FS}} - I_M}$$

where  $R_M$  is the meter resistance,  $I_M$  is the meter full-scale current and  $I_{\text{FS}}$  is the desired full-scale current reading. The shunt resistance is very small for high-current shunts, such that the resistance of the wires or circuit traces can cause a significant error. To reduce that error, connect the meter directly to the leads of the shunt, with no wires or circuit traces in common with the high-current path.

You can make a low-value shunt by wrapping a length of copper wire around a resistor or other component used as a form. Unfortunately, however, the resistance of copper has a poor temperature coefficient, typically around 0.4 percent per degree C. That means the meter reading can change more than 10% between a warm and a cold day. As the wire self-heats from the high current flowing through, the meter reading can easily be in error by 20% or more. Commercial shunts are made from a metal with a low temperature coefficient such as nichrome. Copper-wire shunts should only be used where accuracy is not important. (A table of wire resistance in ohms per foot ( $\Omega/\text{ft}$ ) is available in the **Component Data and References** chapter.)

If the panel meter is to be used to measure voltage, a *voltage multiplier* resistor is inserted in series with the meter. The value is

$$R_{\text{MULT}} = \frac{V_{\text{FS}}}{I_M} R_M$$

where  $V_{\text{FS}}$  is the desired full-scale voltage,  $I_M$  is the meter full-scale current and  $R_M$  is the meter resistance. If the meter has an internal current shunt, it should normally be removed to maximize the value of the multiplier resistor. For high-voltage applications, be aware that in addition to a power rating a resistor also has a working voltage specification, perhaps 200 to 250 V or so for a typical  $\frac{1}{4}$  W, through-hole resistor. Applying voltages higher than the rating — even if the rated power dissipation is not exceeded — can result in arcing across the body of the resistor. If you need to measure a voltage higher than the voltage rating,

**Figure 25.8 — Back-to-back silicon diodes protect the meter by limiting the maximum voltage. See the text for a discussion of how to select the value of R.**

use several resistors in series. For example, to measure a 2000-V power supply, ten  $\frac{1}{4}$  W resistors in series, each with a value of one-tenth the desired resistance, would be suitable.

If you intend to use the same panel meter for several different purposes in your project, be sure to use a *break-before-make* switch to make the selection. That protects the meter by making sure it is never connected to two circuits at the same time, even for an instant.

Analog D'Arsonval meters are easily damaged if subjected to excessive current. A standard technique to protect them is to wire back-to-back diodes in parallel with the meter. Silicon junction diodes have the property that they act like an open circuit for low voltages and start to conduct when the forward voltage reaches about 0.4 V. Most meters can withstand up to two times the full-scale current without damage. So choose resistor R in **Figure 25.8** such that the voltage across the diodes is about 0.2 V when the meter current is at full scale, that is

$$R = \frac{0.2 \text{ V}}{I_M} - R_M$$

where  $I_M$  is the full-scale meter current and  $R_M$  is the meter resistance. If that equation results in a negative value for R, replace each diode with two diodes in series and recalculate using 0.4 V instead of 0.2 V in the equation.

### MAKING NEW PANEL SCALES

It seems like the scale that is printed on the meter scale is never what you need for your project. You can usually disassemble

the meter to remove the scale plate to modify the scale. Be sure you are working in a clean environment and temporarily reassemble the meter while you are working on the scale to prevent any dust or other contaminant from entering the delicate mechanism. Take particular care that magnetic metal debris cannot get into the meter movement where it is attracted by the permanent magnets.

There are several methods for modifying the scale markings for your own purposes. If only the labels are wrong and the tick marks are spaced appropriately, you can add new labels with a permanent marker or dry-transfer labels. If the old labels are not useful, sometimes they can be removed with a pencil eraser. If you need a completely new meter scale, one old trick is to turn the scale plate over and draw the new scale on the back. However, software is available to design and print custom scales. An Internet search will quickly find dozens of low-cost and free programs, such as *Meter Basic* by Jim Tonne, W4ENE, which is included with the downloadable supplemental content.

### DIGITAL PANEL METERS

Digital panel meters (DPMs) are available as preassembled modules that are almost as easy to use as analog meters. The displays are generally of the liquid crystal type, with or without a backlight, and typically have 3 to 4½ digits. A “½” digit is one that can display only a 1 or a blank. Displays with a half-digit usually have a full-scale input voltage of either 2 V or 200 mV minus one count, so that the full-scale voltage is 199.9 mV, for example. Most have programmable decimal points after each digit and some have indicators to indicate the units, such as  $\mu$ , m, V, A and so forth. DPMs have a high input impedance so there is minimal loading on the circuit under test.

The required power supply voltage varies by model. Some require a floating supply, so if the power supply and the voltage being measured need a common ground connection, be sure the meter is capable of that.

Accuracy is typically 0.1% or better. The total accuracy is usually limited by the external circuitry that drives the meter, such as the amplifier, current shunt or attenuator that is required to get the signal within the input voltage range of the DPM.

## 25.3 AC Measurements

This section covers issues that affect all ac signals, while the following section on RF measurements concentrates on aspects of ac measurements that are particular to the higher frequencies.

### 25.3.1 Basic Vocabulary and Units

The **Electrical Fundamentals** chapter includes an introduction to basic electrical units of ac waveforms. The following material emphasizes some additional points that have particular relevance to test and measurement.

#### AC WAVEFORM VALUES

With ac signals, the voltage and current change periodically with time so, as you might expect, there are several ways to express their value. See **Figure 25.9**. The *average* voltage or current is the value averaged over one period and is equal to the *dc component* of the signal. For a symmetric, periodic ac signal with no dc component, the average is always zero. Non-periodic signals must be averaged over a long period of time to obtain a valid average.

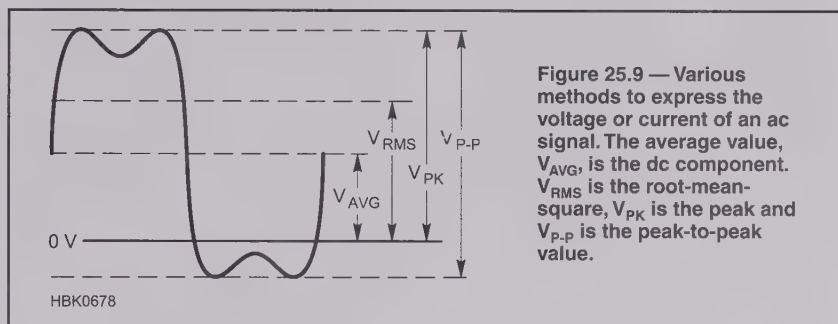

The *peak* value of an ac signal is just as its name implies, the maximum value that the signal ever achieves. The *peak-to-peak* value is the difference between the positive and negative peaks. For a symmetrical-ac waveform such as a sine or square wave, the peak-to-peak is twice the peak.

The *RMS (root-mean-square)* value of voltage or current is that which would produce the same heating in a resistor as a dc voltage or current of the same value. For a sine wave, it is

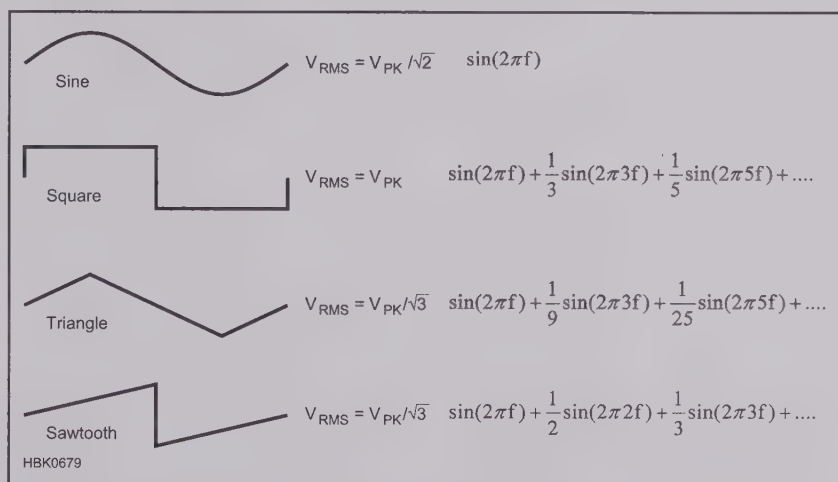

$$V_{\text{RMS}} = \frac{1}{\sqrt{2}} V_{\text{PK}} \approx 0.707 \times V_{\text{PK}}$$

where  $V_{\text{RMS}}$  is the RMS voltage and  $V_{\text{PK}}$  is the peak voltage. A similar equation applies for RMS current. Don't forget that the equation only applies for sine waves. For example, the RMS voltage of a square wave is 1.0 times the peak. See **Figure 25.10**. Also be aware that the RMS value includes the effect of any dc component. If you wish to refer to the RMS value of the ac component only, be sure to state that explicitly.

The formulas for power apply for RMS voltage and current as well as for dc,  $P = E_{\text{RMS}} I_{\text{RMS}}$ ,  $P = E_{\text{RMS}}^2 / R$  and  $P = I_{\text{RMS}}^2 R$ , where  $P$  is power in watts,  $E_{\text{RMS}}$  is RMS potential difference in volts and  $I_{\text{RMS}}$  is RMS current in amperes. However, that assumes that the voltage and current are in phase, as in a resistor or an antenna at resonance. If they are not in phase, then the power in the above equations must be corrected by multiplying

**Figure 25.9** — Various methods to express the voltage or current of an ac signal. The average value,  $V_{\text{AVG}}$ , is the dc component.  $V_{\text{RMS}}$  is the root-mean-square,  $V_{\text{PK}}$  is the peak and  $V_{\text{P-P}}$  is the peak-to-peak value.

At the center are listed the relationships between  $V_{\text{RMS}}$ , the root-mean-square, and  $V_{\text{PK}}$ , the peak value, assuming the waveform has no dc component. it by the *power factor*,

$$\text{PF} = \cos \theta$$

where  $\theta = \arctan (X / R)$ , the phase angle caused by the reactance,  $X$ , and the resistance,  $R$ , of the circuit.

### 25.3.2 Using Multimeters for AC Measurements

Most multimeters can indicate the RMS value of ac voltage and current, but many do not measure the RMS value directly. Instead they measure the rectified average or peak voltage and then apply a correction factor so that the display reads RMS, assuming a sine wave. Unfortunately, that means that the RMS values are not accurate if the ac signal being measured does not have a sinusoidal waveform.

Some meters full-wave rectify the ac signal and then measure the average of that, internally correcting for the difference between the average of a rectified sine wave

$$V_{\text{AVG}} = \frac{2}{\pi} V_{\text{PK}} = 0.637 \times V_{\text{PK}}$$

and the RMS value

$$V_{\text{RMS}} = \frac{1}{\sqrt{2}} V_{\text{PK}} \approx 0.707 \times V_{\text{PK}}$$

so that the reading is in RMS. Very inexpensive analog meters may only use a half-wave rectifier which causes RMS readings for asymmetric waveforms to vary with the orientation of the test connections.

Additional considerations may apply to RMS readings. For example, the accuracy of the RMS reading for most meters varies with frequency of the applied signal. Check the specifications of the multimeter for the frequency range over which it may be used

to measure RMS values.

The only way to accurately measure RMS values of non-sinusoidal signals is with a meter that has *true RMS* capability. Such a meter uses circuitry or software to compute the RMS value of the signal. Note that the measurement bandwidth of the meter must include the significant harmonics of the signal as well as the fundamental in order to give accurate RMS readings.

An example of a measurement that requires a true RMS voltmeter is receiver sensitivity. For that, you need to measure signal and noise levels at the receiver audio output. Standard multimeters using a rectifier and averaging circuit give inaccurate results when measuring noise because noise and sine waves have different peak-to-RMS ratios. Another advantage of true RMS meters is that they tend to have better scale linearity, even for sinusoidal signals. A diode detector is non-linear, especially at the low end of the scale.

Frequency response is another limitation when making ac measurements with a multimeter. Most are specified from below 50 or 60 Hz, to cover power-line frequencies, up to a few hundred Hz. Many receiver measurements use a 1 kHz test frequency, so a meter specified up to at least that frequency is especially useful.

For all of these and other reasons, the ac accuracy is usually significantly worse than the dc accuracy. Generally, an oscilloscope makes more accurate ac measurements than a multimeter. Modern digital oscilloscopes

often have built-in capability to indicate peak, average and true RMS voltage.

One final issue with multimeters is the ac impedance of the probes. While the dc input resistance of a modern electronic multimeter is typically over 1 M $\Omega$ , the capacitive reactance can be a significant factor at radio frequencies. Even if all you care about is the dc voltage, if ac signals are present, reactance of the probe can affect the circuit's operation.

### 25.3.3 Measuring Frequency and Time

#### FREQUENCY COUNTERS

The basic instrument for measuring frequency is the *frequency counter*. A block diagram of a very basic design is shown in Figure 25.11. Three digits are shown, but typically there are more. The signal to be measured is routed through three cascaded decade counters. For 1 Hz frequency resolution, the counters count for 1 second. For 10 Hz resolution, they count for  $\frac{1}{10}$  second, and so on. The count time is determined by a high-stability crystal oscillator, whose frequency is divided down to 1 Hz,  $\frac{1}{10}$  Hz, or whatever resolution is desired. At the end of each count time, control circuitry stores the final count in latches that drive the digit displays and at the same time resets the counters for the next count period.

With this scheme, the displays are updated once per second when 1 second resolution

is chosen, 10 times per second with 10 Hz resolution, and so on. One issue is that if the frequency is part-way between two adjacent displayed values, the least-significant digit will flicker back and forth between the two values on successive counts. Sometimes the designer chooses not to show the least-significant digit for that reason, even though that slows down the display update rate by a factor of 10 for any given display resolution.

Some frequency counters include the ability to measure time as well. In the block diagram, the connections to the first divide-by-10 stage input and the control circuit input are swapped. In that way the signal being measured controls the count time, and the reference oscillator provides the signal being counted. If the divided-down reference oscillator has a frequency of 1 kHz, for example, then the period can be measured to a resolution of 1 ms. This same technique can be used to measure low-frequency signals as well. For example, when measuring the frequency of a subaudible tone encoder, you need at least 0.1 Hz measurement resolution. Normally, that would require a 10-second count time which can be inconvenient. Some counters are able to measure the period, calculate the reciprocal, and display the resulting frequency. Since the count time is only one cycle of the measured signal, the display updates in real time.

Many frequency counters include a *prescaler*, a frequency divider between the input and the main part of the circuitry, to allow

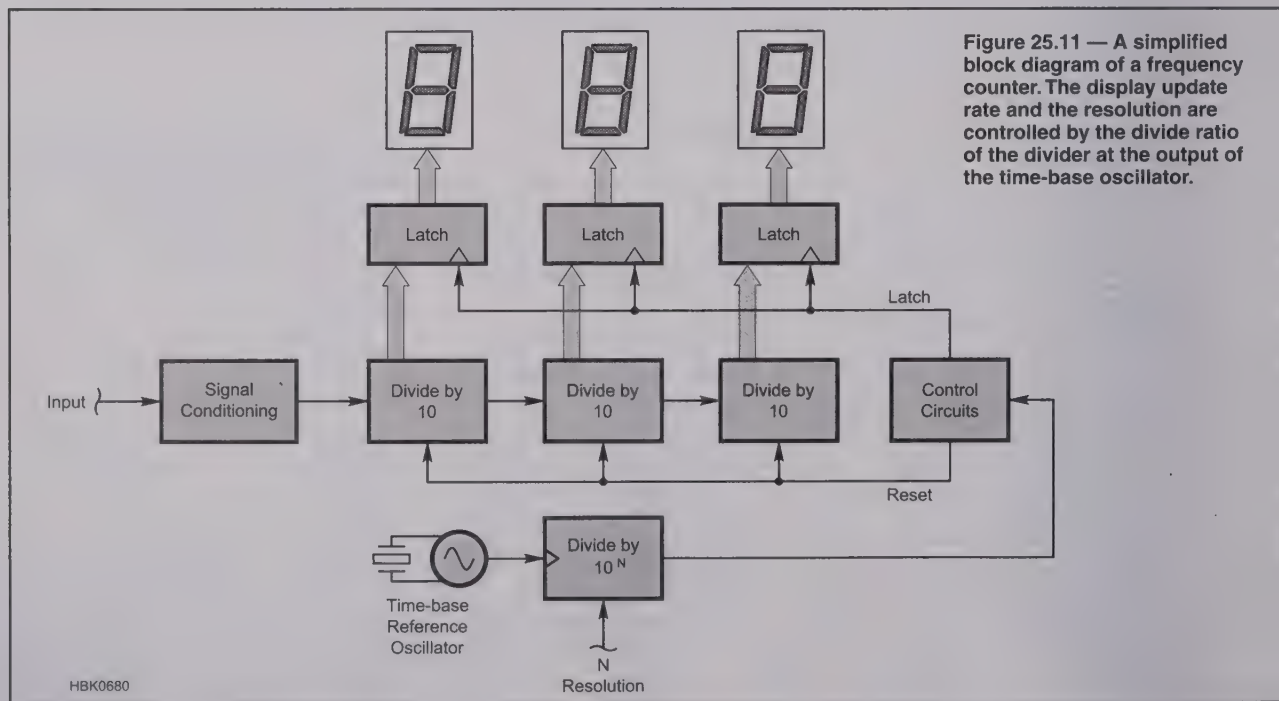

Figure 25.11 — A simplified block diagram of a frequency counter. The display update rate and the resolution are controlled by the divide ratio of the divider at the output of the time-base oscillator.

operation at higher frequencies. Usually the prescaler has a 50-Ω input. For low frequencies, there is a separate high-impedance input, typically 1 MΩ, that bypasses the prescaler. A switch selects between the two inputs.

It is important to realize that the so-called high-impedance input only has a high impedance at low frequencies. For example, if the stray input capacitance is 30 pF, then the impedance is only 177 Ω at 30 MHz. If you try to measure the frequency of an oscillator by connecting the frequency counter's input directly to the circuitry, it likely will alter the oscillator tuning enough to invalidate the measurement. If possible, connect the counter to the output of a buffer amplifier or at some other point in the circuitry that won't be adversely affected. If that isn't possible, another trick is to use a pickup coil placed near the oscillator. The coil could be a few turns of insulated wire soldered between the center conductor and shield of a coaxial cable that connects to the frequency counter input. Hold the coil just close enough to get a stable reading.

When connecting a frequency counter to a circuit, observe the maximum voltage and power ratings, both for dc and ac. An oscilloscope probe with a 10:1 attenuation ratio connected to the high-impedance input is a good method to reduce both the signal level as well as the capacitive loading.

Frequency counters tend to have sensitive inputs. Only a small fraction of a volt is typically enough for valid readings. It is quite practical to measure the frequency of a nearby transmitter off the air with a small whip antenna. The transmitter should not be modulated while measuring its frequency. SSB transmitters should be measured in CW mode.

The principle figure of merit for a frequency counter is its frequency accuracy, which is primarily determined by the reference oscillator, also known as the *time base*. The time base accuracy is affected by the temperature, power supply voltage, crystal aging and quality of calibration. For a temperature-compensated crystal oscillator (TCXO), the total accuracy is typically a few parts per million (ppm). If it is 10 ppm, for example, then the error at 144 MHz is 1.44 kHz.

Normally temperature is the factor with the greatest effect on the short-term stability. For best accuracy, calibrate the reference oscillator at the same temperature at which measurements will be taken.

Other important specifications are the number of digits in the display, frequency resolution, display update time, frequency range, input sensitivity, input impedance and, for portable units, power supply voltage and current. In choosing a frequency counter you'll need to decide if you want a desktop model or a portable handheld unit. Additional features to consider include the size and vis-

ibility of the display, the ability to measure period, a data hold feature, an external time base input, adjustable trigger level and polarity, input attenuator, switchable low-pass filter, and frequency ratio measurement.

Commercial frequency counters have become so common that it hardly pays to construct your own from scratch. Units with a wide range of prices, feature sets and performance levels are available both on-line and from local electronics distributors. Older used and surplus frequency counters tend to be less of a bargain than other types of test equipment because advances in solid-state electronics have made modern instruments inexpensive, lightweight and packed with features and performance.

### FREQUENCY MARKER GENERATORS

Before the advent of digital frequency synthesizers, most shortwave amateur receivers and transceivers included a crystal calibrator, which is a low-frequency (typically 25 or 100 kHz) oscillator with strong harmonics throughout the HF spectrum, used to calibrate the analog dial on the radio. Early units used an actual 100 kHz crystal in the oscillator, but modern units use a higher-frequency crystal and a frequency divider to obtain the low-frequency signal.<sup>4</sup>

Most modern Amateur Radio equipment uses a crystal-controlled synthesizer or digital frequency display, so no crystal calibrator is needed. However, the idea can still be useful for testing homebrew gear. If the low-frequency signal consists of a series of narrow pulses rather than a square wave, then all the harmonics are of the same amplitude up to the point where the pulse width is a significant portion of a cycle. This can be approximated by placing a small-value capacitor in series with the output. The harmonics should have constant amplitude for frequencies below

$$f \ll \frac{1}{2\pi RC}$$

where  $f$  is the frequency in MHz,  $C$  is the capacitance in μF and  $R$  is the load resistance, usually 50 Ω.

### WAVEMETERS

An *absorption wavemeter* is basically a tunable filter with some means of detecting the signal at the filter output. It allows crude spectrum analysis of a signal by manually tuning through the frequencies of interest. Commercial units designed for microwave frequencies often include a carefully-calibrated dial for reading the frequency with some precision. Typically a diode detector is used to indicate the output signal level. A wavemeter suitable for HF or VHF frequencies can be constructed with one or more coils and a variable capacitor.

### DIP METERS

Old timers know this instrument as a grid-dip oscillator (GDO), so-called because the indicating "dip" was in the grid current of the vacuum-tube oscillator. Most dip meters these days are solid-state but the principle is the same. The oscillator coil is external, extending from the end of the instrument. A set of plug-in coils is provided to cover the unit's frequency range.

Along with resonant frequency measurements, the dip meter can also serve as a crude signal generator, capacitor and inductor meter, and antenna and transmission line tester, among other uses.<sup>5</sup> If you are purchasing a dip meter, look for one that is mechanically and electrically stable. On used units, the socket where the coils plug in is a common cause of intermittent operation. The coils should be in good condition. A headphone connection is helpful. Battery-operated models are convenient for antenna measurements.

If you hold the coil near a tuned circuit and adjust the dip meter tuning dial to the frequency of the tuned circuit, there is a dip in the meter reading as the resonant circuits interact with each other. To avoid detuning the circuit being tested, always use the minimum coupling that yields a noticeable indication.

Most dip meters can also serve as absorption wavemeters by turning off the oscillator and looking for a peak instead of a dip in the meter reading. Sometimes frequencies can be detected in this way that would be difficult to read on a frequency counter because of the presence of harmonics. Further, some dip meters have a connection for headphones. The operator can usually hear signals that do not register on the meter.

A dip meter may be coupled to a circuit either inductively or capacitively. Inductive coupling results from the magnetic field generated by current flow. Therefore, inductive coupling should be used when a coil or a conductor with relatively high current is convenient. Maximum inductive coupling results when the axis of the pick-up coil is placed perpendicular to the current path and the coil is adjacent to the wire.

High-impedance circuits have high voltage and low current. Use capacitive coupling when a point of relatively high voltage is convenient. An example might be the output of a 12-V powered RF amplifier. (For safety's sake, *do not* attempt dip-meter measurements on true high-voltage equipment such as vacuum-tube amplifiers of switching power supplies while they are energized.) Capacitive coupling is strongest when the end of the pick-up coil is near a point of high impedance. In either case, the circuit under test is affected by the presence of the dip meter.

To measure resonance, use the following procedure. First, bring the dip meter gradually closer to the circuit while slowly vary-

ing the dip-meter frequency. When a current dip occurs, hold the meter steady and tune for minimum current. Once the dip is found, move the meter away from the circuit and confirm that the dip comes from the circuit under test (the depth of the dip should decrease with distance from the circuit until the dip is no longer noticeable). Finally, move the meter back toward the circuit until the dip just reappears. Retune the meter for minimum current and read the dip-meter frequency from the dial or with a calibrated receiver or frequency counter.

The current dip of a good measurement is smooth and symmetrical. An asymmetrical dip indicates that the dip-meter oscillator frequency is being significantly influenced by the test circuit, degrading the accuracy of the measurement. Increase the distance between the dip meter and the circuit until a shallow symmetrical dip is obtained.

### FREQUENCY CALIBRATION

The best test equipment is of limited use if it is not well-calibrated. The traditional frequency calibration method is to zero-beat a crystal oscillator (or its harmonic) with a radio station of known frequency, preferably a standard frequency station such as WWV or WWVH. Table 25.1 contains the locations and frequencies of some of those stations. A receiver is tuned to one of those frequencies and the oscillator is loosely coupled to the antenna. It may be necessary to use frequency multiplication or division to obtain a common frequency. The frequency difference between the two causes a *beat note*, a rapid variation in the strength of the tone received in the speaker that slows down as the frequencies are brought close together. Maximum beat-note modulation occurs when the off-the-air and oscillator signals are approximately equal in amplitude.

While the transmitted frequencies from WWV and WWVH are highly accurate,

better than 1 part in  $10^{11}$ , after propagation via the ionosphere the received accuracy is significantly degraded by Doppler shift, typically to a few parts in  $10^7$ . Also, due to fading of the received signal, it can be difficult to zero-beat the oscillator to better than about 1 Hz accuracy. Best results generally occur on the highest frequency that provides good reception.

VLF time standards and surplus rubidium standards can be used for frequency references.<sup>6,7</sup> The Global Positioning System (GPS) satellites offer further possibilities for very precise frequency calibration. Various companies sell *disciplined oscillator* units that correct the frequency using the cesium-clock-based signals from the GPS satellites. These can sometimes be found on the surplus market.<sup>8</sup> Amateur-level kits are also available or you can build one from scratch.<sup>9</sup>

### 25.3.4 Oscilloscopes

An *oscilloscope* (“scope” for short) is an instrument that displays voltage versus time

on a screen, similar to the waveforms seen in electronics textbooks. Scopes are broken down into two major classifications: analog and digital. This does not refer to the signals they measure, but rather to the methods used inside the instrument to process signals for display.

### ANALOG OSCILLOSCOPES

Figure 25.12 shows a simplified diagram of a triggered-sweep oscilloscope. At the heart of all analog scopes is a cathode-ray tube (CRT) display. An electron beam inside the CRT strikes the phosphorescent screen causing a glowing spot. Unlike a television CRT, an oscilloscope uses electrostatic deflection rather than magnetic deflection. The exact location of the spot is a result of the voltage applied to the vertical and horizontal deflection plates. To trace how a signal travels through the oscilloscope circuitry, start by assuming that the trigger select switch is in the INTERNAL position.

The input signal is connected to the input COUPLING switch. The switch allows selection of either the ac part of an ac/dc signal or the total signal. If you wanted to measure, for example, the RF swing at the collector of an output stage including the dc level, you would use the *dc-coupling* mode. In the *ac-coupled* mode, dc is blocked from reaching the vertical amplifier chain so that you can measure a small ac signal superimposed on a much larger dc level. For example, you might want to measure a 25 mV 120-Hz ripple on a 13-V dc power supply. Note that you should not use ac coupling at frequencies below the low-frequency cutoff of the instrument in that mode, typically around 30 Hz, because the value of the blocking capacitor represents a high series impedance to very low-frequency signals.

After the coupling switch, the signal is connected to a calibrated attenuator. This is used to reduce the signal to a level within

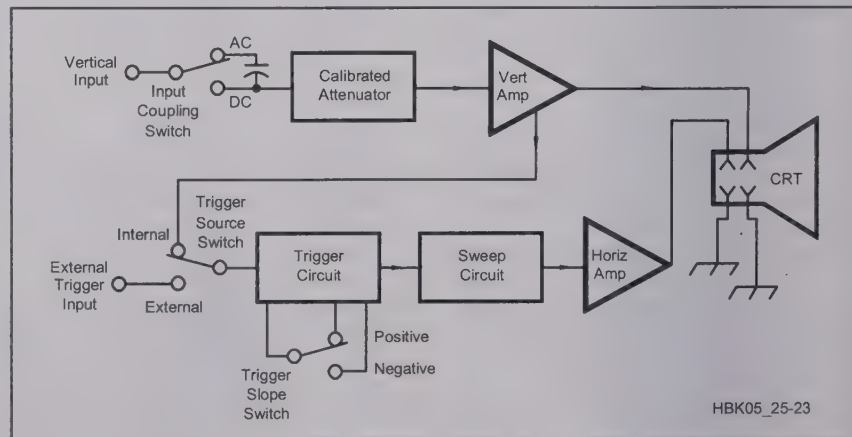

Figure 25.12 — Typical block diagram of a simple triggered-sweep oscilloscope.

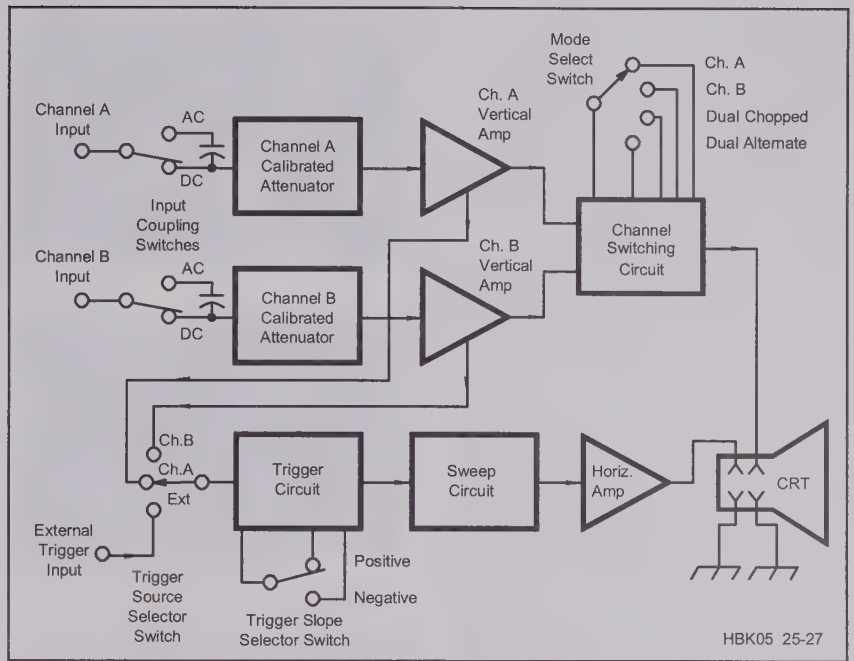

**Figure 25.13** — The sweep trigger starts the ramp waveform that sweeps the CRT electron beam from side to side.

**Figure 25.14** — In order to produce a stable display the selection of the trigger point is very important. Selecting the trigger point in A produces a stable display, but the trigger shown at B will produce a display that “jitters” from side

the range of the scope’s vertical amplifier. The vertical amplifier boosts the signal to a level that can drive the CRT and also adds a bias component to position the waveform on the screen. The result is that the vertical position of the beam on the CRT represents input voltage.

A small sample of the signal from the vertical amplifier is sent to the trigger circuitry. The trigger circuit feeds a start pulse to the sweep generator when the input signal reaches a certain level (*level triggering*) or exhibits a positive- or negative-going edge (*edge triggering*). The sweep generator gives a precisely timed voltage ramp (see **Figure 25.13**). The rising edge of the ramp signal feeds the horizontal amplifier that, in turn, drives the CRT. This causes the scope trace to sweep from left to right, with the zero-voltage

**Figure 25.15** — Simplified dual-trace oscilloscope block diagram. Note the two identical input channels and amplifiers.

point representing the left side of the screen and the maximum voltage representing the right side of the screen. The result is that the horizontal position of the beam on the CRT represents time. At the end of the ramp, the sharp edge of the ramp quickly moves the beam back to the left side of the screen.

The trigger circuit controls the horizontal sweep. It looks at the trigger source (internal or external) to find out if it is positive- or negative-going and to see if the signal has passed a particular level. **Figure 25.14A** shows a typical signal and the dotted line on the figure represents the trigger level. It is important to note that once a trigger circuit is “fired” it cannot fire again until the sweep has moved all the way across the screen from left to right. There normally is a TRIGGER LEVEL control to move the trigger level up and down until a stable display is seen. Some scopes have an AUTOMATIC position that chooses a level to lock the display in place without manual adjustment.

**Figure 25.14B** shows what happens when the level has not been properly selected. Because there are two points during a single cycle of the waveform that meet the triggering requirements, the trigger circuit will have a tendency to jump from one trigger point to another. This will make the waveform jitter from left to right. Adjustment of the TRIGGER LEVEL control will fix that problem.

It is also possible to trigger the sweep system from an external source (such as the

system clock in a digital system). This is done by using the external input jack with the trigger select switch in the EXTERNAL position.

## DUAL-TRACE OSCILLOSCOPES

Dual-trace oscilloscopes have two vertical input channels that can be displayed together on the screen. Although the best dual-trace scopes use a CRT with two electron beams, it is possible to trick the eye into seeing two traces simultaneously using a single-beam CRT. **Figure 25.15** shows a simplified block diagram of a dual-trace oscilloscope using this method. The only differences between this scope and the previous example are the additional vertical amplifier and the “channel switching circuit.” This block determines whether we display channel A, channel B or both (simultaneously).

The dual display is not a true dual-beam display but the appearance of dual traces is created by the scope using one of two methods, referred to as *chopped mode* and *alternate mode*. In the chopped mode a small portion of the channel A waveform is written to the CRT, then a corresponding portion of the channel B waveform is written to the CRT. This procedure is continued until both waveforms are completely written on the CRT. The switching from one channel to the other is so fast that each trace looks as though it were continuous. The chopped mode is essential for *single-shot* signals (signals that do

not repeat periodically). It is most useful at slow sweep speeds. At fast sweep speeds, the switching from channel to channel becomes visible, making each trace into a dotted line.

In the alternate mode, the complete channel A waveform is written to the CRT followed immediately by the complete channel B waveform. This happens so quickly that it appears that the waveforms are displayed at the same time. This mode of operation is not very useful at very slow sweep speeds since the two traces no longer appear simultaneous. It also does not work for single-shot events.

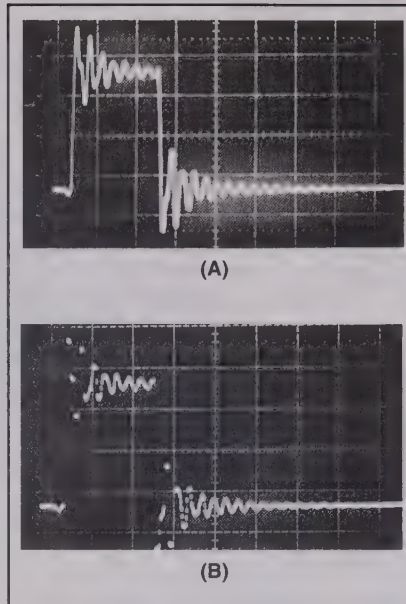

Most dual-trace oscilloscopes also have a feature called “X-Y” mode. This feature allows one channel to drive the horizontal amplifier of the scope (called the X channel) while the other channel (called Y in this mode of operation) drives the vertical amplifier. Some single-trace oscilloscopes support this mode as well. X-Y operation allows the scope to display *Lissajous patterns* for frequency and phase comparison and to use specialized test adapters such as curve tracers or spectrum analyzer front ends. Because of frequency limitations of most scope horizontal amplifiers the X channel is usually limited to a 5 or 10-MHz bandwidth.

## DIGITAL OSCILLOSCOPES

In recent years, semiconductor and display technology have advanced to the point that much of the analog signal processing in an oscilloscope can be replaced with low-cost microprocessor-based digital circuitry. This results in dramatically improved accuracy for both amplitude and time measurements as well as enabling sophisticated features that would be difficult or impossible in an analog scope. For example, a trace can be displayed with infinite persistence and stored as a computer file if desired.

In a digital oscilloscope the vertical amplifiers are replaced with an analog-to-digital converter (ADC), which samples the signal at regular time intervals and stores the samples in digital memory. The samples are stored with an assigned time, determined by the trigger circuits and the microprocessor clock. The samples are then retrieved and displayed on the screen with the correct vertical and horizontal position.

Early digital oscilloscopes used a CRT with electrostatic deflection, similar to an analog scope, with the horizontal and vertical deflection signals generated by digital-to-analog converters (DACs). Modern instruments usually use either a raster-scan CRT similar to a television picture tube or a solid state (LCD) display. The microprocessor determines which pixels to light up to draw the traces on the screen. Even though a digital scope does not have the same internal circuitry as an analog scope, many of the same terms are used to control operation. For example,

**Figure 25.16** — Comparison of an analog scope waveform (A) and that produced by a digital oscilloscope (B). Notice that the digital samples in B are not continuous, which may leave the actual shape of the waveform in doubt for the fastest rise time displays the scope is capable of producing.

“Sweep speed” still describes the amount of time per horizontal division, even though there is no electron beam to be swept across the display in the original sense.

For the vertical signals you will see manufacturers refer to “8-bit digitizing,” or perhaps “10-bit resolution.” This is a measure of the number of digital levels that are shown along the vertical (voltage) axis. More bits give you better resolution and accuracy of measurement. An 8-bit vertical resolution means each vertical screen has  $2^8$  (or 256) discrete values; similarly, 10-bit resolution yields  $2^{10}$  (or 1024) discrete values.

It is important to understand some of the limitations resulting from sampling the signal rather than taking a continuous, analog measurement. When you try to reconstruct a signal from individual discrete samples, you must take samples at least twice as fast as the highest frequency signal being measured. If you digitize a 100-MHz sine wave, you should take samples at a rate of 200 million samples a second (referred to as 200 Megasamples/second). Actually, you really would like to take samples even more often, usually at a rate at least five times higher than the input signal. (See the **DSP and Software Radio Design** chapter for more information on sampled signals.)

If the sample rate is not high enough, very

fast signal changes between sampling points will not appear on the display. For example, **Figure 25.16** shows one signal measured using both analog and digital scopes. The large spikes seen in the analog-scope display are not visible on the digital scope. The sampling frequency of the digital scope is not fast enough to store the higher frequency components of the waveform. If you take samples at a rate less than twice the input frequency, the reconstructed signal has a wrong apparent frequency; this is referred to as *aliasing*. In **Figure 25.16** you can see that there is about one sample taken per cycle of the input waveform. This does not meet the 2:1 criteria established above. The result is that the scope reconstructs a waveform with a different apparent frequency.

Many older digital scopes had potential problems with *aliasing*. A simple manual check for aliasing is to use the highest practical sweep speed (shortest time per division) and then to change to other sweep speeds to verify that the apparent frequency doesn't change. Some modern oscilloscopes use a special technique to increase the effective sample rate for repetitive signals. The phase of the sample clock is adjusted slightly on each successive sweep, so that the new samples occur in between the previous ones. After several sweeps the missing data in the spaces between the original samples are filled in, producing a continuous trace. This only works with periodic signals that trigger at exactly the same point on each sweep.

## OSCILLOSCOPE LIMITATIONS

Oscilloscopes have fundamental limits primarily in frequency of operation and range of input voltages. For most purposes the voltage range can be expanded by the use of appropriate probes. The frequency response (also called the bandwidth) of a scope is usually the most important limiting factor. For example, a 100-MHz 1-V sine wave fed into an oscilloscope with a 100-MHz 3-dB bandwidth will read approximately 0.7 V on the display. The same instrument at frequencies below 30 MHz should be accurate to about 5%.

A parameter called *rise time* is related to bandwidth. This term describes a scope's ability to accurately display voltages that rise very quickly. For example, a very sharp and square waveform may appear to take some time in order to reach a specified fraction of the input voltage level. The rise time is usually defined as the time required for the display to show a change from the 10% to 90% points of the input waveform, as shown in **Figure 25.17**. Assuming the frequency response is primarily limited by a single-pole roll off in the amplifier circuitry, the mathematical definition of rise time is given by:

**Figure 25.17** — The bandwidth of the oscilloscope vertical channel limits the rise time of the signals displayed on the scope.

$$t_r = \frac{0.35}{BW}$$

where  $t_r$  = rise time in  $\mu$ s and BW = bandwidth in MHz of the amplifier.

It is also important to note that inexpensive analog oscilloscopes may not have better than 5% accuracy in these applications. Even moderately-priced oscilloscopes are still useful, however. The most important value of an oscilloscope is that it presents an image of what is going on in a circuit, which is very useful for troubleshooting waveforms and other time-varying phenomena. It can show modulation levels, relative gain between stages, clipping distortion, intermittent oscillations and other useful information.

### USING AN OSCILLOSCOPE

An oscilloscope can measure a signal's shape, amplitude, frequency and whether it is dc, ac or a mixture of both. For example, in **Figure 25.18** it is clear from the shape that the signal is a sine wave. Assuming that the center horizontal line or axis represents zero volts, the signal has no dc component since there is as much above the axis as below it. If the vertical gain has been set to 1 V per division, then the peak value is 2 V and the peak-to-peak value is 4 V.

The horizontal travel of the trace is calibrated in units of time. If the sweep speed is known and we count the number of divisions (vertical bars) between peaks of the waveform (or any similar well-defined points that occur once per cycle) we can find the period of one cycle. The frequency is the reciprocal of the period. In **Figure 25.18**, for example,

**Figure 25.18** — An oscilloscope can measure frequency as well as amplitude. Here the waveform shown has a period of 80 microseconds (8 divisions  $\times$  10  $\mu$ s per division) and therefore a frequency of 1/80  $\mu$ s or 12.5 kHz.

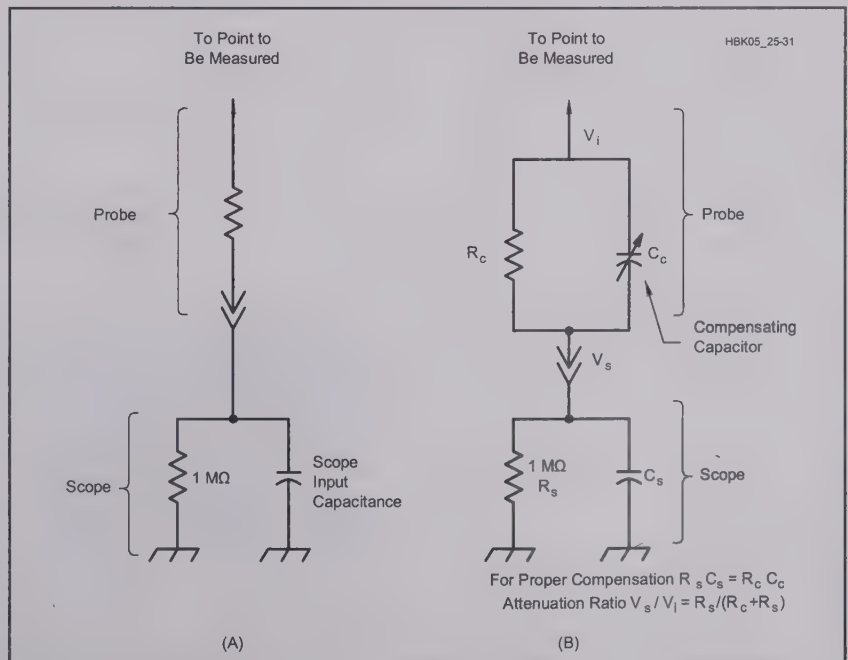

the distance between the peaks is 8 divisions. If the sweep speed is 10  $\mu$ s/division then the period is 80  $\mu$ s. That means that the frequency of the waveform is 1/80  $\mu$ s, or 12,500 Hz. The accuracy of the measured frequency depends on the accuracy of the scope's ramp generator, typically a few percent for an analog instrument. This accuracy cannot compete with even the least-expensive frequency counter, but the scope can still be used to determine

whether a circuit is functioning properly.

Oscilloscopes are usually connected to a circuit under test with a short length of shielded cable and a probe. At low frequencies, a piece of small-diameter coax cable and some sort of insulated test probe might do. However, at higher frequencies the capacitive reactance of the cable would be much less than the one-megohm input impedance of the oscilloscope. In addition each scope has a certain built-in capacitance at its input terminals (usually between 5 and 35 pF). The total capacitance causes problems when probing an RF circuit with relatively high impedance.

Most new oscilloscopes come with specially-designed *scope probes*, one for each vertical channel. They can also be purchased separately. The most common type is a  $\times 10$  probe (called a "times ten" probe), which forms a 10:1 voltage divider using the built-in resistance of the probe and the input resistance of the scope. When using a  $\times 10$  probe, all voltage readings must be multiplied by 10. For example, if the scope is on the 1 V/division range and a  $\times 10$  probe were in use, the signals would be displayed on the scope face at 10 V/division. Some scopes can sense whether a  $\times 10$  probe is in use, and automatically change the scale of the scope's display.

Unfortunately a resistor alone in series with the scope input seriously degrades the scope's rise-time performance and bandwidth because of the low-pass filter formed by the series resistance along with the parallel capacitance

**Figure 25.19** — Uncompensated probes such as the one at A are sufficient for low-frequency and slow-rise-time measurements. However, for accurate display of fast rise times with high-frequency components the compensated probe at B must be used. The variable capacitor is adjusted for proper compensation (see text for details).

of the cable and scope input. This may be corrected by using a compensating capacitor in parallel with the series resistor. If the capacitor value is chosen so that the R-C time constant is the same as the R-C network formed by the input resistance and capacitance of the scope, as shown in **Figure 25.19**, then the probe and scope should have a flat response curve throughout the whole bandwidth of the scope. A  $\times 10$  probe not only reduces the voltage by a factor of 10 but it increases the input resistance and reduces the capacitance as well, which reduces loading on the circuit under test.

To account for manufacturing tolerances in the scope and probe the compensating capacitor is made variable. Most scopes include a “calibrator” output that produces a fast-rise-time square wave for the purpose of adjusting the compensating capacitor in a probe. **Figure 25.20** shows possible responses when the probe is connected to the oscilloscope’s calibrator jack. A misadjusted compensating capacitor can greatly affect the frequency response of the scope and create artifacts in signals that are not actually present.

If a probe cable is too short, do not attempt to extend the length of the cable by adding a piece of common coaxial cable. The compensating capacitor in the probe is chosen to compensate for the provided length of cable. It usually does not have enough range to compensate for extra lengths.

The shortest ground lead possible should be used from the probe to the circuit ground. Long ground leads act as inductors at high frequencies where they create ringing and other undesirable artifacts in the displayed signal.

For the best high-frequency performance, the scope probe can be eliminated entirely and the oscilloscope input converted to a 50- $\Omega$  impedance. Some scopes have a switch to choose between a high-impedance or 50- $\Omega$  input. For others, you can purchase a 50- $\Omega$  through-line termination, which is just a connector with a male BNC on one end, a female BNC on the other, and an internal 50- $\Omega$  termination resistor in parallel. Plug the male connector to the scope’s high-impedance vertical input and connect the 50- $\Omega$  cable from the device under test to the female connector.

Some situations may require the use of a

**Figure 25.20** — Displays of a square-wave input illustrating undercompensated, properly compensated and overcompensated probes.

scope to measure a *current* waveform, rather than a voltage. Specialized current probes are available that make this task possible, with some capable of measuring both dc and ac.

Be wary of using a scope to judge harmonic content or distortion of a sine wave. A waveform that “looks good” to the eye may have significant distortion or high-frequency components unsuitable for on-the-air signals. A spectrum analyzer (described below) should be used for determining the spectral content of signals.

### CHOOSING AN OSCILLOSCOPE

For many years a scope (even a so-called portable) was big and heavy. In recent years, microprocessors and other ICs have reduced the size and weight. Modern scopes can take other forms than the traditional large cabinet with built-in CRT. Nearly all digital oscilloscopes use an LCD display for true portability. (See **Figure 25.21**) You can use your personal computer as an oscilloscope with an external signal digitizer that connects to the PC via a high-speed USB or Firewire interface. This saves money by using the cabinet, power supply, processor and display of the PC. Even stand-alone scopes can attach to a PC and download their data for storage and analysis or transfer it to memory storage devices. Many high-end scopes now incorporate non-traditional functions, such as the Fast Fourier Transforms (FFT). This allows spectrum analysis or other advanced mathematical techniques to be applied to the displayed waveform.

### Features

When choosing an oscilloscope, the first decision is analog versus digital. Used and

surplus instruments are usually analog but more modern units are shifting to digital as the prices of solid-state displays and other components come down. Digital models are generally more accurate and tend to have lots of features not found on analog oscilloscopes.

The next big decision is how many input channels you need. There are many situations in which having a second channel is extremely helpful and even more than two channels is often useful, especially when troubleshooting digital circuits. With two or more channels you typically also get X-Y mode.

Trace storage is essential for viewing very slow signals or single-shot transients. In the old days, high-end analog scopes used special CRTs that could store a trace in an analog fashion. They tended to be rather difficult to adjust properly and the CRTs are expensive and/or impossible to replace if they should ever fail. Trace storage is very easy to implement in a digital scope and nearly all of them have the feature. Ideally, one or more stored traces can be displayed simultaneously with the current trace for easy comparison.

Most scopes come with the ability to select internal, external or power-line synchronous triggering as well as an adjustable trigger level. Digital scopes may draw a horizontal line on the screen so you can see exactly where the trigger level is with respect to the signal, which is very handy. Automatic adjustment of trigger level is a common feature as well. Some scopes offer a noise-rejection feature that adds hysteresis to reduce false triggering. *Single sweep* is useful for looking at a non-repetitive signal. The single sweep can be *armed*, that is, reset and ready to start the next sweep, by pushing a button or sometimes with an external signal. *Trigger delay* allows horizontal centering of

**Figure 25.21** — The Tektronix TDS 2000C series is a typical example of digital oscilloscopes using an LCD display.

the display at a different place from the trigger point. *Trigger hold-off* inhibits the trigger for a selectable time after the sweep to prevent unwanted multiple triggers.

Some older tube-type scopes offered only ac input coupling, but most nowadays have a switch to select between ac, dc and ground. As mentioned before, some include a switch to select 50- $\Omega$  or high input impedance. Some high-speed scopes include a switchable input low-pass filter to reduce wideband noise when measuring lower-frequency signals. A feature sometimes found on multiple-channel scopes is the ability to add or subtract two or more channels.

Digital oscilloscopes often include various data-analysis features. Averaging reduces noise and peak mode makes transient peaks visible. A common feature is the ability to calculate and display the peak, peak-to-peak and RMS values of a signal. For repetitive signals, the period and frequency can be calculated as well. Some scopes include amplitude and/or time markers that allow accurate measurements of specific points on a waveform. Sometimes the instrument state can be stored to one of several internal memories, which can be very handy on complicated instruments that take a long time to set up.

Computer connectivity used to be available only on high-end instruments but is now becoming more and more common. It allows storing traces for later reference and you can produce nice graphical screen shots for that magazine article or notebook entry about your latest creation. With the proper software it allows automated testing as well. Older instruments usually have a GPIB (general purpose interface bus) interface, also known as IEEE-488 or as HPIB on Hewlett-Packard equipment. GPIB-to-USB adapters are available from Prologix and a number of other companies. More modern scopes usually come with an RS-232 or USB interface.

## Specifications

Bandwidth is the main “money spec” for an oscilloscope. The higher the frequency range, the more expensive it tends to be. Rise time is also sometimes specified. For digital scopes, the sample rate is just as important. Theoretically it must be at least twice the bandwidth but practically should be much higher than that to avoid aliasing. For repetitive waveforms, some scopes can do tricks with the sample phase to eliminate aliasing with a lower sample rate, as explained previously.

The range of input signals is normally specified as the maximum and minimum volts per division. Amplitude accuracy is usually specified as a percent of the reading, typically 5-10% for inexpensive analog scopes and perhaps 1-2% for high-quality digital ones. Another important specification is the

maximum input signal that can be accepted without damage. It is typically presented as a maximum dc plus peak ac voltage, that is, the maximum peak voltage of the complete signal. This is increased when using a  $\times 10$  probe, subject to the probe specifications.

For digital scopes, the resolution of the input analog-to-digital converter (ADC) is typically specified as a number of bits. Sometimes the lowest-voltage input ranges are obtained simply by using only the low end of the ADC range, which results in the displayed signal having a stepped response rather than a smooth curve.

The sweep speed is generally specified in seconds (milliseconds, microseconds) per division. The accuracy is typically a few percent for analog scopes and much better than that for digital scopes, often limited just by the screen resolution. The triggering system is a major factor that determines how useful a scope is in actual operation, but it can be hard to tell how well it works by studying the specifications. The trigger sensitivity is the main parameter to look for. It is specified in fractions of a division for internal trigger and in mV for external trigger.

## BUYING A USED SCOPE

Many hams end up buying a used scope due to price. If you buy a scope and intend to service it yourself, be aware all scopes that use tubes or a CRT contain lethal voltages. Treat an oscilloscope with the same care you would use with a tube-type high-power amplifier. The CRT should be handled carefully because if dropped it will crack and implode, resulting in pieces of glass and other materials being sprayed everywhere in the immediate vicinity. You should wear a full-face safety shield and other appropriate safety equipment to protect yourself.

Another concern when servicing an older scope is the availability of parts. The CRTs in older units may no longer be available. Many scopes made since about 1985 used special ICs, LCDs and microprocessors. Some of these may not be available or may be prohibitive in cost. You should buy a used scope from a reputable vendor— even better yet, try it out before you buy it. Make sure you get the operator’s manual also.

Older tube-type models are generally quite serviceable, often needing nothing more than a new tube or two. The massive lab-grade instruments from days of yore made by Tektronix and Hewlett-Packard can still give good service with a little care. They are so large and heavy that a special scope cart was often used to house them and allow easy movement from lab bench to lab bench.

Early generation digital scopes are now showing up on the surplus market at reasonable prices. Unfortunately, the user interface leaves much to be desired on some mod-

els, sometimes requiring the operator to use several layers of menus to access common functions. Look for one with an analog-like feel with separate buttons or knobs for most of the important functions.

## 25.3.5 Audio-Frequency Oscillators and Function Generators

There are a number of ways to generate an audio-frequency tone. If a square-wave output is acceptable, then a simple oscillator can be built with a 555 timer IC, two resistors and two capacitors. It is an inexpensive, time-tested design with good frequency stability.

If a sine-wave signal is needed, a *twin-T* oscillator made with a single bipolar transistor is about the simplest solution. The oscillator in **Figure 25.22** can be operated at any frequency in the audio range by varying the component values. R1, R2 and C1 form a low-pass network, while C2, C3 and R3 form a high-pass network. As the phase shifts are opposite, there is only one frequency at which the total phase shift from collector to base is 180°: Oscillation will occur at that frequency. C1 should be about twice the capacitance of C2 or C3. R3 should have a resistance about 0.1 that of R1 or R2 (C2 = C3 and R1 = R2). Output is taken across C1, where the harmonic distortion is least. Use a relatively high impedance load — 100 k $\Omega$  or more. Most small-signal AF transistors can be used for Q1. Either NPN

**Figure 25.22** — Values for the twin-T audio oscillator circuit range from 18 k $\Omega$  for R1-R2 and 0.05  $\mu\text{F}$  for C1 (750 Hz) to 15 k $\Omega$  and 0.02  $\mu\text{F}$  for 1800 Hz. For the same frequency range, R3 and C2-C3 vary from 1800  $\Omega$  and 0.02  $\mu\text{F}$  to 1500  $\Omega$  and 0.01  $\mu\text{F}$ . R4 is 3300  $\Omega$  and C4, the output coupling capacitor, can be 0.05  $\mu\text{F}$  for high-impedance loads.

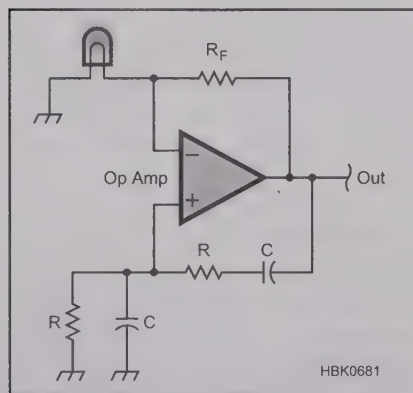

or PNP types are satisfactory if the supply polarity is set correctly. R4, the collector load resistor may be changed a little to adjust the oscillator for best output waveform.

While the twin-T oscillator does give a roughly sinusoidal output, the distortion is rather high and the frequency is not easily tunable. Both of those problems are addressed in the *Wien bridge* oscillator illustrated in **Figure 25.23**. The key to low distortion is to prevent the amplifier from going into saturation. If equal values of R and C are used in both sections of the positive feedback network, then the gain through that network is  $\frac{1}{3}$ . If the negative feedback network also has a 3:1 ratio, then the total loop gain is exactly 1, the condition for oscillation. The light bulb in the bottom leg has a positive temperature coefficient. (Note that a true incandescent bulb must be used — an LED may not be substituted.) As the signal level increases, its resistance goes up, lowering the gain. In this way the amplitude is held steady so that the amplifier does not saturate. The frequency may be tuned with a single control by using a two-section potentiometer for the two resistors labeled R. Typically small fixed-value resistors are placed in series with each potentiometer section to give about a 10:1 tuning range. Additional ranges can be had by switching the capacitors, selected using the equation

$$C = \frac{1}{2\pi fR}$$

A suitable bulb is a number 327 or 1819. Under normal operation, it should be lit to a bit less than full brightness, which is determined by the value of the negative feedback resistor  $R_F$ , typically around 400  $\Omega$ .

The idea of using the positive temperature coefficient of resistance of a light bulb to stabilize the output of a tunable oscillator was used in the very first instrument produced by

**Figure 25.23** — A Wien bridge oscillator has lower distortion than a twin-T oscillator. The light bulb acts to stabilize the feedback to prevent distortion due to amplifier clipping.

the Hewlett-Packard company. (The Model 200A audio oscillator circuit was first described in company founder Hewlett's 1939 college thesis.)

## FUNCTION GENERATORS

A *function generator*, also known as a *waveform generator*, is a type of audio oscillator that can generate several waveforms. In addition to sine waves, most can also generate square waves, triangle waves and sawtooth ramp waveforms. A pulse output with variable duty factor is another common feature. Many models can also linearly sweep the frequency. Frequency coverage is typically from below audio frequencies up to a few MHz.

The heart of most analog function generators is a triangle wave oscillator. To create the sine wave, a diode shaping circuit rounds off the top and bottom of the triangles, resulting in a reasonably-accurate sine wave with distortion on the order of a percent or two. Circuitry that determines when the triangle wave is rising or falling is used to generate the square wave as well. The rise/fall duty factor of the triangle wave can be varied, which also varies the duty factor of the square wave. If the triangle wave duty factor is set near 100% or 0%, it becomes either a rising or falling sawtooth wave.

The easiest way to build your own analog function generator is to use a waveform generator IC that includes most of what you need in one package. The two most common such ICs available today are the MAX038 and XR2206. The ICL8038 is seen in many older circuits but is obsolete and no longer in production. The AD9833 direct digital synthesis (DDS) IC (see **Figure 25.24**) is also designed to be used as a low frequency function generator.<sup>10</sup> (DDS is discussed in the **Oscillators and Synthesizers** and **DSP and Software Radio Design** chapters.)

An *arbitrary waveform generator* (AWG or ARB) has capabilities that are a superset of a waveform generator. The sinusoidal waveform ROM look-up table in **Figure 25.24** is replaced by RAM so that data which creates

waveforms other than a sine wave can be used. Usually a large amount of memory is included so that long non-repetitive waveforms can be generated in addition to periodic signals. ARBs generally include a microprocessor and provide means to generate complicated sequences that may combine repeating and nonrepeating segments.

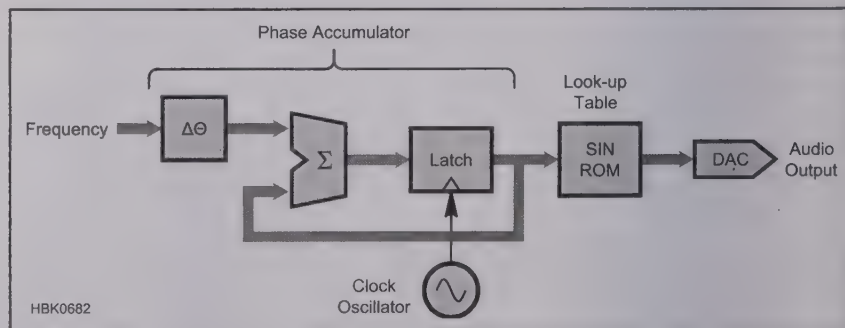

## CHOOSING A FUNCTION GENERATOR

For many applications, the basic analog sine/square wave generator based on a Wien bridge oscillator works fine. The sine wave is adequate for testing the gain, frequency response, and maximum signal level of an audio-frequency circuit. The square wave is useful for checking the transient response of circuits.

The additional wave shapes offered by a function generator are useful for more esoteric applications. Sawtooth and triangle waves can be used to sweep a voltage through a range to test the response of a circuit to various voltages. The pulse output is useful for testing digital circuitry, especially if the instrument has provision for adjusting the on and off voltage levels. Frequency sweep capability is very handy for testing the frequency response of an audio circuit, especially if a sweep ramp or sweep trigger output is provided for synchronizing an oscilloscope. Some instruments provide an input to control the frequency by means of an external voltage.

When selecting a function generator, the first specification to look at is the frequency range. Many units cover low radio frequencies as well as audio. The frequency accuracy may be important for many applications. Digitally-synthesized models use a quartz crystal clock oscillator so are much more accurate than analog models. Some analog models do have a built-in frequency counter, but the accuracy may still be limited by frequency drift.

The amplitude range and accuracy should also be considered. An amplitude of several volts is useful for testing power devices and the ability to accurately set the amplitude to a

**Figure 25.24** — A direct digital synthesizer (DDS) sine-wave generator. Not shown is a low-pass filter at the output that attenuates unwanted spurious frequencies above one-half the clock frequency.

few millivolts may be needed for driving the microphone input of a transmitter. The output impedance is usually either 600 Ω or 50 Ω.

Function generators are available for a wide range of prices, from inexpensive hand-held units to sophisticated bench instruments costing thousands of dollars. Surplus tube-type models can be good values, starting with the venerable Hewlett-Packard 200A, manufactured until the early 1970s. More-recent models can also be found on the used-equipment market made by HP, its successor company Agilent Technologies, Tektronix, B&K, Keithley, Wavetek, Leader, Fluke and others.

An even less-expensive solution is to use a computer sound card as a function generator. A variety of free function generator software can be found on the Internet. Since the sound card output is ac-coupled it is not possible to adjust the dc offset voltage as it is with most function generators. Also, the frequency range, the level range and accuracy, and the output drive capability are not as good as you would expect from a special-purpose instrument. However, quite sophisticated waveforms may be generated with the right software and the price is right.

### 25.3.6 Measuring Inductance and Capacitance

The traditional way to measure inductance (L), capacitance (C), or resistance (R) is with an *LCR bridge* consisting of a Wheatstone bridge driven by a sine-wave voltage and with an ac voltmeter for the null detector. In **Figure 25.25**, the box labeled Z is the reference component. It must be the same type as the device under test, an inductor, capacitor or

resistor. The bridge is nulled when the ratio of the variable resistor  $R_V$  to R is the same as the ratio of the impedance of the device under test to that of Z. The value of  $R_V$  is proportional to the resistance or inductance and inversely proportional to the capacitance. To make it proportional to C, simply swap the positions of  $R_V$  and R in the circuit. In all cases, when  $R_V = R$ , the null is achieved when the value of the device under test equals the value of Z.

Most commercial LCR bridges include a switch to select various values of Z. Typically they are in decade steps so that the dial calibration works on all scales. The frequency of the sine-wave source should be such that the reactance of the capacitor or inductor under test is not so low as to present too small a load impedance to the sine-wave source and not so high that the load presented by the ac voltmeter reduces the depth of the null. Often several frequencies may be selected, the

lower frequencies being used for large-value L and C and higher frequencies used for the smaller values.

A dip meter may be used for measuring either L or C as long as a component of the opposite type is available whose value is accurately known. The technique is to make a tuned circuit by connecting the inductor and capacitor in parallel and then measure the resonant frequency with a grid dip meter. The inductance or capacitance can be determined from the dip frequency, f, using the formula

$$L = \frac{1}{(2\pi f)^2 C} \text{ or}$$

$$C = \frac{1}{(2\pi f)^2 L}$$

Some multimeters have built-in capability to measure inductors and capacitors. It is also possible to build an adapter to allow measuring L and C with any multimeter. Circuit examples are given in the Construction Projects section at the end of this chapter.

The use of capacitors in high-frequency switchmode supplies (see the **Power Sources** chapter) makes it important to measure their *equivalent series resistance (ESR)* and *equivalent series inductance (ESL)*. ESR and ESL cause loss and affect the switching circuit's ability to regulate properly. An ESR meter measures a capacitor's ESR by using short pulses or ac signals. Some ESR meters can be used with the capacitor in-circuit although they should not be used with the capacitor charged or energized. ESL is typically measured with an inductance meter as described above.

**Figure 25.25** — An LCR bridge, which is a type of Wheatstone bridge used to measure inductors (L), capacitors (C) and resistors (R). The box labeled “Z” is the reference component to which the device under test is compared.

## 25.4 RF Measurements

RF measurements are a special case of ac measurements. While everything in the previous section about measuring low-frequency ac applies, there are additional factors to take into consideration for high frequency measurements, such as parasitic values and operational bandwidth. This section concentrates on equipment and techniques especially suited to measuring at radio frequencies. The **RF Techniques** chapter has additional information on circuits at high frequencies.

### 25.4.1 Measuring RF Voltage and Current

An *RF probe* rectifies a radio-frequency signal so that its amplitude can be measured with a dc instrument such as a multimeter. The

circuit is typically quite simple, consisting of a diode, a resistor and a couple capacitors, as in the example of **Figure 25.26**. The resistor value is chosen so that the rectified output voltage is approximately equal to the RMS value of a sine wave input signal. The 390 kΩ value shown assumes the meter has

a 1 MΩ input resistance. The diode can be a high-speed switching diode such as a 1N914 or 1N4148, or it can be a Schottky diode for greater sensitivity.

The detector is located as close to the measuring point as possible to minimize stray inductance and capacitance. The leads to the

**Figure 25.26** — A basic RF probe, used to convert an RF signal into a dc voltage that can be measured by a voltmeter.

dc voltmeter can be longer. The RF probe can be housed in any convenient enclosure that fits easily in the hand and the circuitry can be constructed on a scrap of perforated phenolic board, as long as the leads are kept short. A much more elaborate version with a coaxial input and an integrated compensated voltmeter is described with the downloadable supplemental content.

Measuring RF current is a little more difficult. When measuring the current on an antenna or feed line, it may not be practical to break the connection to insert an ammeter. Even when that can be done, the meter itself often upsets the measurement, either because it must be plugged into ac power or simply because of the instrument's size.

A time-honored technique is to wire a small incandescent lamp in series with the antenna or feed line to be measured. Although you can get a rough idea of the amount of RF current by comparing the brightness to the brightness with a known dc current, this method is only useful for relative measurements where the absolute value does not need to be known.

Another alternative is to construct an RF ammeter using a current transformer that clamps over the wire.<sup>11</sup> That method has the advantage that the wire does not need to be disconnected. It is important that the leads to the meter not couple to the wire or cable being measured.

Highly-accurate commercial RF ammeters made to measure the base current of AM broadcast station antennas can sometimes be found on the surplus market. If you can find one it would give much better accuracy than a homebrew device.

### 25.4.2 Measuring RF Power

Transmitter power is normally given in units of watts. Lower-power RF signals found in receiver and transmitter circuits may be specified in units of milliwatts (mW) or microwatts ( $\mu\text{W}$ ) but it is perhaps more common to see units of *dBm*, decibels with respect to one milliwatt. For example, it is much easier to express the power of an S1 signal as  $-121$  dBm than  $0.0000000076$   $\mu\text{W}$ . The formula is  $\text{dBm} = 10 \log(1000 P)$ , where  $P$  is the power in watts. One milliwatt ( $P = 0.001$ ) is  $0$  dBm,

$10$  mW is  $+10$  dBm,  $0.01$  mW is  $-20$  dBm and so on. **Table 25.2** lists common dBm and power equivalent.

Measuring RF power can be a little confusing because there are several ways to do it. We have already covered the difference between peak and RMS voltage and current. RF power is always based on RMS values. For example, if the RF voltage into a  $50\text{-}\Omega$  dummy load is  $70.7$  V RMS ( $100$  V at the peak of the RF sine waves), then the power is  $P = E^2 / R = 70.7^2 / 50 = 100$  W. (See [www.eznc.com/Amateur/RMS\\_Power.pdf](http://www.eznc.com/Amateur/RMS_Power.pdf) for a more extensive explanation of power and RMS.)

*Peak envelope power* (PEP) has nothing to do with the difference between the peak and average voltage of a sine wave. It is a measure of the power of an RF signal at the modulation peak, averaged over one RF cycle. For a CW signal, the PEP is simply the power when the key is closed, as read on any wattmeter. However, for an SSB signal, the power is constantly changing as you speak. An average-reading wattmeter will read a value much lower than the PEP.

Measuring the peak envelope power is more difficult than measuring the average power. An oscilloscope can be a highly-accurate method within its bandwidth limitations if the load impedance is known accurately. Don't forget that the oscilloscope shows peak-to-peak rather than RMS voltage, so you must divide the maximum reading by  $2 \times \sqrt{2}$  or  $2.828$ . Some wattmeters do have PEP-reading capability. Their circuitry must have very fast response to the detected RF signal to give an accurate reading of the peaks.

A *directional wattmeter* is a device that measures power flowing in each direction on a transmission line. The manner in which RF signals propagate on transmission lines is covered in the **Transmission Lines** chapter. Many amateurs keep a wattmeter permanently connected at their station to monitor the condition of their transmitter and antennas. See the **Station Accessories** chapter for a further discussion of directional wattmeters.

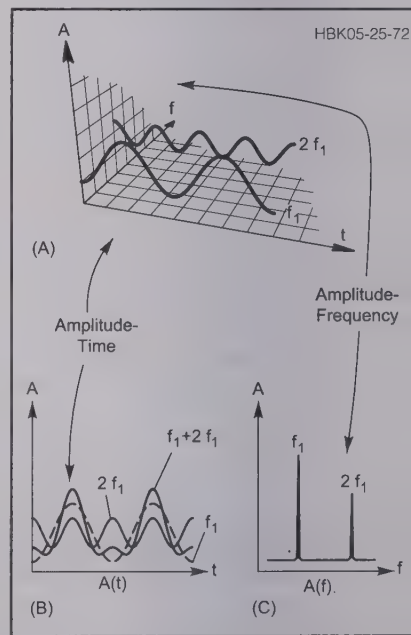

A *bolometer* is a device for measuring transmitter power by measuring the heat dissipated in a resistive load. A thermistor or other device measures the temperature. The device is calibrated with a dc voltage, since dc voltage and current can be measured very precisely. With careful construction and calibration, very high accuracy can be obtained. However, the response time of the measurement is very slow, so a bolometer is normally used to calibrate another wattmeter rather than being used directly for measurements. Bolometers are made commercially, however it is possible to homebrew one using a plastic picnic cooler.<sup>12</sup>

Commercial laboratory power meters are generally intended for measuring power levels in the milliwatt or microwatt range.

There are two basic types, based on either diode or thermocouple detectors. Below a certain power level, the dc output from a diode detector is directly proportional to power, that is, the square of the RF voltage. With a suitable dc amplifier, the detector output can drive a meter with a linear scale to read power directly.

Thermocouple-type power meters feed the RF signal into a resistor that heats up in proportion to the power level. The temperature is measured with a *thermocouple*, which consists of a pair of junctions of dissimilar metals. A voltage is generated based on the temperature difference of the two junctions, which is proportional to the RF power. The thermocouple method gives high accuracy and wide bandwidth, but the measurement time can be up to several seconds at low power levels, rather than being nearly instantaneous as with a diode detector. Older-model surplus diode and thermocouple-type meters can often be found for reasonable prices, but the proper sensors for the desired frequency range and power level often cost more than the power meter itself.

Analog Devices makes a series of integrated circuits that can detect RF signals and output a dc voltage proportional to the logarithm of the power level. That makes it easy to construct an RF power meter that reads directly in dBm. For example, the AD8307 covers dc to  $500$  MHz with  $1$ -dB accuracy over an  $88$ -dB (nearly  $1$  billion-to-one) power range.

### 25.4.3 Spectrum Analyzers

A spectrum analyzer is similar to an oscilloscope. Both present a graphical view of an electrical signal. The oscilloscope is used to observe electrical signals in the *time domain* (amplitude versus time). The time domain, however, gives little information about the frequencies that make up complex signals, which are best characterized in terms of their frequency response. This information is obtained by viewing electrical signals in the *frequency domain* (amplitude versus frequency). One instrument that can display the frequency domain is the spectrum analyzer.

#### TIME AND FREQUENCY DOMAIN

To better understand the concepts of time and frequency domain, see **Figure 25.27**. The three-dimensional coordinates in **Figure 25.27A** show time as the line sloping toward the bottom right, frequency as the line rising toward the top right and amplitude as the vertical axis. The two discrete frequencies shown are harmonically related, so we'll refer to them as  $f_1$  and  $2f_1$ .

In the representation of time domain in **Figure 25.27B**, all frequency components of a signal are summed together. In fact, if the two discrete frequencies shown were applied to the input of an oscilloscope, we would see the solid line (which corresponds to the sum of  $f_1$  and  $2f_1$ ) on the display.

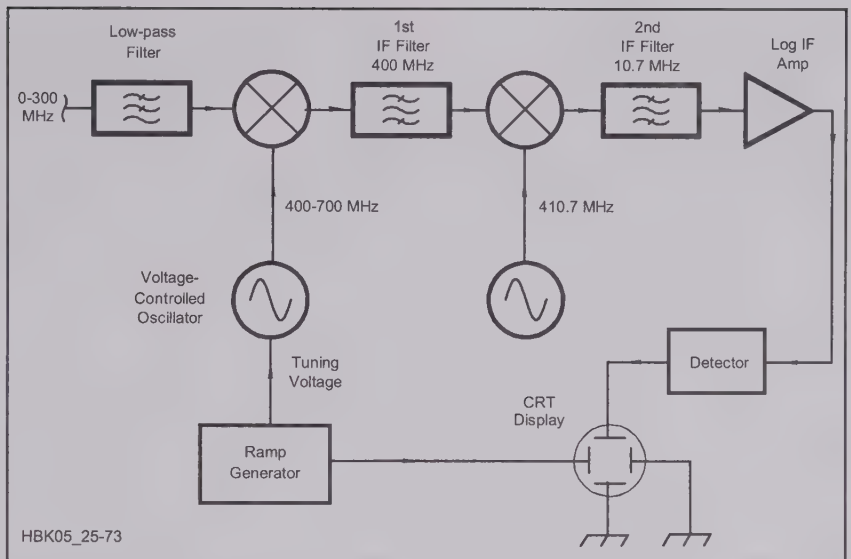

In the frequency domain, complex signals (signals composed of more than one frequency) are separated into their individual frequency components. A spectrum analyzer measures and displays the power level at each discrete frequency; this display is shown at C.

The frequency domain contains information not apparent in the time domain and therefore the spectrum analyzer offers advantages over the oscilloscope for certain measurements, such as harmonic content or distortion as mentioned previously. For measurements that are best made in the time domain, the oscilloscope is the tool of choice.

#### SPECTRUM ANALYZER BASICS

There are several different types of spectrum analyzer, but the most common is nothing more than an electronically tuned superheterodyne receiver. The receiver is tuned by means of a ramp voltage. This ramp voltage performs two functions: First, it sweeps the frequency of the analyzer local oscillator; second, it deflects a beam across the horizontal axis of a CRT display, as shown in **Figure 25.28**. The vertical axis deflection of the CRT beam is determined by the strength of the received signal. In this way, the CRT displays frequency on the horizontal axis and signal strength on the vertical axis.

Most spectrum analyzers use an up-converting technique in which a wide-band input

**Figure 25.28** — A block diagram of a typical superheterodyne spectrum analyzer. Input frequencies of up to 300 MHz are up-converted by the local oscillator and mixer to a fixed frequency of 400 MHz.

is converted to an IF higher than the highest input frequency. Up-conversion is used so that a fixed-tuned input filter can remove any image signals and only the first local oscillator needs to be tuned to the receiver. As with most up-converting communications receivers, it is not easy to achieve the desired ultimate selectivity at the first IF, because of the high frequency. For this reason, multiple conversions are used to generate an IF low enough so that the desired selectivity is practical. In the example shown, dual conversion is used: The first IF is at 400 MHz; the second at 10.7 MHz.

In the example spectrum analyzer, the first local oscillator is swept from 400 MHz to 700 MHz; this converts the input (from nearly 0 MHz to 300 MHz) to the first IF of 400 MHz. The usual rule of thumb for varactor-tuned oscillators is that the maximum practical tuning ratio (the ratio of the highest frequency to the lowest frequency) is an octave, a 2:1 ratio. In our example spectrum analyzer, the tuning ratio of the first local oscillator is 1.75:1, which meets this specification.

The range of image frequency extends from 800 MHz to 1100 MHz and is easily eliminated using a low-pass filter with a cut-off frequency around 300 MHz. The 400-MHz first IF is converted to 10.7 MHz where the ultimate selectivity of the analyzer is obtained. The image of the second conversion, (421.4 MHz), is eliminated by the first IF filter. The attenuation of the image should be large, on the order of 60 to 80 dB. This requires a first IF filter with a high Q, which is achieved by using helical resonators, SAW

resonators or cavity filters. Another method of eliminating the image problem is to use triple conversion; converting first to an intermediate IF such as 50 MHz and then to 10.7 MHz. As with any receiver, an additional frequency conversion requires added circuitry and adds potential spurious responses.

Most of the signal amplification takes place at the lowest IF, 10.7 MHz in this example. Here the communications receiver and the spectrum analyzer differ. A communications receiver demodulates the incoming signal so that the modulation can be heard or further demodulated for RTTY or packet or other mode of operation. In the spectrum analyzer, only the signal strength is needed.

In order for the spectrum analyzer to be most useful, it should display signals of widely different levels. As an example, consider two signals that differ by 60 dB, which is a thousand to one difference in voltage or a million to one in power. That means that if power were displayed, one signal would be one million times larger than the other. In the case of voltage one signal would be a thousand times larger. In either case it would be difficult to display both signals on a CRT. The solution to this problem is to use a logarithmic display that shows the relative signal levels in decibels. Using this technique, a 1000:1 ratio of voltage reduces to a 60-dB difference.

The conversion of the signal to a logarithm is usually performed in the IF amplifier or detector, resulting in an output voltage proportional to the logarithm of the input RF level. This output voltage is then used to drive the CRT display.

## SPECTRUM ANALYZER PERFORMANCE

The performance parameters of a spectrum analyzer are specified in terms similar to those used for radio receivers, in spite of the fact that there are many differences between a receiver and a spectrum analyzer.

The sensitivity of a receiver is often specified as the *minimum discernible signal* (MDS), which means the smallest signal that can be heard. In the case of the spectrum analyzer, it is not the smallest signal that can be heard, but the smallest signal that can be seen. The *dynamic range* of the spectrum analyzer determines the largest and smallest signals that can be simultaneously viewed on the analyzer. As with a receiver, one factor that affects dynamic range is *second- and third-order intermodulation distortion* (IMD). IMD dynamic range is the maximum difference in signal level between the minimum detectable signal and the level of two signals of equal strength that generate an IMD product equal to the minimum detectable signal. (See the **Receivers** chapter for more information on IMD.)

Although the communications receiver is an excellent example to introduce the spectrum analyzer, there are several differences such as the previously explained lack of a demodulator. Unlike the communications receiver, the spectrum analyzer is not a sensitive radio receiver. To preserve a wide dynamic range, the spectrum analyzer often uses passive mixers for the first and second mixers. Therefore, referring to Figure 25.28, the noise figure of the analyzer is no better than the losses of the input low-pass filter plus the first mixer, the first IF filter, the second mixer and the loss of the second IF filter. This often results in a combined noise figure of more than 20 dB. With that kind of noise figure the spectrum analyzer is obviously not a communications receiver for extracting very weak signals from the noise but a measuring instrument for the analysis of frequency spectrum. For some applications, it may be useful to add an external wide-band, low-noise preamplifier to improve the noise figure.

The selectivity of the analyzer is called the *resolution bandwidth* (RBW). This term refers to the minimum frequency separation of two signals of equal level so that the signals are separated by a drop in amplitude of 3 dB between them. The IF filters used in a spectrum analyzer differ from a communications receiver in that they have very gentle skirts and rounded passbands, rather than the flat passband and very steep skirts of an IF filter in a high-quality communications receiver. The rounded passband is necessary because the signals pass through the filter passband as the spectrum analyzer sweeps the desired frequency range. If the signals suddenly pop into

the passband (as they do if the filter has steep skirts), the filter tends to ring. A filter with gentle skirts has less ringing. Another effect, which occurs even with rounded-passband filters, is that the signal amplitudes are reduced at fast sweep rates, which distorts the display and requires that the analyzer not sweep frequency too quickly. When adjusting the resolution bandwidth or the width of the *frequency span* (the range of frequencies being measured), the scan rate may need to be reduced so that the signal amplitude is not affected by fast sweeping.

The signal produced by the detector is known as the *video* signal. Most spectrum analyzers include a low-pass video filter to reduce the displayed noise level. The *video bandwidth* (VBW) is the bandwidth of this filter. Like the RBW, the VBW must also be taken into consideration when setting the sweep speed.

### USING A SPECTRUM ANALYZER

Spectrum analyzers are used in situations where the signals to be analyzed are complex, for very low-level signals, or when the frequency of the signals to be analyzed is very high. Although high-performance oscilloscopes are capable of operation into the UHF region, moderately priced spectrum analyzers can be used well into the gigahertz region.

Unlike the oscilloscope which is a wide-bandwidth instrument, the spectrum analyzer measures the waveform using a narrow bandwidth; thus it is capable of reducing the noise power displayed.

Probably the most common Amateur Radio application of a spectrum analyzer is the measurement of the harmonic content and other spurious signals in the output of a radio transmitter. **Figure 25.29** shows two ways to connect the transmitter and spectrum analyzer. The method shown at A should not be used for wide-band measurements since most line-sampling devices do not exhibit a

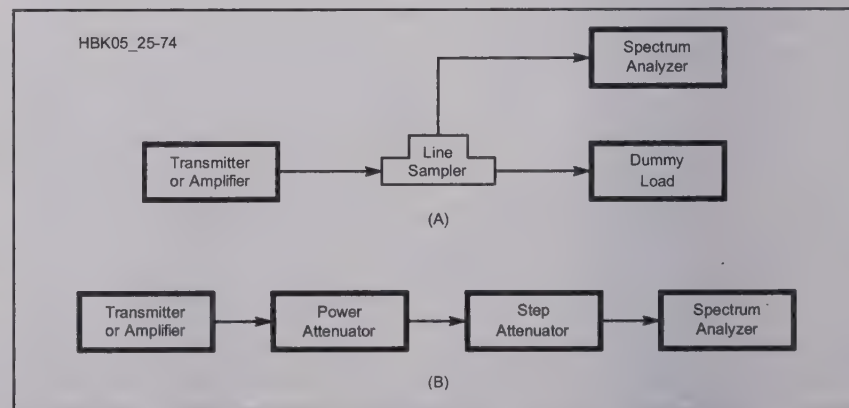

constant-amplitude output over a broad frequency range. Using a line sampler is fine for narrow-band measurements, however.

The method shown at B is used in the ARRL Lab. The attenuator must be capable of dissipating the transmitter power. It must also have sufficient attenuation to protect the spectrum analyzer input. Many spectrum analyzer input mixers can be damaged by only a few milliwatts, so most analyzers have an adjustable input attenuator to provide a reasonable amount of attenuation for protection. The power limitation of the attenuator itself is usually on the order of a watt or so, however. This means that the power attenuator must have 20 dB of attenuation for a 100 W transmitter, 30 dB for a 1000 W transmitter and so on, to limit the input to the spectrum analyzer to 1 W. There are specialized attenuators that are made for transmitter testing; these attenuators provide the necessary power dissipation and attenuation in the 20 to 30-dB range.

When using a spectrum analyzer it is very important that the proper amount of attenuation be applied before a measurement is made. In addition, it is a good practice to start with maximum attenuation and view the entire spectrum of a signal before the attenuator is adjusted. The signal being viewed could appear to be at a safe level, but another spectral component, which is not visible, could be above the damage limit. It is also very important to limit the input power to the analyzer when pulse power is being measured. The average power may be small enough so the input attenuator is not damaged, but the peak pulse power, which may not be readily visible on the analyzer display, can destroy a mixer, literally in microseconds.

### Spurious Responses in Spectrum Analyzers

When using a spectrum analyzer it is neces-

**Figure 25.29** — Alternate bench setups for viewing the output of a high power transmitter or oscillator on a spectrum analyzer. A uses a line sampler to pick off a small amount of the transmitter or amplifier power. In B, most of the transmitter power is dissipated in the power attenuator.

**Figure 25.30** — A notch filter is another way to reduce the level of a transmitter's fundamental signal so that the fundamental does not generate harmonics within the analyzer. However, in order to know the amplitude relationship between the fundamental and the transmitter's actual harmonics and spurs, the attenuation of the fundamental in the notch filter must be known.

**Figure 25.31** — A schematic representation of a voltage probe designed for use with a spectrum analyzer. Keep the probe tip (resistor and capacitor) and ground leads as short as possible.

sary to ensure that the analyzer does not generate additional spurious signals that are then attributed to the system under test. Some of the spurious signals that can be generated by a spectrum analyzer are harmonics and IMD. It is good practice to check for the generation of spurious signals within the spectrum analyzer. When an input signal causes the spectrum analyzer to generate a spurious signal, adding attenuation at the analyzer input will cause the internally generated spurious signals to decrease by an amount greater than the added attenuation. If attenuation added ahead of the analyzer causes all of the visible signals to decrease by the same amount, this indicates a spurious-free display.

If it is desired to measure the harmonic levels of a transmitter at a level below the spurious level of the analyzer itself, a notch filter can be inserted between the attenuator and the spectrum analyzer as shown in

**Figure 25.30.** This reduces the level of the fundamental signal and prevents that signal from generating harmonics within the analyzer, while still allowing the harmonics from the transmitter to pass through to the analyzer without attenuation. Use caution with this technique; detuning the notch filter or inadvertently changing the transmitter frequency will allow potentially high levels of power to enter the analyzer. In addition, use care when choosing filters; some filters (such as cavity filters) respond not only to the fundamental but notch out odd harmonics as well.

The input impedance for most RF spectrum analyzers is 50 Ω, however not all circuits have convenient 50-Ω connections that can be accessed for testing purposes. Using a probe such as the one shown in **Figure 25.31** allows the analyzer to be used as a troubleshooting tool. The probe can be used to track down signals within a transmitter or receiver, much

**Figure 25.32** — A “sniffer” probe consisting of an inductive pick-up. It has the advantage of not directly contacting the circuit under test.

like an oscilloscope is used. The probe shown offers a 100:1 voltage reduction and loads the circuit with about 5000 Ω. A different type of probe is shown in **Figure 25.32.** This inductive pickup coil (sometimes called a “sniffer”) is very handy for troubleshooting. The coil is used to couple signals from the radiated magnetic field of a circuit into the analyzer. A short length of miniature coax is wound into a pickup loop and soldered to a larger piece of coax that connects to the spectrum analyzer. The dimensions of the loop are not critical, but smaller loop dimensions enable the loop to more precisely locate the source of radiated RF. Coax is used for the loop to provide shielding from the electric field component (capacitive coupling). Connecting the coax shield on only one end provides a complete electrostatic shield without introducing a shorted turn.

The sniffer allows the spectrum analyzer to sense RF energy without contacting the circuit being analyzed. If the loop is brought near an oscillator coil, the oscillator can be tuned without directly contacting (and thus disturbing) the circuit. The oscillator can then be checked for reliable startup and the generation of spurious sidebands. With the coil brought near the tuned circuits of amplifiers or frequency multipliers, those stages can be tuned using a similar technique.

Even though the sniffer does not contact the circuit being evaluated, it does extract some energy from the circuit. For this reason, the loop should be placed as far from the tuned circuit as is practical. If the loop is placed too far from the circuit, the signal will be too weak or the pickup loop will pick up energy from other parts of the circuit and not give an accurate indication of the circuit under test.

The sniffer is very handy to locate sources of RF leakage. By probing the shields and cabinets of RF generating equipment (such as transmitters) egress and ingress points of RF energy can be identified by increased indications on the analyzer display.

### Measuring Very Low-Level Signals

One very powerful characteristic of the spectrum analyzer is the instrument's capa-

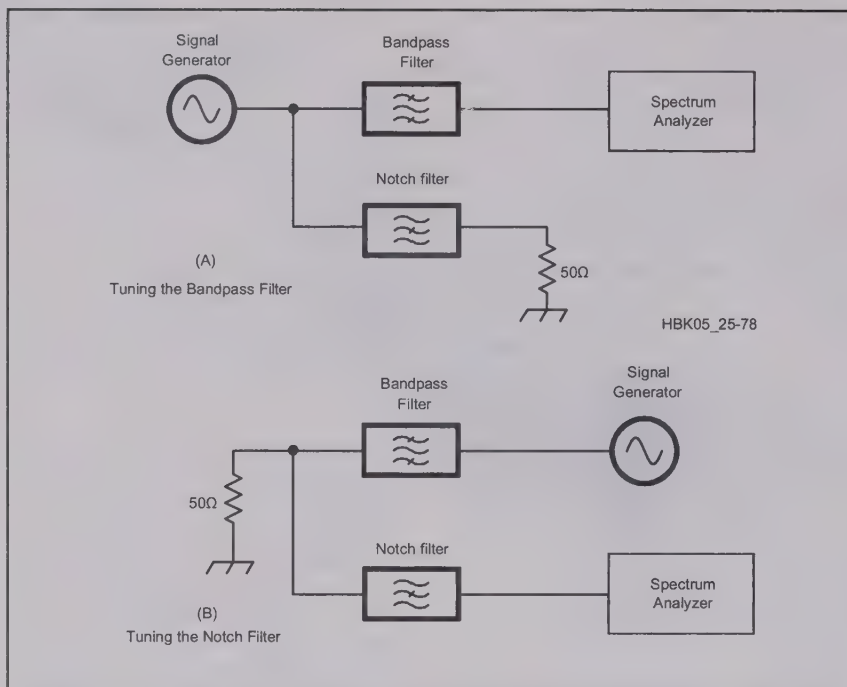

Figure 25.33 — Block diagram of a spectrum analyzer and signal generator being used to tune the band-pass and notch filters of a duplexer. All ports of the duplexer must be properly terminated and good quality coax with intact shielding used to reduce leakage.

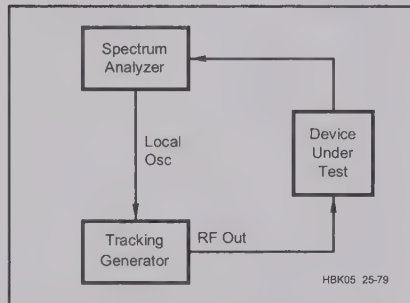

Figure 25.34 — A signal generator (shown in the figure as the “Tracking Generator”) locked to the local oscillator of a spectrum analyzer can be used to determine filter response over a range of frequencies.

bility to measure very low-level signals. This characteristic is very advantageous when very high levels of attenuation are measured. Figure 25.33 shows the setup for tuning the notch and passband of a VHF duplexer. The spectrum analyzer, being capable of viewing signals well into the low microvolt region, is capable of measuring the insertion loss of the notch cavity more than 100 dB below the signal generator output. Making a measurement of this sort requires care in the interconnection of the equipment and a well-designed spectrum analyzer and signal generator. RF

energy leaking from the signal generator cabinet, line cord or even the coax itself, can get into the spectrum analyzer through similar paths and corrupt the measurement. This leakage can make the measurement look either better or worse than the actual attenuation, depending on the phase relationship of the leaked signal.

### EXTENSIONS OF SPECTRAL ANALYSIS

Many measurements involve a signal generator tuned to the same frequency as the spectrum analyzer. It would be a real convenience not to have to continually reset the signal generator to the desired frequency. It is, however, more than a convenience. A signal generator connected in this way is called a *tracking generator* because the output frequency tracks the spectrum analyzer input frequency. The tracking generator makes it possible to make swept frequency measurements of the attenuation characteristics of circuits, even when the attenuation involved is large.

Figure 25.34 shows the connection of a tracking generator to a circuit under test. In order for the tracking generator to create an output frequency exactly equal to the input frequency of the spectrum analyzer, the internal local oscillator frequencies of the spectrum analyzer must be known. This is the reason for the interconnections between the

tracking generator and the spectrum analyzer. The test setup shown will measure the gain or loss of the circuit under test.

Only the magnitude of the gain or loss is available; in some cases, the phase angle between the input and output would also be an important and necessary parameter. That is the function of a *vector network analyzer*, covered in a following section.

### CHOOSING A SPECTRUM ANALYZER

The frequency range is perhaps the most important specification when choosing a spectrum analyzer. Of course it must cover the amateur bands you wish to test, but it must also cover harmonics of those frequencies if you wish to test transmitter harmonics. Many higher-frequency spectrum analyzers only cover down to 10 kHz, so they are not useful for audio spectrum analysis (spectrum analyzers for audio use are also available). Some instruments use a harmonic sampler on the higher microwave bands. You may need to use an external filter to remove any unwanted signals at harmonics or sub-harmonics of the signal you wish to examine.

Frequency stability is vital for narrow-band measurements such as looking at modulation spectra. Some older instruments include a frequency lock scheme that stabilizes the display after the analyzer is tuned to the desired signal.

The range of resolution bandwidths (RBW) available determines what kinds of measurements are possible. To measure two-tone intermodulation distortion of an SSB signal, the minimum RBW must be narrow enough to resolve the two tones, that is, no more than about 100 Hz. If you wish to view the demodulated time-domain video from a fast-scan television signal, the RBW must be wide enough to include the entire signal, perhaps 5 or 6 MHz.

Input sensitivity is normally not very important. An external preamplifier can always be added if needed for a particular measurement. However, dynamic range is a key specification, as previously discussed. Also, the screen display range is important. For example, if there are 8 divisions on the display and the maximum dB-per-division setting is 10 dB/div, then the maximum display range is 80 dB. Many spectrum analyzers can display signals in linear as well as logarithmic (dB) mode, which can be useful to look at modulation.

For accurate power measurements, the amplitude accuracy is important. For doing relative measurements, which are important for measuring spurious signals relative to the carrier, logarithmic linearity is the key specification.

There are several features that expand the spectrum analyzer's utility. *Markers* are pips

that can be moved with a knob back and forth across the signals on the display. By placing a marker at the top of a signal you can read the frequency and amplitude directly. *Peak search* is a feature that automatically places a marker at the peak of the strongest signal. *Marker delta* measures the difference in frequency and amplitude of two markers.

*Zero span* means setting the sweep width to zero hertz to view the change in signal versus time. This is useful for looking at modulation. Many spectrum analyzers include a sweep triggering feature for this purpose, similar to the triggering circuit in an oscilloscope. Some include a speaker so you can hear what the modulating signal sounds like.

Modern spectrum analyzers have many of the features found in digital oscilloscopes, such as trace storage and retrieval. Most include computer connectivity, both to store measured data and to control the instrument with the proper software.

In addition to traditional swept-frequency spectrum analyzers, some modern units use the *Fast Fourier Transform* (FFT) either in place of, or in addition to, the swept-frequency architecture. The FFT allows for much faster screen updates when using narrow spans. Some RF and microwave instruments have a *digital IF* based on the FFT. For narrow spans, the local oscillator is held at a constant frequency and the “sweep” is performed mathematically by the FFT.

There are many used spectrum analyzers on the surplus market, at all different vintages and price points. As usual, try before you buy if at all possible and obtain the operator’s and service manuals, if available. Another alternative is a spectrum analyzer built on a card that plugs into a personal computer or that consists of an external digitizing pod connected to the PC via a serial data link. As with PC-based oscilloscopes, they can represent excellent value because they save the cost of the display, cabinet, power supply, and microprocessor provided by the computer.

The least-expensive alternative is an audio spectrum analyzer based on a PC’s sound card. Free spectrum analysis software is available on the Internet. The main limitation is the frequency coverage, which is typically about 40-45% of the sample rate of the sound card. The sound card that comes standard in a PC typically has a 48 kHz sample rate, so that the frequency response is limited to about 20 kHz. That is plenty for checking out the audio circuits in a communications receiver or transmitter.

## 25.4.4 Measuring RF Impedance

Most RF impedance-measuring devices are based on the Wheatstone bridge, as previously described in the section on LCR

Figure 25.35 — A return-loss bridge for RF. See text for details.

bridges. The difference is that an impedance bridge does not require that the device under test be a pure inductance, capacitance or resistance but may be a complex impedance that includes both resistance and reactance. That means that two adjustments are required to balance the bridge, rather than just one as with an LCR bridge. Both the resistance and reactance must match.

In addition, since an impedance bridge is typically designed to operate at higher frequencies, circuit layout and the connection to the device under test are more important. Usually a coaxial connector is used to connect to the device and the impedance measurements are referenced to 50  $\Omega$ .

A *return-loss bridge* (RLB) is an RF bridge with fixed, usually 50- $\Omega$ , resistors in each leg except the one connected to the device under test. *Return loss* is the ratio of the reflected signal to the signal incident on a component, usually expressed in dB, which is always a positive number for a passive device.<sup>13</sup> (See the **RF Techniques** chapter for a discussion of return loss.)

The schematic of a simple return-loss bridge is shown in **Figure 25.35**. The circuit can also be used as a *hybrid combiner* (see the RF and Microwave Test Accessories section of this chapter), where the port labeled UNKNOWN is the common port and the other two are isolated from each other. For good results at high frequencies, it should be built in a small box with short leads to the coax connectors.

Apply the output of a signal generator or other signal source to the RF IN port of the RLB. The power level should be appropriate for driving the device connected to the UNKNOWN port, after accounting for the 6-dB

loss of the bridge. Connect the bridge POWER METER port to a power meter or other power-measuring device through a step attenuator and leave the UNKNOWN port of the bridge open circuited. Set the step attenuator for a relatively high level of attenuation and note the power meter indication.

Now connect the unknown impedance to the bridge. The power meter reading will decrease. Adjust the step attenuator to produce the same reading obtained when the UNKNOWN port was open circuited. The difference between the two settings of the attenuator is the return loss, measured in dB.

## 25.4.5 Network Analyzers

An electronic *port* is a pair of terminals with equal and opposite current flows. An antenna analyzer can measure the impedance of a single-port network such as an antenna, the input port of an antenna tuner, or a two-terminal component like a resistor or capacitor. An example of a two-port network is an amplifier. The input is one port, the output the other. A low-pass filter is another example. An example of a three-port network is a diplexer, used to connect one transceiver to two antennas. The theory behind two-port networks is covered in the **RF Techniques** chapter.

A *scalar network analyzer* (SNA) is an instrument that can measure, as a function of frequency, the magnitude of the gain or loss between the two ports of a two-port device as well as the magnitude of the return loss (equivalent to the SWR) of each port. The term “scalar” means that only magnitudes of those quantities are measured and not phase angles. In **Figure 25.36**, the signal labeled “REF” is proportional to the sweep oscillator output and the one labeled “A” is proportional to the signal that is reflected back from the device under test due to an imperfect 50- $\Omega$  match. The ratio of A to REF can be used to calculate the return loss and SWR of the device. Signal “B” is proportional to the signal that travels between the two ports of the device. The ratio of B to REF gives the device gain. To find the gain in the opposite direction and the return loss of the other port, simply turn the device around and swap the two ports. Some network analyzers come with a *test set* that includes RF switches to do that automatically.<sup>14</sup>

The box labeled “Signal processing and display” includes circuitry to take the logarithm of the signals so they can be displayed in dB. In modern instruments it normally includes a microprocessor, which does much of the signal processing as well as controlling the sweep oscillator and other circuitry.

A *vector network analyzer* (VNA) is an instrument that can measure both the magnitude and phase of the gain and return loss

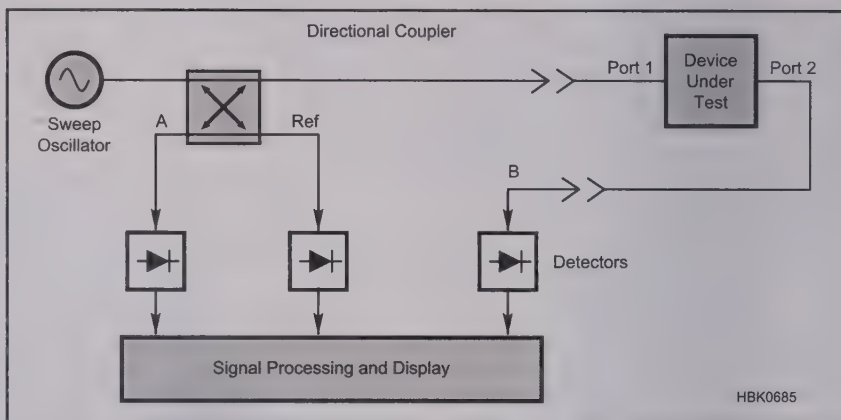

of a two-port network. The block diagram is identical to Figure 25.36 except that the detectors can measure not only the magnitude, but also the phase of each signal with respect to the reference, REF. The measured data are usually presented in terms of *scattering parameters*, or *S parameters*.  $S_{11}$  is the ratio of the incident to the reflected signal at port 1,  $S_{22}$  is the equivalent on port 2,  $S_{21}$  is the gain from port 1 to 2, and  $S_{12}$  is the gain from port 2 to 1. Each S parameter is a complex number, representing both magnitude and phase. Further discussions of S parameters can be found in the **Computer-Aided Circuit Design** and the **RF Techniques** chapters. Usually the VNA provides the capability to plot the S parameters on a Smith chart overlaid on the display for easy evaluation. The Smith chart is discussed in the **Transmission Lines** chapter.

The accuracy of a VNA depends on the performance of the directional couplers, detectors, and other circuitry. The coupler directivity is a key contributor to measurement errors. For example, if the directivity is 20 dB, then even a perfect 50- $\Omega$  load will show 20 dB of return loss, equivalent to a 1.22:1 SWR. Fortunately it is possible to eliminate most errors by measuring several terminations of known impedance and calculating a series of correction factors. The mathematics involved is quite complex, but it is all handled by the instrument software and is invisible to the user. The most popular technique is called a Short-Open-Load-Through (SOLT) calibration because it uses four calibration standards, a short-circuit, an open-circuit, a 50- $\Omega$  load and a through connection between the two ports. One of the sources of error removed by the calibration is any error due to the length of the coaxial cables that connect to the device under test. For that reason, the calibration standards should always be connected at the end of the cables that are to be used for the test. A thorough discussion of VNA error-correction techniques can be found in an Agilent Technologies application note.<sup>15</sup>

## CHOOSING A NETWORK ANALYZER

A spectrum analyzer with tracking generator can be the basis of a high-performance scalar network analyzer. Referring to Figure 25.36, the only pieces that need to be added are the directional coupler and a pair of 50- $\Omega$  loads. The tracking generator takes the place of the sweep oscillator. Connect the spectrum analyzer input to A, B or REF and terminate the other two with 50- $\Omega$  loads. Unlike a conventional scalar network analyzer, a spectrum analyzer has a tuned receiver so it does not respond to spurious frequencies generated by the sweep oscillator or the device under test.

At the other end of the performance “spectrum” a simple SNA for measuring gain or attenuation can be made with any sweep os-

**Figure 25.36** — Block diagram of a scalar network analyzer (SNA). A vector network analyzer has the same block diagram except that the detectors can measure phase as well as amplitude.

cillator, perhaps a function generator with sweep capability, plus a detector of some kind and an oscilloscope to display the detected voltage. If the oscilloscope bandwidth is great enough to cover the desired frequency range, no detector is needed and the RF signal can be displayed directly. Dynamic range is limited with this technique since the displayed signal is linear and not logarithmic. However it is sufficient for many purposes, such as measuring the passband ripple of a filter or the gain versus frequency of an amplifier.

Used scalar network analyzers are readily available on the surplus market. The sweep oscillator is normally a separate unit. Vector network analyzers also may be purchased surplus. Some require an external sweep oscillator while others include an internal signal source. The tests sets may be internal or external as well.

In recent years, several amateur VNA designs have appeared. These tend to be much smaller, lighter and lower-cost than commercial units. One by DG8SAQ down-converts the signals to be detected to frequencies in the audio range so they can be fed to the sound card on a personal computer.<sup>16</sup> It uses a pair of Analog Devices DDS chips for the sweep oscillator and the down-converter’s local oscillator. All signal processing and control is done in the microprocessor in the PC. Paul Kiciak, N2PK, also developed a VNA using DDS chips for the source and a direct-conversion architecture which performs the detection function at dc. Like the DG8SAQ design, it relies on a PC for the processing, control, and display. His design has become available in kit form from several suppliers, and numerous third-parties have written software to support it. A number of VNA kits and products are available, most using a PC as a basis.<sup>16,17,18</sup>

Many VNAs have a low-frequency limit in

the range of 100 kHz to 1 MHz. This limit is imposed by the variable frequency oscillator of the analyzer. The range of the VNA can be extended lower to the audio frequency range by using an external adapter that shifts the output RF signal from the VNA, applies it to the circuit under test, and then re-shifts the circuit’s output signal into the VNA’s RF range. A low frequency adapter project is described later in the projects section at the end of this chapter.

## 25.4.6 RF Signal Generators

An *RF signal generator* is a test oscillator that generates a sine-wave signal that has an accurately-calibrated frequency and amplitude over a wide radio-frequency range. Usually AM and FM modulation capability is provided and sometimes other modulation types as well.

Some instruments also have built-in sweep capability. If not, narrow-band sweep can be obtained by feeding a sawtooth waveform into the FM input. Another feature that is very useful for transceiver testing is *reverse power protection*. It protects the sensitive output circuits in the event that the transceiver accidentally goes into transmit mode while connected to the signal generator.

Before the days of modern digital electronics, all signal generators used free-running oscillators. There is a wide variation in frequency stability and accuracy between the best and the worst. Nearly any modern synthesized signal generator has good enough accuracy for most amateur purposes. However that accuracy sometimes comes at the price of phase noise, a type of wideband noise caused by short-term fluctuations in phase that usually drops off gradually from the carrier frequency. The old tube-type Hewlett-Packard 608-series signal generators have better per-

formance in this respect than some modern synthesized instruments. See **Figure 25.37**. Phase noise is discussed in the **Oscillators and Synthesizers** chapter.

Some signal generators, even professional laboratory-grade types, may not have enough output attenuation to accurately measure the minimum discernible signal (MDS) on a sensitive communications receiver. A 10-dB noise figure in a 500 Hz bandwidth implies an MDS of  $-137$  dBm, which is well below the minimum amplitude level on many signal generators. The problem is easily resolved by adding an external fixed 20-dB attenuator. Just remember to subtract 20 dB from all amplitude readings.

Many signal generators include some way to connect them to a computer so they can be controlled for automated testing. That is useful for testing a receiver at many frequencies across a band to be able to plot sensitivity or dynamic range as a function of frequency, for example. Older instruments usually have a GPIB interface while modern ones are more likely to have RS-232, USB or Ethernet.

Probably the most common use for signal generators is for receiver testing. That is covered in detail in a later section. They are also useful for general-purpose test signals. For example, when developing a new receiver design, you could test the RF, IF and audio stages before the VFO is completed by using a signal generator as the local oscillator.

Critical specifications include the frequency range, frequency accuracy and stability, amplitude range, amplitude accuracy, and the spectral purity, including phase noise, harmonics and non-harmonic spurious emissions. Modulation accuracy and the capabilities of the internal modulation generator, if present, may be important as well, depending on the application.

Many inexpensive signal generators made for the hobbyist and consumer electronics service industry are not suitable for measuring receiver sensitivity because when the output attenuator is at maximum, there is more signal leaking out the cabinet and radiating from the power cord than is coming out the coax connector. Such instruments also tend to have poor frequency stability and the tuning dial tunes so fast that they are difficult to set to a precise frequency. They are useful for simple troubleshooting but are not capable of making accurate measurements.

Better-quality signal generators intended for servicing land-mobile and other communications equipment sometimes become available on the surplus market. They don't have the precision specifications of lab instruments but are generally rugged, reliable and easy to use.

Laboratory-grade signal generators are generally too expensive for the home hobbyist if purchased new but older models such

**Figure 25.37** — A classic Hewlett-Packard 608F tube-type signal generator. While not as stable as modern synthesized signal generators, in other respects the performance is quite up to date.

as the HP8640B or its military version (AN/USM323) are widely available and have excellent specifications. Of course they may be less reliable than new instruments but in many cases the older technology is repairable without special equipment. Service manuals are sometimes available from the manufacturer on their website.

### 25.4.7 Using Noise Sources

Most of the time, noise is something to be avoided in electronic circuits. It can be quite useful for testing, however, precisely because the calibrated noise that you create on purpose has the same properties as the unwanted circuit noise that you are trying to minimize. Thus, calibrated sources of noise are used as test instruments for various measurements. (See the **RF Techniques** chapter for a discussion of noise and its associated terminology.)

#### MEASURING RECEIVER NOISE FIGURE

A noise source can be used to measure the noise figure of an SSB or CW receiver. The *excess noise ratio (ENR)* is the ratio of the noise added by the noise source to the thermal noise level, normally expressed in dB. An explanation of noise figure is given in the **RF Techniques** chapter. The basic

idea is to connect the noise source to the receiver antenna input and then measure the difference in the noise level at the receiver speaker terminals when the noise source is turned on or off. When it is off, the measured noise contains only thermal noise and the noise contributed by the receiver. When it is on, the noise includes the excess noise from the noise source. The noise figure can then be calculated from the ratio of those two values,

$$NF_M = ENR - 10 \log \left( \frac{E_{ON}^2}{E_{OFF}^2} - 1 \right)$$

where  $NF_M$  is the measured noise figure in dB, ENR is the excess noise ratio in dB,  $E_{ON}$  is the RMS output noise voltage with the noise source on, and  $E_{OFF}$  is the RMS output noise voltage with the noise source off.

Rather than using the equation, another technique is to include a step attenuator with 1-dB steps at the noise source output. See **Figure 25.38**. Adjust the attenuator so that the noise increases by 3 dB (1.414 times the voltage) when the noise source is turned on. The noise figure is then simply the ENR of the noise source minus the attenuation.

The nice thing about measuring noise with noise is that the accuracy of the voltage reading is not important so long as the ratio of the two readings is accurate. A non-RMS ac voltmeter is not accurate when measuring noise, but so

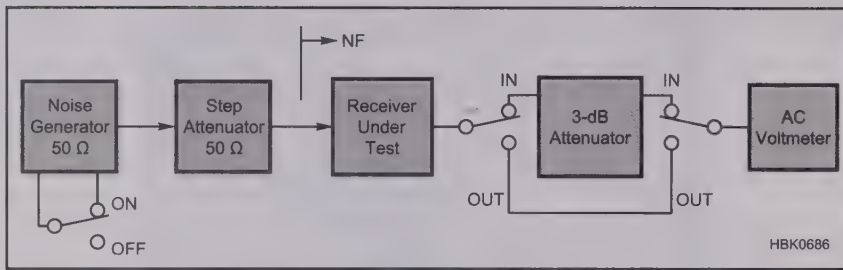

Figure 25.38 — Setup for measuring receiver noise figure.

long as the inaccuracy is the same for both voltage levels the ratio is correct. When using a non-RMS instrument, follow the step attenuator technique described in the previous paragraph along with a 3-dB attenuator (1/1.414 voltage divider) in front of the ac voltmeter. First take a voltmeter reading with the noise source off and the 3-dB attenuator bypassed. Then turn on the 3-dB attenuator and the noise source and adjust the step attenuator for the same reading. The noise figure is the ENR of the noise source minus the attenuation.

There are some potential errors to watch out for. The receiver AGC must be turned off for this test so that the gain does not change when the noise source is turned on or off. In addition, the audio gain and perhaps the IF gain must be adjusted so that there is no clipping of the noise peaks under any condition. With the noise source turned on, the RMS value of the noise at the speaker output should be adjusted to no more than 1/2 the maximum output level to prevent the peaks from clipping.

### OTHER USES FOR A NOISE SOURCE

You can take advantage of the flat spectrum of a noise source to measure the frequency response of RF devices. It requires either a spectrum analyzer or a receiver that can be tuned manually across the frequency range of interest. With sufficient averaging, the output noise level at each frequency accurately reflects the response of the device at that frequency. For example it is quite easy to measure the total response of a receiver from antenna to speaker output using an RF noise source and free software running on a PC that turns the computer sound card into an audio spectrum analyzer. With the noise source connected to the receiver antenna and the audio output connected to the sound card input, the total response, including the IF crystal filter and all the audio stages, is shown by the average noise level in the spectrum analyzer window.

In addition to receivers, noise sources can also be used to measure the noise figure of other devices such as amplifiers. The technique is basically the same, except that the output signal to be measured is at a radio frequency instead of audio. Another differ-

ence is that the noise figure of the measuring instrument can affect the results. That is almost never a concern when measuring receivers since the gain from the antenna to the speaker output is normally so high as to swamp out the effect. The corrected noise figure is

$$NF = 10 \log \left[ 10^{NF_M/10} - 10^{(NF_{NMI}-G)/10} \right]$$

where  $NF_M$  is the measured noise figure in dB,  $NF_{NMI}$  is the noise figure of the noise-measuring instrument in dB, and  $G$  is the gain of the device under test in dB. For that equation to be valid, the bandwidth of the measuring instrument must be no greater than the bandwidth of the device under test.

Commercial noise figure meters combine everything you need to perform noise figure measurements of amplifiers and other devices into one box. While the noise source itself is usually a separate module, the switched power is provided by the noise figure meter. Calculations are performed internally and the noise figure reads out directly on a meter or display. The noise source is repeatedly switched on and off to produce a continuously-updated noise figure reading, which is handy for adjusting or tuning the device under test. Older units typically operate at a small number of fixed intermediate frequencies and it is up to the user to heterodyne the signal to the IF. Many modern units operate over a wide range of frequencies and some can

sweep to provide a plot of noise figure versus frequency. Agilent Technologies has a good application note on noise figure measurement that is available for free download.<sup>19</sup>

### 25.4.8 RF and Microwave Test Accessories

The following section assumes that all coaxial devices are designed for 50-Ω characteristic impedance. While that is by far the most common value for Amateur Radio systems, most of the information applies as well for other impedances, such as 75 Ω which is common in the video and television industry.

#### ATTENUATORS AND TERMINATIONS

Most amateurs are familiar with the concept of a *dummy load*, which is nothing more than a high-power 50-Ω resistor with a coaxial connector. The term comes from the fact that it is often used as a dummy antenna to provide a low-SWR load for transmitter testing. The resistor must have low stray reactance throughout the desired frequency range. Common wire-wound power resistors are not suitable for a dummy load because they have too much inductance. Commercial loads, such as the power attenuator in **Figure 25.39**, use special resistors encased in a finned enclosure for dissipating the heat generated by the power absorbed from the transmitter. One technique used in some amateur dummy loads is to enhance the power dissipation capability of less-expensive, lower-power resistors by submerging them in a bath of oil.

Low-power dummy loads, normally called *terminations*, are used whenever a device being tested needs to have one of its coaxial connectors terminated in a load that has good return loss over a wide band of frequencies. A *feed-through termination*, such as the one in **Figure 25.40**, is one that has two coaxial connectors with a straight-through connection between them as well as a 50-Ω load resistor connected between the center conductors and the shield. It is used to provide a 50-Ω load

Figure 25.39 — A 100-watt power attenuator rated for dc-3000 MHz. The transmitter is connected to the male type-N connector. The female connector is for the low-power connection.

when using a measuring device with a high-impedance input, such as an oscilloscope. To avoid standing waves on the coaxial transmission line connected to the device under test, it is important to place the feed-through termination directly at the oscilloscope's input connector so that the transmission line is properly terminated.

Another technique to maintain a low SWR is to use a *T connector* at the oscilloscope input. The device under test is connected to one side of the T and some other device that provides a good 50- $\Omega$  load is connected to the other side. The high-impedance oscilloscope input does not excessively disturb the 50- $\Omega$  system. This is a good way to "tap into" a signal traveling between two devices on a coaxial line while maintaining the connection between the devices.

A *fixed attenuator* is useful both for reducing a signal level as well as for improving the 50- $\Omega$  match. For example, a 10-dB attenuator guarantees a minimum of 20 dB of return loss (1.22:1 SWR) even if the load SWR is infinite. A 20-dB attenuator makes a high-quality 50- $\Omega$  termination, even with nothing connected to its output.

A *step attenuator* is used when you need to adjust the signal level in fixed steps. The term "10-dB step attenuator" means that the step size is 10 dB. The maximum attenuation would typically be perhaps 70 to 120 dB. An

## RF Measurement Test Set

Many low-level RF measurements require similar test setups so why not combine them into one package? This also makes it easier to perform the tests and get consistent results. NØADL and KE4PT show an example in the *QEX* article "Apparatus for RF Measurements" that you can download with the supplemental online information.

attenuator with 1 dB steps and 10 dB of maximum attenuation would be called a "1 dB step attenuator" or a "0 to 10 dB step attenuator." Two attenuators, one with 10 dB steps and one with 1 dB steps, can be connected in series to obtain 1 dB resolution over a very wide range of attenuation. At microwave frequencies, continuously-variable attenuators are available for waveguide transmission lines. They can sometimes be obtained used at reasonable prices.

## OTHER TEST ACCESSORIES

Other accessories available for waveguide include coax-to-waveguide adapters, detectors, directional couplers, isolators, absorption wavemeters, mixers and terminations of

various kinds. Each size of waveguide covers about a 1.5:1 frequency range. Be aware that over the years there have been several systems for assigning letters to the various microwave frequency bands. For example, "X" band in the Agilent Technologies (formerly part of Hewlett-Packard) catalog is 8.2 to 12.4 GHz, but the old US Navy definition was 6.2 to 10.9 GHz, and the ITU assignment for X-band radar is 8.5 to 10.68 GHz. The IEEE standard definition is 8.0 to 12.0 GHz. When buying surplus waveguide accessories be sure they cover the frequency range you need.

Adapters such as those shown in **Figure 25.41** are useful for making connections among various pieces of test equipment.

A *coaxial detector* is just what the name implies, a diode detector in a coaxial package, usually with a 50- $\Omega$  RF load impedance. Silicon Schottky diodes are usually used to obtain good sensitivity although gallium arsenide devices are sometimes employed for the high microwave and millimeter-wave frequencies. Below a certain signal level, typically about -15 dBm, the detected output voltage is proportional to the square of the input voltage, that is, it is proportional to the input power. Sensitivity is typically specified in mV/mW, assuming a high-impedance load for the detected signal.

Wideband amplifiers can often be useful in test systems. They are available with various connector types in packages sized appropriately for the power level. A low-noise amplifier is useful as a preamplifier for a spectrum analyzer, for example. A higher-power amplifier can be used at the output of a signal generator either for receiver dynamic range testing or as an input signal for testing an RF power amplifier.

Directional couplers and bridges are useful network analyzer accessories as previously described but can also be used to acquire a small amount of signal for other test purposes. For example, a 30-dB coupler at the output of a 100-W transmitter produces a 100-mW signal that can be fed to a coaxial detector or a spectrum analyzer, while passing the rest of the 100-W signal through to the antenna or dummy load.

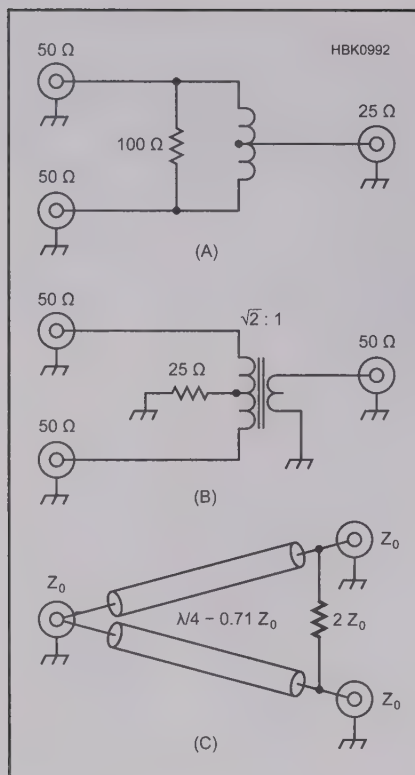

A *power divider*, also known as a *splitter*, is a device that divides an input signal equally among its output ports. A *combiner* is basically a power divider hooked up backward; the signals from the input ports are combined at the output port. Some power dividers consist only of a network of resistors.

**Figure 25.40** — Various RF test accessories. At the rear is a 10 dB step attenuator with a 0-120 dB range. In the foreground from left to right are a BNC "T" connector, a 50- $\Omega$  feed-through termination, a 0.1-500 MHz low-noise amplifier, and a 10-dB fixed attenuator.

**Figure 25.41** — Coaxial connector adapters. From the left are: BNC male to type-N male, BNC female to UHF male, BNC female to SMA male, type-N male to SMA female, and type-N female to SMC male.

**Figure 25.42** — Three forms of the Wilkinson power combiner/splitter. A and B show a lumped-element implementation. The version at C uses a pair of  $\lambda/4$  transmission lines acting as synchronous transformers. If all three ports are terminated in  $Z_0$ , then ports A and B are isolated from each other.

The insertion loss is typically at least 6 dB for 2-port splitters, meaning that a quarter of the power comes out each port and half the power is absorbed in the resistors.

A *hybrid combiner*, such as the *Wilkinson combiner* shown in **Figure 25.42**, includes a transformer as part of the network. It has the advantage that, so long as there is a good, low-SWR match on the output port, there is excellent isolation between the two input ports. That is very useful when combining the signals from two signal generators for high-level dynamic range testing of a receiver. The port-to-port isolation prevents the two signals from combining in the output amplifiers of the signal generators, where they could generate distortion products greater than the ones generated by the receiver that you are trying to measure. The insertion loss is nominally 3 dB.

The traditional Wilkinson combiner has a 2:1 ratio of input to output impedance. The variation in **Figure 25.42B** uses a transformer

with a  $\sqrt{2} : 1$  turns ratio (2:1 impedance ratio) to obtain 50  $\Omega$  on all ports.

The Wilkinson combiner can also be used as a power divider. The transmission line version in **Figure 25.42C** replaces the transformer of **Figure 25.42A** with a pair of  $\lambda/4$ -wavelength transmission line transformers (see the **Transmission Lines** chapter) to divide the input signal between the pair of output ports. All three ports must have the same impedance,  $Z_0$ . A resistor between the output ports with a value of  $2Z_0$  reduces loss and increases isolation. The  $\lambda/4$ -wavelength sections must have a characteristic impedance of

$$Z_0 \times \frac{\sqrt{2}}{2} = 0.707 Z_0$$

Since most amateur equipment and loads have an input of 50  $\Omega$ , using RG-59 or RG-11 with an impedance of 75  $\Omega$  will result in acceptable performance.

## 25.5 Receiver Measurements

Receivers present a special measurement challenge because of the wide range of signal levels they must be able to handle. In a state-of-the-art receiver, the difference between the minimum discernible signal and the blocking level can be as high as 130 or 140 dB. It requires special care and high-quality test equipment to measure that level of performance.

### 25.5.1 Standard ARRL Lab Tests

The ARRL laboratory staff has standardized on a suite of tests for receivers, transmitters and several other types of RF equipment. The exact procedures for each test are meticulously specified in a 163-page document to ensure that tests performed at different times by different people are done in the same way. We won't attempt to repeat that level of detail here but rather describe the tests in general terms suitable for use by the home experimenter. (The full set of procedures is available online in the Product Review Testing area of the ARRL website at [www.arrl.org/product-review](http://www.arrl.org/product-review).) Additional information on receiver design and performance is available in the **Receiving** and **RF Techniques** chapters.

### RECEIVER SENSITIVITY

Several methods are used to determine receiver sensitivity. The modulation mode often determines the best choice. One of the most common sensitivity measurements is *minimum discernible signal* (MDS) or *noise floor*, which is suitable for CW and SSB receivers. The minimum discernible signal is

defined as that which will produce the same audio-output power as the internally generated receiver noise. Hence, the term “noise floor.”

To measure MDS, use a signal generator tuned to the same frequency as the receiver. Be certain that the receiver is peaked on the generator signal. In **Figure 25.43** a step attenuator is included at the receiver input since most signal generators cannot accurately generate the low signal levels required for MDS measurements. An audio-frequency ac voltmeter is connected to the receiver's speaker terminals. If no speaker is connected, then a resistor of the same resistance as the speaker impedance should be substituted. Set the receiver to CW mode with a bandwidth of 500 Hz, or the nearest to that bandwidth that is available. Since the noise power is directly proportional to the bandwidth, always use identical filter bandwidths when comparing readings. Turn off the AGC, if possible. With

### Sherwood Labs Receiver Testing

Rob Sherwood, NCØB, is a long-time contributor to amateur testing of receiver performance ([www.sherweg.com/table.html](http://www.sherweg.com/table.html)). He has contributed four papers to the downloadable supplemental information for this book. The subjects include his procedures and lab setup, along with a discussion of receiver noise and band noise.

**Figure 25.43** — A general test setup for measuring receiver MDS, or noise floor. Signal levels shown are for an example discussed in the text.

the generator output turned off, you should hear nothing but noise in the speaker. Note the voltmeter reading at the receiver audio output. Next, turn on the generator and increase the output level until the voltmeter shows a 3-dB increase (1.414 times the voltage). The signal input at this point is the minimum discernible signal, which can be expressed in  $\mu\text{V}$  or dBm.

In the hypothetical example of Figure 25.43, the signal generator was adjusted to  $-133\text{ dBm}$  to cause the 3-dB increase in audio output power and the step attenuator is set to 4 dB. MDS is calculated with this equation:

$$\text{MDS} = -133\text{ dBm} - 4\text{ dB} = -137\text{ dBm}$$

where the MDS is the minimum discernible signal and 4 dB is the loss through the attenuator.

Note that the voltmeter really should be a true-RMS type to accurately measure the RMS voltage of the noise. A typical average-reading multimeter is calibrated to indicate the RMS voltage of a sine wave but reads low on Gaussian noise. The error is small for the MDS test, however. To correct for the error, adjust the signal generator for a 3.2-dB increase (1.445 times the voltage) instead of 3.0 dB.

Another issue to watch out for is that the peak noise voltage is much greater than the RMS, typically by a factor of 4 or 5. The receiver volume should be adjusted so that the RMS output voltage is no more than about one-fifth the clipping level of the audio amplifier.

For AM modulation, receiver sensitivity is expressed as the RF signal level that results in a 10 dB signal plus noise to noise ratio at the audio output. The AM signal is 30% modulated with a 1000 Hz tone. Otherwise, the test setup is the same as for the MDS test. The signal generator output level is adjusted until there is a 10 dB (3.16 voltage ratio) increase in audio output voltage when the modulation is switched from off to on. Again, there is an error if a typical average-reading multimeter is used instead of a true-RMS voltmeter. For the AM sensitivity measurement, the error is 0.8 dB. Adjust the signal generator output to give a 10.8 dB (3.47 voltage ratio) increase in signal when the modulation is turned on. If an audio distortion meter is used in place of the RMS voltmeter, you can leave the modulation turned on and adjust the signal generator output level for 31.6% distortion.

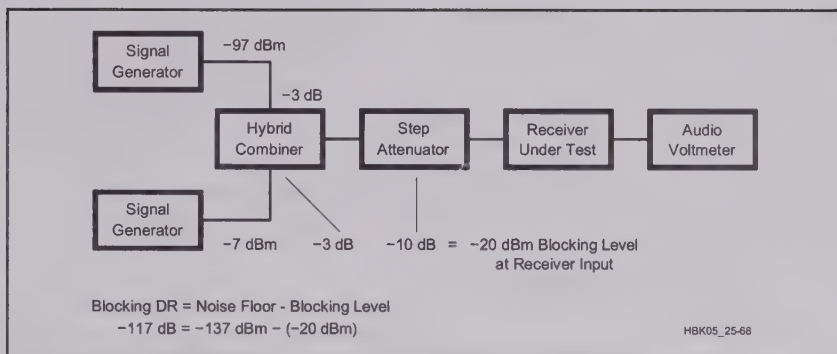

Figure 25.45 — Receiver blocking dynamic range is measured with this equipment and arrangement. Signal levels shown are for the example discussed in the text.

For FM modulation, receiver sensitivity is expressed as the RF signal level that results in 12 dB SINAD. SINAD stands for “signal plus noise and distortion” and is calculated from

$$\text{SINAD} = 10 \log \left[ \frac{\text{signal} + \text{noise} + \text{distortion}}{\text{noise} + \text{distortion}} \right] \text{ dB}$$

where signal, noise and distortion are all entered in units of power (watts or milliwatts). It is very similar to the signal plus noise to noise ratio used for AM testing except that any distortion in the audio signal is added to the noise measurement. It means, however, that the signal, the noise and the distortion must all be measured at the same time, without turning off the modulation. For that, a distortion analyzer is needed as shown in Figure 25.44. A distortion analyzer includes a switchable band-reject filter to null out the 1 kHz tone for the noise-and-distortion measurement. The filter is bypassed for the signal-plus-noise-and-distortion measurement. For the test, the signal generator is set for FM modulation with a 1 kHz tone and the desired FM deviation, normally 3 kHz for VHF repeater operation. Adjust the signal generator output level until the distortion analyzer indicates 25% distortion, which is equivalent to 12 dB SINAD. Don’t forget to subtract the attenuation of the step attenuator from the signal generator output level, as was done for the MDS test.

Noise figure is a measure of receiver sensitivity that, unlike the other methods presented so far, is independent of the receiver bandwidth and operating mode. It can be calculated from the MDS so long as the noise bandwidth of the receiver filtering is known.

Noise bandwidth is the bandwidth of a hypothetical perfect filter with a rectangular spectrum shape that would produce the same total noise power as the receiver filter. Accurate measurement of a filter’s noise bandwidth requires integrating the spectral response using a swept signal source, but the filter’s 3 dB bandwidth can be used as a reasonable approximation. The formula is

$$\text{NF} = \text{MDS} - (10 \log (\text{BW}) - 174) \text{ dB}$$

where MDS is the minimum discernible signal in dBm and BW is the noise bandwidth in Hz. Assuming the noise bandwidth is 500 Hz, we get  $\text{NF} = \text{MDS} + 147\text{ dB}$ . For example, if the MDS is  $-137\text{ dBm}$  then  $\text{NF} = -137 + 147 = 10\text{ dB}$ .

## RECEIVER DYNAMIC RANGE

Dynamic range is a measure of a receiver’s ability to receive weak signals without being overloaded by strong signals. It is easy to design a receiver with good sensitivity to weak signals. It is also easy to design a receiver that is not overloaded by strong signals. It is much more difficult to design a receiver that can do both at the same time.

Blocking dynamic range (BDR) is the difference between the noise floor and the signal level at which blocking occurs, that is, the level that causes a 1 dB reduction in gain for nearby weaker signals. The noise floor is just the MDS and can be measured using the technique described in the previous section.

The blocking level is measured using a test setup similar to the one used for measuring MDS except that two signal generators are connected to the input through a hybrid combiner, as shown in Figure 25.45. The receiver AGC should be turned off for this test. The mode is set to CW and the bandwidth to 500 Hz or the closest available. Two signal generators are used. One generates the weak signal that the receiver is tuned to. The ARRL standard specifies  $-110\text{ dBm}$  at the receiver

Figure 25.44 — FM SINAD test setup.

input, which requires  $-97$  dBm at the input to the hybrid combiner, assuming it has 3 dB loss. The other signal generator generates the strong interfering signal on a nearby frequency. Standard frequency separations are plus and minus 20, 5 and 2 kHz. The level of the strong signal is increased until the level of the weaker signal measured at the receiver audio output decreases by 1 dB.

Referring to Figure 25.45, the blocking level is the level from the signal generator minus the loss of the hybrid combiner and attenuator,

$$BL = -7 - 3 - 10 = -20 \text{ dBm}$$

The blocking dynamic range is given by

$$BDR = BL - MDS = -20 - (-137) = 117 \text{ dB}$$

assuming an MDS of  $-137$  dBm as in the previous examples.

One complication is that it may be difficult to measure the amplitude of the audio tone because of the presence of noise caused by the phase noise of the signal generator and the receiver's local oscillator, especially at the 2 and 5 kHz frequency spacings. The solution is to use an audio-frequency spectrum analyzer to measure the change in tone amplitude. The absolute accuracy of the spectrum analyzer is not important so long as it can accurately show a 1-dB change in signal level. An instrument based on a computer sound card and free spectrum analysis software should be adequate.

*Reciprocal mixing* is the name for the mixing of a nearby interfering signal with the phase noise of the receiver's local oscillator, which causes noise in the audio output. Although the ARRL BDR test eliminates this effect from the measurement, in actual on-the-air operation the phase noise is often the factor that limits the effective dynamic range. To address this issue, the ARRL test suite includes a separate measurement for reciprocal mixing. The test setup is the same as for MDS except that the signal generator in Figure 25.43 is replaced with a low-phase-noise crystal oscillator with an output power level of  $+15$  dBm. The step attenuator block should include both a unit with 10-dB steps to be able to adjust the signal level over a wide range as well as a 1-dB step attenuator for fine adjustment. The receiver is tuned to 20, 5 or 2 kHz above or below the oscillator frequency. The output noise level is first measured with the oscillator turned off, then the oscillator is turned on and the step attenuator gradually reduced until the noise increases by 3 dB. Reciprocal mixing is expressed as a negative number:

$$\text{reciprocal mixing} = MDS - (+15 - A) \text{ dB}$$

where MDS is the noise floor,  $+15$  is the signal

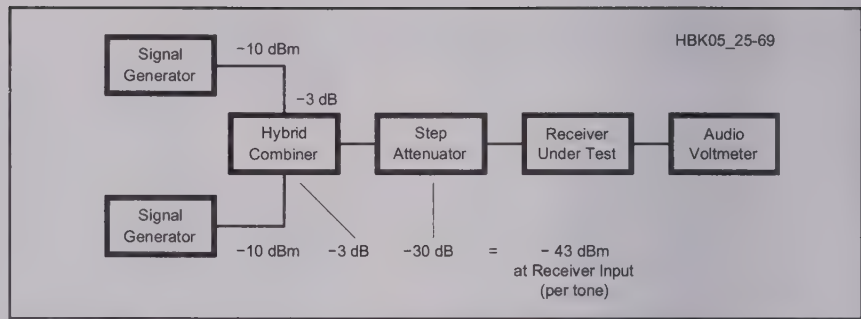

Figure 25.46 — The test setup for receiver intermodulation distortion dynamic range. Signal levels shown are for the example discussed in the text.

level of the crystal oscillator in dBm, and A is the total attenuation in dB.

*Intermodulation distortion (IMD)* means the creation of unwanted signals at new frequencies because of two or more strong interfering signals modulating each other. If there are two interfering signals at frequencies  $f_1$  and  $f_2$ , then *second-order IMD* products occur at  $f_1 + f_2$ . If  $f_1$  and  $f_2$  are close together, then the second-order products occur near the second harmonics. *Third-order IMD* products occur at  $2f_1 - f_2$  and  $2f_2 - f_1$ . If  $f_1$  and  $f_2$  are close together, then the third-order products occur close by. For example, if  $f_1$  and  $f_2$  differ by 10 kHz, then the third-order IMD products are 10 kHz above the higher frequency and 10 kHz below the lower.

The two-tone IMD test setup shown in Figure 25.46 is the same for second and third-order IMD. To obtain sufficient output power and isolation of the two signal generators, it may be necessary to follow each one with a wide-band power amplifier, not shown. The receiver under test is set to receive CW with the same bandwidth as for the MDS test and is tuned to the frequency of the distortion product to be measured. The two signal generators are always set to the same output amplitude level, which is increased until IMD products equal in amplitude to the noise floor appear, resulting in a 3-dB increase in the audio voltmeter reading. The *IMD dynamic range* is then the difference in dB between the level of the interfering signals and the MDS.

For the second-order IMD measurement, the standard ARRL test sets the two signal generators to 6.000 MHz and 8.020 MHz and the receiver is tuned to 14.020 MHz. For the third-order IMD measurements, the two signal generators are set to frequencies 20, 5 and 2 kHz apart, separated from the receiver frequency by plus and minus 20, 5 and 2 kHz so that the lower or upper IMD product falls within the receiver passband.

For example, tune the receiver to 14.020 MHz and the two signal generators to 13.980 MHz and 14.000 MHz. With the signal generators turned off, measure the noise level with the audio voltmeter. Turn on the signal

Figure 25.47 — The third-order intercept point can be determined by extending the lines representing the interfering signal level and the third-order intermodulation products on a plot of the signal levels in dB.

generators and increase their amplitudes until the voltmeter shows a 3-dB increase. If the signal generator amplitudes are  $-10$  dBm, the loss in the hybrid combiner is 3 dB, and the step attenuator is set to 30 dB attenuation, then the third-order IMD level is

$$IMD = -10 - 3 - 30 = -43 \text{ dBm}$$

If the MDS is  $-137$  dBm, then the third-order IMD dynamic range is

$$IMD\_DR = IMD - MDS = -43 - (-137) = 94 \text{ dB}$$

As with the blocking dynamic range test, the phase noise of the signal generators and the receiver LO may obscure the IMD product being measured. Again, the solution is to use an audio spectrum analyzer to measure the tone amplitude. Calibrate the amplitude by temporarily tuning one of the signal generators to the receiver frequency and setting the amplitude level so that the signal level at the receiver is the MDS. Note the level on the spectrum analyzer. Then return the signal generator to the interfering frequency and adjust the signal

generators' amplitudes until the IMD product is at the same level as the MDS signal. The ARRL test bench actually uses a third signal generator and a second hybrid combiner at the receiver input to generate the calibration signal so that it and the IMD product can be seen on the spectrum analyzer at the same time for a more-accurate comparison.

In most analog components such as mixers and amplifiers, the second-order products increase in amplitude by 2 dB for each 1 dB increase in the interfering signals and third-order products increase 3 dB per dB. If the output signal levels are plotted versus the input levels on a log-log chart (that is, in units of dB), the desired signal and the undesired IMD products theoretically trace out straight lines as shown for third-order products in **Figure 25.47**. Although the IMD products increase more rapidly than the desired signal, the lines never actually cross because blocking occurs before that level, however, the point where the extensions of those two lines cross is called the *third-order intercept point* (IP3).

Although the third-order intercept is an artificial point, it is a useful measure of the strong-signal-handling capability of a receiver. It can be calculated from the equation

$$IP3 = MDS + 1.5 \times IMD\_DR \text{ dBm}$$

where IP3 is the third-order intercept point, MDS is the minimum discernible signal in dBm and IMD\_DR is the third-order IMD dynamic range in dB. Using the numbers from the previous example,  $IP3 = -137 + 1.5 \times 94 = +4 \text{ dBm}$ .

The second-order intercept may be calculated in an analogous way.

$$IP2 = MDS + 2 \times IMD\_DR$$

where IP2 is the second-order intercept and IMD\_DR is the second-order IMD dynamic range in this case.

An alternate method of measuring third-order IMD is to use S5 (-97 dBm) instead of the MDS as the reference level to which the IMD products are adjusted. That results in a higher IMD level but a smaller value of IMD dynamic range (the difference between the IMD level and the reference). It may be a more accurate method of determining the third-order intercept because the signal levels do not have to be measured in the presence of noise that is at the same level as the signal.

The third-order intercept is generally not a valid concept for software-defined receivers (SDRs) that do not use an analog front end. Some SDRs do not use a mixer but feed the signal from the antenna directly to an analog-to-digital converter (ADC). ADCs usually do not exhibit the 3 dB per dB relationship between signal level and third-order products,

## Dynamic Range Metrics: Superheterodyne vs. SDR Receivers

By Bob Allison, WB1GCM, ARRL Laboratory Assistant Manager

*Reciprocal Mixing (RM)* is the noise generated in a superheterodyne receiver when noise from the local oscillator (LO) mixes with strong, adjacent signals. All oscillators have noise sidebands, and some types and designs have more than others. The noise sidebands mix with the strong adjacent off-channel signal, creating noise products in the mixer's output. This noise can degrade the sensitivity of the receiver and is most notable when a strong signal is just outside the IF passband. Reciprocal mixing is worse with a single strong signal 2 kHz away from the tuned frequency than it is 5 or 20 kHz away.

It's interesting to compare to the two-tone third-order IMD dynamic range (3IMD DR) to the reciprocal mixing dynamic range (RMDR). In the case of 3IMD, two strong adjacent signals add up to cause an unwanted effect, but in the case of RM, a single strong adjacent station 5 or 2 kHz away from the desired signal has more of an impact on the ability to hear a desired weak signal. For most superheterodyne receivers, RMDR is the worst dynamic range figure at 2 kHz spacing.

It has been observed in the ARRL Laboratory that many direct-sampling SDR receivers exhibit little, if any reciprocal mixing up to the point of analog-to-digital converter (ADC) overload. These receivers have no front-end mixer and local oscillator, thus, no sideband noise of an oscillator to mix with adjacent signals.

We perform the reciprocal mixing test at 14.025 MHz, using a very low-noise Wenzel test oscillator with a measured output of +14 dBm to generate the off-channel, strong signal. A test oscillator must have the lowest sideband noise as possible — considerably lower than the reciprocal mixing being measured. An excellent receiver will exhibit 100 dB of RMDR at 2 kHz spacing.

*Blocking* — an apparent reduction in receiver gain due to the presence of a strong signal — was problematic in years past. With the AGC off, the desired signal, especially if weak, would disappear from the receiver audio if a strong, off-channel signal was present. The ability to reject adjacent signals has improved greatly in recent years, so much so that blocking dynamic range (BDR) greatly exceeds the other dynamic ranges. During Lab tests, reciprocal mixing in a receiver can raise the audio output noise enough to drown out the desired signal! Some of our laboratory consultants have expressed that the BDR figure is a bit useless because of this behavior. Agreed! Still, some still wish for us to report blocking, since we have the use of signal analyzers set to narrow audio bandwidths (2 or 5 Hz).

Many SDR receivers measured for QST Product Review exhibit little or no blocking effects up to the point of analog-to-digital converter (ADC) overload. This behavior, along with an SDR's reciprocal mixing behavior is most desirable. Typical BDR of modern receivers at 2 kHz spacing is 110 dB or greater.

*Two-tone Third-Order Intermodulation Distortion (3IMD)* happens when two strong signals (2 and 4 kHz away from the tuned frequency, for example) appear at the antenna jack, with a resulting unwanted "phantom" signal heard at the tuned frequency. With a superheterodyne receiver, IMD is generated at the input stages to the first IF, with the undesired mixing products passing through the rest of the receiver stages. In an SDR receiver, the ADC clock quality and the cumulative signal level input to the ADC determines the level of IMD at the speaker (see other sidebar). Due to design improvements of both superheterodyne and SDR receivers, typical 3IMD DR at 2 kHz spacing is 90 dB or greater.

Due to changes in technology, most modern receivers do not exhibit a 3:1 relationship between the IMD signal level and the IMD input level. The ratio can be significantly greater or less than 3:1. Since the third order intercept point (IP3) figure is calculated based on the assumption of a 3:1 ratio, this figure is meaningless with today's receivers. Emphasis must be placed on all three dynamic ranges. The lowest dynamic range at 2 kHz of the three dynamic ranges we publish is the dynamic range of the receiver. The benchmark for excellent performance is 100 dB.

## SDR Behavior with Two-tone Third Order Intermodulation Dynamic Range: the Third Signal

By Bob Allison, WB1GCM, ARRL Laboratory Assistant Manager

The ARRL Laboratory determined that our normal two-tone third order IMD dynamic range (3IMD DR) tests did not always apply to the way software defined radio (SDR) receivers work in the real world.\* With an SDR receiver, all of the demodulation is done by software. An SDR converts a block of analog RF spectrum to a digital stream of data, then uses software to select and demodulate a desired signal from that data. The digitization of an analog signal results in a sequence of small steps in signal level. These small steps are a type of nonlinearity that forms intermodulation (IMD) products, similar to those observed in analog receivers.

For analog receivers, once intermodulation occurs, it gets strong quickly as the off-channel signals used for testing are increased. With an SDR, however, because the small steps are the same for all levels of the signal being digitized, intermodulation at low levels does not vary significantly with the level of test signals. For the steady-state sine waves seen from signal generators in a laboratory environment, the steps are the same for each cycle of RF. Any intermodulation that is created adds coherently in the receiver output.

In some SDR designs, random noise is added to the RF input to randomize the digitization process, preventing intermodulation products from adding coherently. This technique is called dithering. When a receiver is connected to the antenna, band noise present at the input to the analog to digital converter (ADC) can, in most cases, serve to randomize the digitization. The net effect is the same — low-level intermodulation seen in a laboratory test environment will not be present when that receiver is connected to an antenna and used to receive on-the-air signals. This effect was verified by measurements in the Lab by adding a receive antenna (acting as our dithering source) to our two-tone IMD test fixture; the level of band noise varied with local conditions and propagation, thus, the amount of dithering present also varied, causing IMD products to vary as well.

With such observations, we had to find out if the IMD products varied as a function of noise or as a function of level. We substituted a random noise generator as our dithering source. The result: low-level IMD products were masked by the raised noise level with little change in the level of the IMD products. Varying the level of the noise had no effect, except the unwanted effect of a raised noise floor. Since noise or its level had no effect on the level of the IMD products, the only other dithering source received on an antenna must be discrete signals!

We soon discovered that by using a strong, off frequency, single signal as our dithering source (the third signal), the IMD product level could be reduced. By varying the level of the third signal (generator), the IMD product level also varied. Thus, when connected to an antenna, the levels of all the signals at the input to the ADC vary considerably with propagation and mode, and thus the dynamic range varies with propagation and mode. This significant discovery determined that adding noise (dithering) does not necessarily improve an SDR's 3IMD DR, but that a single, strong, constant, off-frequency signal does. By experimenting, we found that by varying both the third signal's level and frequency, a "sweet spot" could easily be found that maximizes the 3IMD DR. A third signal at a level of  $-43$  dBm, 200 kHz away from the tuned frequency is a good example of a "sweet spot."

This single additional signal, at a specific level and frequency, hardly represents actual on-air conditions. In reality, the 3IMD DR can be a moving target, varying by 30 dB or more depending on conditions! With SDRs that exhibit improved 3IMD DR, QST Product Reviews report "up to XX dB", which represents the absolute best-case dynamic range. A user of such devices can expect much lower dynamic range under average band conditions, with an effort made to mention the expected dynamic range during "quiet" conditions.

It is interesting to note that by design, some manufacturers of SDRs now employ a "third signal" to improve 3IMD DR; the third signal is internally generated and tracks with the tuned signal, at a specific level, which minimizes IMD products and maximizes 3IMD DR.

Please keep in mind that when an antenna is attached to a receiver, atmospheric, solar and man-made noise will mask much of the low-level IMD products that are measured in a laboratory environment. That is, the dynamic range can be higher under laboratory "quiet" conditions, where a receiver's noise floor is measurable.

at least over major portions of their operating range. Comparing third-order dynamic range measurements of an SDR and a conventional analog radio may give misleading results.

Figure 25.48 shows the relationship between the various dynamic range values. The base line represents different power levels, with very small signals at the left and large signals at the right. The numbers listed are from the previous examples for a typical receiver. The thermal noise and the noise floor are referenced to a 500 Hz bandwidth. The third-order IMD dynamic range is less than the blocking dynamic range, which means that signals as low as  $-43$  dBm may cause IMD interference while signals must exceed  $-20$  dBm to cause blocking. However, the intermodulation distortion may actually cause fewer problems since the IMD products only appear at certain discrete frequencies. A signal that exceeds the blocking level can cause interference across the entire band.

Third-order IMD dynamic range may also be measured on an FM receiver. The test setup is the same as Figure 25.46 except that the audio voltmeter is replaced with an audio distortion meter, as in Figure 25.44. The frequencies involved are the same as in that example. For this test, one of the signal generators (the one tuned to the frequency farthest from the receiver under test) is FM-modulated with a 1000 Hz tone at 3 kHz deviation. That causes the IMD products also to be FM-modulated, which can be measured with the distortion meter. The signal generator amplitudes are increased until the distortion product produces 12 dB SINAD (25% distortion) on the meter. The FM third-order IMD dynamic range is calculated using the same equation as for SSB and CW except that the SINAD sensitivity is substituted for the MDS. For example, if the 12 dB SINAD sensitivity is  $-120$  dBm, the signal generator outputs are  $-10$  dBm, the combiner loss is 3 dB, and the step attenuator is set to 30 dB, then

$$FM\_IMD\_DR = -10 - 3 - 30 - (-120) = 77 \text{ dB}$$

where FM\_IMD\_DR is the third-order FM IMD dynamic range.

### OTHER ARRL RECEIVER TESTS

Most modern communications receivers are superheterodyne types. The first *IF rejection* and *image rejection* test measures the signal levels at the intermediate frequency and the image frequency that produces an audio output signal equivalent to the MDS, or noise floor. The test setup is the same as for the MDS test, as shown in Figure 25.43. The receiver is set to CW mode and 500 Hz bandwidth. The signal generator is tuned to the receiver first intermediate frequency or to the image frequency, which is the receiver

frequency plus or minus two times the IF. The signal generator output level is gradually increased until there is a 3-dB increase in the audio voltmeter reading. As with the MDS test, if a multimeter is used instead of a true-RMS voltmeter, the signal generator should be adjusted for a 3.2-dB increase. The IF or image rejection is just the signal generator level at the receiver input less the MDS. For example, if the MDS is  $-137$  dBm, the signal generator level is  $-40$  dBm, and the attenuator is set for 10 dB, then the IF or image rejection is  $IR = -40 - 10 - (-137) = 87$  dB.

*FM adjacent-channel rejection* is a measure of an FM receiver's ability to detect a weak signal in the presence of a strong interfering FM-modulated signal on an adjacent frequency channel. The test setup is the same as for the two-tone IMD dynamic range test shown in Figure 25.46 except that a distortion meter is substituted for the audio voltmeter, as was done for the FM SINAD test illustrated in Figure 25.44. The standard channel spacing is 20 kHz. The weak signal is modulated with a 1000 Hz tone and the interfering signal with a 400 Hz tone, both with 3 kHz deviation. The receiver under test is set for FM modulation and is tuned to the frequency of the weak signal. The weak signal is adjusted for 12 dB SINAD (25% distortion) on the distortion meter and then the interfering signal level is increased until the SINAD drops to 6 dB (50% distortion). The adjacent channel rejection is the difference between the power of the interfering signal and the 12 dB SINAD sensitivity, which is just the difference in level between the two signal generators.

Another test that applies especially to FM receivers is the *scquelch sensitivity test*. As usual, the signal generator is set for FM modulation with a 1 kHz tone and 3 kHz deviation. If squelch is available for SSB, it can be tested in that mode as well. With the signal generator off, the squelch control on the receiver is adjusted just to the point where the noise is squelched. Then the signal generator is turned on and the level increased until the signal is heard.

Audio power output is tested with the same setup as the FM SINAD test illustrated in Figure 25.44. The receiver under test is set for SSB mode with the widest bandwidth available. A load resistor of the specified resistance, usually  $8\ \Omega$ , is connected to the speaker output in place of the speaker. The signal generator level is set for an S9 level and the receiver is tuned for a 1 kHz output tone frequency. The receiver volume control is increased until the specified distortion level, usually 10%, is indicated on the distortion meter. The output power is given by the equation

$$P = V_{\text{RMS}}^2 / R$$

where  $P$  is the power in watts,  $V_{\text{RMS}}$  is the RMS output voltage, and  $R$  is the load resistance.

The audio and IF frequency response measures the audio frequencies at which receiver audio output drops by 6 dB from the peak. It includes the total response of the entire receiver, from the antenna connector to the speaker output. The test setup is the same as for the audio power output test except that some method must be included to measure the output audio frequency, such as a digital oscilloscope or frequency counter. The receiver is set for SSB mode at the bandwidth to be tested and the AGC is turned off. First tune the signal generator for a peak audio output signal and record the level of the audio signal. Then tune the signal generator downward until the signal drops 6 dB ( $\frac{1}{2}$  the voltage) and record the audio frequency. Then tune the signal generator upward and record the high-end frequency at which the signal drops by 6 dB. The 6-dB bandwidth is the difference between the two frequencies.

There are several other miscellaneous ARRL receiver tests that are commonly reported in product reviews. The S meter test measures the signal level required to produce an S9 indication on the meter. The notch filter test uses a setup similar to the IMD dynamic range test in Figure 25.46 with an audio spectrum analyzer at the output. One signal is notched and the other is used as a level reference; the notch depth is the amplitude difference between the two tones. The DSP noise reduction test uses a similar setup except that one signal generator is replaced with a wide-band noise generator. The signal generator is adjusted for S9 and the noise source for a 3-dB increase in the audio voltmeter so that the noise and signal are at the same level. The DSP noise reduction is then turned on and the reduction in noise level recorded.

## 25.5.2 Other Common Receiver Measurements

There are a few other useful receiver tests that are not covered in the standard ARRL test suite. For example, in addition to the IF and image response, it is possible for a receiver to have spurious responses at other frequencies as well. Testing for that can be a time-consuming process since it involves tuning the signal generator through a wide frequency range with the receiver tuned to each of a number of representative frequencies, typically at least one on each band. Start with the signal generator at maximum output power. When you find a response, reduce the level until the received signal level is at the noise floor (MDS). The spurious response amplitude is the difference between the signal generator level and the MDS.

Another time-consuming test is for internally-generated spurious signals, sometimes called *birdies* because they sometimes sound like a bird chirping as you tune through the

signal. Birdies are typically caused by harmonics of the local oscillator(s) and BFO and their IMD products. For this test, connect a  $50\text{-}\Omega$  termination to the antenna connector and tune the receiver through its entire frequency range, writing down the frequency and S meter reading for each spurious signal found. You must tune very slowly because many birdies pass through the IF passband much faster than regular signals, sometimes in the opposite direction.

The ARRL S meter test only measures the response at the S9 level. If the S meter is accurate throughout its range it can be used to measure signal levels off the air. The standard definition is that, on the HF bands, S9 should correspond to  $-73$  dBm ( $50\ \mu\text{V}$  into  $50\ \Omega$ ) and each S unit corresponds to 6 dB, or a doubling of RF voltage. So S8 is  $-79$  dBm or  $25\ \mu\text{V}$ , S7 is  $-85$  dBm or  $12.5\ \mu\text{V}$ , and so on. The S unit calibration of most commercial equipment varies considerably from 6 dB per S unit, but the S meters accuracy can easily be measured with a calibrated signal generator.

The automatic gain control circuitry has a major effect on the operation of a receiver. The static AGC performance can be measured on a CW or SSB receiver with a signal generator and an audio voltmeter connected to the speaker output. You can plot a graph of audio output in dBV (decibels with respect to one volt) versus RF input level in dBm to see how good a job the receiver does in keeping the output level constant. Some receivers have menu settings to set the slope of the curve and the threshold, which is the small signal level at which the AGC circuitry starts to reduce the gain. The dynamic response is also important, although it is difficult to measure. A short attack time is important to reduce transients on sudden strong signals, but if it is too short then in-channel intermodulation distortion between strong signals can make signals sound "mushy."

The ARRL test suite includes a measurement of the 6 dB bandwidth at the audio output, but the sound is also affected by slope and ripple in the passband response. Using the same test setup as for the 6 dB measurement, you can measure the output voltage at a number of equally-spaced frequencies and plot the results on a graph. Output power is measured at the 10% distortion level, but it also is useful to measure the distortion at a volume level closer to what is used in actual practice. An output level of  $1\ V_{\text{RMS}}$  is commonly used for that test.

Frequency accuracy and stability are important performance criteria for a receiver. If a signal generator of sufficient frequency accuracy is not available, a standard time signal such as from radio station WWV can be used. The traditional method is to put the receiver in SSB mode and *zero-beat* the carrier, which means to tune the receiver until the audio

tone (the beat note) is at zero Hz. Since most receivers' audio frequency response only extends down to a couple hundred Hertz, it is difficult to get good accuracy using that

method. If a frequency counter or other means of measuring the audio output frequency is available, you can tune the receiver to obtain a 1000 Hz tone and add (for LSB) or subtract

(for USB) 1000 Hz from the receiver's indicated frequency. The frequency drift from cold turn-on can be measured by plotting the audio output frequency versus time.

## 25.6 Transmitter Measurements

The signal levels found in a transmitter do not vary nearly as much as in a receiver. All the signals are generated internally, rather than being received off the air, so are much better controlled. Partly for that reason transmitter measurements tend to be simpler than receiver measurements and there are fewer of them.

### 25.6.1 Standard ARRL Lab Tests

For a transmitter, the RF power output is probably the first measurement that comes to mind. The test setup is straightforward: connect the transmitter output to the input of an RF wattmeter and connect the wattmeter output to a suitable dummy load. For CW, AM and FM modes, simply key the transmitter and measure the power on the wattmeter. For AM and FM the modulation should be turned off. For SSB, a two-tone audio oscillator should be connected to the microphone input to take the place of the voice signal. For the SSB test the wattmeter must be a peak-reading type to measure the PEP power

#### TRANSMITTER SPECTRAL PURITY

Ideally a transmitter confines its emissions to a narrow frequency range around the desired signal. Unwanted emissions can be divided into two categories, those that fall close to the desired signal and those that extend far away.

In the latter category are included harmonics and other discrete spurious frequencies. The measurement is done with the transmitter in CW mode using the test setup shown in **Figure 25.49**. Tune up the transmitter as specified in the manual, set it for the desired power level, and adjust the frequency from one end of the band to the other while observing the spectrum analyzer. This should be done on each band. It may be necessary to retune the transmitter occasionally as the frequency is adjusted. The spurious-signal and harmonic suppression is the difference in dB between the carrier and the maximum spurious signal. It is important that the power level into the spectrum analyzer be maintained at a low enough level that spurious signals are not generated in the spectrum analyzer itself. To test for that, try changing the step attenuator setting; the desired carrier and all spurious signals should change by the same amount. If not, increase the attenuation until they do.

**Figure 25.49** — The transmitter spectral purity test uses a spectrum analyzer to display the spurious frequencies.

**Figure 25.50** — Comparison of the spurious signal levels of two 100-watt transmitters, as shown on the spectrum analyzer display. The display on the top shows about 63 dB worst-case spurious signal suppression while the one on the bottom has a second harmonic suppressed approximately 42 dB. For transmitters below 30 MHz installed after January 1, 2003, the worst-case spurious emission must be at least 43 dB below the carrier power.

**Figure 25.51** — Spectral display of an amateur transmitter output during composite-noise testing in the ARRL Lab. Power output was 200 W on the 14 MHz band. The carrier, off the left edge of the plot, is not shown. This plot shows composite transmitted noise 100 Hz to 1 MHz from the carrier on a logarithmic scale. The vertical scale is in dB with respect to the carrier.

Representative spectrum analyzer plots are shown in **Figure 25.50**. The horizontal (frequency) scale is 5 MHz per division. The desired carrier frequency at 7 MHz appears 1.4 divisions from the left of the plot. Although not shown, a large apparent signal is often seen at the extreme left edge. This signal at zero Hz is caused by leakage of the spectrum analyzer local oscillator frequency

and should be ignored.

In addition to the discrete spurious signals measured by the previous test, a transmitter may also generate broadband noise. It can be due both to the phase noise of the local oscillator as well as AM noise from all the devices in the amplifier chain. Generally the phase noise predominates, at least for frequencies close to the carrier. The composite noise test measures

**Figure 25.52** — An SSB transmitter two-tone test as seen on a spectrum analyzer. Each horizontal division represents 2 kHz and each vertical division is 10 dB. The third-order products are 30 dB below the PEP (top line), the fifth-order products are down 38 dB and seventh-order products are down 40 dB.

**Figure 25.54** — Typical CW keying waveform for a modern Amateur Radio transceiver during testing in the ARRL Lab. This plot shows the first two dits in full break-in (QSK) mode using external keying. Equivalent keying speed is 60 WPM. The upper trace is the actual key closure; the lower trace is the RF envelope. (Note that the first key closure starts at the left edge of the figure.) Horizontal divisions are 10 ms. The transceiver was being operated at 100 W output on the 14 MHz band.

the total noise from both sources as well as any close-in spurious frequencies that don't show up in the wideband spurious signal and harmonic suppression test. Measuring phase noise requires high-performance test equipment and special measuring techniques.<sup>20</sup> The ARRL lab uses a special low-noise oscillator and a Hewlett-Packard (now Agilent Technologies) phase noise test set under computer control to perform this sophisticated measurement, which takes about 15 minutes to perform once it is set up. The result is a plot of the noise spectrum such as the one in **Figure 25.51**.

The most important unwanted emissions close to the carrier frequency are caused by distortion in the transmitter amplifier stages. In an SSB transmitter, this distortion creates a signal that is wider than the bandwidth of

**Figure 25.53** — CW keying waveform test setup.

**Figure 25.55** — PTT-to-RF-output test setup for voice-mode transmitters.

the original modulation and causes interference to other stations. For this test, the same test setup is used as for the harmonics and spurious frequencies test shown in **Figure 25.49** except that a two-tone audio generator is connected to the transmitter microphone input to simulate a voice signal, which contains many frequency components. The two tone frequencies must be non-harmonically related to prevent tone harmonics from being confused with IMD products. The ARRL Lab uses 700 Hz and 1900 Hz for these tests. Because many transmitters' modulation frequency response is not flat, the relative amplitudes of the two audio-frequency tones must be adjusted to obtain equal-amplitude RF tones on the spectrum analyzer. The test should be done for both lower and upper-sideband modes.

Two-tone IMD products are measured with respect to the transmitter peak-envelope power (PEP) which is 6 dB greater than the amplitude of either of the two tones. By adjusting the spectrum analyzer reference level to place the two tones 6 dB below the zero-dB reference line, as shown in **Figure 25.52**, the IMD distortion may be read out directly. For the signal shown, the third-order products are at -30 dB from PEP.

Carrier and unwanted sideband suppression may be measured with the same setup. In this case the 700 Hz tone of the two-tone generator is turned off and only the 1900 Hz tone is used. The single tone is set to the 0-dB reference line of the spectrum analyzer. For USB, the suppressed carrier shows as a small pip 1900 Hz below the desired signal and the unwanted sideband is 3800 Hz below. For LSB the unwanted signal frequencies are above the desired signal.

## TESTS IN THE TIME DOMAIN

Oscilloscopes are used for transmitter testing in the time domain. Dual-trace instruments are best in most cases, providing easy to read time-delay measurements between keying input and RF- or audio-output signals. Common transmitter measurements performed with 'scopes include CW keying waveform and SSB/FM transmit-to-receive turnaround tests (important for many digital modes).

A typical setup for measuring CW keying waveform and time delay is shown in **Figure 25.53**. A keying test generator is used to key the transmitter at a controlled rate. The generator can be set to any reasonable speed, but ARRL tests are usually conducted at 20 ms on and 20 ms off (25 Hz, 50% duty cycle), which corresponds to a series of dits at 60 WPM. **Figure 25.54** shows a typical display. The first two dits at the beginning of the transmission are displayed in order to show any transients or truncations that occur when the transceiver transitions from receive to the transmit state. The rise and fall times of the RF output pulse are measured between the 10% and 90% points on the leading and trailing edges, respectively. The delay times are measured between the 50% points of the keying and RF output waveforms. Look at the **Transmitting and Transceiver Design Topics** chapters for further discussion of CW keying issues.

For voice modes, a PTT-to-RF output test is similar to CW keying tests. It measures rise and fall times, as well as the on- and off-delay times just as in the CW test. See **Figure 25.55** for the test setup. For SSB the transmitter is modulated with a single 700-Hz tone. For FM the transmitter is unmodulated. The keying generator is set to a speed that

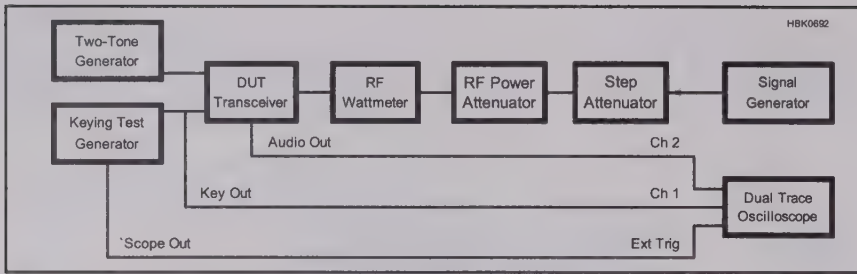

Figure 25.56 — Transmit-receive turnaround time test setup.

allows plenty of time for the transceiver to recover between dits. The ON or OFF delay times are measured from the 50% point of the falling or rising edge of the key out line to the 50% point of the RF waveform.

The transmit-receive turnaround time is the time it takes for a transceiver to switch from the 50% rise time of the key line to 50% rise of audio output. Turnaround time is an important consideration in some digital modes with required turnaround times of less than 50 ms in some cases. The test setup is shown in Figure 25.56. This test requires extreme care to prevent excessive transmitter power from reaching the signal generator and exceeding its specifications. The step attenuator is preset to maximum and gradually decreased until the receiver's S meter reads S9. Receiver AGC is usually on and set for the fastest response for this test but experimentation with AGC and signal input level can reveal surprising variations. As for the PTT-to-RF output test, the transmitter is tuned to full power output with a single 700 Hz tone. The keying rate must be considerably slower than the turnaround time; rates of 200 ms on/200 ms off or faster, have

been used with success in Product Review tests at the ARRL Lab.

### 25.6.2 Other Common Transmitter Measurements

The peak envelope power (PEP) of a 100%-modulated AM signal is four times the average power. For that reason, the specified AM power level of most SSB transmitters is generally about 25% of the PEP SSB power rating.

The modulation percentage can most easily be measured with a wide-band oscilloscope connected to the 50-Ω dummy load. It is OK to exceed the specified bandwidth somewhat as long as a clean signal is displayed since this is a relative measurement only. With 100% modulation, the negative modulation peaks just reach zero signal level and the positive peaks are twice the amplitude of the unmodulated carrier. The exact value can be calculated with the equation,

$$M = 100 \frac{\max - \min}{\max + \min}$$

where M is the modulation percentage, max

is the signal amplitude at the peaks and min is the amplitude at the troughs. An alternative is to use an RF spectrum analyzer. With 100% sine-wave modulation, the two sidebands are each -6 dB with respect to the carrier. In this case,  $M = 100 \times 10^{(S+6)/20}$ , where S is the sideband level with respect to the carrier (a negative number) and M is the modulation percentage.

The equivalent measurement for an FM transmitter is the *deviation*, which is the amount the RF frequency deviates from the center carrier frequency. It is possible to purchase an instrument that measures FM deviation directly; the function is generally included in two-way radio test sets. Another way is to use slope detection with a standard analog spectrum analyzer. Start by choosing a resolution bandwidth (RBW) on the spectrum analyzer such that as you tune away from the unmodulated carrier the signal level changes approximately linearly (the same number of kHz per dB) over at least a 10 kHz range. An RBW of 10 kHz is usually about right. Record the kHz per dB sensitivity value. Then adjust the frequency for the middle of the linear range and set the spectrum analyzer for zero span. With modulation applied to the transmitter, the deviation is equal to one-half the peak-to-peak dB variation of the signal on the screen, times the kHz per dB value determined previously.

Yet another way to measure FM deviation with a spectrum analyzer is to use the fact that the carrier disappears for a modulation index of 2.405, as explained in the **Modulation** chapter. To set the deviation to 3 kHz, for example, apply sine wave modulation at a frequency of  $3.0/2.405 = 1.25$  kHz and adjust the modulation level to null the carrier.

## 25.7 Antenna System Measurements

This section discusses measurements of antenna systems. The antenna system typically includes the antenna along with the transmission line and any other accessories such as switches, filters, matching networks, antenna tuners, and so forth. The instruments and measurements in this section assist with construction and installation, performance assessment, and troubleshooting of the entire antenna system. Related information is available in the **Transmission Lines**, **Antennas**, and **Station Construction** chapters.

### 25.7.1 Field Strength Measurements

To determine how well an antenna is actually radiating, a way to detect the signal level at some distance from the antenna is needed.

For measurements in the vicinity of the antenna, a *field-strength meter*, generally with a built-in antenna, picks up the radiated signal off the air and indicates the level on a meter or display. Professional field-strength meters use a carefully-calibrated antenna and circuitry that can read out the actual radiated signal strength in volts per meter or watts per square meter. Most amateur field-strength meters such as the one shown in Figure 25.57 are not calibrated but give a relative indication only. They are useful for tuning an antenna, antenna tuner, or transmitter for maximum signal as well as for comparing different antennas. A field strength meter is a simple one-evening construction project. Figure 25.58 shows the schematic of a simple field strength meter.<sup>21</sup> (This article is also included in the book's downloadable supplemental material.)

If you have a *reference antenna* (such as a half-wave dipole) that has a known gain, then the gain of a second antenna can be calculated by alternately transmitting with each antenna and measuring the difference in signal level at a receiver whose antenna is located far enough away to be outside the *near field*, typically up to several wavelengths from the antenna under test. At first glance, it seems like this should be an easy measurement to make but in practice there are a number of devilish details that can ruin the measurement accuracy.

The biggest issue is reflections. If there is any significant reflector of RF signals between the transmitting and receiving antennas, the signal comparison may not be accurate if the test and reference antenna patterns are significantly different. Even if there

**Figure 25.57 —**  
The VE7NI field-  
strength meter.

are no wires, bodies of water, fences or other conducting objects in the vicinity, the ground reflection can result in an apparent additional gain of 6 dB or conversely a loss of many dB if the receive antenna happens to be in a null.

At microwave

frequencies it is sometimes possible to use a high-gain, narrow-beamwidth receive antenna and mount the antenna under test high enough so that the ground reflection is outside the receive antenna's beamwidth.<sup>22</sup> At HF frequencies that is rarely possible.

Commercial antenna companies use elaborate *antenna test ranges* that employ various techniques to assure measurement accuracy. Absent a proper test range, the best solution is probably to measure the reference antenna and antenna under test at various heights above ground to get an idea of how much ground reflections are affecting the measurement. [The subject of antenna measurements is addressed by Paul Wade, W1GHZ in his "Microwavelengths" *QST* columns for October 2012 (covering the antenna range) and January 2013 (discussing measurements and equipment).]

The most common way to compare antennas is to ask for signal reports on the air. Unfortunately, propagation is so variable on most amateur bands (fading of more than 20 dB in a few seconds is common) that a signal report gives only a very rough idea of how well your antenna is working, unless it can be compared with another antenna (perhaps at another local amateur's station) at the same time.

An improved method of assessing antenna performance from distant stations is to use one of the automated receiving systems; the *Reverse Beacon Network* or RBN (**reverse-beacon.net** for CW signals), *PSKReporter* (**pskreporter.info** for PSK signals) and *WSPRNet* (**wsprnet.org** for WSPR signals). These systems consist of a worldwide network of independent receivers that decode signals and report the call sign and signal

The samples of induced voltage  $e_i$  and line voltage  $e_v$  sum in the RF detector formed by D and C, producing a voltage that drives the meter. The meter is then switched to display the output of an identical circuit oriented in the opposite direction to pick up the forward components. The meter is then calibrated according to the SWR equation in the text.

strength to a central server. To use the systems for antenna system testing, the server can be queried for comparative signal strengths after switching between antennas or making adjustments.

### 25.7.2 SWR Meters

The modern SWR meter is a descendent of the 1959 "Monimatch," introduced to amateurs by Lew McCoy, W1ICP, and explained by Walter Bruene, W5OLY.<sup>26,27</sup> Additional information about standing wave ratio is provided in the *Transmission Lines* chapter. Directional RF wattmeters are covered in this chapter's section on Measuring RF Power.

**Figure 25.59** shows the schematic of a typical unit. SWR can be computed from forward and reflected power, as shown by the following equation:

$$SWR = \frac{1 + \sqrt{P_R / P_F}}{1 - \sqrt{P_R / P_F}}$$

If voltages representing the two powers are provided, it's straightforward to create a circuit that computes SWR. This is the reason for the CAL (calibration) control on the meter. The meter is set to FWD (indicating the voltage representing forward power), power is applied, and the CAL control adjusted so that the forward power indication is the full-scale value of 1. By assuming  $P_F = 1$  and  $P_R$  is a value between 0 and 1, the equation for SWR simplifies to:

$$SWR = \frac{1 + \sqrt{P_R}}{1 - \sqrt{P_R}}$$

The voltage representing reflected power will always be some fraction of the full-scale voltage, so the meter scale can then be calibrated to read SWR directly, instead of voltage. (An alternative SWR meter design is provided in the *Station Accessories* chapter.)

### THE DIRECTIONAL COUPLER

Inductive and capacitive coupling are used to create a *directional coupler* that can pro-

vide the independent measurement voltages. The coupling provides samples of forward and reflected voltage and current from the undisturbed center conductor of the coaxial feed line. Figure 25.59 shows how voltages representing reflected power are obtained. As described by W5OLY, “A pickup wire placed parallel to the inner conductor samples the line current by inductive coupling. The voltage  $e_i$  induced in the pickup is determined by spacing, length, line current, and frequency. The mechanical dimensions determine the mutual inductance,  $M$ . The induced voltage due to line current is:

$$e_i \approx -j\omega IM = -j2\pi fIM$$

where  $f$  is frequency in Hz and  $j$  represents a phase shift of  $90^\circ$ . This shows that the higher the frequency, the larger the induced voltage.

“The sample of voltage is picked up by capacitive coupling ( $C_{CPLG}$ ) from the inner conductor to the pickup wire. A current due to this capacitance flows through  $R$  and develops a voltage across it; this voltage also increases with frequency because the reactance of the coupling capacitance goes *down* with frequency. That is:

$$e_v = E R / X_C R = ER / -j(1/2\pi fC) = j2\pi fERC$$

when  $X_C$  is much larger than  $R$ .”  $D$  and  $C$  form an RF detector that sums  $e_i$  and  $e_v$ , creating a single voltage proportional to the power in the line.

Since the line current and voltage contain components of both forward and reflected power, the single resulting output voltage also contains components of both. The current and voltage components of reflected power are  $180^\circ$  out-of-phase, compared to those of forward power. So  $e_i$  is added to  $e_v$ , producing a voltage proportional only to reflected power in the figure.

The different polarities of  $e_i$  are obtained by reversing the current sensing pickup. This is accomplished by two identical pickup circuits in the meter;  $e_v$  is the same in both circuits, but the  $e_i$  pickup direction is reversed from one to the other. One circuit produces a voltage proportional only to forward power and the other proportional only to reflected power. Display of forward or reflected power is controlled by the switch that selects which voltage is applied to the meter.

Continuing with a note from W5OLY, “Since the current and voltage pickups both increase with frequency, their ratio will stay the same. The variation in pickup just means that the sensitivity goes down at lower frequencies.” That’s why the CAL adjustment is necessary not only at different power levels, but at different frequencies. The meter scale is calibrated according to the equation for SWR when the calibration adjustment places the voltage representing  $P_F$  at full-scale.

For best performance from a Monimatch type of directional coupler, the value of  $R$  in one of the detector circuits should be adjusted so that the two circuits produce the same value of  $e_i$  for any given current. In addition, balanced detector diodes would also provide better performance at low power levels where the detected voltage level is small enough for variations in the diode forward voltage to introduce significant errors. However, for low-cost equipment, using fixed components is generally “good enough.”

For meters that have been damaged, repair is very simple. The manufacturer calibrated the meter assuming very similar component values. Replace both detector diodes with the same type of diode, preferably from the same batch of components. The diodes can be matched by using a multimeter with a diode test function that displays the diode’s

forward voltage. If one of the original diodes is undamaged, choose a pair of diodes with a similar forward drop.

### 25.7.3 Noise Bridges

The noise bridge includes an adjustable bridge circuit similar to that in Figure 25.35. A wide-band noise generator is connected as the source and a conventional receiver is attached to the Power Meter port as a detector. Tune the receiver to the desired frequency and adjust the resistance and reactance controls for minimum noise in the receiver. If the receiver has a panadapter display, the null frequency can be seen on the screen, speeding the adjustment. Noise bridges are rarely used today in favor of the more convenient antenna analyzers as described in the following section. See the References entry for “The Noise Bridge” by Althouse for a more complete description of how a noise bridge works and how it is used.

### 25.7.4 Antenna Analyzers

Traditionally, amateurs have measured coax-fed antennas using a standing wave ratio (SWR) meter as described above. While often used to determine an antenna’s resonant frequency, the meter can only measure SWR at the point in the feed line where the meter is placed, relative to the SWR meter’s calibrated impedance. The actual SWR on the feed line is determined solely by how well-matched the load or the antenna’s feed point impedance is to the characteristic impedance of the feed line.

Most SWR meters are calibrated for  $50 \Omega$ . Because most transmitters are designed to drive a  $50 \Omega$  load, the measured SWR indicates how closely the feed line impedance matches that of the transmitter output. When the antenna feed point impedance at resonance is not  $50 \Omega$  (for example, a dipole might present  $70\text{--}85 \Omega$  at the feed point), the frequency of minimum indicated SWR will differ by 1–2% from the actual antenna resonant frequency. i.e. Where the feed point resistance is purely resistive.

More information about the impedance can be very helpful in determining antenna resonant frequency and feed point impedance. An RF impedance analyzer capable of measuring both the magnitude and the phase of impedance is often called an *antenna analyzer*, since the most common use by amateurs is for measuring antennas. Such an instrument can obtain more detailed information about the complex impedance versus frequency anywhere in the antenna system.

To keep size and cost to a minimum, portable antenna analyzers usually use a narrow-band source (an internal oscillator) and wide-band detector (a diode). Some units

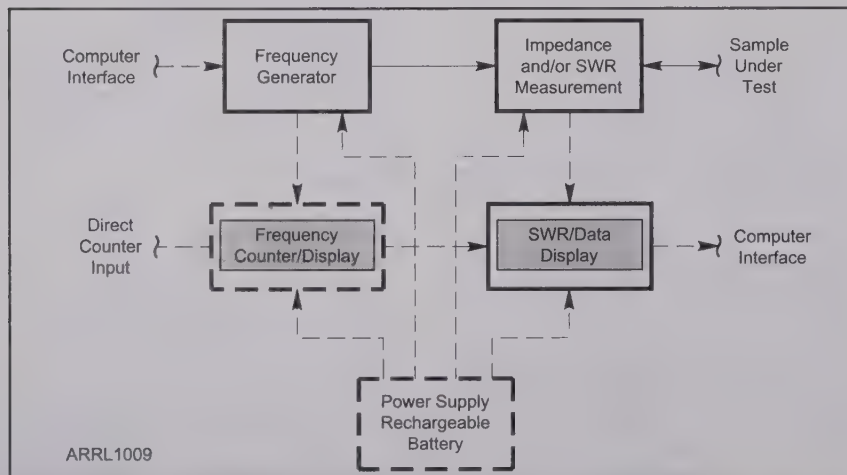

Figure 25.60 — Block diagram showing the elements of typical antenna analyzers. The items shown with dashed lines may not be part of every model.

include a microprocessor and can display SWR, return loss, resistance, reactance, and the magnitude and phase of the impedance. Antenna analyzers suitable for amateur use are available from a number of manufacturers — search for “antenna analyzers” on the Internet to find them.

When shopping for an antenna analyzer, pay careful attention to the capabilities and limitations. Several basic designs are available with tradeoffs between performance and cost. Be aware that some units measure only the SWR or impedance magnitude while others measure both the resistive and reactive parts of the impedance. Some units give the magnitude of the reactance but not the sign, requiring the operator to change frequency a small amount and watch the change in impedance magnitude to determine the sign and thus the type of the impedance, inductive or capacitive.

These analyzers have many more uses than impedance and SWR measurements. Paul Wade, W1GHZ, has contributed the paper “Antenna Analyzer Pet Tricks” in this book’s downloadable supplemental information. It includes how-to guides for a number of useful antenna system measurements.

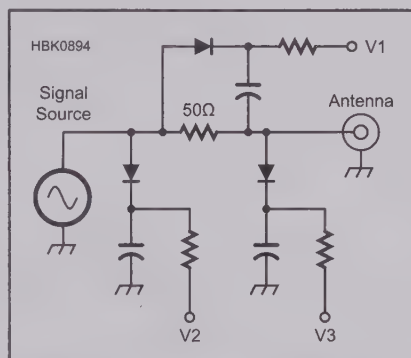

Some users have reported difficulties in obtaining accurate impedance measurements on low-band antennas when there is a nearby AM broadcast station. This is due to the wideband detector responding to the incoming signal from the AM station. Some manufacturers offer external high-pass broadcast-reject filters to allow the analyzers to be used in the presence of these strong

signals. The filter can affect measurements near the broadcast band, particularly in the 3.5 MHz and lower-frequency bands. Check with the filter manufacturer about the limitations of using filters with the analyzer.

### BASIC OPERATION

**Figure 25.60** shows the block diagram of a typical antenna analyzer. The functions in solid lines are required and those in dashed lines are included depending on feature set and price.

**Figure 25.61** shows a relatively simple circuit that uses diodes for detecting voltages corresponding to voltage and current at the external load. This inexpensive circuit is useful but at low signal levels the diodes

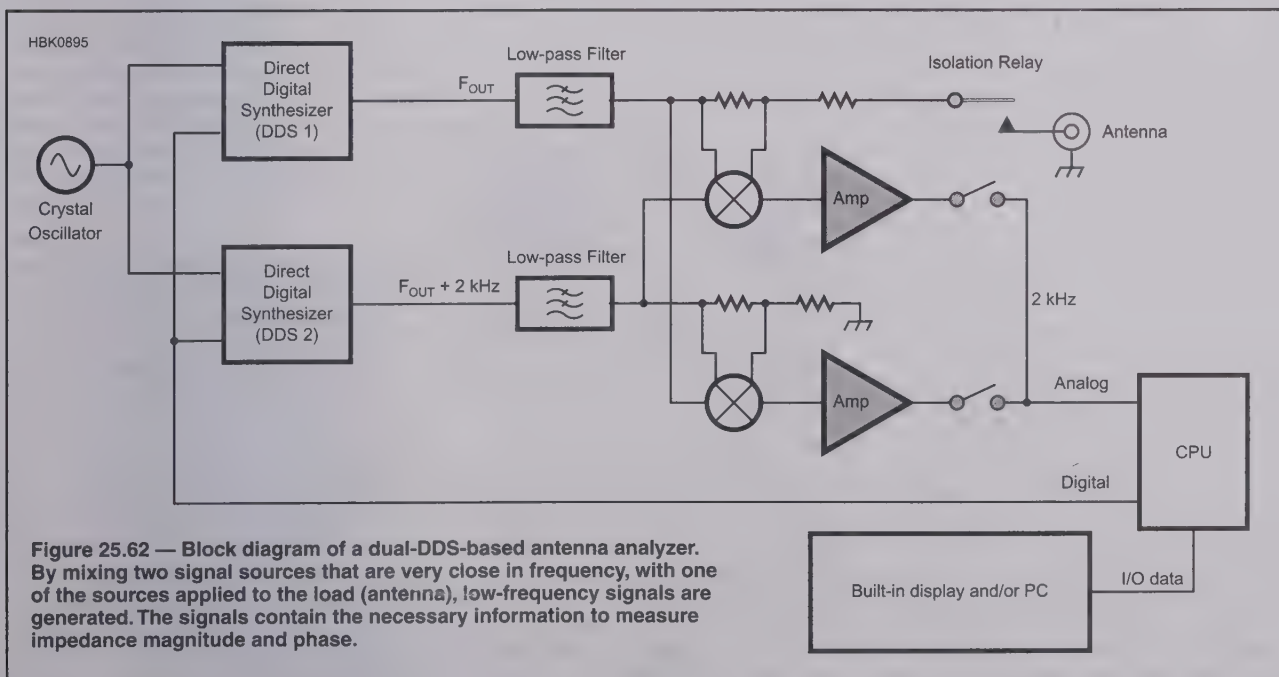

**Figure 25.61** — A relatively diode detector circuit for measuring impedance that gives adequate results for many applications.

introduce some non-linearity and temperature drift which may be an issue. This type of diode detector responds to signals over a wide frequency range and there may be stray pickup from nearby broadcasting stations that makes the measurement results inaccurate.

The rectified voltages can be digitized by a microprocessor and the results displayed numerically. The signal source is typically a varactor-tuned LC oscillator in the “analog” units or a direct digital synthesizer (DDS) in more sophisticated models. The DDS signal source is very stable since it is controlled by a crystal oscillator and it can be set to the desired frequency quickly with a keyboard entry. The DDS version costs somewhat more but compared to the varactor-tuned oscillator, it has significant performance and operating conveniences. (See the **Oscillators and Synthesizers** chapter for information on DDS signal sources.)

For a more detailed analysis of the antenna system, an instrument with a narrowband detector such as for a radio receiver gives much better performance than the broadband diode detector. **Figure 25.62** shows how two DDSs can be used with one applied to the antenna system and the other used as a reference. Typically, the clock oscillator is crystal-controlled for high accuracy. One DDS is programmed to output a signal at the actual test frequency and the other DDS is programmed to a slightly higher frequency in the 1 to 10 kHz range, shown in the figure as 2 kHz. See the reference entry for an article by Michael Knitter, DG5MK, that gives a detailed design description of this type of analyzer.

**Figure 25.62** — Block diagram of a dual-DDS-based antenna analyzer. By mixing two signal sources that are very close in frequency, with one of the sources applied to the load (antenna), low-frequency signals are generated. The signals contain the necessary information to measure impedance magnitude and phase.

The signals are then mixed to produce a low frequency output that can easily digitized by an inexpensive analog to digital converter (ADC). The measurements are then processed mathematically in a microprocessor or PC to yield full information about the complex impedance being measured. This type of analyzer is actually a one-port, swept-frequency impedance meter that measures both the magnitude and phase of a test impedance over a wide range of frequencies. A two-port vector network analyzer (VNA) can also be configured to do one-port swept frequency measurements.

One signal corresponds to the voltage applied to the antenna system and the other signal corresponds to the current flowing in the antenna system. The ratio of these signals is the impedance of the circuit and the difference of their phases is the phase angle of the circuit:

$$\text{Magnitude}(Z) = \text{Magnitude}(V1) / \text{Magnitude}(V2)$$

$$\text{Phase}(Z) = \text{Phase}(V1) - \text{Phase}(V2)$$

The PC shown in the figure can be a desktop computer or a small tablet computer. The tablet provides good portability, but if the size of the screen is too small it may be hard to read. The analyzer is able to generate a lot of data and it's helpful to be able to see as much as possible at one time on one screen, especially when making tuning adjustments. Another tradeoff is the size of the menu buttons on a tablet. If they are too small it may be hard to make menu selections.

Some analyzers can store sets of measurements in a file for review later and transfer to a PC for further processing and display. The standard format for swept impedance data (frequency and impedance) is called *Touchstone* ([en.wikipedia.org/wiki/Touchstone\\_file](http://en.wikipedia.org/wiki/Touchstone_file)). Files in the Touchstone format can be read and processed by a wide variety of software, including as the input to design software.

The most useful analyzers can create a calibration table to automatically correct for imperfections in the analyzer. The calibration process takes data at selected frequencies over the measurement range. This is usually done by sequentially attaching three known loads to the input of the analyzer and running a special calibration routine that saves the data for each load in memory. (See this chapter's section on vector network analyzers.) This process is very quick and easy and the final results of any measurement are much more accurate than from a simple analyzer that does not have a calibration procedure. The calibration is performed with three known loads: a short circuit, an open circuit, and a resistor of known value. The mathematics to apply this correction data is very complex

but the microprocessor does it easily and the user does not have to worry about the details.

The impedance data can be used to calculate several parameters for the antenna system. Using the specified value for the system reference impedance, which can be any value (it doesn't have to be 50 Ω), For example, the reflection coefficient ( $\rho$  or rho) can be calculated as:

$$\rho = (Z_L - Z_0) / (Z_L + Z_0)$$

where  $Z_L$  is the measured impedance of the load and  $Z_0$  is the specified impedance of the transmission line, which can be any value.  $Z_L$  is a complex number; therefore,  $\rho$  is, in general, a complex number with a magnitude between zero and one. Rho is approximately equal to zero when the line is matched to the antenna because there is no reflection, all the transmitter power is absorbed by the antenna. When the antenna is poorly matched to the line,  $\rho$  is larger and it approaches 1 when the mismatch is large.

$$\text{SWR} = (1 + |\rho|) / (1 - |\rho|)$$

Note that SWR only depends on the *magnitude* of  $\rho$  denoted by the vertical bars as  $|\rho|$  so it is not a complex number.

## CALIBRATION

Different test situations may require adapters, interconnecting cables, common-mode chokes, isolation transformers, or filters. The calibration process is able to compensate for the externally connected accessories, so their exact properties are not critical. By placing the calibration loads *after* the external hardware, characteristics of the whole

**Figure 25.63** — A simple choke balun made by winding multiple turns of coax through a ferrite toroid, creating a high-impedance on the shield's outer surface. The choke is made of 12 turns of RG-193 miniature coax through a 2.4-inch OD, Type 31 core (Fair-Rite 2631803802 or Amidon FT-240-31) and is effective from 1.8 through 30 MHz. The best choke should present at least 5,000 Ω of resistive impedance at the measurement frequency.

measurement system can be accounted for in the calibration table. The point at which the calibration loads are attached is called the analyzer's *reference plane*. (See the Agilent application note on vector network analyzers — reference 15.) For example, a filter with a response that is less than perfect can be used as long as it is included in the measurement system during calibration. The effects of the filter on measurements can then be cancelled mathematically.

Most antenna analyzers have a single-ended (unbalanced) output with a coax connector. For making measurements on a two-wire transmission line, such as window line or ladder line, a common-mode choke can be added between the analyzer's RF connector and the input to the transmission line as in **Figure 25.63**. The calibration loads are attached to the output side of this balun so that its imperfections are automatically canceled during the measurement. The measurement results displayed by the analyzer program then correspond to the input to the transmission line itself.

This calibration procedure can be extended to allow measuring the actual driving point impedance of the antenna. The transmission line is disconnected at the antenna, and the calibration loads are attached at the far end instead of the antenna. This shifts the measurement point (the reference plane) to the antenna itself which is handy when designing matching networks. The final result is much more accurate than using a transmission line that is one-half of a wavelength long because the calibration of the analyzer compensates for the transmission line parameters: length, velocity factor and loss.

A word of caution when using an antenna analyzer is in order. These are sensitive instruments with low-power components at their input. They can be damaged by static electricity if care is not exercised. Antennas can collect a significant static charge from rain or wind. Be sure to momentarily ground the transmission line before connecting it to an

## Determining Reactance Type

Some antenna analyzers can show the positive or negative sign of the reactance. Less expensive units may only show a reactance magnitude. To determine whether reactance is inductive or capacitive on a unit that doesn't indicate the sign, make a slight increase in frequency. If the reactance increases, it is inductive, and if reactance decreases, it is capacitive. This is a helpful trick when adjusting antennas with a portable analyzer that doesn't indicate reactance sign.

analyzer to reduce the risk of damage to the sensitive components on the input.

Static buildup can be minimized by providing a dc path between center conductor and the grounded shield for the antenna being measured, offering some protection both for the analyzer and for station equipment. The dc path can be a shunt indicator in the tuning circuit or it can be a large value resistor with a power rating suitable for the transmitter power. (Antennas with elements mounted directly on a grounded boom or support are also dc-grounded.)

Using the analyzer when another transmitter is active can also cause damage if enough signal is picked up by the antenna under test. The analyzer illustrated in Figure 25.62 includes an isolation relay that protects the input when a measurement is not in progress.

### MEASURING COMPONENT VALUES

The antenna analyzer can be used to measure components other than antennas. For example, an inductor can be measured over a wide frequency range to see if it is resonant within the frequency range where it will be used.

Figure 25.64 shows a graph generated from swept-frequency impedance data collected by an antenna analyzer of the type in Figure 25.62. The figure shows the impedance of an air-core inductor with a nominal inductance of 7.4  $\mu\text{H}$  at low frequencies. (The traces are labeled with the measurement they represent.) The self-resonant frequency is 45.4 MHz. This resonance occurs because of the coil's inter-turn capacitance. (See the **RF Techniques** chapter for a discussion of stray and parasitic capacitance.)

Far below the resonant frequency the inductance has a positive reactance and the coil presents its expected value, 7.4  $\mu\text{H}$ . As the test frequency approaches the self-resonant frequency, the parasitic (stray) capacitance that causes self resonance causes the total reactance to increase, so the inductance appears to be larger. At resonance, the impedance is a resistance of high value. Above the self-resonant frequency, the component increasingly looks like a capacitor, as indicated by the negative phase angle.

The analyzer is also very handy for determining the material of a toroid core. Cores of different ferrite or powdered iron mixes cannot be told apart by their physical appearance, but you can sometimes separate them by comparison with a core of known material. Small inductances of one or two turns can be tested side by side to differentiate the cores of different mixes. A single turn through the center of a core or bead will create enough inductance for an accurate measurement on a good analyzer. Be wary of confusing mixes that are designed for EMI suppression with mixes intended for inductive applications.

The permeability of the different mixes has resistive and reactive components that dominate over different frequency ranges. See the discussion of ferrites in the **RF Techniques** chapter for an explanation. Comparison to cores of known material is much more reliable than a simple calculation of  $\mu$  ( $\mu$  —

permeability) or  $A_L$ , the inductance index.

Capacitors are usually closer to the ideal component than inductors, but they do have some inductance in their leads and eventually at some high frequency they too become self-resonant. This self-resonance should be checked for capacitors that will be used in

Figure 25.64 — Example of an antenna analyzer (AIM-4170 and companion software) being used to measure an air-core inductor's behavior. The inductor has a nominal value of 7.4  $\mu\text{H}$  and a self-resonant frequency of 45.4 MHz.

Figure 25.65 — Example of an antenna analyzer (AIM-4170 and companion software) being used to trim a transmission line stub. The cable is being trimmed to get a phase shift of 90° (0.25 wavelengths) at 7.15 MHz. From the current length (where the three curves intersect at the left), cut off 6 feet 6.4 inches (199.1 cm). As the cable is trimmed, the phase plot will move toward the target line at the right.

the VHF/UHF range, and ESR can be critical in power handling circuits. Above the self-resonant frequency, a capacitor looks like an inductor. Depending on their construction, capacitors also have some loss. While the loss may be due to leakage in the dielectric, it is mostly commonly described as an “equivalent series resistance” (ESR), which appears in series with its capacitive reactance. The ESR in most capacitors increases with frequency. (See the **Circuits and Components** chapter.)

Resistors have an effective capacitance in parallel with them as well as inductance in their leads so they are not ideal over a wide frequency range. Physically large power resistors used for dummy loads have larger parasitic components. (Thin-film power resistors in TO-220 packages are available with significantly lower reactance.) Tubular metal and carbon film resistors are often trimmed with a laser to create a spiral track in the deposited film, creating inductance. If the resistor is to be used in an RF circuit, it is prudent to verify its effective frequency range.

## TRANSMISSION LINE MEASUREMENTS

Sections of transmission line can be used to make tuning stubs for antennas as discussed in the **Transmission Lines** chapter. These stubs can be measured with the antenna analyzer as shown in **Figure 25.65** and cut to the proper length for the required phase shift. Some analyzer software can measure phase shift and indicate how much needs to be trimmed to achieve the desired amount. Be cautious when using this information to make large changes in line length. Because VF varies with frequency (see the section Effect of Velocity Factor), stubs should be measured as close as practical to the frequency at which they are intended to operate. (The highest accuracy is achieved by computing the frequency nearest the operating frequency at which the stub should look like a short circuit at that frequency.)

As discussed in the next section on time domain reflectometry (TDR), some analyzers have a software feature called *Distance to Fault*. This measures the length of a transmission line to any point(s) along the line where the impedance differs from its characteristic impedance ( $Z_0$ ). The “different impedance” can be an open or short circuit, the point at which an antenna is connected, or it can be some small change in the impedance such as that which occurs at a connector, or is the result of damage to the cable. With the best TDR systems, the line can be accurately measured with or without an antenna connected.

If the line is disconnected from the antenna, the distance to fault is the total length of the line. If the line has been damaged somewhere

this measurement gives you an idea where the damage is, which is very handy when the line is buried or otherwise requires special access. TDR can also locate impedance discontinuities or other changes in the line’s characteristic impedance.

To measure transmission line loss with an antenna analyzer, a calibrated mismatch is often used. This method is described in the **Transmission Lines** chapter section on Transmission Line Loss.

## 25.7.5 Time-Domain Reflectometry

*Time domain reflectometry* (TDR) shows what happens to a short, abrupt pulse as it travels through a transmission line. The pulse is reflected by any changes in impedance, such as an open or short (complete reflection) or a change in the line’s characteristic impedance (partial reflection). The resulting series of pulses and reflections is displayed as a sequence in time, thus the name of the technique.

In an ideal transmission line terminated by its characteristic impedance,  $Z_0$ , the pulse will travel to the far end and be dissipated in the termination, so the trace will be a perfectly flat line. But at any point along the line where the impedance changes (called a *discontinuity*) some of the pulse’s energy will be reflected back toward the line’s input. The reflected component of the pulse creates an artifact (visually, a “bump”) on the otherwise straight line.

The sequence of pulses and their reflections is the *impulse response* of the line. An *impulse* is basically a very short pulse that begins and ends before the system can respond and stabilize. A mathematical impulse is an

infinitely-narrow made up of all frequencies from zero to infinity.

While it is not possible to create an ideal (perfect) impulse, a very fast rising edge of a longer pulse is a good enough approximation to measure the line’s impulse response and the same information can be measured. The longer pulse is called a *step function*. The ideal step function is an infinitely fast change from one level to another, after which it remains at that level. The response of the line to this longer pulse is called the *step response*. Like the impulse, the infinitely fast change in level also contains all frequencies.

A *time domain reflectometer* is the instrument that generates the pulse and displays the results. A TDR displays amplitude (voltage) on the vertical axis and time on the horizontal axis. The position of each artifact along the TDR trace corresponds to the distance from the transmission line input to the discontinuity that produced it. Large discontinuities occur when a line is open-circuited or short-circuited, or when it is connected to an antenna. (Most antennas are matched to the line at their operating frequency, but at other frequencies they are not. Since the pulse contains all frequencies, an antenna is a large discontinuity.) Small discontinuities occur at splices or when a line is damaged.

The delay between the input pulse’s rising edge and the artifact is the round-trip time of the line from the TDR to the discontinuity. If the line’s velocity of propagation (VF) is known, the physical distance from the input to the discontinuity can be calculated. The shape of each reflection can sometimes provide a clue as to the nature of the discontinuity.

In this sense, the TDR is very much like a radar display in which a pulse is transmitted

**Figure 25.66** — Example of a direct method TDR (see text) connected to a length of RG-58 coaxial cable (50  $\Omega$  impedance) followed by a short length of 75  $\Omega$  RG-59 and a 100  $\Omega$  load. The discontinuities are clearly shown as the reflections add to the input pulse.

shown at the center on a radar display) and any echoes from discontinuities in the air (i.e. targets) reflect some of the pulse back toward the transmitter. The farther away the target, the longer it takes for the pulse to travel to the target and back to the receiver. A radar screen shows echoes from all directions. The TDR only shows echoes from one direction, along the line. The larger the echo, the larger the target or discontinuity.

The usefulness of TDR is not limited to RF systems. Some of the first uses of TDR were for finding faults in cabling systems carrying all sorts of signals, including ordinary telephone lines, and it is still widely used for that purpose.

## DIRECT METHOD TDR

There are two common TDR implementations, with variations of both. In the “direct method,” which is the oldest and simplest, the line is driven by a pulse. This can be a single pulse, or it may be a train of pulses like a square wave.

The pulse and all of the reflections are displayed on an oscilloscope trace that is triggered by the pulse’s rising edge. The rise time of the pulse must be much shorter than the round-trip time for the impulse to travel to and from the discontinuity. **Figure 25.66** shows an example of a direct method TDR with the pulse generator and cable attached to the oscilloscope which is displaying the pulse.

Although a digital scope can capture a single pulse and its reflections, making the pulse repetitive means that multiple responses can be averaged to improve the signal-to-noise ratio. The signal-to-noise ratio of a system excited by a single pulse can be rather limited. Repeated pulses also sustain the trace so the operator to see it if the scope is an analog model. The repetition rate of the pulse must be much slower than it takes for the impulse to make a complete round trip through the line, however. This insures the line’s response dies out completely before the next pulse excites the line again. See the reference article by King about this type of TDR and the *ARRL Antenna Book* also includes material on TDR.

Modern antenna analyzers can use the direct method, as well. For example, the AIM family of analyzers, designed by WSBIG and sold by Array Solutions ([www.array-solutions.com](http://www.array-solutions.com)), excite the line with a step function waveform having a very fast rise time. This implementation provides a display of the impedance at every point on the line — it can, for example, show the relative impedance of cables having different  $Z_0$ , as well as the position of discontinuities. **Figure 25.66** shows a TDR display from an AIM analyzer connected to a length of RG-58 (50  $\Omega$  cable), a short length of RG-59 (75  $\Omega$ ), and a 100  $\Omega$  load. The discontinuities at the cable and load transitions are clearly shown. Software con-

verts the raw data from the pulse amplitudes into impedance and the time is converted into distance along the line.

The TDR function can be used to determine if the line has been degraded, for example, by water leaking into the coax or if the line has been shorted or cut somewhere between the transmitter and the antenna. Damage or defects can be located within a few inches and this reduces the effort required to repair the line. Defective connectors can also be indicated by short glitches in the trace corresponding to the location of the connectors.

## TRANSFORM METHOD TDR

The other common implementation could be described as the “transform method.” Instead of determining the impulse response of the cable with a pulse, the excitation is a sine wave swept over a range of frequencies and the analyzer captures the *frequency response*. An inverse Fourier Transform (see the chapter on **Digital Signal Processing**) is performed on that frequency response, producing the time-domain response. (Frequency and time are the inverse of each other; the complete frequency response of a system contains its time response and the response to an ideal impulse contains the frequency response. A Fourier Transform (FFT) of the time response provides the frequency response, an Inverse FFT of the frequency response provides the time response.)

Some antenna analyzers and vector network analyzers use this method. (Several well-suited for amateur use can be found by an Internet search for “vector antenna analyzer” or “vector network analyzer.”) One example is the handheld SARK-110 vector

impedance antenna analyzer ([www.steppir.com](http://www.steppir.com)) The sine wave exciting the cable need not be a continuous sweep — rather, it can be stepped over a wide range of frequencies and the frequency response is computed from that data. Sweep range, spacing between data points, and the settling time at each data point are set by the user.

An inverse Fourier Transform produces spurious artifacts which must be removed by applying a mathematical windowing function to the transformed data. Several mathematically different windowing functions are commonly used, and which of the windows provides the most useful display depends on the shape of the impulse response.

The frequency content of the excitation strongly influences the degree of detail that the measurement can reveal. When the excitation is an impulse, a very fast rise time reveals greater detail. When the excitation is a swept sine wave, a wider frequency range reveals the greatest detail. Currently available analyzers can sweep from 1 kHz to more than 1 GHz.

For TDR studies using the sweep method, a sweep from 5 to 500 MHz (or from 500 MHz to 1 GHz) will clearly show detail that would be missed with a sweep to only 100 MHz, while a 5 MHz to 1GHz sweep may provide too much detail (or show discontinuities that don’t matter below 50 MHz). Beginning the sweep in the HF range avoids smearing of the data due to the variation of VF with frequency (see section Effect of Velocity Factor).

## EXAMPLES OF USING THE TRANSFORM METHOD

**Figure 25.67** is the impulse response of the feed line for a 30 meter half-wave dipole at

**Figure 25.67** — The impulse response of a feed line attached to a 30 meter dipole. The system is swept from 50 to 500 MHz. See text for an explanation of the markers.

a height of 100 feet, computed from a sweep over the range of 50 to 500 MHz. Marker 1 shows the effect of lightning protectors at the station entry bulkhead. Marker 2 is a coax splice (two PL-259s and a PL-258 double-receptacle). Markers 3, 4, and 5 are coax defects. Marker 6 is the antenna feed point. Marker 7 is the end of the antenna (displayed distances are for the feed line, so for the antenna are divided by 0.795) the peak at Marker 8 is unexplained, but most TDR sweeps show multiple reflections after the antenna.

Figure 25.68 is the step response (similar to that from the direct method shown in Figure 25.66) computed from the same sweep as that used for Figure 25.67. The data revealed (and a visual inspection confirmed) that the cable inside the shack and from the bulkhead to the

coax splice is 50 Ω, but that the cable from there to the antenna is 75 Ω.

TDR measures time; to convert that measurement to physical distance, we must provide the velocity factor. The 75 Ω cable is Belden 8213, this sample of which has a measured VF of 0.795 at VHF. The 50 Ω cable has a measured VF of 0.8425 at VHF. In the setup screen for this TDR measurement, VF was set at 0.795, so distance measurements will be correct for the 75 Ω cable, but wrong for the 50 Ω cable. Computed results could be made correct for the 50 Ω cable by changing VF in that setup screen, or by leaving VF at 0.795 and applying a correction factor of (0.8425/0.795) to the dimensions of the 50 Ω cable.

## THE EFFECT OF VELOCITY FACTOR

The velocity of propagation in any transmission line is not constant — it varies with frequency. At the lowest audio frequencies, the velocity factor (VF) is quite a bit lower than the published specification, rising rapidly throughout the audio spectrum, continuing to increase through the radio spectrum until it reaches a nearly constant value in the VHF range. It is this constant value that is computed by simple equations for VF that don't take frequency into account.

For most cables, VF at 2 MHz is typically 1-2% slower than this constant value. In other words, an actual transmission line is 1-2% longer electrically than using the "nominal" (VHF) value that the simplified

## Transforming Analyzer Data

Like the trace on a simple oscilloscope, the TDR plot of the impulse response contains all frequencies (or the range of frequencies if it is transformed from a sweep). The scope and the TDR plot are "frequency blind" — that is, they display information only about the time response, and no information about the frequency response.

An impulse or sweep measurement can, theoretically, be manipulated mathematically to compute the impedance at every point in the line over the same range of frequencies. The precision of that computation and whether it is practical, depends on how the data is gathered (sweep rate, sweep range, spacing of data points) and the software tools available. Frequency sweep ranges chosen for TDR may be inappropriate for examination of other line properties.

Free software such as *SimSmith* ([www.ae6ty.com/smith\\_charts.html](http://www.ae6ty.com/smith_charts.html)) and *ZPlots* ([ac6la.com/zplots.html](http://ac6la.com/zplots.html)) can accept swept measurements made at discrete frequencies to compute and plot the impedance at any point on a line if the characteristics of the line are known. Data is interchanged between a measurement device and software programs (and between one software program and another) by means of a plain text file. These files, defined by the Touchstone format (see text) can take several forms that are defined by the first line(s), called a "header." The filename extension indicates the type of measurements: .s1p files describe single port measurements, like impedance or a time response and .s2p files describe two-port measurements such as the S21 (gain) transfer function produced by a vector network analyzer.

Figure 25.68 — The step response similar to the direct method for the same antenna system in Figure 25.10. See text for an explanation of the graph.

Figure 25.69 — VF and characteristic impedance for an RG-11 cable computed by *ZPlots* software from a swept-frequency measurement. See text.

equation for VF predicts. Because of this change, the physical length of a stub for the lower frequency bands is 1-2% shorter than predicted from the specified value.

When using software to transform antenna measurements made in the station to the actual impedance at the feed point, the variability of VF must be applied to data for antennas for the lower bands (14 MHz and below). AC6LA's free *Zplots* shareware (based on *Excel* spreadsheets, see [ac6la.com/zplots.html](http://ac6la.com/zplots.html)) computes and plots VF,  $Z_0$ , and attenuation versus frequency from measurements of a known length of a transmission made with the far end open and with the far

end shorted. *ZPlots* can accept data in the Touchstone format discussed earlier.

**Figure 25.69** is a plot of VF and attenuation computed by *ZPlots* from such measurements on a 176 foot length of RG-11 cable with a #14 AWG solid copper center conductor, a foam dielectric, and a copper braid shield. This behavior and general curve shape are typical of all transmission lines as predicted by fundamental transmission line equations. Exact values for each line will differ based on their physical dimensions and their dielectric.

It should also be noted that  $Z_0$  also varies

with frequency and below VHF is complex—that is, not a pure resistance, and is slightly capacitive. The *TLW* program (*Transmission Lines for Windows* by N6BV), included with the *ARRL Antenna Book*, provides  $Z_0$  data for most commonly used cables, and can plot voltage and current along the line. These plots clearly show standing waves on a line at 2 MHz when the termination is only resistive. The mismatch is small and the effect on attenuation is insignificant, but it clearly shows up in carefully made measurements of long cable lengths over a range of frequencies as a small ripple in attenuation values.

## 25.8 Miscellaneous Measurements

While receiver and transmitter measurements are perhaps the type of testing most associated with Amateur Radio, the home experimenter will have occasion to do other measurements as well.

### 25.8.1 Testing Digital Circuitry

Virtually every electronic device these days includes digital circuitry. Even a simple QRP transceiver usually either includes or is used with a digital keyer and it may include other digital circuitry, such as a display, as well. A multimeter is generally of little use for testing digital circuits because it cannot respond fast enough to indicate the high and low transitions.

An oscilloscope is a very useful tool because it gives a visual display of the digital signal versus time. It can show impairments such as transient glitches, overshoot, slow rise times, and high or low logic levels that are out of spec. A scope with at least two channels is greatly desired because you often need to see the time relationships between different signals. A separate external trigger input is also very useful for the same reason. The oscilloscope's bandwidth must be high enough to accurately display the signals to be tested. Bandwidths in the GHz range are needed for state-of-the-art digital circuitry, but 100 MHz should be adequate for most needs.

A hand-held *logic probe* is a device that indicates whether a circuit node is high, low or toggling in between the two states (even with very narrow pulses). While it does not give as much information as an oscilloscope, it is much smaller, cheaper and easier to use. In many cases it is all that is needed to troubleshoot a circuit of moderate complexity. For example, many circuit faults result in a "stuck bit" that remains high or low all the time, which is easy to detect with a logic probe.

Typically the logic probe has two wires with clip leads on the ends that connect to the ground and power supply of the circuit under test. The operator then touches the probe tip to the point to be tested and LEDs light up to indicate the logic state.

At the other end of the complexity spectrum is the *logic analyzer*. This is typically the size of an oscilloscope with one or more external pods that can connect to dozens or hundreds of circuit nodes at the same time. Models that use an external digitizing pod and connect to a PC via USB are also available.

A graphics screen shows individual signals with an oscilloscope-like display or multiple signals can be treated as a bus, with the display reading out the values as a series of hexadecimal numbers versus time. Unlike an oscilloscope, a logic analyzer does not indicate actual voltage levels, but only whether a signal is high or low and the timing of the transitions. Sophisticated triggering modes allow synchronization to various clocks or data patterns. Usually a large on-board memory allows capturing long data traces for display or later analysis. Some models include a pattern generator to generate a long series of multi-bit test vectors. Logic analyzers are quite expensive to buy new but are commonly available on the surplus market.

### 25.8.2 Service Monitors

A *service monitor* is a "one-box tester" for transceivers. It includes a signal generator for testing the receiver and a spectrum analyzer for testing the transmitter, using the same RF connector so that only one connection to the transceiver's antenna jack is required. Other common features are an RF wattmeter and dummy load, a frequency counter, an FM deviation meter, audio tone generators to connect to the microphone, and an audio voltmeter and distortion analyzer/SINAD meter

to connect to the speaker output. Some units contain additional features such as DTMF (touch-tone) and CTCSS (sub-audible tone) generators, an audio frequency counter and adjacent-channel power (ACP) measurement capability.

Older service monitors found on the surplus market were designed for testing analog two-way radios and repeaters. Many are portable for easy transportation to a mountaintop repeater site. Later units may be more oriented to testing cellular telephone base stations. Modern instruments cover the latest digital modes, with bit error rate (BER) testers for the receiver and various modulation quality tests for the transmitter.

While all the functions of a service monitor are available in separate instruments, having everything integrated in one box is more convenient and allows faster testing, which is something a commercial enterprise is willing to pay extra for. A brand-new service monitor is not inexpensive, but older used units made by such companies as Singer-Gertsch, Cushman and IFR that are suitable for testing analog radios can sometimes be found for reasonable prices.

### 25.8.3 Testing Digital Modulation

As digital modulation modes become more and more important in Amateur Radio, it is increasingly important to have ways of testing the performance. There are dozens of different digital formats in use, from traditional radio teletyping (RTTY) using frequency-shift keying (FSK) to the latest systems that employ sophisticated error detection and correction along with various modulation types that pack multiple bits into each symbol. Despite the wide differences in modulation and coding, nearly all have in common a relatively-narrow bandwidth suitable for

use with a voice transceiver using SSB or FM modulation.

If you're having trouble with reception or transmission of digital signals using a PC sound card, one straightforward troubleshooting technique is to install the software on two computers and see if you can transmit data from one computer to the other by connecting the sound card output of one to the input of the other and vice versa. If you don't get perfect reception, that indicates a problem with the computer software or hardware.

The next step is to transmit into a dummy load and receive the signal with a separate receiver located close by so it picks up the stray radiation from the dummy load. A piece of wire plugged into the receiver antenna connector can be moved around to adjust the signal level. Many software programs for receiving digital signals include a spectrum display, which can indicate faults in the transmitted signal such as distortion and *skew*, the amplitude imbalance among the tones of a multi-tone modulation signal. To see what the signal is supposed to look like, connect the two computers directly, as previously described. Then when you examine the RF signal transmitted into the dummy load, any additional bandwidth due to distortion or skew in the spectrum shape should be apparent.

If the demodulation software does not include a spectrum display, there are separate programs available that can display the spectrum of the signal at the sound-card input, as discussed in the Spectrum Analyzer section of this chapter. An RF spectrum analyzer measuring the RF output signal directly would give an even better idea of modulation quality because it is not affected by the filters and other circuitry of the receiver. A receiver panadapter as described earlier is a less-expensive substitute.

Comprehensive testing of a digital communications system is quite complicated because of all the variables involved. The *bit error ratio* (BER) is the number of single-bit errors divided by the number of bits sent in a certain time interval. It requires special test equipment to measure because the individual bits are typically decoded deep inside the demodulation software where they are difficult to access. The *packet error ratio* (PER) is easier to measure. In a packetized data system it is the number of incorrect packets divided by the number of packets sent. It can be measured either before or after error correction. In a non-packetized system like PSK31 the character error ratio is a useful figure of merit. BER is affected by the signal-to-noise ratio (SNR), interference, distortion, synchronization errors and multipath fading. PER is further affected by the effectiveness

of the coding and error correction of the particular digital mode used.

It is interesting to measure BER or PER as a function of the SNR. For some digital systems with lots of error correction the errors are nearly zero down to a certain signal level and then degrade very sharply below that. However, in real-world operation the SNR is almost never constant. The signal is constantly changing, both in amplitude and phase, as propagation changes due to movement of the ionosphere (on HF) or of the vehicle (VHF and above), as explained in the **Propagation of Radio Signals** chapter. Measuring actual on-the-air performance is not a good way to compare systems because propagation varies so much at different times. For a repeatable test, you need a *channel simulator*, which is a device that intentionally degrades a test signal in a precise way as to simulate an over-the-air radio channel. Moe Wheatley, AE4JY offers a free software HF channel simulator which can be downloaded from the Internet.<sup>23</sup> A hardware HF channel simulator has been described by Johann B Forrer, KC7WW.<sup>24</sup>

### 25.8.4 Software-Based Test Equipment

Most amateurs these days own a personal computer with a powerful microprocessor, tons of memory and mass data storage, a large color display and a sound card that provides stereo high-fidelity audio input/output. It doesn't take a great deal of imagination to realize that these resources can be harnessed to make low-cost measuring instruments of various types.

Audio-frequency instruments can be implemented directly using the computer sound card, which typically has a frequency response from perhaps 50 Hz up to about 20 kHz. While computer sound cards can be quite useful for measurement, the low-cost sound cards built into computers may not have good noise performance. They may also distort at levels near their rated output. It is good practice to keep their output level at least 6 dB below rated output to minimize distortion on signal peaks. Signal levels should also be set so that the lowest amplitude components are at least 10 dB above the noise floor.

Inexpensive (less than \$100) USB sound cards made for use in semi-pro recording studios have better quality than most, and work well in ham applications such as computer-to-radio interfaces for digital modes. Because these products are made for a mass market, models tend to be updated every year or two, but the quality brands tend to offer stable designs. Careful testing has found older models made by Tascam and Numark to work well

for digital modes.

Free software is available on the Internet for instruments such as audio function generators, DTMF and CTCSS tone generators, DTMF and CTCSS decoders, two-tone generators for SSB transmitter testing, distortion/SINAD analyzers, oscilloscopes and audio spectrum analyzers. In addition to the frequency-response limitations of a typical sound card, another issue is that the device can be damaged by applying excessive voltage to the inputs or outputs. It is wise to add external buffer amplifiers that include over-voltage protection.

Radio-frequency test equipment can also use the sound card inputs by means of some type of frequency converter, consisting of a local oscillator and mixer. If the mixer is a quadrature type, the two outputs may be fed to the stereo sound card inputs so that software can treat the left and right channels as the in-phase and quadrature signals. A common application is a narrow-band RF spectrum analyzer. The RF bandwidth is typically limited to twice the sound card's audio bandwidth. Low-cost hardware is available in kit form that can be used with free software downloaded from the Internet.<sup>25</sup>

One problem with using a sound card is that the signals may be susceptible to ground loops and radio-frequency interference (RFI). Since the computer and the device under test are grounded separately to the ac power system, hum and noise can be generated from currents flowing in the ground connection between the two. It is helpful to use a short, low-resistance ground connection between the sound card and the device under test. It is also possible to use isolation transformers or differential amplifiers to isolate the grounds and thus break the ground loop. Good quality cables and attention to proper shielding and grounding help prevent hum and noise pickup.

It is always good practice to bond together the chassis or shielding enclosure of every piece of equipment in a system with short, heavy copper wires (#14 AWG or larger). Failure to do so often results in hum, buzz, and RFI being introduced into the signals and data. For the same reasons, all interconnected equipment should be powered from the same ac outlet or from outlets that share the same 'green wire' (that is, they plug into the same multiple wall outlet box). If the equipment is powered from different outlets, the green wires of those outlet boxes should be bonded together. Good quality cables and attention to proper shielding help prevent hum, buzz, noise, and RFI. (See the discussions of bonding in the **Safety** and **RF Interference** chapters.)

# 25.9 Construction Projects

## 25.9.1 Bipolar Transistor Tester

Here is a basic “good/bad” tester for bipolar transistors, designed by Alan Bloom, N1AL. This tester is small enough to carry in your pocket to a flea market (Figure 25.70). A printed-circuit board is available from FAR Circuits ([www.farcircuits.net](http://www.farcircuits.net)) but the simple circuit can easily be hand-wired on perfboard. (Printed-circuit board layout graphics are also available with the downloadable supplemental content.)

To test an unknown NPN or PNP transistor, just remove the tester’s working NPN or PNP transistor from its socket and replace it with the device to be tested. If you hear a tone in the headphones the transistor is good, otherwise it is bad. More elaborate instruments can measure various transistor parameters such as current gain, breakdown voltage and high-frequency performance, however this simple tester suffices in most situations. It is rare for a transistor to be damaged in such a way that it still works but no longer meets its specifications.

When testing a batch of transistors of unknown condition you can use this tester to quickly sort them into a “good” and a “bad” pile and be fairly confident that the ones in the “good” pile are working correctly.

Metal-can TO-5 transistors are shown here, but small plastic transistors work just as well if you bend the leads a little. The TO-5 parts can be pressed down flat against the socket and so are less likely to fall out in a pocket.

The circuit in Figure 25.71 is simply two transistors connected with positive feedback through a frequency-selective network, forming an oscillator at a frequency of approximately 500 Hz. Each transistor is configured for a voltage gain of about 2.0 and the feedback network has a gain of about 1/3, so that the total loop gain is a little greater than unity, the condition required for oscillation.

It should be nearly impossible to damage an unknown transistor by plugging it in wrong or into the wrong socket because the supply voltage is less than the base-emitter breakdown voltage of a bipolar transistor and the current is limited to a few milliamps. No on/off switch is included; simply unplug the headphones when you’re done testing.

The prototype was built in an Altoids tin, as shown in Figure 25.72, but any handy enclosure would do. You’ll need four mounting holes for the circuit board and two clearance holes for the transistor sockets. The headphone jack is best mounted on the side of the enclosure. If such a shallow enclosure is used, line the inside bottom with some insulating material such as electrical tape.

Figure 25.72— Mounting of the circuit board inside the case.

Figure 25.73 — A logic probe is small and easy to use.

All components are mounted on the top side of the printed circuit board except the battery clips and the headphone jack, which go on the bottom. Leave a little extra lead length on the two 0.1  $\mu\text{F}$  capacitors if they need to be bent over to clear the enclosure cover. The PC board from FAR Circuits does not have plated-through holes, so the leads of R5 and R6 must be soldered on both sides.

The transistor sockets are designed for TO-5 metal-can transistors but the smaller TO-18 or TO-92 plastic-cased devices can also be tested by bending the leads to fit. Nearly all TO-92 bipolar transistors have the base lead in the middle. Bend the center (base) lead toward the flat side of the transistor body, spread the three leads a little, and it should plug right in. Additional solder pads are provided for the base, emitter and collector of each transistor in case you wish to wire up additional sockets for other case types such as TO-220 or TO-3 power transistors. A transistor cross-reference guide is also handy to have to determine lead assignments.

### 25.9.2 Logic Probe

This simple logic probe (Figure 25.73) was designed by Alan Bloom, NIAL. It works with several different logic types, including TTL, 5 V CMOS and 3.3 V CMOS. A printed circuit board is available from FAR Circuits at [www.farcircuits.net](http://www.farcircuits.net) or the simple circuit may be hand-wired on perf-board. (Printed-circuit board layout graphics are also available with the downloadable

supplemental content.)

The purpose of a logic probe is to indicate whether signals are present at various circuit nodes. That's most of what troubleshooting a simple digital circuit requires. The probe has indicators to show whether the signal is high, low or toggling between the two states. It doesn't give as much information as an oscilloscope or logic analyzer but it is much smaller, cheaper and easier to use.

### CIRCUIT OPERATION

This logic probe features a seven-segment LED display that forms letters to indicate the state of the signal at the probe's tip. A capital "L" is displayed if the signal is low and "H" if the signal is high. If it is toggling between low and high with roughly a 50% duty factor, the letter "B" is displayed to indicate that "Both" high and low are present. If the signal is mostly low with short-duration positive pulses, then a "C" is displayed. If the signal is mostly high with low-going pulses, the LED indicates an "A". "C" and "A" can be remembered as Cathode (mostly low) and Anode (mostly high), respectively.

The circuit is shown in Figure 25.74. Each of the common-anode seven-segment LED display segments is lit when its pin is low. The 74ACT04 inverters are arranged so that a continuous low input signal lights up the proper segments to form an "L" and a continuous high forms an "H". The 74LS122 retriggerable multivibrator outputs a 33-ms pulse whenever there is a positive-going transition on its B2 input. Repetitive transitions

with a period less than about 33 ms (30 Hz or greater) assert the 74LS122 output continuously, which causes the top segment to light. If the signal is mostly low, the "L" turns into a "C" and if the signal is mostly high, the "H" turns into an "A".

### CONSTRUCTION

The logic probe can be built in a plastic spice jar as in Figure 25.75 but any clear plastic container big enough to accommodate the 1.2  $\times$  3.5-inch printed-circuit board would also work. Batteries B1 and B2 and the test lead jack, J1, are mounted on the bottom side; all other components are on the top. Place a piece of tape under the top terminal of B3 to keep it from shorting to the ground plane. The PC board from FAR Circuits does not have plated-through holes so at least the following must be soldered on both sides: R5, R6, R8, B1 and B3 (inner contacts), U2 pins 1 and 14, and U3 pins 1, 2, 3, 7 and 11. Also solder a wire to both sides of the via hole to the left of pin 1 of the display (U1). If you wish, you can use a socket for the LED display to raise it up higher, but don't use sockets for U2 and U3 since some of their leads must be soldered on both sides. Note that the L-brackets that attach the board to the bottle cap have a long and a short side. The long side is placed against the board.

The socket for the probe is a standard 0.08 inch diameter tip jack. The probe is just a nail soldered into the end of a mating tip plug. You can also use a standard test lead plugged into the jack. The component labeled "J2" on the

### USING THE LOGIC PROBE

The probe includes a self-contained, battery-operated power supply so only the ground lead needs to be connected to circuit ground.

It's amazing how much useful information you can get from such a simple device. One of the most common faults in a digital circuit is a node that is "stuck" low or high due to a short circuit or a faulty component. The logic probe is perfect for detecting that condition.

You can also get a rough idea of what percentage of time the signal is low or high by looking at the relative brightness of the segments. If the signal is low 100% of the time, an "L" is displayed. If there are narrow positive pulses, a "C" is shown. As the pulse width increases, the center and the two right segments start to glow dimly, finally forming a "B" when the duty factor is near 50%. As the duty factor increases further, the bottom segment dims, eventually turning the "B" into an "A". And finally, if the signal is high 100% of the time, the top segment goes out, leaving an "H".

### 25.9.3 Inductance Tester

Many inexpensive DVMs offer a capacitance measurement feature but measuring inductance is much less common. This project describes a simple test fixture for using a signal generator to measure inductance. It was originally published as "Mystery Inductor Box," by Robert J. Rogers, WA1PIO, in the January 2011 issue of *QST*.

### MEASURING INDUCTANCE

One way to measure the value of an inductor is to connect it in parallel with a known capacitance and measure the resulting resonant frequency. In the past, grid-dip oscillators (GDO) have been used to determine the resonant frequency of such parallel tuned circuits. (See the project "Gate-Dip Oscillator" elsewhere in this section.) Using a dip oscillator, a dip, or drop in meter current was noted at the point of resonance.

This test fixture provides a convenient substitute for the dip meter method. A separate signal generator is used to provide the needed signal source and switched internal capacitors are used to resonate the inductors. An internal meter is provided as is a port for an external detector to indicate resonance. The schematic with parts list is shown in Figure 25.76.

### BUILDING THE BOX

Figure 25.77 shows the layout of the internal components. Construction is straightforward with no critical dimensions or layout requirements. The 470-Ω resistor is used to

Figure 25.75 — The logic probe was built into a spice bottle.

provide a better peak in the voltage seen at resonance by the oscilloscope or meter movement. Most of the generator voltage will appear across this resistor until the point of resonance when the highest fraction of the applied signal voltage will then appear across the parallel circuit.

An oscilloscope is connected to the right BNC connector and its high input impedance, typically 1 MΩ, will not load the parallel tuned circuit at the relatively low frequen-

cies used with this test fixture. Instead of the oscilloscope, the internal meter movement may be used to give a peak indication at resonance. Large capacitance values were used to minimize the effects of lead length, a concern while operating test equipment at higher frequencies.

### USING THE TEST FIXTURE

The test fixture can be used to accurately determine the value of inductors in the mH

and μH range. Selecting the 0.01 μF capacitor allows measurement of inductors in the μH range using a signal generator with a 159 kHz to 5 MHz output. Selecting the 0.22 μF capacitor measures larger mH-range inductors using signal generator frequencies in the 1 to 34 kHz region.

Figure 25.78 shows a typical test setup using the built-in meter as the peak indicator. A signal generator's sine wave output is connected to J1, the input BNC connector, and the unknown inductor to the terminal posts. Select one of the capacitors with the switch. Connect an oscilloscope to J2, the output BNC connector, or use the built-in meter. Adjust the signal generator output to give some indication on the meter. Adjust the frequency of the signal generator until a peak is obtained on the oscilloscope or meter.

If the switch is in the wrong position, there will not be a sharp peak in the voltage seen by the oscilloscope or built-in meter. Avoid the band edges of the generator frequency range where output voltages tend to fall off from the mid-range values. Use the capacitor value selected, C, and the frequency of the signal generator at resonance, f, in the following formula:

$$L = \frac{1}{4\pi^2 f^2 C} = \frac{1}{39.5f^2 C}$$

where f is in hertz, C is in farads and the resulting L is in henrys. A chart of frequency versus inductance for each of the two internal capacitors used to measure small and large inductors is shown in Table 25.3.

The SPDT switch also has a center-off position which disconnects the internal

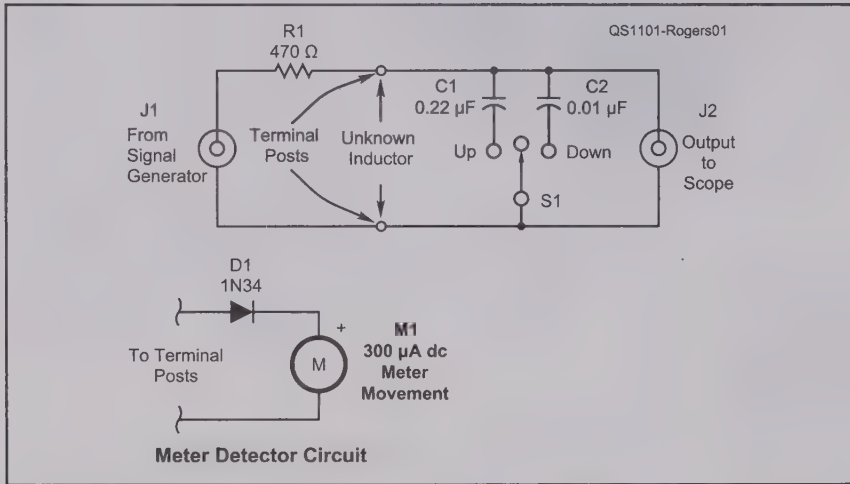

Figure 25.76 — Schematic diagram and parts list of the inductor test fixture. The switch's center-off position is used to disconnect the internal capacitors so that a desired value of capacitance can be placed in parallel with the inductor under test at the terminal posts. Measurement accuracy will depend on the actual value of C1 and C2 — determining the capacitor values with a capacitance meter will result in more accurate inductance values.

capacitors. This allows testing a particular capacitor-inductor combination connected to the terminal posts. The internal meter movement is always connected across the banana terminal posts.

### 25.9.4 Fixed-Frequency Audio Oscillator

An audio signal generator should provide a reasonably pure sine wave. The best oscillator circuits for this use are RC-coupled, the amplifiers operating as close to class A as possible. Variable frequencies covering the entire audio range are needed for determining frequency response of audio amplifiers.

A circuit of a simple RC oscillator that is useful for general testing is given in **Figure 25.79**. This Twin-T arrangement gives a waveform that is satisfactory for most purposes.

The oscillator can be operated at any frequency in the audio range by varying the component values. R1, R2 and C1 form a low-pass network, while C2, C3 and R3 form a high-pass network. As the phase shifts are opposite, there is only one frequency at which the total phase shift from collector to base is 180°: Oscillation will occur at this frequency. When C1 is about twice the capacitance of C2 or C3 the best operation results.

R3 should have a resistance about 0.1 that of R1 or R2 (C2 = C3 and R1 = R2). Output is taken across C1, where the harmonic distortion is least. Use a relatively high impedance load — 100 k $\Omega$  or more. Most small-signal AF transistors can be used for Q1. Either NPN or PNP types are satisfactory if the supply polarity is set correctly. R4, the collector load resistor may be changed a little to adjust the oscillator for best output waveform.

### 25.9.5 Wide-Range Audio Oscillator

A wide-range audio oscillator that will provide a moderate output level can be built from a single 741 operational amplifier (see **Figure 25.80**). Power is supplied by two 9-V batteries from which the circuit draws 4 mA. The frequency range is selectable from about 7 Hz to around 70 kHz. Distortion is approximately 1%. The output level under a light load (10 k $\Omega$ ) is 4 to 5 V. This can be increased by using higher battery voltages, up to a maximum of plus and minus 18 V, with a corresponding adjustment of R<sub>F</sub>.

Pin connections shown are for the eight-pin DIP package. Variable resistor R<sub>F</sub> is trimmed for an output level of about 5% below clipping as seen on an oscilloscope. This should be done for the temperature at which the oscillator will normally operate, as the lamp is sensitive to ambient temperature. This unit was originally described by Shultz in November 1974 *QST*; it was later modified by Neben as reported in June 1983 *QST*.

### 25.9.6 Two-Tone Audio Generator

This generator is used in the ARRL Laboratory to test SSB transmitters for ARRL Product Reviews and makes a very convenient signal source for testing the linearity of a single-sideband transmitter. To be suitable for transmitter evaluation, a generator of this type must produce two non-harmonically related tones of equal amplitude. The level of harmonic and intermodulation distortion must be sufficiently low so as not to confuse the measurement. The frequencies used in this generator are 700 and 1900 Hz,

both well inside the normal audio passband of an SSB transmitter. Spectral analysis and practical application with many different transmitters has shown this generator to meet all of the requirements mentioned above. While designed specifically for transmitter testing it is also useful any time a fixed-frequency, low-level audio tone is needed.

### CIRCUIT DETAILS

Each of the two tones is generated by a separate Wien bridge oscillator, U1B and U2B. (see **Figure 25.81**) The oscillators are followed by RC active low-pass filters, U1A and U2A. Because the filters require nonstandard capacitor values, provisions have been made on the circuit board for placing two capacitors in parallel in those cases where standard values cannot be used. (The circuit board artwork for layout and part placement is available as graphics with the downloadable supplemental content.) The oscillator and filter capacitors should be polystyrene or Mylar film types if available.

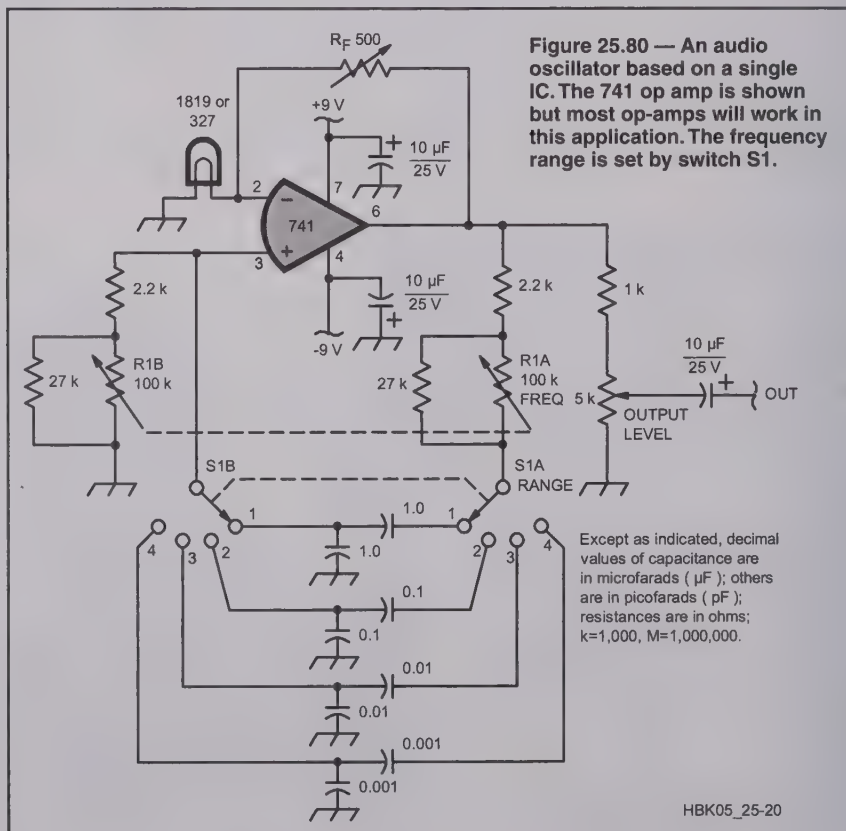

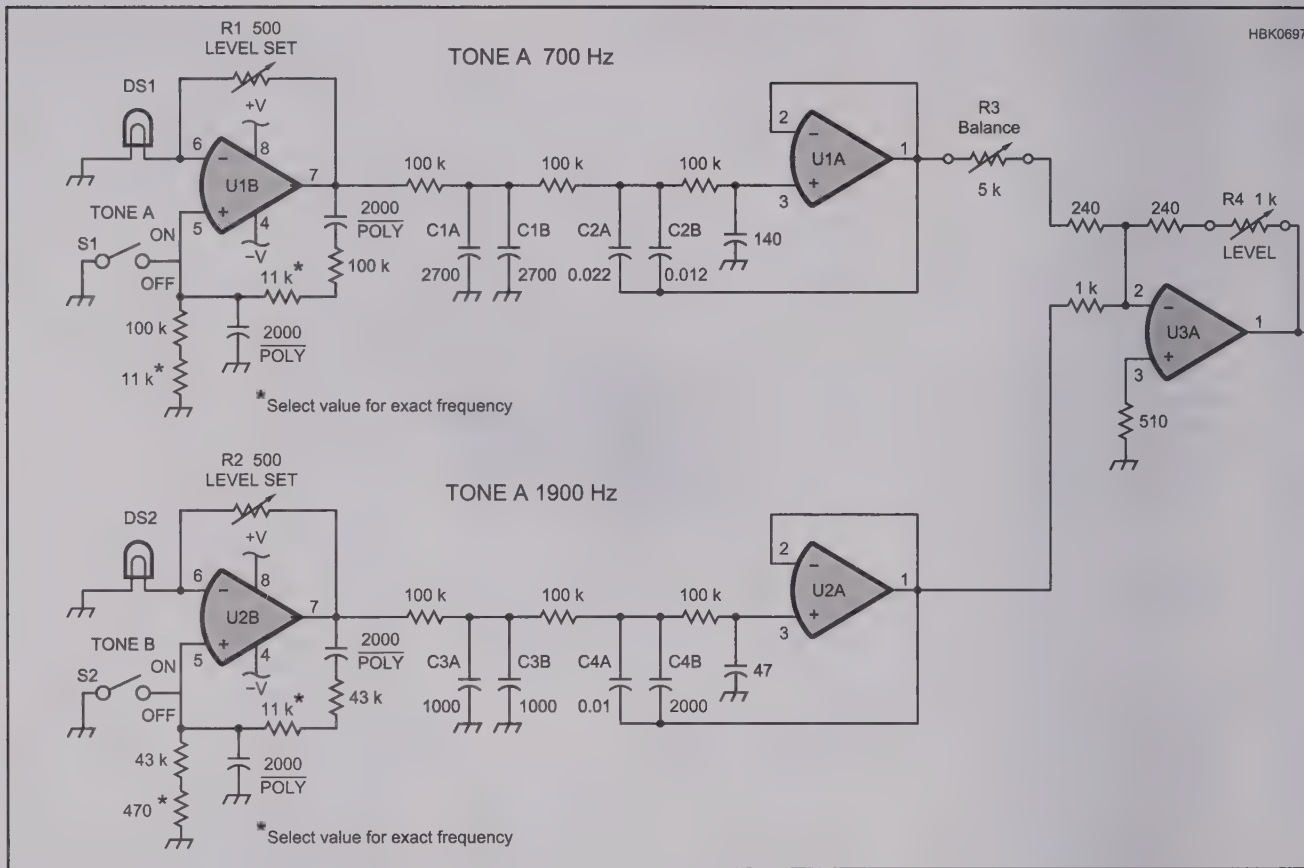

The two tones are combined by op amp U3A, a summing amplifier. This amplifier has a variable resistor, R4, in its feedback loop which serves as the output LEVEL control. While R4 varies the amplitude of both tones together, R3, the BALANCE control, allows the level of tone A to be changed without affecting the level of tone B. This is necessary because some transmitters do not have

equal audio response at both frequencies. Multi-turn pots are recommended for both R3 and R4 so that fine adjustments can be made. Following the summing amplifier is a step attenuator; S3 controls the output level in 10-dB steps. The use of two output level controls, R4 and S3, allows the output to cover a wide range and still be easy to set to a specific level.

The remaining op amp, U3B is connected as a voltage follower and serves to buffer the output while providing a high-impedance load for the step attenuator. Either high or low output impedance can be selected by S4. The values shown are suitable for most transmitters using either high- or low- impedance microphones.

## CONSTRUCTION AND ADJUSTMENT

Component layout and wiring are not critical, and any type of construction can be used with good results. Because the generator will normally be used near a transmitter, it should be enclosed in some type of metal case for shielding. Battery power was chosen to reduce the possibility of RF entering the unit through the ac line. With careful shielding and filtering, the builder should be able to use an ac power supply in place of the batteries.

The only adjustment required before use is the setting of the oscillator feedback trimmers, R1 and R2. These should be set so that the output of each oscillator, measured at pin 7 of U1 and U2, is about 0.5 volts RMS. A DVM or oscilloscope can be used for this measurement. If neither of these is available, the feedback should be adjusted to the minimum level that allows the oscillators to start reliably and stabilize quickly. When the oscillators are first turned on, they take a few seconds before they will have stable output amplitude. This is caused by the lamps, DS1 and DS2, used in the oscillator feedback circuit. This is normal and should cause no difficulty. The connection to the transmitter should be through a shielded cable.

## 25.9.7 RF Current Meter

The following project was designed by Tom Rauch, W8JI ([http://w8ji.com/building\\_a\\_current\\_meter.htm](http://w8ji.com/building_a_current_meter.htm)). The circuit of **Figure 25.82** is based on a current transformer (T1) consisting of a T157-2 powdered-iron toroid core with a 20-turn winding. The meter is used with the current-carrying wire or antenna inserted through the middle of the core as a one-turn primary

When 1 A is flowing in the single-turn

primary, the secondary current will be 50 mA = primary current divided by the turns ratio of 20:1. R1 across the transformer flattens the frequency response and limits the output voltage. The RF voltage is then detected and filtered by the D1 (a low-threshold Schottky diode for minimum voltage drop) and C1. The adjustable sum of R2 and R3 allow for full-scale (FS) calibration of the 100  $\mu\text{A}$  meter. C2 provides additional filtering. The toroid core and all circuitry are glued to the back of the meter case with only R2 exposed — a screwdriver-adjustable calibration pot.

It is important to minimize stray capacitance by using a meter with all-plastic construction except for the electrical parts. The meter in **Figure 25.83** has an all-plastic case including the meter scale. The meter movement and all metallic areas are small. The lack of large metallic components minimizes stray capacitance from the proximity of the meter. Low stray capacitance ensures the instrument has the least possible affect on the circuit being tested.

A value of 100  $\Omega$  for R1 gave the flattest response from 1.8 to 30 MHz. With 50 mA of secondary current, the voltage across R1

**Figure 25.83** — Assembly of the RF current probe. Use an all-plastic meter and mount the circuits and toroid directly on the back of the meter case.

is  $0.05 \times 100 = 5 \text{ V}_{\text{RMS}}$ . The peak voltage is then  $1.414 \times 5 = 7.1 \text{ V}$ . At full current, power dissipation in  $R1 = 50 \text{ mA} \times 5 \text{ V}_{\text{RMS}} = 0.25 \text{ W}$  so a  $\frac{1}{2}\text{-W}$  or larger resistor should be used.

The meter used here was a  $10,000 \text{ }\Omega/\text{V}$  model so for full-scale deflection from a primary current of 1 A producing a secondary voltage of  $\sim 7 \text{ V}$ , the sum of  $R2$  and  $R3$  must be set to  $7 \times 10,000 = 70 \text{ k}\Omega$ . The low-current meter combined with high detected voltage improves detector linearity.

Calibration of the meter can be performed by using a calibrated power meter and a test fixture consisting of two RF connectors with a short piece of wire between them and through the transformer core. With 50 W applied to a  $50\text{-}\Omega$  load, the wire will be carrying 1 A of current. Full-scale accuracy is not required in comparison measurements, since the meter references against itself, but linearity within a few percent is important.

This transformer-based meter is much more reliable and linear than thermocouple RF ammeters and perturbs systems much less. Stray capacitance added to the system being tested is very small because of the proximity of the meter and the compact wiring area. Compared to actually connecting a meter with its associated lead lengths and capacitance in line with the load, the advantages of a transformer-coupled meter become apparent.

### 25.9.8 RF Ammeters

When it comes to getting your own RF ammeter, there's good news and bad news as related by John Stanley, K4ERO. First, the bad news. New RF ammeters are expensive, and even surplus pricing can vary widely between \$10 and \$100 in today's market.

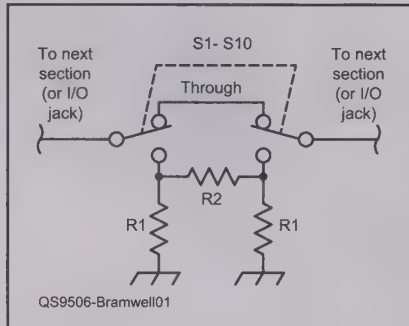

**Table 25.4**

225	73.17	225	0.4
450	75.83	450	0.84

AM radio stations are the main users of new units. The FCC defines the output power of AM stations based on the RF current in the antenna, so new RF ammeters are made mainly for that market. They are quite accurate, and their prices reflect that!

The good news is that used RF ammeters are often available. For example, Fair Radio Sales in Lima, Ohio has been a consistent source of RF ammeters. Ham flea markets are also worth trying. Some grubbing around in your nearest surplus store or some older ham's junk box may provide just the RF ammeter you need. Be sure you are really buying an RF ammeter as meters labeled "RF Amps" may just be regular current meters intended for use with an external RF current sensing unit.

### RF AMMETER SUBSTITUTES

Don't despair if you can't find a used RF ammeter. It's possible to construct your own. Both hot-wire and thermocouple units can be homemade. Pilot lamps in series with antenna wires, or coupled to them in various ways, can indicate antenna current (F. Sutter, "What, No Meters?," *QST*, Oct 1938, p 49) or even forward and reflected power (C. Wright, "The Twin-Lamp," *QST*, Oct 1947, pp 22-23, 110 and 112).

Another approach is to use a small low-

voltage lamp as the heat/light element and use a photo detector driving a meter as an indicator. (Your eyes and judgment can serve as the indicating part of the instrument.) A feed line balance checker could be as simple as a couple of lamps with the right current rating and the lowest voltage rating available. You should be able to tell fairly well by eye which bulb is brighter or if they are about equal. You can calibrate a lamp-based RF ammeter with 60-Hz or dc power.

As another alternative, you can build an RF ammeter that uses a dc meter to indicate rectified RF from a current transformer that you clamp over a transmission line wire (Z. Lau, "A Relative RF Ammeter for Open-Wire Lines," *QST*, Oct 1988, pp 15-17).

### 25.9.9 RF Step Attenuator

A good RF step attenuator is one of the key pieces of equipment that belongs on your workbench. The attenuator in this project offers good performance yet can be built with a few basic tools. The attenuator is designed for use in  $50\text{-}\Omega$  systems, provides a total attenuation of 71 dB in 1-dB steps, offers respectable accuracy and insertion loss through 225 MHz and can be used at 450 MHz as shown in Table 25.4. This material was originally published as "An RF Step Attenuator" by Denton Bramwell, K7OWJ, in the June 1995 *QST*.

The attenuator consists of 10 resistive  $\pi$ -attenuator sections such as the one in Figure 25.84. Each section consists of a DPDT slide switch and three  $\frac{1}{4}\text{-W}$ , 1%-tolerance metal-film resistors. The complete unit contains single 1, 2, 3 and 5-dB sections, and six 10-dB sections. Table 25.5 lists the resis-

tor values required for each section.

The enclosure is made of brass sheet stock, readily available at hardware and hobby stores. By selecting the right stock, you can avoid having to bend the metal and need only perform a minimum of cutting.

## CONSTRUCTION

The enclosure can be built using only a nibbling tool, drill press, metal shears, and a soldering gun or heavy soldering iron. (Use a regular soldering iron on the switches and resistors.) One method of cutting the small pieces of rectangular tubing to length is to use a drill press equipped with a small abrasive cutoff wheel.

Brass is easy to work and solder. For the enclosure, you'll need two pre-cut  $2 \times 12 \times 0.025$ -inch sheets and two  $1 \times 12 \times 0.025$ -inch sheets. The 2-inch-wide stock is used for the front and back panels; the 1-inch-wide stock is used for the ends and sides. For the internal wiring, you need a piece of  $\frac{3}{32} \times \frac{1}{16}$ -inch rectangular tubing, a  $\frac{1}{4} \times 0.032$ -inch strip, and a few small pieces of 0.005-inch-thick stock to provide inter-stage shields and form the 50- $\Omega$  transmission lines that run from the BNC connectors to the switches at the ends of the step attenuator.

For the front panel, nibble or shear a piece of 2-inch-wide brass to a length of about  $9\frac{1}{2}$  inches. Space the switches from each other so that a piece of the rectangular brass tubing lies flat and snugly between them (see **Figure 25.85**). Drill holes for the #4-40 mounting screws and nibble or punch rectangular holes for the bodies of the slide switches.

Before mounting any parts, solder in place one of the 1-inch-wide chassis side pieces to make the assembly more rigid. Solder the side piece to the edge of the top plate that faces the "through" side of the switches; this makes later assembly easier (see **Figure 25.86**). Although the BNC input and output connectors are shown mounted on the top (front) panel, better lead dress and high-frequency performance may result from mounting the connectors at the ends of the enclosure.

DPDT slide switches designed for sub-panel mounting often have mounting holes tapped for #4-40 screws. Enlarge the holes to allow a #4-40 screw to slide through. Before mounting the switches, make the "through" switch connection (see **Figure 25.84**) by bending the two lugs at one end of each switch toward each other and soldering the lugs together or solder a small strip of brass between the lugs and clip off the lug ends. Mount the switches above the front panel, using  $\frac{3}{32}$ -inch-high by  $\frac{1}{32}$ -inch-OD spacers. Use the same size spacer on the inside. On the inside, the spacer creates a small post that helps reduce capacitive coupling from one side of the attenuator to the other. The spacers position the switch so that the 50- $\Omega$

**Figure 25.85** — Key to obtaining acceptable insertion loss in the "through" position is to make the whole device look as much as possible like 50- $\Omega$  coax. The rectangular tubing and the  $\frac{1}{4} \times 0.032$ -inch brass strip between the switch sections form a 50- $\Omega$  stripline.

**Figure 25.86** — Solder one of the 1-inch-wide chassis side pieces in place to make the assembly more rigid during construction. Solder the side piece to the edge of the top plate that faces the "through" side of the switches; this makes the rest of the assembly easier.

stripline can be formed later.

The trick to getting acceptable insertion loss in the "through" position is to make the attenuator look as much as possible like 50- $\Omega$  coax. That's where the rectangular tubing and the  $\frac{1}{4} \times 0.032$ -inch brass strip come into the picture (see **Figure 25.85**); they form a 50- $\Omega$  stripline. (See the **Transmission Lines** chapter for information on stripline.)

Cut pieces of the rectangular tubing about  $\frac{3}{4}$ -inch long, and sweat solder them to the front panel between each of the slide switches. Next, cut lengths of the  $\frac{1}{4}$ -inch strip long enough to conveniently reach from switch to switch, then cut one more piece. Drill  $\frac{1}{16}$ -inch holes near both ends of all but one of the  $\frac{1}{4}$ -inch strips. The undrilled piece is used as a temporary spacer, so make sure it is flat and deburred.

Lay the temporary spacer on top of the rectangular tubing between the first two switches, then drop one of the drilled  $\frac{1}{4}$ -inch pieces over it, with the center switch lugs through the  $\frac{1}{16}$ -inch holes. Before soldering, check the

**Figure 25.87** — The attenuator before final mechanical assembly. The  $\frac{1}{4}$ -inch strips are spaced 0.033 inch apart to form a 50- $\Omega$  connection from the BNC connector to the stripline. There are  $\frac{1}{2}$ -inch square shields between 10-dB sections. The square shields have a notch in one corner to accommodate the end of the rectangular tubing.

**Figure 25.88** — The completed step attenuator in the enclosure of brass sheet. The BNC connectors may be mounted on the front panel at the end of the switches or on the end panels.

strip to make sure there's sufficient clearance between the  $\frac{1}{4}$ -inch strip and the switch lugs; trim the corners if necessary. Use a screwdriver blade to hold the strip flat and solder the lugs to the strip. Remove the temporary spacer. Repeat this procedure for all switch sections. This creates a 50- $\Omega$  stripline running the length of the attenuator.

Next, solder in place the three 1%-tolerance resistors of each section, keeping the leads as short as possible. Use a generous blob of solder on ground leads to make the lead less inductive. Install a  $\frac{1}{2}$ -inch-square brass shield between each 10-dB section to ensure that signals don't couple around the sections at higher frequencies.

Use parallel  $\frac{1}{4}$ -inch strips of 0.005-inch-thick brass spaced 0.033 inch apart to form 50- $\Omega$  feed lines from the BNC connectors to the switch contacts at each end of the stripline as shown in **Figure 25.86**. (Use the undrilled piece of 0.032-inch-thick brass to insure the proper line spacing.) The attenuator with all switches and shields in place is shown ready for final mechanical assembly in **Figure 25.87**.

Finally, solder in place the remaining enclosure side, cut and solder the end pieces,

and solder brass #4-40 nuts to the inside walls of the case to hold the rear (or bottom) panel. Drill and attach the rear panel and round off the sharp corners to prevent scratching or cutting anyone or anything. Add stick-on feet and labels and your step attenuator of Figure 25.88 is ready for use.

Remember that the unit is built with 1/4-W resistors, so it can't dissipate a lot of power. Remember, too, that for the attenuation to be accurate, the input to the attenuator must be a 50-Ω source and the output must be terminated in a 50-Ω load.

### 25.9.10 High-Power RF Samplers

If one wants to measure characteristics of a transmitter or high-powered amplifier, some means of reducing the power of the device to 10 or 20 dBm must be used. The most straightforward way to do this is to use a 30 or 40 dB attenuator capable of handling the high power. A 30 dB attenuator will reduce a 100 W transmitter to 20 dBm. A 40 dB attenuator will reduce a 1 kW amplifier to 20 dBm. If further attenuation is needed, a simple precision attenuator may be used after the signal has been reduced to the 20 dBm level.

The problem with high-powered attenuators is that they are expensive to buy or build since the front end of the attenuator must handle the output power of the transmitter or amplifier. If one already has a dummy load, an RF sampler may be used to produce a replica of the signal at a reduced power level. The sampler described here was originally presented in *QST* Technical Correspondence for May 2011 by Tom Thompson, WØIVJ.

A transformer sampler passes a single conductor (usually the insulated center conductor from a piece of coaxial cable) from the transmitter or amplifier to the dummy

load through a toroidal inductor forming a transformer with a single turn primary. The secondary of the transformer is connected to a resistor network and then to the test equipment as shown in Figure 25.89. Assume that the source, whether a transmitter or amplifier, is a pure voltage source in series with a 50-Ω resistor. This most likely is not exactly the case but is sufficient for analysis.

If a current,  $I$ , flows into the dummy load, then a current,  $I/N$  flows in the secondary of the transformer, where  $N$  is the number of turns on the secondary. Figure 25.89 also shows the equivalent circuit, substituting a current source for the transformer. The attenuation is 40 dB and 15 turns for the secondary of the transformer. If  $R_{SHUNT} = 15 \Omega$ , and  $R_{SERIES} = 35 \Omega$ , then the voltage across a 50-Ω load resistor,  $R_{SAMPLE}$ , is 1/100 of the voltage across the dummy load, which is 40 dB of attenuation.

Reflecting this resistor combination back through the transformer yields 0.06 Ω in series with the 50-Ω dummy load impedance. This is an insignificant change. Furthermore, reflecting 100 Ω from the primary to the secondary places 22.5 kΩ in parallel with  $R_{SHUNT}$ , which does not significantly affect its value. The test equipment sees a 50-Ω load looking back into the sampler. Even at low frequencies, where the reactance of the secondary winding is lower than 15 Ω, the impedance looking back into the sample port remains close to 50 Ω.

The samplers described here use an FT37-61 ferrite core followed by two resistors as described above. The through-line SWR is good up to 200 MHz, the SWR is fair looking into the sampled port, and the useful bandwidth extends from 0.5 MHz to about 100 MHz. If you are interested in an accurate representation of the third harmonic of your HF transmitter or amplifier, it is important

Figure 25.90 — RF sampler using box construction.

for the sampler to give accurate attenuation into the VHF range.

Figure 25.90 shows a photo of a sampler built into a 1.3 × 1.3 × 1 inch (inside dimensions) box constructed from single-sided circuit board material. The through-line connection is made with a short piece of UT-141 semi-rigid coax with the shield grounded only on one side to provide electrostatic shielding between the toroid and the center conductor of the coax. (Do not ground both ends of the shield or a shorted turn is created.)  $R_{SHUNT}$  is hidden under the toroid, and  $R_{SERIES}$  is shown connected to the sample port. This construction technique looks like a short piece of 200-Ω transmission line in the through-line which affects the SWR at higher frequencies. This can be corrected by compensating with two 3 pF capacitors connected to the through-line input and output connectors as shown in the photo. The through-line SWR was reduced from 1.43:1 to 1.09:1 at 180 MHz by adding the capacitors. This compensation, however, causes the attenuation to differ at high frequencies depending on the direction of the through-line connection. A sampler

constructed using the box technique is useable from below 1 MHz through 30 MHz.

**Figure 25.91** shows a different approach using  $\frac{1}{8}$ -inch diameter, 0.014-inch wall thickness, hobby brass tubing. This lowers the impedance of the through-line so that no compensation is needed. The through-line SWR for the tube sampler is 1.08:1 at 180 MHz which is as good as the box sampler and the sensitivity to through-line direction is reduced. Although the high frequency attenuation is not as good as the box sampler, the construction technique provides a more consistent result. A sampler constructed using the tube technique should be useable through 200 MHz.

### CONSTRUCTION OF THE TUBE SAMPLER

Both samplers use 15 turns of #28 AWG wire on an FT37-61 core, which just fits over the UT-141 semi-rigid coax.  $R_{SHUNT}$  is a 15  $\Omega$ ,  $\frac{1}{2}$  W, non-inductive metal oxide resistor and  $R_{SERIES}$  is a 34.8  $\Omega$ ,  $\frac{1}{4}$  W, 1% non-inductive metal film resistor. The power dissipation of the resistors and the flux handling capability of the ferrite core are adequate for sampling a 1500-W source. For those uncomfortable using BNC connectors at high power, an SO-239 version may be constructed using an FT50A-61 core and larger diameter tubing. Construction details are included with the downloadable supplemental content.

#### 25.9.11 RF Oscillators for Circuit Alignment

Receiver testing and alignment can make use of inexpensive RF signal generators which are available as complete units and in kit form. Any source of signal that is weak enough to avoid overloading the receiver usually will serve for alignment work and troubleshooting.

A crystal oscillator is often a satisfactory signal source for amplifier testing and receiver repair or alignment. Several example circuits can be found in the **Oscillators and Synthesizers** chapter. The output frequencies of crystal oscillators, while not adjustable, are quite precise and very stable. The Elecraft XG2 ([www.elecraft.com](http://www.elecraft.com)) and NorCal S9 ([www.norcalqrp.org](http://www.norcalqrp.org)) are good examples of simple fixed-frequency signal source kits. The harmonics of the output signals are on known frequencies and can also be used as low-level signal sources. The fundamental signals have known output amplitudes for calibrating S meters and other gain stages.

Variable frequency oscillators can be used as signal generators and there are several kits or assembled units available based on a direct digital synthesis (DDS) integrated circuit. See the **DSP and Software Radio Design** chapter.) The Elecraft XG3 is a programmable

**Figure 25.91**— RF sampler using tube construction.

signal source that operates from 1.5 to 200 MHz with four programmable output levels between  $-107$  and 0 dBm.

For receiver performance testing, precise frequency control, signal purity, noise, and low-level signal leakage become very important. A lab-quality instrument is required to make these measurements. Commercial and military-surplus units such as the HP608-series are big and stable, and they may be inexpensive. Recently, the HP8640-series of signal generators have become widely available at very attractive prices. When buying a used or inexpensive signal generator, look for these attributes: output level is calibrated, the output doesn't "ring" too badly when tapped, and doesn't drift too badly when warmed up.

#### 25.9.12 Hybrid Combiners for Signal Generators

Many receiver performance measurements require two signal generators to be attached to a receiver simultaneously. This, in turn, requires a combiner that isolates the two signal generators (to keep one generator from being frequency or phase modulated by the other). Commercially made hybrid combiners are available from Mini-Circuits Labs ([www.minicircuits.com](http://www.minicircuits.com)).

Alternatively, a hybrid combiner is not difficult to construct. The combiners described here (see **Figure 25.92**) provide 40 to 50 dB of isolation between ports, assuming the

**Figure 25.92**—The hybrid combiner on the left of A is designed to cover the 1 to 50-MHz range; the one on the right 50 to 500 MHz. B shows the circuit diagram of the hybrid combiner. Transformer T1 is wound with 10 bifilar turns of #30 AWG enameled wire. For the 1 to 50-MHz model, T1 is an FT-23-77 ferrite core. For the 50 to 500-MHz model, use an FT-23-67 ferrite core. Keep all leads as short as possible when constructing these units.

common port is terminated in a 50-ohm load. Attenuation in the desired signal paths (each input to output) is 6 dB. Loads with low return loss typical of receiver inputs will reduce isolation.

The combiners are constructed in small boxes made from double-sided circuit-board material as shown in Figure 25.92A. Each piece is soldered to the next one along the entire length of the seam. This makes a good RF-tight enclosure. BNC coaxial fittings are used on the units shown. However, any type of coaxial connector can be used. Leads must be kept as short as possible and precision non-inductive resistors (or matched units from the junk box) should be used. The circuit diagram for the combiners is shown in Figure 25.92B

The combiner may also be constructed and used as a *return loss bridge* as described in the *QST* article by Jim Ford, N6JF, "Build a Return Loss Bridge," from September 1997 and included with the downloadable supplemental content. Return loss is discussed in the *RF Techniques* chapter.

### 25.9.13 Gate-Dip Oscillator (GDO)

The project is adapted from the May 2003 *QST* article, "A Modern GDO — the "Gate" Dip Oscillator" by Alan Bloom, N1AL. A GDO is a tunable oscillator with the coil mounted outside of the chassis. The external coil allows you to measure the resonant frequency of a tuned circuit without any electrical connection to it. Just place the GDO

coil near the tuned circuit and tune the GDO while watching for a dip in its meter reading.

This "no connection" measurement capability is handy in other applications. For example, you can measure the resonant frequency of a Yagi's parasitic elements that don't have a feed line connection or measure the resonant frequency of antenna traps. The GDO can "sniff out" spurious resonances

in a linear amplifier's tank circuit with the amplifier powered down. (Be sure no high voltage is present!)

The GDO has other uses on the workbench. To measure inductance, temporarily connect a known-value capacitor in parallel with the unknown inductor and find the circuit's resonant frequency. Use the formula  $L = 1/(2\pi f)^2 C$  or the reactance vs frequency chart in the **Electrical Fundamentals** chapter to find the value of the inductor. (If C is measured in  $\mu F$  and f in MHz, the resulting value of L is in  $\mu H$ .) The same process works to find the value of a capacitor, such as that of an unmarked air-variable capacitor at a hamfest, by using the formula  $C = 1/(2\pi f)^2 L$ .

A GDO can be used as a simple signal generator to test amplifiers, mixers, and filters. To troubleshoot a receiver, tune the GDO to each of the IF frequencies, starting with the last IF stage and hold the coil close to that part of the circuitry. If you can hear a signal at the receiver's output, then that IF stage and all circuitry after it are working. This is especially handy on densely packed, surface-mount boards that are difficult to probe.

With the oscillator turned off, the GDO functions as a tuned RF detector known as an *absorption frequency meter* or *wavemeter*. An obvious use is to determine if RF energy in a tuned circuit has the right frequency. Using the capacity probe as an antenna, it can be used as a frequency-selective field-strength meter. By holding the coil near a cable, you can detect RF current flowing on the outside of a shield and the GDO makes an excellent

Figure 25.93 — The "gate dipper" fits comfortably in the hand.

Figure 25.94 — Photograph of the GDO with the cover off. The tuning capacitor was oriented for the shortest possible connection to the coil connector. The prototype was constructed with two batteries but three result in better operation.

“sniffer” to detect RF leakage from a shielded transmitter at the fundamental and harmonic frequencies.

A headphone output is provided to listen for key clicks, hum or buzz, and low-frequency parasitic oscillations in a transmitted signal. By coupling the coil to an antenna, you can even use the GDO as a tunable “crystal radio”!

### CIRCUIT DESIGN

**Figure 25.93** shows the completed GDO. **Figure 25.94** is a view inside the case and **Figure 25.95** pictures the entire set of coils. The schematic and parts list are shown in **Figure 25.96**. A pair of source-coupled N-channel JFETs (Q1 and Q2) form the oscillator portion of the circuit. No RF chokes are

required. This eliminates false resonances resulting from self-resonance of the chokes.

Q4, a bipolar 2N3904 transistor, serves a dual purpose. Its base-emitter junction acts as the RF detector. Further, it amplifies the rectified current flowing in the base and sends it to the emitter-follower Q5, a 2N2907. Transistor Q3 is a JFET source-follower amplifier for the output RF connector. The RF output may be used as a signal source or to drive a frequency counter for more accurate frequency display.

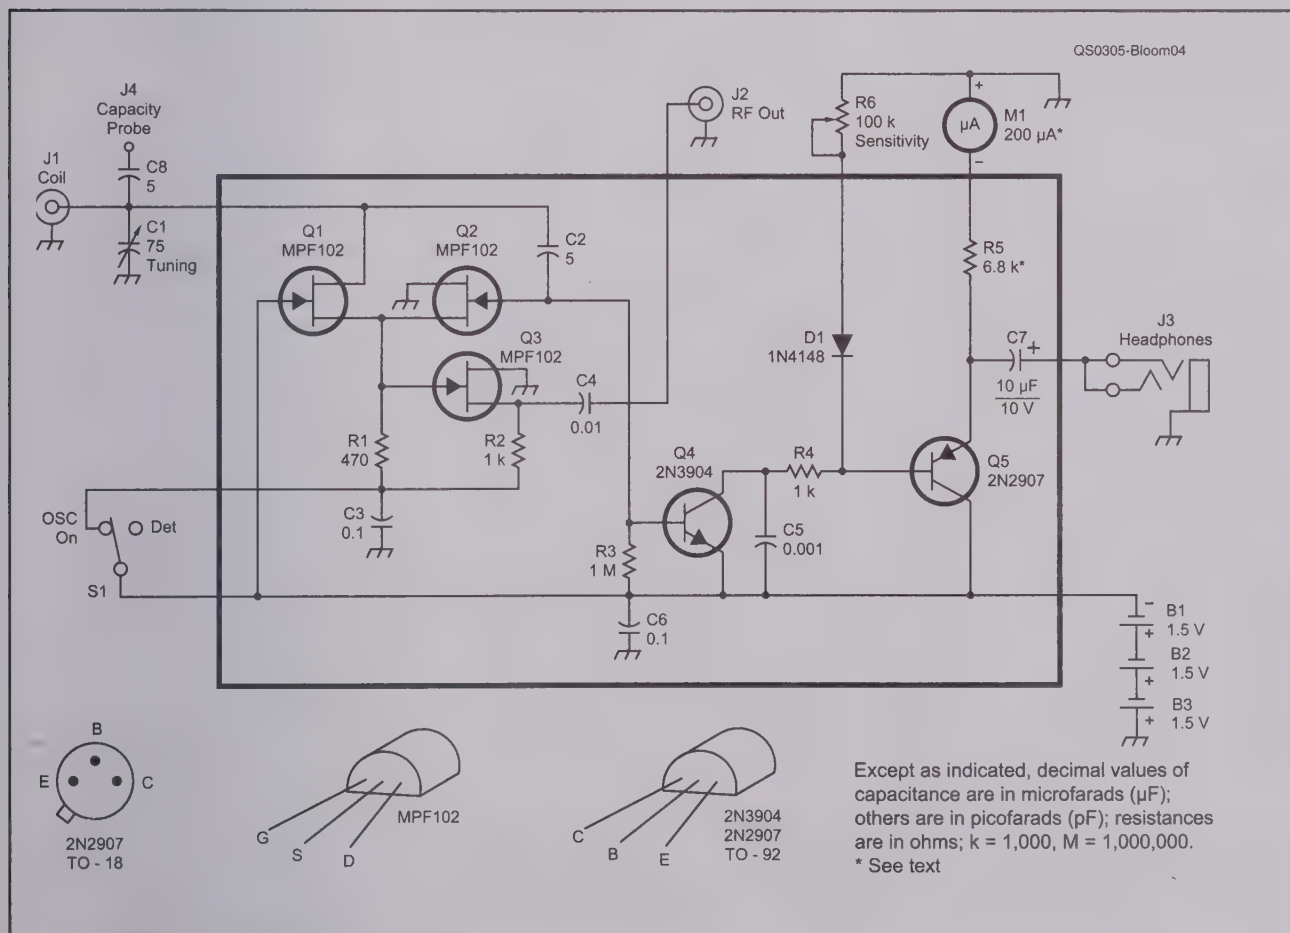

Determine the value of R5 using the formula  $R5 = (1.5/I_m) - R_m$ , where  $I_m$  is the full-scale meter current and  $R_m$  is the meter resistance. To measure your meter's resistance, be sure to use an ohmmeter that does not use more than the GDO meter's full-scale current. Most

modern DVMs use test currents in the range off 50-200  $\mu\text{A}$  for measuring resistance. The value of R5 in the parts list is for a 200  $\mu\text{A}$  full-scale meter used by the author. Meters from 50 to 500  $\mu\text{A}$  full-scale are suitable.

In detector mode, the power to the oscillator and RF buffer is turned off. Q4 detects and amplifies any signals picked up by the coil. The meter sensitivity control works in both oscillator and wavemeter mode and also controls the volume to the headphones. Battery current is 3-5 mA with the oscillator on and zero in wavemeter mode when no signal is being received.

transistors Q1, Q2, and Q4, which should be the types specified or their equivalents.

The 2¼ × 2¼ × 5 inch chassis is a compromise; it's large enough to allow all parts to fit easily and small enough to fit comfortably in the hand. The coil is mounted off-center, both to allow the shortest connection to the tuning capacitor and to afford easier coil coupling to an external circuit.

The prototype used a perforated test board for the RF portion of the circuitry and a solder terminal strip for the meter circuitry. If you prefer, a printed circuit board pattern and parts layout are available on this book's CD-ROM and circuit boards are available from FAR Circuits ([www.farcircuits.net](http://www.farcircuits.net)). Note that the battery's positive terminal is connected to ground which is backwards from the normal arrangement.

The coil forms are "¾ inch" flexible plastic water tubing. The inside diameter is actually slightly less than ¾ inch, which makes a nice force-fit onto the ¾-inch threads of a chassis-mount BNC plug (not the more common chassis-mount receptacle). The lowest-frequency coil is wound on a pill bottle with two 1-inch diameter aluminum washers at the connector mount for added strength.

To construct the coils, start by running the wire through the center of each form and soldering it to the BNC connector's center pin connection. Then press the form onto the connector threads and cut a small notch in the form's opposite end to hold the wire in place for the winding. After winding the coil, cut and tin the wire end, then solder it to the ground lug mounted on the connector. Cover each coil with a layer of heat-shrink tubing or electrical tape to hold the turns in place and protect the wire. Clear tubing allows you to see the coil and a small label with the coil's frequency range can be placed under the tubing before shrinking. Figure 25.95 shows the coils before the heat shrink tubing is added.

Winding data is listed in Table 25.6. Unless you happen to duplicate the prototype exactly, the frequency range of each coil is likely to be different. However, this data can be used as a starting point for your own coil designs.

The heavy wire for the two highest-frequency coils is bare copper scrap from house wiring cable. The other coils are wound with enamel-insulated magnet wire. The exact wire gauge is not critical although it may affect the number of turns required.

The three smallest coils (29.5-150 MHz) were space wound to the lengths listed. The remaining coils were close-wound. On the 0.9-1.5 and 1.5-2.8 MHz coils, there are too many turns to fit in a single layer. Wind these coils by overlapping turns a few at a time. Winding two complete overlapping layers increases the inter-winding capacitance which can cause spurious resonances and reduced tuning range.

The range of the lowest-frequency coil can be extended by connecting it to the GDO through a BNC "T" connector to which one or two 53 pF capacitors are attached using clip leads (see Table 25.6). Adding extra capacitance is a useful way to slow down the tuning rate for measuring narrow-band devices such as crystals.

With the smallest coil, the GDO oscillates over only a small portion of the capacitor tuning range. Fortunately, this range covers the 2 meter amateur band. With the second-smallest coil, the oscillation amplitude drops off at lower frequencies but is useable down to about 62 MHz in the prototype. A lower-inductance tuning capacitor would improve performance at VHF.

The small 75-pF tuning capacitor results in a tuning range of only about 2:1. The advantage of the low ratio is that tuning is not so critical and the frequency dial is easier to read. The disadvantage is that it requires more coils to cover the overall frequency range. Substituting a 365-pF AM broadcast radio tuning capacitor will increase the tuning range to nearly 3:1 with a consequent sharpening of adjustment.

The tuning dial in Figure 25.97 was made from a circular piece of ¼-inch clear plastic glued to a knob. Making the diameter slightly larger than the chassis width allows one handed operation with a thumb adjusting the tuning as in Figure 25.93. The scale,

cemented to the chassis under the dial, was drawn using a computer graphics program although measuring the frequency and creating the scales was very time-consuming. A better solution would be to include a small frequency counter with the GDO using the RF output. 4- or 5-digit accuracy is sufficient.

## OPERATION

To measure the resonant frequency of a tuned circuit, switch to oscillator mode and adjust the meter sensitivity to about ¼ scale. Then orient the GDO coil close to and approximately parallel to the coil under test and tune the dial until you get a strong dip on the meter. Tune slowly or you may miss the dip. Overly-close coupling to the circuit under test causes such a strong dip that the oscillator is pulled far off-frequency. Once a dip is found, move the GDO coil farther from the circuit under test until the dip is barely visible — this results in the most accurate measurement.

Coupling to toroids or shielded coils can be difficult. One solution is to connect a wire from the capacitance probe to the "hot" end of the circuit to be tested. For looser coupling, just place the wire close to the circuit under test instead of connecting it to the circuit. When measuring the inductance of a toroid with a test capacitor, the capacitor leads often form enough of a loop to allow coupling to the GDO coil. Some authors recommend decoupling the GDO to a one-turn loop through the toroid, but that creates a shorted secondary winding, changing the inductance of the toroid winding.

Antenna measurements are best made at the high-current point of the antenna conductor. For a half-wave dipole, this is near the center. Orient the coil perpendicular to the conductor for maximum coupling. Be sure to short the feed point of the antenna before making the measurement. If you can't find the dip, make the shorting wire into a 1-turn loop for better coupling to the GDO coil. You should also see resonance at the odd harmonic frequencies as well as the fundamental.

To measure the electrical length of a tran-

mission line, couple the GDO to a small wire loop; connect it to one end of the line and leave the other end disconnected. (For best accuracy use the smallest loop that gives sufficient coupling.) The line is  $\frac{1}{4}$  wavelength long at the lowest resonant frequency, so the electrical length in meters is  $75/f$ , where  $f$  is the resonant frequency in MHz. Again, you will also see resonance at the odd harmonics. The voltage level at the RF output connector varies from coil to coil but typically runs about 250 mV<sub>RMS</sub> into an open circuit and 100 mV<sub>RMS</sub> into a 50-Ω load. That is sufficient for a typical frequency counter or to serve as a test signal for troubleshooting.

Additional uses of the GDO are presented in the following articles with the downloadable supplemental content: “The Art of Dipping” in Jan 1974 *QST*, “Add-Ons for Greater Dipper Versatility” in Feb 1981 *QST*, and “What Can You Do with a Dip Meter?” in May 2002 *QST*.

### 5.9.14 RF Power Meter

The following section is an overview of the January 2011 *QST* article by Bill Kaune, W7IEQ, “A Modern Directional Power/SWR Meter”. The complete article including firmware and printed circuit board artwork is available with the downloadable supplemental content.

The primary use for this unit is to monitor the output power and tuning of a transceiver. The author’s station configuration is shown in Figure 25.98. RF power generated by the transmitter is routed via RG-8 coaxial cable through a directional coupler to an antenna tuner, which is connected to the antenna with RG-8. The directional coupler contains circuits that sample the RF power flowing from the transmitter to the tuner (the forward power) and the RF power reflected back from the tuner to the transmitter (the reflected power).

Figure 25.98 — W7IEQ station setup, including the power meter being described here.

These samples are sent via RG-58 cable to the two input channels of the power meter. This project includes the directional coupler and the power meter. Enough detail is provided in the full article so that an amateur can duplicate the device or modify the design.

### DIRECTIONAL COUPLER

The directional coupler is based on the unit described in “The Tandem Match” by John Grebenkemper, KI6WX in the Jan 1987 issue of *QST* and also included with the downloadable supplemental content. A pair of FT-82-67 toroids with 31 turns of #26 AWG magnet wire over lengths of RG-8 form the basis of the directional coupler shown in Figure 25.99.

The forward and reflected power samples coupled are reduced by a factor of  $1/N^2$ , where  $N = 31$  is the number of turns of wire on each toroid. Thus the forward and reflected power samples are reduced by about 30 dB. For example, if a transceiver were delivering a power of 100 W to a pure 50 Ω load, the forward power sample from the directional coupler would be about 0.1 W (20 dBm).

The directivity of a directional coupler is defined as the ratio of the forward power sample divided by the reflected power sample when the coupler is terminated in 50 Ω. In this coupler, the directivity measured using an inexpensive network analyzer is at least 35 dB at 3.5 MHz and 28 dB at 30 MHz.

### POWER/SWR METER — CIRCUIT DESCRIPTION

Figure 25.100 shows a front panel view of the power meter. An LCD displays the measured peak (PEP) and average (AEP) envelope powers as well as the standing wave ratio (SWR). The power meter calculates either the peak and average envelope power traveling from the transceiver to load (the forward power) or the peak and average envelope

Figure 25.99 — Completed directional coupler.

Figure 25.100 — Front panel of power meter. The LCD shows the peak envelope power (PEP), the average envelope power (AEP) and the SWR. The two knobs control the contrast and back lighting of the LCD. One toggle switch determines whether forward or load powers are displayed. A second switch sets the averaging time for the AEP calculation. The meter displays SWR and is used for tuning purposes.

lope powers actually delivered to the load (the forward power minus reflected power). The average envelope power (AEP) represents an average of the forward or load powers over an averaging period of either 1.6 or 4.8 seconds.

A 1 mA-movement analog meter on the front panel facilitates antenna tuning. This meter continuously displays the quantity  $1 - 1/SWR$ , where SWR is the standing wave ratio on the line. Thus, an SWR of 1.0 corresponds to a meter reading of 0 — no deflection of the meter. An SWR of 2 results in 50% deflection of the meter, while an SWR of 5 produces an 80% deflection of the meter.

The forward and reflected power samples from the directional coupler are applied to a pair of Analog Devices AD8307 logarithmic detectors. External 20 dB attenuators (Mini-Circuits HAT-20) reduce the signals from the directional coupler to levels compatible with the AD8307. As noted earlier, the directional coupler has an internal attenuation of about 30 dB, so the total attenuation in each channel is about 50 dB. Thus, a rig operating at a power level of 1 kW (60 dBm) will result in an input to the forward power channel of about 10 dBm. (The schematic diagram and parts list of the power meter are provided with the downloadable supplemental content.) The detectors are configured such that the time constant of their output follows the modulation envelope of the RF signal.

LF398 sample-and-hold ICs stabilize the voltages from the forward and reflected power logarithmic detectors. In this way both voltages can be sampled at the exact same time and held for subsequent analog-to-digital conversion and calculation of power and SWR by the PIC16F876A microprocessor ([www.microchip.com](http://www.microchip.com)). The processor also includes a pulse-width-modulated (PWM)

output used to drive the analog SWR meter on the front panel.

### 25.9.15 RF Voltmeter

Anthony Langton, GM4THU, designed this simple RF voltmeter to measure low RF voltages from oscillators and other low-power RF circuits through several MHz. It has an approximately 10 k $\Omega$  input impedance to avoid loading the circuit under test but not so high that it is unduly affected by stray capacitance.

Figure 25.101 shows the meter's circuit. C1 blocks dc voltage and R1 sets the input impedance. The upper section of the NE5532 op-amp is a precision rectifier. D1-D4 should be 1N4148. The lower section of the NE5532 is a supply splitter and can be replaced by a low-bandwidth op-amp, such as a 741 or equivalent. If substituted, the upper op-amp should have a gain-bandwidth product of at least 10 MHz.

R3 adjusts the voltage-to-current conversion ratio. With a 100  $\mu$ A full-scale meter, maximum voltage range is approximately 1 V. There is enough adjustment range to calibrate the meter for peak, RMS, or peak-to-peak voltage readings.

Figure 25.102 shows the meter circuit construction. Leads should be kept short and the entire circuit can be constructed as point-to-point wiring and mounted directly on the back of the analog meter. The original meter used a BNC connector for input connections.

### 25.9.16 A Low-Frequency VNA Adapter

(The following project is based on the QEX article "A Low Frequency Adapter for you Vector Network Analyzer (VNA)" by Jacques Audet, VE2AZX. An overview is given here while the full description, including links to construction files and other

information, is provided in PDF with the downloadable supplemental content.)

The Low Frequency Adapter adds low frequency capability to a vector network analyzer (VNA), as well as adding audio frequency generation, 1 M $\Omega$  probe amplified interface, and direct conversion receiver capability. In the VNA application, an IF bandwidth of 10 Hz must be used to extend the lowest frequency down to 20 Hz. The low frequency adapter has allowed the author to measure R, L and C components down to 20 Hz, using a Hewlett Packard 8753D VNA. He has also been able to accurately characterize and document the response of many audio type amplifiers that otherwise would have required tedious measurement methods. More information on this adapter is available at [ve2azx.net/technical/LFA/LowFreqAdapter.htm](http://ve2azx.net/technical/LFA/LowFreqAdapter.htm).

All  $S_{21}$  measurements are performed

within the 10 to 15 MHz frequency range of the VNA. The low frequency measurements include:

- $S_{21}$  magnitude and phase
- Group delay
- Compression point at a single frequency
- TRU calibration, with the device under test bypassed with a short circuit, to set a reference amplitude and phase frequency response.

The adapter can also be used as probe buffer/amplifier, a low frequency signal generator, a direct conversion receiver, and a vector voltmeter at low frequencies.  $S_{11}$  (reflection coefficient) measurements cannot be made directly with this adapter but the author provides a method and supporting spreadsheet for converting transmission measurements to impedance values. Construction of the adapter is shown in Figure 25.103 and Figure 25.104.

Figure 25.104 — The assembled circuit board for the adapter. R, L, and C components are 0805 SMT packages. Smaller 0603 components may also be used and will fit on the pads. See the full article included with the downloadable supplemental information and the author's website for additional information on the PCB.

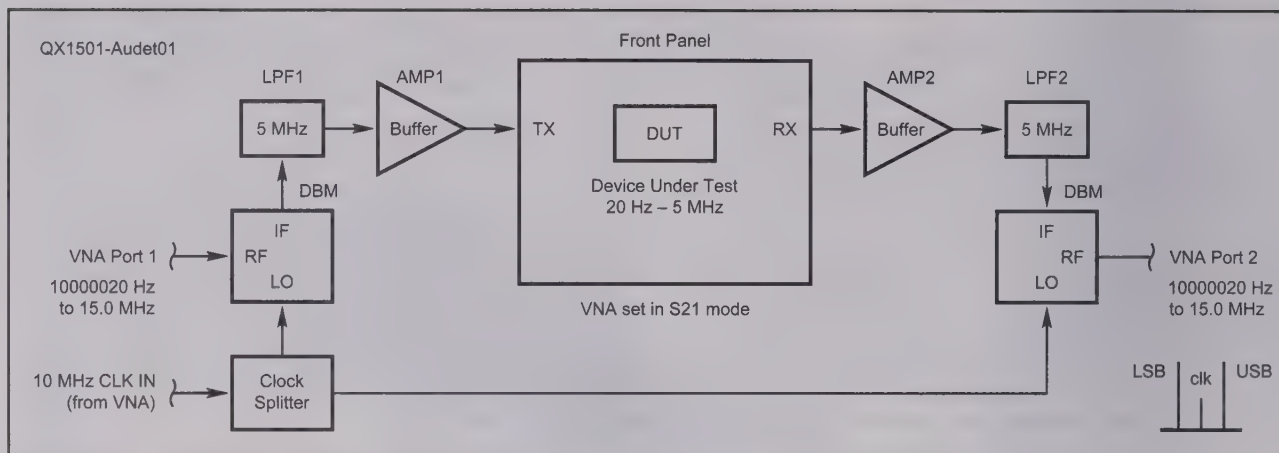

Figure 25.105 — Basic block diagram of the low frequency adapter for vector network analyzers.

The VNA is configured to use frequencies from 10 MHz to 15 MHz on its output (port 1) when measuring  $S_{21}$  (attenuation or gain as well as phase shift between ports 1 and 2). **Figure 25.105** shows the adapter's block diagram. The output signal is mixed in a double balanced mixer (DBM) with a local oscillator (LO) of 10 MHz. The difference signals from 20 Hz to 5 MHz are passed through a low-pass filter (LPF) and are available at the transmit (TX) output port for frequency response testing. The output of the device under test (DUT) is fed to a high impedance buffer and to a 5 MHz low pass filter before being re-multiplexed in the 10 to 15 MHz range by a second DBM.

The signal at the RF output of the first mixer generates sidebands (mixing products)

above and below the 10 MHz LO frequency. The VNA synchronously demodulates the upper sideband and uses this signal to compute the attenuation or gain of the device under test. Both the first and second 5 MHz filters (LPF1 and LPF2) provide attenuation of the 10 MHz LO signal, so it does not pass thru the device under test. These filters also greatly attenuate the sum frequencies in the 20 to 25 MHz range, which could decrease the accuracy if these were present at the second DBM IF input.

Since the VNA does coherent detection of the signal (in order to measure the phase), it is necessary to synchronize its internal clock with the low frequency adapter LO signal. This is normally done by using a common external 10 MHz clock feeding the VNA and

the low frequency adapter. This also enables the low frequency adapter to do  $S_{21}$  phase measurements from 20 Hz to 5 MHz.

In order for the low frequency adapter to be as transparent as possible to the VNA, it has unity gain from its input and output. Also the TX output port has a  $50\ \Omega$  impedance to drive low impedance loads. On the receive side, the input impedance consists of  $1\ \text{M}\Omega$  in parallel with  $8\ \text{pF}$  so that it is compatible with oscilloscope probes. An additional capacitor may be added to match a specific scope's input capacitance, thus providing a flat frequency response with an external  $\times 10$  probe. The high impedance allows the user to terminate the device under test by shunting a parallel termination across the receive (RX) input.

## 25.11 Test and Measurement Glossary

- Accuracy** — The maximum expected error in a measurement.
- Ammeter** — A device for measuring electrical current.
- Antenna analyzer** — A device to measure the RF impedance of a one-port network such as an antenna.
- Antenna test range** — An area designed to minimize the effect of RF reflections to permit accurate antenna gain and pattern testing.
- Attenuator** — A broadband device that reduces the amplitude of a signal by a specified, well-controlled amount.
- Autoranging** — The ability of a *multimeter* to set its range automatically based on the signal level.
- AWG (arbitrary waveform generator, also ARB)** — An instrument that can generate a complex signal based on waveforms stored in memory.
- Birdies** — Slang term for internally-generated spurious signals in a receiver that may be steady, warble, or pulsate.
- Blocking dynamic range** — The difference between the *blocking level* and the *MDS*.
- Blocking level** — The level of an interfering signal that causes weak signals to be reduced in amplitude by 1 dB.
- Bolometer** — A device for measuring RF power by measuring the heat dissipated in a dummy load.
- Bridge** — A circuit used to indicate the relative values of passive circuit elements by observing the null on a meter or other indicator. See this chapter's discussion of Wheatstone bridges.
- Burden voltage** — The full-scale voltage drop of an ammeter.
- Coaxial detector** — An RF detector with a coaxial connector.
- Combiner** — A device to combine signals from two sources. A *power splitter* in reverse. See *Hybrid combiner*.
- D'Arsonval meter** — The most common type of mechanical meter, consisting of a permanent magnet and a moving coil with pointer attached.
- Dip meter (dip oscillator)** — An instrument with an oscillator whose coil is external to the enclosure so it can be coupled to the circuit under test. The meter value drops (dips) when the oscillator frequency is tuned to the frequency of resonance of the circuit under test.
- Directional coupler, directional bridge** — A device that senses the RF power flowing in one direction on a transmission line.
- DMM (digital multimeter)** — A test instrument that measures voltage, current, resistance and possibly other quantities and displays the result on a numeric digit display, rather than on an analog meter.
- DVM (digital volt meter)** — See *DMM*.
- Dynamic error** — An error whose value depends on the time of measurement.
- Dynamic range** — The difference in dB between the strongest and weakest signals that a receiver can handle.
- Electronic voltmeter** — An amplified analog *multimeter*.
- ENR (excess noise ratio)** — The ratio of the noise added by a noise source to the thermal noise, normally expressed in dB.
- Feed-through termination** — See *Through-line termination*.
- Field-strength meter** — A device to indicate radiated RF field strength.
- Four wire** — A technique for measuring small resistances or large currents that uses four wires rather than two to reduce errors due to test lead resistance.
- Frequency counter** — A device that measures the frequency of a periodic signal and displays the result on a digital readout.
- Frequency domain** — Description of signals as a function of frequency, as opposed to as a function of time.
- Function generator** — An audio tone generator that generates tones in the shape of various functions, such as sine, square, triangle and ramp waveforms.
- Frequency markers** — Test signals generated at selected intervals (such as 25 kHz, 50 kHz, 100 kHz) for calibrating the dials of receivers and transmitters.
- Gaussian distribution** — The distribution of the probability of the instantaneous voltage of a noise signal as a function of the voltage. It forms a bell-shaped curve with a maximum at the dc value of the signal (typically zero volts).
- GDO (grid-dip oscillator)** — A *dip meter* that uses a vacuum tube.
- Harmonic signal** — A periodic signal. Its frequency spectrum consists only of the fundamental and harmonics of the repetition rate.
- Hybrid combiner** — A passive device used to combine two signals in such a way as to reduce the interaction between the signal sources.
- IF and image rejection** — The difference in level between an interfering signal at a receiver's IF or image frequency and the level of the desired signal that produces the same response.
- IMD (intermodulation distortion)** — The creation of unwanted frequencies because of two or more strong signals modulating each other.
- IMD dynamic range** — The difference in signal level between two signals that cause IMD products at the level of the MDS and the MDS.
- LCR Bridge** — A device for measuring inductors, capacitors or resistors using a Wheatstone bridge.
- Lissajous Pattern** — As used by amateurs, the combined display of two sine wave signals on an oscilloscope to determine the relationship between their frequencies. (Also called Lissajous figure.)
- Logic analyzer** — A sophisticated instrument for analyzing digital circuitry.
- Logic probe** — A simple device for sensing and displaying a digital signal's state.
- Marker** — An indicator on the screen of a *spectrum analyzer* that allows reading out the frequency and amplitude of a specific signal. See also *Frequency marker*.
- Marker delta** — A *spectrum analyzer* feature that reads out the difference in frequency and amplitude of two markers.
- MDS (minimum discernible signal)** — The level of the *noise floor* at the antenna connector of a receiver. Depends on the measurement bandwidth.
- Multimeter** — A device that measures several electrical quantities, such as voltage, current and resistance, and displays them on an analog meter or digital display.
- Multiplier (voltage multiplier)** — A resistor placed in series with a meter to increase the full-scale voltage reading.
- Near field** — The area close to an antenna where the electromagnetic wave is not completely formed. Antenna gain and pattern measurements are not valid in this region.
- Network analyzer** — An instrument to measure the return loss and transmission gain between the two ports of a two-port network.
- NIST (National Institute of Standards and Technology)** — A non-regulatory agency of the US federal government that manages measurement standards. It used to be called NBS, the National Bureau of Standards.
- NIST traceable** — Refers to a device whose accuracy is based on NIST standards using rules and procedures specified by NIST.
- Noise bandwidth** — The bandwidth of a rectangular-spectrum filter that would produce the same total noise power as the filter under consideration.
- Noise density** — Noise power per hertz.
- Noise figure** — A figure of merit for the sensitivity of receivers and other RF devices. It is the ratio of the effective noise level to the thermal noise level, usually expressed in dB.
- Noise floor** — The noise received by a receiver in a specified bandwidth,

referenced to the antenna connector. It is the thermal noise in dBm plus the noise figure in dB.

**Noise source** — An instrument that generates well-calibrated white noise for test purposes.

**OCXO (oven-controlled crystal oscillator)** — A crystal oscillator mounted in a temperature-controlled oven to improve the frequency stability.

**Ohmmeter** — A meter that measures resistance. Usually part of a *multimeter*. See *VOM* and *DDMM*.

**Ohms per volt** — A measure of the sensitivity of a voltmeter that has multiple scales. It is the reciprocal of the current drawn by the meter.

**Oscilloscope** — An instrument that displays signals in the *time domain*. Has a graphical display that shows amplitude on the vertical axis and time on the horizontal axis.

**Peak search** — A feature of a *spectrum analyzer* in which a marker is automatically placed on the strongest signal in the display.

**Peak to peak value** — The difference between the most positive and most negative signal values. For a symmetrical signal it is twice the peak value.

**Peak value** — The highest value of a signal during the measuring time.

**Periodic** — Refers to a signal that repeats exactly at a regular time interval, the period.

**Phase noise** — Wideband noise on an RF signal caused by random fluctuations of the phase.

**Port** — A pair of connections to a network, typically via a coaxial connector

**Power divider (power splitter)** — A device to divide an RF signal between two loads. A *combiner* in reverse.

**Prescaler** — A circuit used ahead of a counter to extend the frequency range. A counter capable of operating up to 50 MHz can count up to 500 MHz when used with a divide-by-10 prescaler.

**Random error** — A non-repeatable error caused by noise in the measurement system.

**Reciprocal mixing** — The mixing of a nearby interfering signal with the phase noise of the receiver local oscillator, which causes noise in the audio output.

**Resolution** — The smallest distinguishable difference in a measured value.

**Resolution bandwidth** — The smallest frequency separation between two RF signals that a *spectrum analyzer* can resolve. It is determined by the IF filters in the *spectrum analyzer*.

**Return loss** — The ratio, usually expressed in dB, between the incident and reflected RF signals.

**Return-loss bridge (RLB)** — A bridge used for measuring the return loss of an RF circuit, transmission line or antenna.

**Reverse power protection** — A *signal generator* feature to protect the instrument from accidental transmission by a transceiver under test.

**RF probe** — A hand-held probe with a detector to allow measuring RF signals with a dc voltmeter.

**Scalar network analyzer (SNA)** — A *network analyzer* that measures only the magnitude of the gain and return loss.

**Scattering parameters (S parameters)** — A set of four parameters to characterize the complex return loss and transmission gain in both directions of a two-port network.

**Scope** — Slang for *oscilloscope*.

**Second-order IMD** — IMD caused by strong signals at frequencies  $f_1$  and  $f_2$  that occurs at a frequency of  $f_1 + f_2$ .

**Service monitor** — An integrated package of test equipment packaged as a single instrument for testing receivers and transmitters.

**Shunt (meter shunt)** — A resistor connected in parallel with a meter to increase the full-scale current reading.

**SI (Système International d'Unités)** — The modern, revised version of the metric system.

**Signal generator** — An instrument that generates a calibrated variable-frequency RF signal, usually with adjustable amplitude and modulation capability.

**SINAD (signal plus noise and distortion)** — A measure of the relative level of signal compared to the noise and distortion at the audio output of an FM receiver.

**Single-shot** — Refers to a non-periodic signal that can be measured in a single time interval.

**Spectrum analyzer** — An instrument that displays signals in the *frequency domain*. Has a graphical display that shows amplitude (normally in logarithmic, or dB, form) on the vertical axis and frequency on the horizontal axis.

**Spurious emissions, or spurs** — Unwanted energy generated by a transmitter or other circuit. These emissions include, but are not limited to, harmonics.

**Standard** — A rule for the proper method to measure some quantity. A standard may involve a standard artifact that defines the unit.

**Step attenuator** — An attenuator that can be switched between different attenuation values.

**Systematic error** — A repeatable error due to some characteristic of the measurement system.

**TCXO (temperature-compensated crystal oscillator)** — A crystal oscillator that includes circuitry to compensate for frequency drift with temperature.

**Termination** — A resistor with a coaxial connector used to terminate a transmission line in its characteristic impedance.

**Test set** — A *network analyzer* accessory that automatically configures the connections to the device under test for various measurements.

**Third-order IMD** — IMD caused by strong signals at frequencies  $f_1$  and  $f_2$  that appears at frequencies  $2f_1 - f_2$  or  $2f_2 - f_1$ .

**Third-order IMD intercept point (IP3)** — The power level representing the intersection of plots on a dBm scale of the power level of the two strong signals and their IMD products.

**Through-line termination** — A termination with two coaxial connectors that connect straight through and a terminating resistor to ground.

**Time base** — A highly-accurate reference oscillator used in a frequency counter or other device that needs an accurate time or frequency reference.

**Time domain** — Refers to the variation in time of electronic signals, as opposed to their frequency spectrum.

**Tracking generator** — A *spectrum analyzer* accessory that consists of a signal generator whose frequency tracks the frequency of the analyzer.

**True RMS** — Refers to a meter that measures the actual RMS voltage or current instead of measuring the average or peak value and calculating the RMS value assuming a sinusoidal waveform.

**VCXO (voltage-controlled crystal oscillator)** — A crystal oscillator whose frequency can be adjusted slightly using an external applied voltage.

**Vector network analyzer (VNA)** — A *network analyzer* that measures both the magnitude and phase of the gain and return loss of a two-port network.

**Video bandwidth** — The bandwidth of the post-detection filter in a *spectrum analyzer*. It limits the maximum sweep speed.

**VOM (volt-ohm meter)** — A *multimeter* that does not include active circuitry such as an amplifier.

**VTVM (vacuum-tube voltmeter)** — A *multimeter* that uses one or more vacuum tubes.

**Wheatstone bridge** — See *Bridge circuit*.  
**Wilkinson combiner** — A type of hybrid combiner.

# Troubleshooting and Maintenance

The robust and self-reliant ethic of Amateur Radio is nowhere stronger than in the amateur's ability to maintain, troubleshoot and repair electronic equipment. Amateurs work with not just radios, but all sorts of equipment from computers and software to antennas and transmission lines. This flexibility and resilience are keys to fulfilling the Basis and Purpose for Amateur Radio.

The sections on troubleshooting approaches, tools and techniques build on earlier material written by Ed Hare, W1RFI. They will help you approach troubleshooting in an organized and effective manner, appropriate to your level of technical experience and tools at hand. This material shows how to get started and ask the right questions — often the most important part of troubleshooting.

Additional sections on troubleshooting power supplies, amplifiers, radios and antenna systems and tuners (contributed or updated by Matt Kastigar, W0MJ; Tom Schiller, N6BT; Ted Thrift, VK2ARA; and Ross Pittard, VK3CE) tackle the most common troubleshooting needs. Restoring and maintaining vintage equipment is a popular part of ham radio and so there are some sections by John Fitzsimmons, W3JN, and Pat Bunsold, WA6MHZ, on the special needs of this equipment.

This chapter is organized in three groups of sections to be consulted as required for any particular troubleshooting need. You will not need to read it from end-to-end in order to troubleshoot successfully. The first group of sections covers test equipment details, pertinent information about components, and safety practices. The second group presents general guidelines and techniques for effective troubleshooting. The third group presents specific advice and information on equipment that is commonly repaired by amateurs.

## TROUBLESHOOTING — ART OR SCIENCE?

Although some say troubleshooting is as much art as it is science, the repair of electronic gear is not magic. It is more like detective work as you work carefully to uncover each clue. Knowledge of advanced math or electronics theory is not required. However, you must have, or develop, a good grasp of basic electronics and simple measurements, guided by the ability to read a schematic diagram and to visualize signal flow through the circuit. As with most skills, these abilities will develop with practice.

Not everyone is an electronics wizard; your gear may end up at the repair shop in spite of your best efforts. The theory you learned for the FCC examinations and the information in this *Handbook* can help you decide if you can fix it yourself. Even if the problem appears to be complex, most problems have simple causes. Why not give troubleshooting a try to the best of your abilities? Maybe you can avoid the effort and expense of shipping the radio to the manufacturer. It is gratifying to save time and money, but the experience and confidence you gain by fixing it yourself may prove even more valuable.

## SAFETY FIRST! — SWITCH TO SAFETY

Always! Death is permanent. A review of safety must be the first thing discussed in a troubleshooting chapter. Some of the voltages found in amateur equipment can be fatal! Only 50 mA flowing through the body is painful; 100 to 500 mA is usually fatal. Under certain conditions, as little as 24 V can kill. RF exposure in a high-power amplifier can create severe burns very quickly. Batteries can deliver huge amounts of power that can melt tools and wires or create an explosion when short-circuited. Charging lead-acid cells can create a buildup of explosive hydrogen gas, as well.

Make sure you are 100% familiar with all safety rules and the dangerous conditions that might exist in the equipment you are servicing. A list of safety rules can be found in **Table 26.1**. You should also read the **Safety** chapter of this *Handbook* — all of it — before you begin to work on equipment.

Remember, if the equipment is not working properly, dangerous conditions may exist where you don't expect them. Treat every component as potentially "live." Some older equipment uses "ac/dc" circuitry. In this circuit, one side of the chassis is connected directly to the ac line, a condition unexpected by today's amateurs who are accustomed to modern safety standards and practices. This is an electric shock waiting to happen.

The maximum voltage rating of voltmeters and oscilloscopes is not often noted by the hobbyist but it is crucial to safety when working on voltages higher than the household ac line voltage. Test equipment designed to measure voltage always has a maximum safe voltage rating

**Table 26.1**

**Safety Rules**

1. Keep one hand in your pocket when working on live circuits or checking to see that capacitors are discharged.
2. Include a conveniently located ground-fault current interrupter (GFCI) circuit breaker in the workbench wiring.
3. Use only grounded plugs and receptacles.
4. Use a GFCI protected circuit when working outdoors, on a concrete or dirt floor, in wet areas, or near fixtures or appliances connected to water lines, or within six feet of any exposed grounded building feature.
5. Use a fused, power limiting isolation transformer when working on ac/dc devices.
6. Switch off the power, disconnect equipment from the power source, ground the output of the internal dc power supply, and discharge capacitors when making circuit changes.
7. Do not subject electrolytic capacitors to excessive voltage, ac voltage or reverse voltage.
8. Test leads should be well insulated and without cracks, fraying, or exposed conductors
9. Do not work alone!
10. Wear safety glasses for protection against sparks and metal or solder fragments.
11. Be careful with tools that may cause short circuits.
12. Replace fuses only with those having proper ratings.
13. Never use test equipment to measure voltages above its maximum rating.

between the circuit being measured and the equipment user — you! This is particularly important in handheld equipment in which there is no metal enclosure connected to an ac safety ground. Excessive voltage can result in a flashover to the user from the internal electronics, probes, or test leads, resulting in electric shock. Know and respect this rating.

If you are using an external high voltage probe, make sure it is in good condition with no cracks in the body. The test lead insulation should be in good condition — flexible and with no cracks or wire exposed. If practical, do not make measurements while holding the probe or meter. Attach the probe with the voltage discharged and then turn the power on. Turn power off and discharge the voltage before touching the probe again. Treat high voltage equipment with care and respect!

**Soldering Safety**

Remember that soldering tools and melted solder can be hot and dangerous! Wear protective goggles and clothing when soldering. A full course in first aid is beyond the scope of this chapter, but if you burn your skin, run the burn immediately under cold water and seek first aid or medical attention. Always seek medical attention if you burn your eyes; even a small burn can develop into serious trouble.

**UNDERSTANDING THE BASICS**

To fix electronic equipment, you need to understand the system and circuits you are troubleshooting. A working knowledge of electronic theory, circuitry and components is an important part of the process. When you are troubleshooting, you are looking for specific conditions that cause the symptoms

you are experiencing. Knowing how circuits are supposed to work will help you to notice things that are out of place or that indicate a problem.

To be an effective troubleshooter, review and understand the following topics discussed elsewhere in this book:

- Ohms law and basic resistor circuits (**Electrical Fundamentals**)
- Basic transistor and diode characteristics (**Circuits and Components**)
- Fundamental digital logic and logic signals (**Digital Basics** supplement)
- Voltage and current measurements (**Test Equipment and Measurements**)
- SWR and RF power measurement (**Transmission Lines**)

You would be surprised at how many problems — even problems that appear

complicated — turn out to have a simple root cause found by understanding the fundamentals and methods of one of these categories

**GETTING HELP**

Other hams may be able to help you with your troubleshooting and repair problems either with a manual or technical help. Check with your local club or repeater group. You may get lucky and find a troubleshooting wizard. (On the other hand, you may get some advice that is downright dangerous, so be selective.) Most clubs have one or two troubleshooting gurus who can provide guidance and advice, if not some on-the-workbench help.

There is a wealth of information available online, too. Many of the popular brands of equipment and even specific models have their own online communities or user groups. The archives of these groups — almost universally free to join — contain much valuable troubleshooting, modification and operating information. If the problem doesn't appear to have been described, you can ask the group.

The Technology area of the ARRL's web site also has an extensive section on Servicing Equipment ([www.arrl.org/servicing-equipment](http://www.arrl.org/servicing-equipment)). That page features articles and other resources, including links to schematic databases.

Your fellow hams in the ARRL Field organization may also help. Technical Coordinators (TC) and Technical Specialists (TS) are volunteers who are willing to help hams with technical questions. For the name and address of a local TC or TS, contact your Section Manager (listed in the front of any recent issue of *QST*).

**Using Search Engines for Troubleshooting**

The power of Internet search engines can save huge amounts of time when troubleshooting equipment. The key is in knowing how to construct the right list of words for them to find. Precision is your friend — be exact and use words others are likely to use if they had the same problem. Use the primary model number without suffixes to avoid being too specific. For example, when troubleshooting the well-known PLL potting compound problem exhibited by Kenwood TS-440 transceivers, entering the search string "TS-440 display dots" immediately finds many web pages dealing with the problem, while simply entering "Kenwood transceiver blank display" returns dozen of unrelated links.

Start with a very specific description of the problem and gradually use less exact terms if you don't find what you want. Learn how to use the "Advanced Search" functions of the search engine, too.

# 26.1 Test Equipment

Many of the steps involved in efficient troubleshooting require the use of test equipment. We cannot see electricity directly, but we can measure its characteristics and effects. Our test equipment becomes our electrical senses.

The **Test Equipment and Measurements** chapter is where you can find out more about various common types of equipment, how to operate it, and even how to build some of your own. There are many articles in *QST* and in books and websites that explain test equipment and offer build-it-yourself projects, too. Surplus equipment of excellent quality is widely available at a fraction of its new cost.

You need not purchase or build every type of test equipment. Specialty equipment such as spectrum analyzers or UHF frequency counters can often be borrowed from a club member or friend — maybe one of those troubleshooting gurus mentioned earlier. If you own the basic instruments and know how to use them, you'll be able to do quite a bit of troubleshooting before you need the special instruments.

## 26.1.1 Senses

Although they are not test equipment in the classic sense, your own senses will tell you as much about the equipment you are trying to fix as the most-expensive spectrum analyzer. We each have some of these natural test instruments.

**Eyes** — Use them constantly. Look for evidence of heat and arcing, burned components, broken connections or wires, poor solder joints or other obvious visual problems.

**Ears** — Severe audio distortion can be detected by ear. The snaps and pops of arcing or the sizzling of a burning component may help you track down circuit faults. An experienced troubleshooter can diagnose some circuit problems by the sound they make. For example, a bad audio-output IC sounds slightly different from a defective speaker.

**Nose** — Your nose can tell you a lot. With experience, the smells of ozone, an overheating transformer, and a burned resistor or PC board trace each become unique and distinctive. Many troubleshooting sessions begin with “something smells hot!”

**Finger** — After using a voltmeter to ensure no hazardous voltages are present, you can use a fingertip to determine low heat levels—never do this in a high-voltage circuit. Use a temperature probe if using a finger is unsafe. Small-signal transistors can be fairly warm, but being very hot indicates a circuit problem. Warm or hot capacitors are always suspect. High-power devices and resistors can be quite hot during normal operation.

**Brain** — More troubleshooting problems have been solved with a multimeter and a brain than with the most expensive spectrum analyzer. You must use your brain to analyze data collected by other instruments.

## 26.1.2 Internal Equipment

Some test equipment is included in the equipment you repair. Nearly all receivers include a speaker. An S meter is usually connected ahead of the audio chain. If the S meter shows signals, that indicates that the RF and IF circuitry is probably functioning. Transmitters often have a power supply voltage and current meter, along with power output, SWR, ALC and speech compression readings that give valuable clues about what is happening inside the equipment.

The equipment also has visual indicator lights that provide additional information such as transmit status, high SWR, low voltage, squelch status, and so forth. These readings or indicators are often specifically referenced by the troubleshooting sections of manuals to help sort out problems.

Microprocessor-controlled equipment often provides error indications, either through a display or by indicator lights. In addition, faults detected by the control software

are sometimes communicated through patterns of beeps or flashing of LEDs. Each sequence has a specific meaning that is described in the operating or service manual.

## 26.1.3 Bench Equipment

The following is a list of the most common and useful test instruments for troubleshooting. Some items serve several purposes and may substitute for others on the list. The theory and operation of most of this equipment is discussed in detail in the **Test Equipment and Measurements** chapter. Notes about the equipment's use for troubleshooting are listed here.

**Multimeters** — The most often used piece of test equipment, the digital multimeter or DMM, can often test capacitors of most values in addition to voltage, current and resistance. Most can test diodes and transistors on a go/no-go basis, while some can measure gain. Some can even measure frequency or use an external probe to measure temperature.

Some DMMs are affected by RF, so most technicians keep an old-style analog moving-needle VOM (volt-ohm-meter) on hand for use in strong RF fields. Some technicians prefer the moving needle for peaking or nulling adjustments.

Figure 26.1 — An array of test probes for use with various test instruments.

**Test or clip leads** — Keep an assortment of these wires with insulated alligator clips. Commercially-made leads have a high failure rate because they use small wire that is not soldered to the clips, just crimped. You can slip off the clip jackets and solder the wire yourself for better reliability. Making a set of heavier-gauge leads is a good idea for currents above several hundred milliamps.

Individual wire leads (**Figure 26.1A**) are good for dc measurements, but they can pick up unwanted RF energy. This problem is reduced somewhat if the leads are twisted together (**Figure 26.1B**). Coaxial cable test leads can avoid RF pickup but also place a small capacitance across the circuit being measured. The added capacitance may affect performance.

**Test probes** — The most common probe is the low-capacitance ( $\times 10$ ) oscilloscope probe shown in **Figure 26.1C**. This probe isolates the oscilloscope from the circuit under test, preventing the scope's input and test-probe capacitance from affecting the circuit and changing the reading. A network in the probe serves as a 10:1 divider and compensates for frequency distortion in the cable and test instrument.

Demodulator probes (see the **Test Equipment and Measurements** chapter and the schematic shown in **Figure 26.1D**) are used to demodulate or detect RF signals, converting modulated RF signals to audio that can be heard in a signal tracer or seen on a low-bandwidth scope.

You can make a probe for inductive coupling as shown in **Figure 26.1E**. Connect a two or three-turn loop across the center conductor and shield before sealing the end. The inductive pickup is useful for coupling to high-current points and can also be used as a sniffer probe to pick up RF signals without contacting a circuit directly.

Other common types of probes are the non-contact clamp-on probes shown in **Figure 26.2** that use magnetic fields to measure current. A high-voltage probe for use with DMMs or VOMs is shown in **Figure 26.3** and is discussed more in this chapter's section on power supply troubleshooting.

Thermocouple and active temperature sensor probes are also commonly available. These display temperature directly on the meter in  $^{\circ}\text{F}$  or  $^{\circ}\text{C}$ .

**RF power and SWR meters** — Simple meters indicate relative power SWR and are fine for adjusting matching networks and monitoring transmission line conditions for problems. However, if you want to make accurate measurements, a calibrated directional RF wattmeter with the proper sensing elements for the frequencies of signals being measured is required.

**Dummy load** — Do not put a signal on the air while repairing equipment. Defective

**Figure 26.2** — A clamp-on meter probe is used with a digital multimeter for measuring ac current (left). Meters are also available integrated with the clamp-on probe (right).

equipment can generate signals that interfere with other hams or other radio services. A dummy load also provides a known, matched load (usually  $50\ \Omega$ ) for use during adjustments and test measurements. See the **Transmitting** chapter.

**Dip meter** — As described in the **Test Equipment and Measurements** chapter, dip meters are used to adjust and troubleshoot resonant circuits. Many can perform as an absorption frequency meter, as well. Dip meters can be used as low-power signal sources but are not very stable.

New dip meters are fairly rare. When purchasing a dip meter, look for one that is

mechanically and electrically stable. All of the coils should be present and in good condition. A headphone connection is helpful. Battery operated models are easier to use for antenna measurements. Dip meters are not nearly as common as they once were.

**Oscilloscope** — The oscilloscope, or scope, is the second most often used piece of test equipment, although a lot of repairs can be accomplished without one. The trace of a scope can give us a lot of information about a signal at a glance. For example, when signals from the input and output of a stage are displayed on a dual-trace scope, stage linearity and phase shift can be checked (see **Figure 26.4**).

**Figure 26.3** — A probe used for measuring high-voltage with a standard multimeter.

**Figure 26.4** — A dual-trace oscilloscope display of amplifier input and output waveforms.

An oscilloscope will show gross distortions of audio and RF waveforms, but it cannot be used to verify that a transmitter meets FCC regulations for harmonics and spurious emissions. Harmonics that are down only 20 dB from the fundamental would be illegal in most cases, but they would not change the oscilloscope waveform enough to be seen.

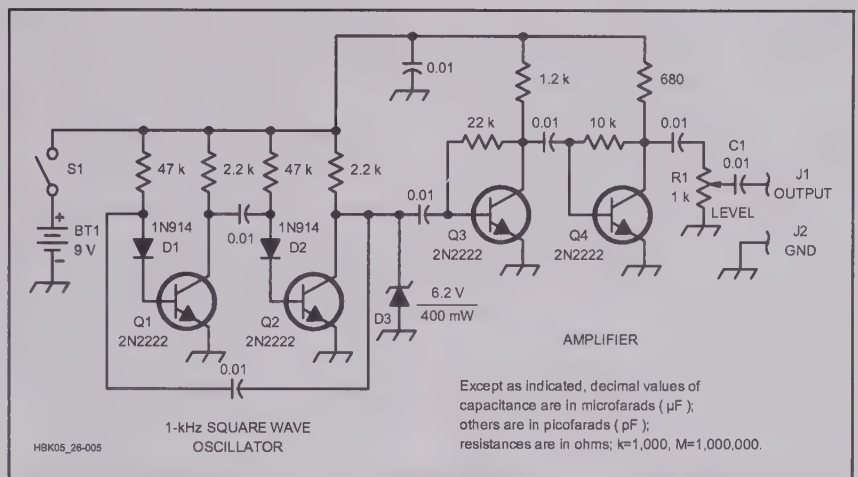

When buying a scope, get the highest bandwidth you can afford. Old Hewlett-Packard or Tektronix instruments are usually quite good for amateur use.

**Signal generator** — Although signal generators have many uses, in troubleshooting they are most often used for signal injection (more about this later) and alignment of vintage equipment.

When buying a generator, look for one that can generate a sine wave signal. A good signal generator is double or triple shielded against leakage. Fixed-frequency audio should be available for modulation of the RF signal and for injection into audio stages. The most versatile generators can generate amplitude and frequency modulated signals. Used Hewlett-Packard (Agilent) and Tektronix units are typically available for reasonable prices but may not be repairable if they fail due to unavailable parts.

Good generators have stable frequency controls with no backlash. They also have multiposition switches to control signal level. A switch marked in dBm is a good indication that you have located a high-quality test instrument. The output jack should be a coaxial connector (usually a BNC or N), not the kind used for microphone connections.

In lieu of a fully tunable generator, you can build some simple equipment that generates a signal. For example, Elecraft makes the XG3 kit — a programmable signal source ([www.elecraft.com](http://www.elecraft.com)) that generates 160 through 2 meter signals with four calibrated output levels. It's very useful for receiver calibration, sensitivity tests and signal tracing.

**Figure 26.5** — Schematic of the AF/RF signal injector. All resistors are ¼ W, 5% carbon units, and all capacitors are disc ceramic. A full-size etching pattern and parts-placement diagram can be found in the downloadable supplemental content.

**BT1** — 9 V battery.

**D1, D2** — Silicon switching diode, 1N914 or equiv.

**D3** — 6.2 V, 400 mW Zener diode.

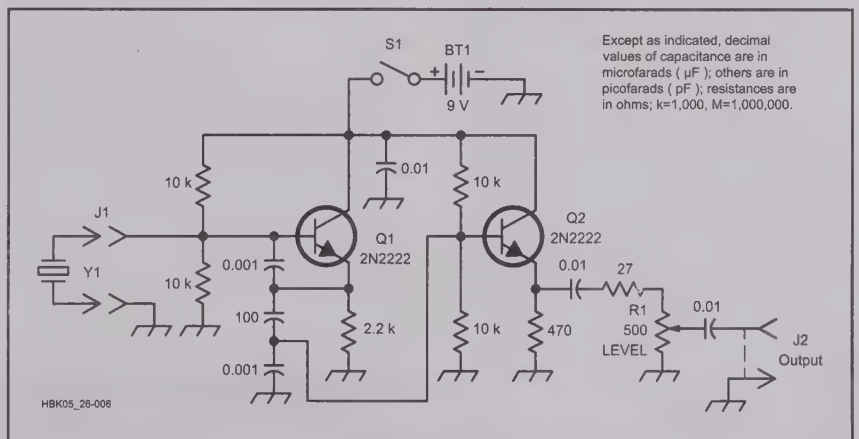

**J1, J2** — Banana jack.

**Q1-Q4** — General-purpose silicon NPN transistors, 2N2222 or similar.

**R1** — 1 kΩ panel-mount control.

**S1** — SPST toggle switch.

Except as indicated, decimal values of capacitance are in microfarads (µF); others are in picofarads (pF); resistances are in ohms; k=1,000, M=1,000,000.

**Figure 26.6** — Schematic of the crystal-controlled signal source. All resistors are ¼ W, 5% carbon units, and all capacitors are disc ceramic. A full-size etching pattern and parts-placement diagram can be found in the downloadable supplemental content.

**BT1** — 9 V transistor radio battery.

**J1** — Crystal socket to match the crystal type used.

**J2** — RCA phono jack or equivalent.

**Q1, Q2** — General-purpose silicon NPN transistors, 2N2222 or similar.

**R1** — 500 Ω panel-mount control.

**S1** — SPST toggle switch.

**Y1** — 1 to 15-MHz crystal.

Except as indicated, decimal values of capacitance are in microfarads (µF); others are in picofarads (pF); resistances are in ohms; k=1,000, M=1,000,000.

Even simpler, you can homebrew the AF/RF signal-injector schematic as shown in **Figure 26.5**. If frequency accuracy is needed, the crystal-controlled signal source of **Figure 26.6** can be used. The AF/RF circuit provides usable harmonics up to 30 MHz, while the crystal controlled oscillator will

function with crystals from 1 to 15 MHz. These two projects are not meant to replace standard signal generators for alignment and precision testing, but they are adequate for generating signals that can be used for general troubleshooting. (See the section on Signal Tracing and Signal Injection.)

**Signal tracer** — Signals can be traced with a voltmeter and an RF probe, a dip meter with headphones or an oscilloscope, but signal tracers combine these functions especially for signal tracing through a receiver or other RF signal processing circuit. Articles describing the use of signal tracers, including a project you can build yourself, are provided with the downloadable supplemental content.

A general-coverage receiver can be also used to trace RF or IF signals, if the receiver covers the necessary frequency range. Most receivers, however, have a low-impedance input that severely loads the test circuit. To minimize loading, use a capacitive probe or loop pickup as in Figure 26.1. When the probe is held near the circuit, signals will be picked up and carried to the receiver. It may also pick up stray RF, so make sure you are listening to the correct signal by switching the circuit under test on and off while listening.

**Transistor tester** — Most transistor failures appear as either an open or shorted junction. Opens and shorts can be found easily with an ohmmeter or the diode junction checker of a standard DMM; a special tester is not required.

Transistor testers measure device current while the device is conducting or while an ac signal is applied at the control terminal.

Transistor gain characteristics vary widely even between units with the same device number. Testers can be used to measure the gain of a transistor. DMM testers measure only transistor dc alpha and beta. Testers that apply an ac signal show the ac alpha or beta. Better testers also test for leakage.

In addition to telling you whether a transistor is good or bad, a transistor tester can help you decide if a particular transistor has sufficient gain for use as a replacement. It may also help when matched transistors are required. The final test is the repaired circuit.

**Frequency counter** — Most inexpensive frequency counters display frequency with 1 Hz resolution or better up to around low VHF frequencies. Some may include a prescaler that divides higher frequencies by 10 to extend the counter's range. Good quality used counters are widely available.

**Power supplies** — A well-equipped test bench should include a means of varying the ac-line voltage, a variable-voltage regulated dc supply and an isolation transformer.

AC-line voltage varies slightly with load. An autotransformer with a movable tap (also known by the trade name Variac) lets you boost or reduce the line voltage slightly. This is helpful to test circuit functions with supply-voltage variations.

An isolation transformer is required to work safely on vintage equipment that often ties one side of the ac line to the chassis. An isolation transformer is also required when working on any equipment or circuits that operate directly connected to the line. Note that your test equipment will also have to be powered through the isolation transformer in such cases!

A good multi-voltage supply will help with nearly any analog or digital troubleshooting project. Many electronics distributors stock bench power supplies. A variable-voltage dc supply may be used to power various small items under repair or provide a variable bias supply for testing active devices. Construction details for a laboratory power supply appear in the **Power Sources** chapter.

**Heat and cold sources** — Many circuit problems are sensitive to temperature. A piece of equipment may work well when first turned on (cold) but fail as it warms up. In this case, a cold source will help you find the intermittent connection. When you cool the bad component, the circuit will suddenly start working again (or stop working). Cooling sprays are available from most parts suppliers.

A heat source helps locate components that fail only when hot. A small incandescent lamp can be mounted in a large piece of sleeve insulation to produce localized heat for test purposes. The tip of a soldering iron set to low heat can also be used.

A heat source is usually used in conjunction with a cold source. If you have a circuit that stops working when it warms up, heat the circuit until it fails, then cool the components one by one. When the circuit starts working again, the last component sprayed was the bad one.

**Stethoscope** — A stethoscope (with the pickup removed — see Figure 26.7) or a long piece of sleeve insulation can be used to listen for arcing or sizzling in a circuit. Remove any metal parts at the end of the pickup tube before use for troubleshooting live equipment.

**Figure 26.7** — A stethoscope, with the pickup and all metal hardware removed from the listening tube, is used to listen for arcing in crowded circuits.

## The Shack Notebook

A shack notebook is an excellent way to keep track of test results, wiring, assembly notes and so forth. If you haven't already started one, now is a good time. All it takes is an inexpensive composition book or spiral-bound notebook. The books filled with graph paper are especially good for drawing and making graphs.

The goal is to have one place where information is collected about how equipment was built, performs, or operates. The notebook is invaluable when trying to determine if performance has changed over time or what color code was used for a control cable, for example.

Before beginning a test session or when adding a new piece of equipment to your shack, get out the shack notebook first and have it available as you work. For new equipment, record serial numbers, when installed, whether it was modified or specially configured to work in your station, etc. For a new antenna or feed line, it's a good idea to make a few SWR measurements so you can refer to them later if something seems wrong in the antenna system. Be sure to include the date of any entries, as well.

You can also make good use of that digital camera, even the one in your mobile phone. Take pictures of equipment, inside and out, to document how it is assembled or configured. This can be very helpful when you have to maintain the equipment later.

## 26.2 Components

Once you locate a defective part, it is time to select a replacement. This is not always an easy task. Each electronic component has a function. This section acquaints you with the functions, failure modes and test procedures of resistors, capacitors, inductors and other components. Test the components implicated by symptoms and stage-level testing. In most cases, a particular faulty component will be located by these tests. If a faulty component is not indicated, check the circuit adjustments. As a last resort, use a “shotgun” approach — replace all parts in the problem area with components that are known to be good.

### 26.2.1 Check the Circuit

Before you install a replacement component of any type, you should be sure that another circuit defect didn't cause the failure. Check the circuit voltages carefully before installing any new component, especially on each trace or connection to the bad component. The old part may have died as a result of a lethal voltage. Measure twice — repair once! (With apologies to the old carpenter...) Of course, circuit performance is the final test of any substitution.

### 26.2.2 Fuses

Most of the time, when a fuse fails, it is for a reason — usually a short circuit in the load. A fuse that has failed because of a short circuit usually shows the evidence of high current: a blackened interior with little blobs of fuse element everywhere. Fuses can also fail by fracturing the element at either end. This kind of failure is not visible by looking at the fuse. Check even fuses thought to be good with an ohmmeter. You may save hours of troubleshooting.

For safety reasons, always use *exact* replacement fuses. Check the current and voltage ratings. The fuse timing (fast, normal or slow blow) must be the same as the original. Never attempt to force a fuse that is not the right size into a fuse holder. The substitution of a bar, wire or penny for a fuse invites a smoke party.

### 26.2.3 Wires and Cables

Wires seldom fail unless abused. Short circuits can be caused by physical damage to insulation or by conductive contamination. Damaged insulation is usually apparent during a close visual inspection of the conductor or connector. Look carefully where conductors come close to corners or sharp objects. Repair worn insulation by replacing the wire or securing an insulating sleeve (spaghetti) or heat-shrink tubing over the worn area.

When wires fail, the failure is usually

caused by stress and flexing. Nearly everyone has broken a wire by bending it back and forth, and broken wires are usually easy to detect. Look for sharp bends or bulges in the insulation.

When replacing conductors, use the same material and size, if possible. Substitute only wire of greater cross-sectional area (smaller gauge number) or material of greater conductivity. Insulated wire should be rated at the same, or higher, temperature and voltage as the wire it replaces.

Cables used for audio, control signals, and feed lines sometimes fail from excessive flexing, being crimped or bent too abruptly, or getting pulled out of connectors. As with replacing wires, use the same cable type or one with higher ratings.

### 26.2.4 Connectors

Connection faults are one of the most common failures in electronic equipment. This can range from something as simple as the ac-line cord coming out of the wall, to a connector having been inserted into the wrong socket, to a defective IC socket. Connectors that are plugged and unplugged frequently can wear out, becoming intermittent or noisy. Inspect male connectors for bent pins, particular miniature connectors with very small pins. Check connectors carefully when troubleshooting.

Connector failure can be hard to detect. Most connectors maintain contact as a result of spring tension that forces two conductors together. As the parts age, they become brittle and lose tension. Any connection may deteriorate because of nonconductive corrosion at the contacts. Solder helps prevent this problem but even soldered joints suffer from corrosion when exposed to weather.

Signs of excess heat are sometimes seen near poor connections in circuits that carry moderate current. The increase in dissipated power at the poor connection heats the contacts, and this leads to more resistance and soon the connection fails. Check for short and open circuits with an ohmmeter or continuity tester. Clean those connections that fail as a result of contamination.

Occasionally, corroded connectors may be repaired by cleaning, but replacement of the conductor/connector is usually required, especially for battery holders supplying moderate currents. Solder all connections that may be subject to harsh environments and protect them with acrylic enamel, RTV compound or a similar coating. An anti-corrosion compound or grease is a good idea for connections located outside. See the entry on Weatherproofing RF Connectors in the Antenna and Tower Safety section of the **Safety** chapter.

Choose replacement connectors with consideration of voltage and current ratings. Use connectors with symmetrical pin arrangements only where correct insertion will not result in a safety hazard or circuit damage.

### 26.2.5 Resistors

Resistors usually fail by becoming an open circuit. More rarely they change value. Both failures are usually caused by excess heat. Such heat may come from external sources or from power dissipated within the resistor. Sufficient heat burns the resistor until it becomes an open circuit.

Resistors can also fracture and become an open circuit as a result of physical shock. Contamination on or around a high-value resistor (100 k $\Omega$  or more) can cause a change in value by providing a leakage path for current around a resistor. This contamination can occur on the resistor body, mounts or printed-circuit board. Resistors that have changed value should be replaced. Leakage is cured by cleaning the resistor body and surrounding area.

In addition to the problems of fixed-value resistors, potentiometers and rheostats can develop noise problems, especially in dc circuits. Dirt often causes intermittent contact between the wiper and resistive element. To cure the problem, spray electronic contact cleaner into the control, through holes in the case, and rotate the shaft a few times.

The resistive element in wire-wound potentiometers eventually wears and breaks from the sliding action of the wiper. In this case, the control needs to be replaced.

Replacement resistors should be of the same value, tolerance, type and power rating as the original. The value should stay within tolerance. Replacement resistors may be of a different type than the original, if the characteristics of the replacement are consistent with circuit requirements. (See the **Electrical Fundamentals** chapter for more information on resistor types.)

Substitute resistors can usually have a greater power rating than the original, except in high-power emitter circuits where the resistor also acts as a fuse or in cases where the larger size presents a problem.

Variable resistors should be replaced with the same kind (carbon or wire wound) and taper (linear, log, reverse log and so on) as the original. Keep the same, or better, tolerance and pay attention to the power rating.

In all cases, mount high-temperature resistors away from heat-sensitive components. Keep carbon composition and film resistors away from heat sources. This will extend their life and ensure minimum resistance variations.

## 26.2.6 Capacitors

Capacitors usually fail by shorting, opening or becoming electrically (or physically) leaky. They rarely change value. Capacitor failure is usually caused by excess current, voltage, temperature or aging of the dielectric or materials making up the capacitor. Leakage can be external to the capacitor (contamination on the capacitor body or circuit) or internal to the capacitor.

### TESTS

If you do not have a multimeter with a capacitor test function or a component tester, the easiest way to test capacitors is out of circuit with an ohmmeter. In this test, the resistance of the meter forms a timing circuit with the capacitor to be checked. Capacitors from 0.01  $\mu\text{F}$  to a few hundred  $\mu\text{F}$  can be tested with common ohmmeters. Set the meter to its highest range and connect the test leads across the discharged capacitor. When the leads are connected, current begins to flow. Current is high when the capacitor is discharged, but drops as the capacitor voltage builds up. This shows on the meter as a low resistance that builds, over time, toward infinity.

The speed of the resistance build-up corresponds to capacitance. Small capacitance values approach infinite resistance almost instantly. A 0.01  $\mu\text{F}$  capacitor checked with a meter having an 11 M $\Omega$  input impedance would increase from zero to a two-thirds scale reading in 0.11 second, while a 1  $\mu\text{F}$  unit would require 11 seconds to reach the same reading. If the tested capacitor does not reach infinity within five times the period taken to reach the two-thirds point, it has excess leakage. If the meter reads infinite resistance immediately, the capacitor is open. (Aluminum electrolytics normally exhibit high-leakage readings.)

Capacitance can also be measured for approximate value with a dip meter by constructing a parallel-resonant circuit using an inductor of known value. The formula for resonance is discussed in the **Electrical Fundamentals** chapter of this book.

It is good practice to keep a collection of known components that have been measured on accurate L or C meters. Alternatively, a standard value can be obtained by ordering 1 or 2% components from an electronics supplier. A 10% tolerance component can be used as a standard; however, the results will be known only to within 10%. The accuracy of tests made with any of these alternatives depends on the accuracy of the standard value component. Further information on this technique appears in Bartlett's article, "Calculating Component Values," in Nov 1978 *QST*.

Older capacitors can also be checked and the dielectric reformed, if necessary, with a

**Figure 26.8** — Partial view of an air-dielectric variable capacitor. If the capacitor is noisy or erratic in operation, apply electronic cleaning fluid where the wiper contacts the rotor plates.

capacitor checker of similar vintage. See this chapter's section on Restoration and Repair of Vintage Radios for more information about this technique.

### CLEANING

The only variety of common capacitor that can be repaired is the air-dielectric variable capacitor. Electrical connection to the moving plates is made through a spring-wiper arrangement (see **Figure 26.8**). Dirt normally builds on the contact area, and they need occasional cleaning. Before cleaning the wiper/contact, use gentle air pressure and a soft brush to remove all dust and dirt from the capacitor plates. Apply some electronic contact cleaning fluid. Do not lubricate the contact point. Rotate the shaft quickly several times to work in the fluid and establish contact. Use the cleaning fluid sparingly, and keep it off the plates except at the contact point.

## Batteries and Tools

When working on equipment powered by a battery with a capacity of more than a few ampere-hours (Ah), take special care to avoid short circuits and always have a fuse or circuit-breaker in-line to the battery. If possible, fuse both the positive and negative connections. This is particularly important for vehicle batteries and mobile equipment. A short circuit can do thousands of dollars of damage to a vehicle's electrical power system in a matter of seconds! When working on mobile equipment, disconnect the battery's positive terminal or at least disconnect the circuit that powers the equipment by removing the fuse.

A tool that accidentally short-circuits the battery terminals can cause an instantaneous current flow of thousands of amps, often destroying both the battery and the tool and creating a significant fire and burn hazard.

## REPLACEMENTS

Replacement capacitors should match the original in value, tolerance, dielectric, working voltage and temperature coefficient. Use only ac-rated capacitors for line service (capacitors connected directly to the ac line) to prevent fire hazards. If exact replacements are not available, substitutes may vary from the original part in the following respects: Bypass capacitors may vary from one to three times the capacitance of the original. Coupling capacitors may vary from one-half to twice the value of the original. Capacitance values in tuned circuits (especially filters) must be exact. (Even then, any replacement will probably require circuit realignment.)

If the same kind of capacitor is not available, use one with better dielectric characteristics. Do not substitute polarized capacitor for non-polarized parts. Capacitors with higher working voltage may be used, although the capacitance of an electrolytic capacitor used significantly below its working voltage will usually increase with time.

The characteristics of each type of capacitor are discussed in the **Electrical Fundamentals** and **RF Techniques** chapters. Consider these characteristics if you're not using an exact replacement capacitor.

## 26.2.7 Inductors and Transformers

The most common inductor or transformer failure is a broken conductor. More rarely, short circuit can occur across one or more turns of a coil. In an inductor, this changes the value. In a transformer, the turns ratio and resultant output voltage changes. In high power circuits, excessive inductor current can generate enough heat to melt plastics used as coil forms.

Inductors may be checked for open circuit failure with an ohmmeter. In a good inductor, dc resistance rarely exceeds a few ohms. Shorted turns and other changes in inductance show only during alignment or inductance measurement.

The procedure for measurement of inductance with a dip meter is the same as that given for capacitance measurement, except that a capacitor of known value is used in the resonant circuit.

Replacement inductors must have the same inductance as the original, but that is only the first requirement. They must also carry the same current, withstand the same voltage, and present nearly the same Q as the original part. Given the original as a pattern, the amateur can duplicate these qualities for many inductors. Note that inductors with ferrite or iron-powder cores are frequency sensitive, so the replacement must have the same core material.

If the coil is of simple construction, with the form and core undamaged, carefully count and write down the number of turns and their placement on the form. Also note how the coil leads are arranged and connected to the circuit. Then determine the wire size and insulation used. Wire diameter, insulation and turn spacing are critical to the current and voltage ratings of an inductor. (There is little hope of matching coil characteristics unless the wire is duplicated exactly in the new part.) Next, remove the old winding — be careful not to damage the form — and apply a new winding in its place. Be sure to dress all coil leads and connections in exactly the same manner as the original. Apply Q dope (a solution of polystyrene plastic) or a thin coating of plastic-based glue to hold the finished winding in place.

Follow the same procedure in cases where the form or core is damaged, except that a suitable replacement form or core (same dimensions and permeability) must be found.

Ready-made inductors may be used as replacements if the characteristics of the original and the replacement are known and compatible. Unfortunately, many inductors are poorly marked. If so, some comparisons, measurements and circuit analysis are usually necessary.

When selecting a replacement inductor, you can usually eliminate parts that bear no physical resemblance to the original part. This may seem odd, but the Q of an inductor depends on its physical dimensions and the permeability of the core material. Inductors of the same value, but of vastly different size or shape, will likely have a great difference in Q. The Q of the new inductor can be checked by installing it in the circuit, aligning the stage and performing the manufacturer's passband tests. Although this practice is all right in a pinch, it does not yield an accurate Q measurement. Methods to measure Q appear in the **Test Equipment and Measurements** chapter.

Once the replacement inductor is found, install it in the circuit. Duplicate the placement, orientation and wiring of the original. Ground-lead length and arrangement should not be changed. Isolation and magnetic shielding can be improved by replacing solenoid inductors with toroids. If you do, however, it is likely that many circuit adjustments will be needed to compensate for reduced coupling and mutual inductance. Alignment is usually required whenever a tuned-circuit component is replaced.

A transformer consists of two inductors that are magnetically coupled. Transformers are used to change voltage and current levels (this changes impedance also). Failure usually occurs as an open circuit or short circuit of one or more windings. Insulation

failures can also occur that result in short circuits between windings or between windings and the core or case. It is also common for the insulated wire leads to develop cracks or abrasion where they come out of the case. This can be repaired easily by replacing the lead, or if the conducting wire strands are not burned or broken, by sliding an insulation sleeve over the wire to protect the insulation from further wear.

Amateur testing of power transformers is mostly limited to ohmmeter tests for open circuits and voltmeter checks of secondary voltage. Make sure that the power-line voltage is correct, then check the secondary voltage against that specified. There should be less than 10% difference between open-circuit and full-load secondary voltage. A test setup and procedure for evaluating power transformers is also provided in the **Power Sources** chapter.

Replacement transformers must match the original in voltage, volt-ampere (VA), duty cycle and operating-frequency ratings. They must also be compatible in size. (All transformer windings should be insulated for the full power supply voltage.)

When disconnecting a transformer for testing or repair, be sure to carefully record the color and connection for each of the transformer leads. In power transformers it is common for leads to be mostly one color but with a contrasting stripe or other pattern that can be overlooked. If in doubt, use tape or paper labels to note the connection for each lead. Recording transformer color codes and connections is a good use of the shack notebook.

## 26.2.8 Relays

Although relays have been replaced by semiconductor switching in low-power circuits, they are still used extensively in high-power Amateur Radio equipment for applications such as amplifier TR switching and in antenna systems or ac power control. Relay action may become sluggish. AC relays can buzz (with adjustment becoming impossible). A binding armature or weak springs can cause intermittent switching. Excessive use or hot switching ruins contacts and shortens relay life.

You can test relays with a voltmeter by measuring voltage across contacts (power on, in-circuit) or with an ohmmeter (out of circuit). Look for erratic readings across the contacts, open or short circuits at contacts or an open circuit at the coil. A visual inspection with a magnifying glass should show no oxidation or corrosion. Limited pitting is usually OK.

Most failures of simple relays can be repaired by a thorough cleaning. Clean the contacts and mechanical parts with a residue-free cleaner. Keep it away from the coil and plastic

parts that may be damaged. Dry the contacts with lint-free paper, such as a business card; then burnish them with a smooth steel blade. Do not use a file to clean contacts because it will damage the contact surface.

Replacement relays should match or exceed the original specifications for voltage, current, switching time and stray impedance (impedance is significant in RF circuits only). Many relays used in transceivers are specially made for the manufacturer. Substitutes may not be available from any other source.

Before replacing a multi-contact relay, make a drawing of the relay, its position, the leads and their routings through the surrounding parts. This drawing allows you to complete the installation properly, even if you are distracted in the middle of the operation. (This is a good use of the shack notebook!)

## 26.2.9 Semiconductors

Testing diodes and transistors with the ohmmeter function of an analog VOM used to be the normal method. Today's inexpensive multimeters nearly always provide a forward and reverse junction voltage drop test function. This almost eliminates the need for resistance-based tests for functional troubleshooting with the attendant variability and dependence on meter circuits. However, it is occasionally useful to perform threshold and voltage-current testing to match components or troubleshoot a specialized circuit. In support of those tests, a short article "Diode and Transistor Test Circuits" containing test circuits and procedures for measuring leakage, gain, Zener point voltage and so forth is included with the downloadable supplemental content. This section will focus on simple go/no-go testing.

### DIODES

The primary function of a diode is to pass current in one direction only. They can be easily tested with an ohmmeter, and most multimeters have a diode junction test function built-in as well.

**Signal or switching diodes** — The most common diode in electronics equipment, signal diodes are used to convert ac to dc, to detect RF signals or to take the place of relays to switch ac or dc signals within a circuit. Signal diodes usually fail open, although shorted diodes are not rare.

**Power rectifiers** — Most equipment contains a power supply, so power rectifier diodes are the second-most common diodes in electronic circuitry. They usually fail shorted, blowing the power-supply fuse.

**Other diodes** — Zener diodes are made with a predictable reverse-breakdown voltage and are used as voltage regulators. Varactor diodes are specially made for use as voltage controlled variable capacitors. (Any semiconductor diode may be used as

a voltage-variable capacitance, but the value will not be as predictable as that of a varactor.) A diac is a special-purpose diode that passes only pulses of current in each direction.

**Diode testing** — There are several basic tests for most diodes. First, is it a diode? Does it conduct in one direction and block current flow in the other? A simple resistance measurement is suitable for this test in most cases.

Diodes should be tested out of circuit. Disconnect one lead of the diode from the circuit, then perform the test. We can also test diodes by measuring the voltage drop across the diode junction while the diode is conducting.

A functioning diode will show high resistance in one direction and low resistance in the other. A DMM with a diode-test function is the best instrument to use. If using an analog meter, make sure more than 0.7 V and less than 1.5 V is used to measure resistance. Use the highest resistance scale of the meter that gives a reading of less than full-scale. Check a known-good diode to determine the meter polarity if there is any question. Compare the forward and reverse resistance readings for a known-good diode to those of the diode being tested to determine whether the diode is good.

Diode junction forward voltage drops are measured by a multimeter's diode test function. Silicon junctions usually show about 0.6 V at typical test current levels, while germanium is typically 0.2 V. Junction voltage drop increases with current flow.

Multimeters measure the junction resistances at low voltage and are not useful for testing Zener diodes. A good Zener diode will not conduct in the reverse direction at voltages below its rating. See the article included with the downloadable supplemental content, and mentioned at the beginning of this section for procedures and a circuit to determine Zener diode performance.

**Replacement diodes** — When a diode fails, check associated components as well. Replacement rectifier diodes should have the same current and peak inverse voltage (PIV) as the original. Series diode combinations are often used in high-voltage rectifiers. (The resistor and capacitor networks used to distribute the voltage equally among the diodes are no longer required for new rectifiers but should be retained for older parts. See the **Power Sources** chapter for more information.)

Switching diodes may be replaced with diodes that have equal or greater current ratings and a PIV greater than twice the peak-to-peak voltage encountered in the circuit. Switching time requirements are not critical except in RF, logic and some keying circuits. Logic circuits may require exact replacements to assure compatible switching speeds and load characteristics. RF switching diodes used near resonant circuits must have exact

replacements as the diode resistance and capacitance will affect the tuned circuit.

Voltage and capacitance characteristics must be considered when replacing varactor diodes. Once again, exact replacements are best. Zener diodes should be replaced with parts having the same Zener voltage and equal or higher power rating, and equal or lower tolerance. Check the associated current-limiting resistor when replacing a Zener diode.

## BIPOLAR TRANSISTORS

Transistor failures occur as an open junction, a shorted junction, excess leakage or a change in amplification performance. Most transistor failure is catastrophic. A transistor that has no leakage and amplifies at dc or audio frequencies will usually perform well over its design range. For this reason, transistor tests need not be performed at the planned operating frequency. Tests are made at dc or a low frequency (usually 1000 Hz). The circuit under repair is the best test of a potential replacement part. Swapping in a replacement transistor in a failed circuit will often result in a cure.

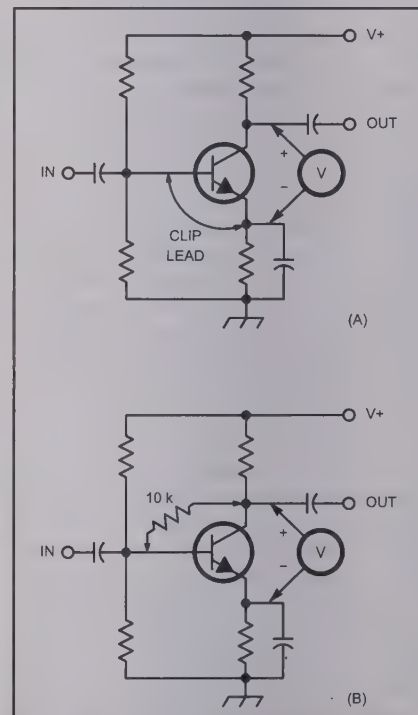

A simple and reliable test of bipolar transistors can be performed with the transistor in a circuit and the power on. It requires a test lead, a 10 k $\Omega$  resistor and a voltmeter. Connect the voltmeter across the emitter/collector leads and read the voltage. Then use the test lead to connect the base and emitter (Figure 26.9A). Under these conditions, conduction of a good transistor will be cut off and the meter should show nearly the entire supply voltage across the emitter/collector leads. Next, remove the clip lead and connect the 10 k $\Omega$  resistor from the base to the collector. This should bias the transistor into conduction and the emitter/collector voltage should drop (Figure 26.9B). (This test indicates transistor response to changes in bias voltage.)

Transistors can be tested (out of circuit) with an ohmmeter in the same manner as diodes or a multimeter with a transistor test

function can be used. Before using the ohmmeter-transistor circuit, look up the device characteristics before testing and consider possible consequences of testing the transistor in this way. Limit junction current to 1 to 5 mA for small-signal transistors. Transistor destruction or inaccurate measurements may result from careless testing.

The reverse-to-forward resistance ratio for good transistors may vary from 30:1 to better than 1000:1. Germanium transistors — still occasionally encountered — sometimes show high leakage when tested with an ohmmeter. Bipolar transistor leakage may be specified from the collector to the base, emitter to base or emitter to collector (with the junction reverse biased in all cases). The specification may be identified as  $I_{cbo}$ ,  $I_{ebo}$ , collector cutoff current or collector leakage for the base-collector junction,  $I_{ebc}$ , and so on for other junctions. Leakage current increases with junction temperature. (See the **Circuits and Components** chapter for definitions of these and other transistor parameters.)

While these simple test circuits will identify most transistor problems, RF devices should be tested at RF. Most component manufacturers include a test-circuit schematic on

**Figure 26.9** — An in-circuit semiconductor test with a clip lead, resistor and voltmeter. The meter should read  $V+$  at (A). During test (B) the meter should show a decrease in voltage, ranging from a slight variation down to a few millivolts. It will typically cut the voltage to about half of its initial value.

## Cross-Reference Replacement Semiconductors

Semiconductors from older equipment, even ICs, may be available as a cross-reference generic replacement. The primary source for these devices is NTE Electronics ([www.nteinc.com](http://www.nteinc.com)). Enter the part number of the device you are trying to replace in the "Cross-Reference" window. NTE also supplies cross-referenced replacements for ECG part numbers which were the original generic replacement parts.

the data sheet. The test circuit is usually an RF amplifier that operates near the high end of the device frequency range. If testing at RF is not possible, substitution of a known-good device is required.

Semiconductor failure is sometimes the result of environmental conditions. Open junctions, excess leakage (except with germanium transistors) and changes in amplification performance result from overload or excessive current.

Shorted junctions (low resistance in both directions) are usually caused by voltage spikes. Electrostatic discharge (ESD) or transients from lightning can destroy a semiconductor in microseconds.

Transistors rarely fail without an external cause. Check the surrounding parts for the cause of the transistor's demise, and correct the problem before installing a replacement.

### JFETs

Junction FETs can be tested with a multimeter's diode junction test function in much the same way as bipolar transistors (see text and **Figure 26.10**). Reverse leakage should be several megohms or more. Forward resistance should be 500 to 1000  $\Omega$  if measured with an analog meter.

### MOSFETs

Small-signal MOS (metal-oxide semiconductor) layers are extremely fragile. Normal body static is enough to damage them. Even gate protected (a diode is placed across the MOS layer to clamp voltage) MOSFETs may be destroyed by a few volts of static electricity. MOSFETs used for power circuits and RF amplifiers are much more resistant to damage. The manufacturer's sheet will specify any special static-protection measures that are required. (See the **Construction Techniques** chapter for more information about managing static at the workbench.)

When testing small MOSFETs make sure the power is off, capacitors discharged and the leads are shorted together before installing or removing it from a circuit. Use a voltmeter to be sure the chassis is near ground potential, then touch the chassis before and during MOSFET installation and removal. This assures that there is no difference of potential between your body, the chassis and the MOSFET leads. Ground the soldering-iron tip with a clip lead when soldering MOS devices. The FET source should be the first lead connected to and the last disconnected from a circuit. The insulating layers in MOSFETs prevent testing with an ohmmeter. Substitution is the only practical means for amateur testing of MOSFETs.

### FET CONSIDERATIONS

Replacement FETs should be of the same

**Figure 26.10 — Ohmmeter tests of a JFET. The junction is reverse biased at A and forward biased at B. (Analog meters are shown for convenience of illustration.)**

type as the original part: JFET or MOSFET, P-channel or N-channel, enhancement or depletion. Consider the breakdown voltage required by the circuit. The breakdown voltage should be at least two to four times the power-supply and signal voltages in amplifiers. Allow for transients of 10 times the line voltage in power supplies. Breakdown voltages are usually specified as  $V_{(BR)GSS}$  or  $V_{(BR)GDO}$ .

The gate-voltage specification gives the gate voltage required to cut off or initiate channel current (depending on the mode of operation). Gate voltages are usually listed as  $V_{GS(OFF)}$ ,  $V_p$  (pinch off),  $V_{TH}$  (threshold) or  $I_{D(ON)}$  or  $I_{TH}$ .

Dual-gate MOSFET characteristics are more complicated because of the interaction of the two gates. Cutoff voltage, breakdown voltage and gate leakage are the important traits of each gate.

## INTEGRATED CIRCUITS

The basics of integrated circuits are covered in earlier chapters of this book. Amateurs seldom have the sophisticated equipment required to test ICs. Even a multi-channel oscilloscope can view only their simplest functions. We must be content to check every other possible cause, and only then assume that the problem lies with an IC. Experienced troubleshooters will tell you that — most of the time anyway — if a defective circuit uses an IC, it is the IC that is bad.

**Linear ICs** — There are two major classes of ICs: linear and digital. Linear ICs are best replaced with identical units. Original equipment manufacturers are the best source of a replacement; they are the only source with a reason to stockpile obsolete or custom-made items. If substitution of an IC is unavoidable, first try the cross-reference website of NTE mentioned in the sidebar. You can also look in manufacturers' websites and compare pin-outs and other specifications.

**Digital ICs** — It is usually not a good idea to substitute digital devices. While it may be okay to substitute an AB74LS00YZ from one manufacturer with a CD74LS00WX from a different manufacturer, you will usually not be able to replace an LS (low-power Schottky) device with an S (Schottky), C (CMOS) or any of a number of other families. The different families all have different speed, current-consumption, input and output characteristics. You would have to analyze the circuit to determine if you could substitute one type for another.

## SEMICONDUCTOR SUBSTITUTION

In all cases try to obtain exact replacement semiconductors. Specifications vary slightly from one manufacturer to the next. Cross-reference equivalents such as NTE ([www.nteinc.com](http://www.nteinc.com)) are useful, but not guaranteed to be an exact replacement. Before using an equivalent, check the specifications against those for the original part. When choosing a replacement, consider:

- Is it a PNP or an NPN?
- What are the operating frequency and input/output capacitance?
- How much power can it dissipate (often less than  $V_{max} \times I_{max}$ )?
- Will it fit the original socket or pad layout?
- Are there unusual circuit demands (low noise and so on)?
- What is the frequency of operation?

Remember that cross-reference equivalents are not guaranteed to work in every application. In cases where an absolutely exact replacement is required for an obsolete part, Rochester Electronics ([www.rocelec.com](http://www.rocelec.com)) or 4 Star Electronics ([www.4starelectronics.com](http://www.4starelectronics.com)) maintain extensive stocks, although the

cost is likely to be rather high.

There may be cases where two dissimilar devices have the same part number, so it pays to compare the listed replacement specifications with the intended use. If the book says to use a diode in place of an RF transistor, it isn't going to work! Derate power specifications, as recommended by the manufacturer, for high-temperature operation.

### 26.2.10 Tubes

The most common tube failures in amateur service are caused by cathode depletion and gas contamination. Whenever a tube is operated, the coating on the cathode loses some of its ability to produce electrons. It is time to replace the tube when electron production (cathode current,  $I_c$ ) falls to 50 to 60% of that exhibited by a new tube.

Gas contamination in a tube can often be identified easily because there may be

a greenish or whitish-purple glow between the elements during operation. (A faint deep-purple glow is normal in most tubes.) The gas reduces tube resistance and leads to runaway plate current evidenced by a red glow from the anode, interelectrode arcing or a blown power supply fuse. Less common tube failures include an open filament, broken envelope and inter-electrode shorts.

The best test of a tube is to substitute a new one. Another alternative is a tube tester; these are sometimes available at hamfests or through antique radio or audiophile groups. You can also do some limited tests with an ohmmeter. Tube tests should be made out of circuit so circuit resistance does not confuse the results.

Use an ohmmeter to check for an open filament (remove the tube from the circuit first). A broken envelope is visually obvious, although a cracked envelope may appear as a gassy tube. Interelectrode shorts are evident during voltage checks on the operating stage.

Any two elements that show the same voltage are probably shorted. (Remember that some inter-electrode shorts, such as the cathode-suppressor grid, are normal.)

Generally, a tube may be replaced with another that has the same type number. Compare the data sheets of similar tubes to assess their compatibility. Consider the base configuration and pinout, inter-electrode capacitances (a small variation is okay except for tubes in oscillator service), dissipated power ratings of the plate and screen grid and current limitations (both peak and average). For example, the 6146A may usually be replaced with a 6146B (heavy duty), but not vice versa.

In some cases, minor type-number differences signify differences in filament voltages, or even base styles, so check all specifications before making a replacement. (Even tubes of the same model number, prefix and suffix vary slightly, in some respects, from one supplier to the next.)

## 26.3 Getting Started

### INSTINCTIVE OR SYSTEMATIC

A systematic approach to troubleshooting uses a defined process to analyze and isolate the problem. An instinctive approach relies on troubleshooting experience to guide you in selecting which circuits to test and which tests to perform.

When instinct is based on experience, searching by instinct may be the fastest procedure. If your instinct is correct, repair time and effort may be reduced substantially. As experience and confidence grow, the merits of the instinctive approach grow with them. However, inexperienced technicians who choose this approach are at the mercy of chance.

A systematic approach is a disciplined procedure that allows us to tackle problems in unfamiliar equipment with a reasonable hope of success. The systematic approach is usually chosen by beginning troubleshooters.

### 26.3.1 The Systematic Approach

Armed with a collection of test equipment, you might be tempted to immediately dig in and start looking for the problem. While it is sometimes obvious what piece of equipment or subassembly inside equipment is at fault, the many connections that make up nearly all ham stations today make it far more effective to begin troubleshooting by looking at the problem from the system perspective. By *system*, we mean more than one piece of equipment or subassemblies connected

together — nothing fancier than that.

Amateur stations are full of systems: a digital mode system is made up of a radio, power supply, and PC. An antenna system consists of the antenna tuner, feed line, and antenna. Inside a radio there is a system made up of the power circuits, receiver, transmitter, control panel, and transmit-receive switching circuits. Connections between parts of the system need not be cables; wireless data links can also be part of a system.

In general, it's best to approach any problem — even the supposedly obvious problems — from the perspective of the system it affects. The first step is to determine the system with the smallest number of components that

exhibits the problem. Then you can start looking for the problem in one of those components or the connection between them. We'll start with an example to illustrate the process.

**Problem** — After a year of trouble-free operation, when you transmit with more than 50 W of output power using PSK31, other stations now report lots of distortion products around your signal on the waterfall display, even though the ALC is not active at all and no software level settings have been changed. This could be RF interference, a problem with the digital interface between the PC and the radio, settings in the PC, settings in the radio, a bad connection...there are lots of possibilities.

Figure 26.11 — The complete system of radio and power supply, data interface, laptop PC with a couple of accessories (Accy) and power supply, antenna tuner, antenna switch, antenna 1 and 2, and interconnecting cables.

**Figure 26.12** — The minimum system of radio and power supply, digital interface, laptop on battery power, antenna 1, and interconnecting cables.

Get a pad of paper and sketch out the system that is exhibiting the problem, such as in **Figure 26.11**. Write down what the symptom(s) is(are) and the conditions under which they occur. Figure 26.11 shows that you have a system that has a lot of parts involved, including the interconnecting cables. Let's simplify that system! For this type of problem, it would be very helpful to have a friend available to listen on the air as you troubleshoot. To find the minimum system, start by removing any accessories that aren't being used from the radio and PC and trying to reproduce the problem, writing down each step and noting whether the problem changed. Not only will you simplify the problem but in the process you will have an excellent opportunity to inspect and check connections and configurations — perhaps even discovering the problem!

Let's say that the distortion persists with the mouse and external display disconnected and the laptop running from its internal battery. Then you were able to remove the antenna tuner and antenna switch, manually attaching just one antenna to the radio at a time, and found that the problem only occurred when using antenna 1. Removing any other part of the system makes it non-functional, so you have found the minimum system with the problem as shown in **Figure 26.12**.

Now it's time to start making small changes in the minimum system to observe the effect, again taking notes as you go. Changing the microphone gain a little bit up and down has hardly any effect. Changing the PC sound card output audio level a little bit also has hardly any effect. Reducing RF output power a little bit has a *big* effect: as power is reduced, so are the distortion products. Below 35 W, the problem was completely gone! This is an important clue, dutifully recorded on the pad of paper. Replacing antenna 1 with a dummy load had a similar effect — the problem disappeared according to your friend, who lives

close enough to hear the weak signal leaking out of your greatly reduced antenna system. Putting antenna 1 back on the radio causes the problem to come back above 35 W, too.

The behavior of the problem points strongly to RF being picked up by a cable in your minimum system and interfering with the low-level digital audio. It's time for a close inspection of each remaining cable. Removing the radio's microphone connector shell and checking the wires inside didn't turn up anything — all of the connections were intact and only touching what they were supposed to touch. Looking at the cable between the digital interface and the sound card, though, you see that the shield of the cable at the PC end is badly frayed and barely making contact at all! In a few minutes, you've trimmed and re-soldered the cable, plugging it back into the PC. Testing even at full power output shows no distortion products on either antenna.

You fixed the problem by finding the minimum system and then inspecting one thing at a time until the root cause was found and eliminated.

What if the root cause didn't appear when you checked the cables? Then you would have to continue to test the system at the interfaces where the system components are connected together. You could measure signal levels with a sensitive voltmeter. You could add ferrite beads or cores on cables that might be picking up RF. You could check to see if the radio's power supply output is stable and clean as the transmitter power increases.

Another strategy would be to substitute known good components, one at a time, and see if the problem changes or disappears: You might swap in a different data interface. You could change the cables. Try a different power supply or radio or laptop.

Most systematic testing combines direct testing or inspection and a process of substitution. The goal is to either find the root cause or find the system component in which the

## Read the Manual!

Your equipment may be working as designed. Many electronic "problems" are caused by a switch or control in the wrong position, a misconfigured menu item, or a unit that is being asked to do something it was not designed to do. Before you open up your equipment for major surgery, make sure you are using it correctly. Most user's manuals have a procedure for setting up the equipment initially and for performing partial and full resets of microprocessor-controlled gear.

root cause is hiding. Once you have a system component identified as the culprit, treat the component as a system itself and start the process all over again. Eventually, you'll find the problem.

Here are some guidelines to systematic troubleshooting in the ham shack:

1. Take the time to define and understand the system exhibiting the problem.
2. Remove system components one at a time.
3. Verify that the problem still exists. If not, restore that component.
4. Continue to remove components and test until the minimum system exhibiting the problem has been reached.
5. Inspect what is happening at each interface between system components by testing or substitution. In the example, you inspected the cables connecting the radio and other system components.
6. If a problem is identified, correct it and re-test.
7. Otherwise, continue to test or substitute each system component until the root cause has been identified or isolated to one component.

8. Treat that component as a new system and return to step 1.

Systematically reducing the number of components and testing each interface between them is almost always the fastest way to determine where the problem's root cause really lies. You may be a lucky guesser and sometimes a little plume of smoke is a dead giveaway, but in the long run, the system approach will save you time and money.

### 26.3.2 Assessing the Symptoms

An important part of the troubleshooting process is a careful definition of just what the symptoms of the problem really are. It is important to note exactly how the problem

manifests itself and the conditions under which the problem occurs. Avoid vague descriptions such as “broken” and “not working.” Train yourself to use precise descriptions such as “relay fails to activate” or “no speaker output.”

Ask yourself these questions:

1. What functions of the equipment do not work as they should; what does not work at all?
2. What kind of performance can you realistically expect?
3. Has the trouble occurred in the past? (Keep a record of troubles and maintenance in the owner’s manual, shack notebook or log book.)

Write down the answers to the questions. The information will help with your work, and it may help service personnel if their advice or professional service is required.

Question your assumptions and verify what you think you know. Are you *sure* that power supply output is OK under all conditions? Did you actually confirm that there is continuity at every position of the antenna switch? If there is any doubt, make a confirming measurement or inspection. Countless hours have been wasted because of unjustified assumptions!

Intermittent problems are generally harder to track down, so try to note the conditions under which the problem occurs — those are often important clues.

Troubleshooting is a good reason to do regular maintenance. Not only will you have fewer problems, but when something is just a little off or out of place, you are much likelier to notice it. Learn to listen to the little voice in your head noting something out of the ordinary. Don’t discount the wild cards that occasionally cause problems.

Occasionally step away from the workbench and relax. Take a walk. Your mind will continue to think about the problem and

## Newly Constructed Equipment

What if you built a piece of equipment and it doesn’t work? In most repair work, the troubleshooter is aided by the knowledge that the circuit once worked so that it is only necessary to find and replace the faulty part(s). This is not the case with newly constructed equipment.

Repair of equipment with no working history is a special, and difficult, case. You may be dealing with a defective component, construction error or even a faulty design. Carefully checking for these defects can save you hours. This is a good reason to test homebrew equipment at each possible step and on a section-by-section basis, if possible. In that way, you’ll know more about what does work if the completed project has a problem.

you may surprise yourself when you sit back down to work!

If you can bounce ideas off a friend, try explaining the problem and letting the friend ask you questions. It’s common for someone else with a different perspective to ask questions you haven’t thought of.

### 26.3.3 External Inspection

Inspection is the easiest part of troubleshooting to do and careful, detailed inspection will often find the problem or a clue that leads to it. Make sure you have some paper to keep notes on as you go so when something occurs to you it can be recorded.

Try the easy things first. If you are able

to solve the problem by replacing a fuse or reconnecting a loose cable, you might be able to avoid a lot of effort. Many experienced technicians have spent hours troubleshooting a piece of equipment only to learn the hard way that the on/off switch was set to OFF, the squelch control was set too high, or that they were not using the equipment properly.

Next, make sure that equipment is plugged in, that the ac outlet does indeed have power, that the equipment is switched on and that all of the fuses are good. If the equipment uses batteries or an external power supply, make sure they supply the right voltage under load.

Check that all wires, cables and accessories are working and plugged into the right connectors or jacks. In a system of components, it is often difficult to be sure which component or subsystem is bad. Your transmitter may not work on SSB because the transmitter is bad, but it could also be a bad microphone.

Connector faults or misconnections are common. Consider them prime suspects in your troubleshooting detective work. Do a thorough inspection of the connections. Is the antenna connected? How about the speaker, fuses and TR switch? Are transistors and ICs firmly seated in their sockets? Are interconnection cables sound and securely connected? Are any pins bent or is a connector inserted improperly? Many of the problems are obvious to the eye, so look around carefully.

While you are performing your inspection, don’t forget to use all of your senses. Do you smell anything burnt or overheated? Is something leaking electrolyte or oil? Perhaps a component or connector looks overheated and discolored. Is mounting hardware secure?

Once you’re done with your inspection, retest the equipment to be sure the problem is still there or note if it has changed in some way.

## 26.4 Inside the Equipment

At this point, you’ve determined that a specific piece of equipment has a problem. A visual inspection of all the operating controls and connections hasn’t turned up anything, but the problem is still there. It is time to really dig in, take it apart, and fix it!

### 26.4.1 Documentation

In order to test any piece of equipment, you’ll probably need at least a user’s manual. If at all possible, locate a schematic diagram and service manual. It is possible to troubleshoot without a service manual, but a schematic is almost indispensable.

The original equipment manufacturer is the best source of a manual or schematic. However, many old manufacturers have gone out of business. Several sources of equipment manuals can be located by a web search or from one of the *QST* vendors that sell equipment needs. In addition K4XL’s Boat Anchor Manual Archive ([www2.faculty.sbc.edu/kgrimm/boatanchor](http://www2.faculty.sbc.edu/kgrimm/boatanchor)) has hundreds of freely downloadable electronic copies of equipment manuals. If there is a user’s group or email list associated with your equipment, a request to the group may turn up a manual and maybe even troubleshooting assistance.

If all else fails, you can sometimes reverse

engineer a simple circuit by tracing wiring paths and identifying components to draw your own schematic. By downloading data sheets for the active devices used in the circuit, the pin-out diagrams and application notes will sometimes be enough to help you understand and troubleshoot the circuit.

### THE BLOCK DIAGRAM

An important part of the documentation is the block diagram. It shows the signal paths for each circuit function. The paths may run together, cross occasionally or not at all. Those blocks that are not in the paths of faulty functions can be eliminated

s suspects. Sometimes the symptoms point to a single block and no further search is necessary. In cases where more than one block is suspect, several approaches may be used. Each requires testing a block or stage.

## 26.4.2 Disassembly

This seemingly simple step can trap the unwary technician. Most experienced service technicians can tell you the tale of the equipment they took apart and were unable to easily put back together. Don't let it happen to you.

Take photos and lots of notes about the way you take it apart. Take notes about each component you remove. Take a photo or make a sketch of complicated mechanical assemblies before disassembly and then record how you disassembled them. It is particularly important to record the position of shields and ground straps.

Write down the order in which you do things, color codes, part placements, cable routings, hardware notes, and anything else you think you might need to be able to reassemble the equipment weeks from now when the back-ordered part comes in.

Put all of the screws and mounting hardware in one place. A plastic jar with a lid works well; if you drop it the plastic is not apt to break and the lid will keep all the parts from lying around the work area (you will never find them all). It may pay to have a separate labeled container for each subsystem. Paper envelopes and muffin pans also work well.

## 26.4.3 Internal Inspection

Many service problems are visible, if you

look for them carefully. Many a technician has spent hours tracking down a failure, only to find a bad solder joint or burned component that would have been spotted in careful inspection of the printed-circuit board. Internal inspections are just as important as external inspections.

It is time consuming, but you really need to look at every connector, every wire, every solder joint and every component. A low power magnifying glass or head-mounted magnifier enables you to quickly scan the equipment to look for problems. A connector may have loosened, resulting in an open circuit. You may spot broken wires or see a bad solder joint. Flexing the printed-circuit board or tugging on components a bit while looking at their solder joints will often locate a defective solder job. Look for scorched components.

Make sure all of the screws securing the printed-circuit board are tight and making good electrical contact. Check for loose screws on chassis-mounted connectors. (Do not tighten any electrical or mechanical adjusting screws or tuning controls, however!) See if you can find evidence of previous repair jobs; these may not have been done properly. Make sure that ICs are firmly seated in sockets if they are used. Look for pins folded underneath the IC rather than inserted into the socket. If you are troubleshooting a newly constructed circuit, make sure each part is of the correct value or type number and is installed correctly.

## POWER SUPPLIES

If your careful inspection doesn't reveal anything, it is time to apply power to the unit under test and continue the process. Observe all safety precautions while troubleshooting equipment. There are voltages inside some equipment that can kill you. If you are not qualified to work safely with the voltages and conditions inside of the equipment, do not proceed. See Table 26.1 and the **Safety** chapter.

You may be able to save quite a bit of time if you test the power supply right away. If the power supply is not working at all or not working properly, no other circuit in the equipment can be expected to work properly either. Once the power supply has either been determined to be OK or repaired, you can proceed to other parts of the equipment. Power supply diagnosis is discussed in detail later in this chapter.

With power applied to the equipment, listen for arcs and look and smell for smoke or overheated components. If no problems are apparent, you can move on to testing the various parts of the circuit. For tube equipment, you may want to begin with ac power applied at a reduced voltage as described in the sections on repair of vintage equipment.

## 26.4.4 Signal Tracing and Signal Injection

There are two common systematic approaches to troubleshooting radio equipment at the block level. The first is signal tracing; the second is signal injection. The two techniques are very similar. Differences in test equipment and the circuit under test determine which method is best in a given situation. They can often be combined.

Both of these approaches are used on equipment that is designed to operate on a

## Block-Level Testing for DSP and SDR

More and more functions of today's radio equipment are implemented by microprocessor-based digital signal processing up to and including full SDR with direct digitization of RF signals very close to the antenna input. A look at the PC boards of such a radio show a few large, many-leaded ICs surrounded by control and interface components, power supply circuits, filtering, and transmitter power amplifiers. The individual stages of the classic super-heterodyne architecture are nowhere to be seen. How do you troubleshoot such a radio?

Start with the same basic approach as for an older radio — begin at the input or output and work your way towards the "other end" of the radio. In a DSP-based radio however, you'll rapidly encounter the point at which the signal "goes digital" and disappears into the microprocessor or an analog/digital converter. Jump to the point where the signal returns to analog form on the "other side" of the microprocessor (or PC in the case of most SDR equipment) and resume testing. In this way you can simply treat the microprocessor as one very large stage in the radio. If the problem turns out to be in the surrounding circuitry or in the interface between a PC and the RF circuits, you can troubleshoot it as you would any other piece of equipment.

If the problem turns out to be in the microprocessor or analog/digital converter, in all probability you will have to get a replacement board from the manufacturer. It is possible to replace the converter or processor (if you can obtain the pre-programmed part) but most manufacturers treat the entire circuit board as the lowest-level replaceable component. This makes repair more expensive (or impossible if no replacements are available) but the positive tradeoff is that the microprocessors rarely fail by themselves, resulting in fewer repairs being required in the first place.

## Knowing When to Quit

It is common for experienced repair techs to be given "basket cases" — equipment that the original troubleshooter disassembled but then couldn't reassemble for whatever reason or couldn't find the problem. One of the most important decisions in the troubleshooting process is knowing when to quit. That is, realizing that you are about to go beyond your skills or understanding of the equipment.

If you proceed past this point, the chances of a successful outcome go down pretty quickly. It's far better to ask for help, work with a more knowledgeable friend, or carefully re-assemble the equipment and take it to a repair tech. Don't let your equipment wind up as a box full of partially connected pieces and mounting hardware under the table at the hamfest with a sign that says, "Couldn't fix — make offer!"

signal (RF or audio or data) in a sequence of steps. A transceiver based on the superheterodyne architecture is probably the best example of this type of equipment in the ham shack. Audio equipment is also built this way. More information about the signal injector and signal sources appears in "Some Basics of Equipment Servicing," from February 1982 *QST* (Feedback, May 1982).

Newer equipment that incorporates DSP and specialized or proprietary ICs is much less amenable to stage-by-stage testing techniques. (See the sidebar "Block-Level Testing for DSP and SDR") Nevertheless, the techniques of signal tracing and signal injection are still useful where the signal path is accessible to the troubleshooter.

### SIGNAL TRACING

In signal tracing, start at the beginning of a circuit or system and follow the signal through to the end. When you find the signal at the input to a specific stage, but not at the output, you have located the defective stage. You can then measure voltages and perform other tests on that stage to locate the specific failure. This is much faster than testing every component in the unit to determine which is bad.

It is sometimes possible to use over-the-air signals in signal tracing, in a receiver for example. However, if a good signal generator is available, it is best to use it as the signal source. A modulated signal source is best.

Signal tracing is suitable for most types of troubleshooting of receivers and analog amplifiers. Signal tracing is the best way to check transmitters because all of the necessary signals are present in the transmitter by design. Most signal generators cannot supply the wide range of signal levels required to test a transmitter.

### Equipment

A voltmeter with an RF probe is the most common instrument used for signal tracing.

Low-level signals cannot be measured accurately with this instrument. Signals that do not exceed the junction drop of the diode in the probe will not register at all, but the presence, or absence, of larger signals can be observed.

A dedicated signal tracer can also be used. It is essentially an audio amplifier. (See the downloadable supplemental content for a project to build your own signal tracer.) An experienced technician can usually judge the level and distortion of the signal by ear. You cannot use a dedicated signal tracer to follow a signal that is not amplitude modulated (single sideband is a form of AM). A signal tracer is not suitable for tracing CW signals, FM signals or oscillators. To trace these, you will have to use a voltmeter and RF probe or an oscilloscope.

An oscilloscope is the most versatile signal tracer. It offers high input impedance, variable sensitivity, and a constant display of the traced waveform. If the oscilloscope has sufficient bandwidth, RF signals can be observed directly. Alternatively, a demodulator probe can be used to show demodulated RF signals on a low-bandwidth oscilloscope. Dual-trace scopes can simultaneously display the waveforms, including their phase relationship, present at the input and output of a circuit.

### Procedure

First, make sure that the circuit under test and test instruments are isolated from the ac line by internal transformers, an isolation transformer, or operate from battery power. Set the signal source to an appropriate level and frequency for the unit you are testing. For a receiver, a signal of about 100  $\mu\text{V}$  should be plenty. For other circuits, use the schematic as an analysis of circuit function and your own good judgment to set the signal level.

In signal tracing, start at the beginning of the work toward the end of the signal path. Switch on power to the test circuit and connect the signal-source output to the test-circuit input. Place the tracer instrument at the circuit input and ensure that the test signal is present. Observe the characteristics of the signal you are using a scope (see **Figure 26.13**). Compare the detected signal to the source signal during tracing.

Move the test instrument to the output of the next stage and observe the signal. Signal level should increase in amplifier stages and may decrease slightly in other stages. The signal will not be present at the output of a dead stage.

Low-impedance test points may not provide sufficient signal to drive a high-impedance signal tracer, so tracer sensitivity

important. Also, in some circuits the output level appears low where there is an impedance change from input to output of a stage. For example, in a properly-working common-collector (emitter follower) circuit, the input (high-impedance) and output (low-impedance) signals are in phase and have roughly equal voltages. The voltages at TP1 and TP2 are approximately equal and in phase.

There are two signals — the test signal and the local oscillator signal — present in a mixer stage. Loss of either one will result in no output from the mixer stage. Switch the signal source on and off repeatedly to make sure that the test instrument reading varies (it need not disappear) with source switching.

## SIGNAL INJECTION

Signal injection is a good choice for receiver troubleshooting because the receiver already has a detector as part of the design. If the detector is working or a suitable detector is devised (see the signal tracing section), a test signal can be injected at different points in the equipment until the faulty stage is discovered.

## Equipment

Most of the time, your signal injector will be a signal generator. There are other injectors available, some of which are square-wave audio oscillators rich in RF harmonics (see Figure 26.5). These simple injectors do have their limits because you can't vary their output level or determine their frequency. They are still useful, though, because most circuit failures are caused by a stage that is completely dead.

Consider the signal level at the test point when choosing an instrument. The signal source used for injection must be able to supply appropriate frequencies and levels for each stage to be tested. For example, a typical superheterodyne receiver requires AF, IF and RF signals that vary from 6 V at AF, to 200  $\mu$ V at RF. Each conversion stage used in a receiver requires a different IF from the signal source. When testing the signal path of an AM radio, such as a broadcast receiver, you'll need a modulated RF signal before the detector stage. Use an unmodulated RF signal to simulate the local oscillator.

The simple test circuit of **Figure 26.14** can be used as a quick-and-dirty signal injector for RF stages in a receiver. The antenna can be anything that will receive a signal at the stage's frequency of operation.

## Procedure

If an external detector is required, set it to the proper level and connect it to the test circuit. Set the signal source for AF, and inject a signal directly into the signal detector to test operation of the injector and detector. Move the signal source to the input of

## Divide and Conquer

If the equipment has a single primary signal path, the block-by-block search may be sped up considerably by testing between successively smaller groups of circuit blocks. Each test thus exercises some fraction of the remaining circuit.

This "divide and conquer" tactic cannot be used in equipment that splits the signal path between the input and the output. Test readings taken inside feedback loops are misleading unless you understand the circuit and the waveform to be expected at each point in the test circuit. It is best to consider all stages within a feedback loop as a single block during the block search.

Divide-and-conquer is a good tactic for those inclined to take the instinctive approach to troubleshooting. As you gain more experience, you'll find yourself able to quickly isolate problems this way. You can then test each block in more detail.

the preceding stage, and observe the signal. Continue moving the signal source to the inputs of successive stages.

When you inject the signal source to the input of the defective stage, there will be no output. Prevent stage overload by reducing the level of the injected signal as testing progresses through the circuit. Use suitable frequencies for each tested stage.

Make a rough check of stage gain by injecting a signal at the input and output of an amplifier stage. You can then compare how much louder the signal is when injected at the input. This test may mislead you if there is a radical difference in impedance from stage input to output. Understand the circuit operation before testing.

Mixer stages present a special problem because they have two inputs, rather than one. A lack of output signal from a mixer can be caused by either a faulty mixer or a faulty local oscillator (LO). Check oscillator operation with an oscilloscope or by listening on another receiver. If none of these instruments are available, inject the frequency of the LO at the LO output. If a dead oscillator is the only problem, this should restore operation.

If the oscillator is operating, but off frequency, a multitude of spurious responses will appear. A simple signal injector that produces many frequencies simultaneously is not suitable for this test. Use a well-shielded signal generator set to an appropriate level at the LO frequency.

## 26.4.5 Microprocessor-Controlled Equipment

The majority of today's amateur equipment

and accessories have at least one microprocessor and sometimes several. While reliability of this equipment is greatly improved over the older analog designs, troubleshooting microprocessor-based circuitry takes a different approach. While a tutorial on microprocessor troubleshooting is well outside the scope of this *Handbook*, the following basic guidelines will help determine whether the problem is inside the microprocessor (or its firmware) or in the supporting circuitry. In addition, the downloadable **Digital Basics** chapter contains lots of information about the operation of digital circuits.

1) Start by obtaining the microprocessor datasheet and identifying all of the power and control pins if they are not identified on the equipment schematic. Determine which state the control pins should be in for the device to run.

2) Test all power and control pins for the proper state (voltage). Verify that the microprocessor clock signal is active. If not, determine the reason and repair before proceeding.

3) If there is an address and data bus for external memory and input-output (I/O) devices (less common in newer equipment), use a logic probe or scope to verify that they are all active (changing state). If not, there is a program or logic fault.

4) Determine which pins are digital inputs or outputs of the microprocessor and verify that a valid digital logic level exists at the pin. If not, check the external circuit to which the pin is attached.

5) Determine which pins are analog inputs or outputs of the microprocessor. Analyze the external circuit to determine what constitutes a proper voltage into or out of the processor. If the voltage is not valid, check the external circuit to which the pin is attached. If an external voltage reference is used, verify that it is working.

6) External circuits can often be checked by disconnecting them from the microprocessor and either driving them with a temporary voltage source or measuring the signal they are attempting to send to the microprocessor.

7) If all control and power signals and the external circuitry checks out OK, it is likely that a microprocessor or firmware fault has occurred.

If you determine that the microprocessor is faulty, you will have to contact the manufacturer in most cases, since firmware is most often contained within the processor which must be programmed before it is installed. Older equipment in which the program and data memory are external to the microprocessor can be very difficult to repair due to obsolescence of the parts themselves and the requirement to program EPROM or PROM devices.

## 26.5 Testing at the Circuit Level

Once you have followed all of the troubleshooting procedures and have isolated your problem to a single defective stage or circuit, a few simple measurements and tests will usually pinpoint one or more specific components that need adjustment or replacement.

First, check the parts in the circuit against the schematic diagram to be sure that they are reasonably close to the design values, especially in a newly built circuit. Even in a commercial piece of equipment, someone may have incorrectly changed them during attempted repairs. A wrong-value part is quite likely in new construction, such as a homebrew or kit project.

### 26.5.1 Voltage Levels

Check the circuit voltages. If the voltage levels are printed on the schematic, this is easy. If not, analyze the circuit and make some calculations to see what the circuit voltages should be. Remember, however, that the printed or calculated voltages are nominal; measured voltages may vary from the calculations.

When making measurements, remember the following points:

- Make measurements at device leads, not at circuit-board traces or socket lugs.
- Use small test probes to prevent accidental shorts.
- Never connect or disconnect power to solid-state circuits with the switch on.
- Remember that voltmeters, particularly older analog meters may load down a high-impedance circuit and change the voltage, as will  $\times 1$  and low-impedance scope probes.

Voltages may give you a clue to what is wrong with the circuit. If not, check the active device. If you can check the active device in the circuit, do so. If not, remove it and test it, or substitute a known good device. After connections, most circuit failures are caused

directly or indirectly by a bad active device. The experienced troubleshooter usually tests or substitutes these first. Analyze the other components and determine the best way to test each as described earlier.

There are two voltage levels in most analog circuits ( $V+$  and ground, for example). Most component failures (opens and shorts) will shift dc voltages near one of these levels. Typical failures that show up as incorrect dc voltages include: open coupling transformers; shorted capacitors; open, shorted or overheated resistors and open or shorted semiconductors.

Digital logic circuits require that signals be within specific voltage ranges to be treated as a valid logic-low or logic-high value.

### 26.5.2 Noise

A slight hiss is normal in all electronic circuits. This noise is produced whenever current flows through a conductor that is warmer than absolute zero. Noise is compounded and amplified by succeeding stages. Repair is necessary only when noise threatens to obscure normally clear signals.

Semiconductors can produce hiss in two ways. The first is normal — an even white noise that is much quieter than the desired signal. Faulty devices frequently produce excessive noise. The noise from a faulty device is often erratic, with pops and crashes that are sometimes louder than the desired signal. In an analog circuit, the end result of noise is usually sound. In a control or digital circuit, noise causes erratic operation: unexpected switching and so on.

Noise problems usually increase with temperature, so localized heat may help you find the source. Noise from any component may be sensitive to mechanical vibration. Tapping various components with an insulated screwdriver may quickly isolate a bad part. Noise can also be traced with an oscilloscope or signal tracer.

Nearly any component or connection can be a source of noise. Defective components are the most common cause of crackling noises. Defective connections are a common cause of loud, popping noises.

Check connections at cables, sockets and switches. Look for dirty variable capacitor wipers and potentiometers. An arcing mica trimmer capacitor can create static crashes in received or transmitted audio. Test them by installing a series 0.01  $\mu\text{F}$  capacitor. If the noise disappears, replace the trimmer.

Potentiometers are particularly prone to noise problems when used in dc circuits. Clean them with a small amount of spray contact cleaner and rotate the shaft several times.

Rotary switches may be tested by jumping the contacts with a clip lead. Loose

contacts may sometimes be repaired, either by cleaning, carefully rebending the switch contacts or gluing loose switch parts to the switch deck. Operate variable components through their range while observing the noise level at the circuit output.

### 26.5.3 Oscillations

Oscillations occur whenever there is sufficient positive feedback in a circuit that has gain. (This can even include digital devices.) Oscillation may occur at any frequency from a low-frequency “putt-putt” (often called *motorboating*) well up into the RF region.

Unwanted oscillations are usually the result of changes in the active device (increased junction or interelectrode capacitance), failure of an oscillation suppressing component (open decoupling or bypass capacitors or neutralizing components) or new feedback paths (improper lead dress or dirt on the chassis or components). It can also be caused by improper design, especially in home-brew circuits. A shift in bias or drive levels may aggravate oscillation problems.

Oscillations that occur in audio stages do not change as the radio is tuned because the operating frequency — and therefore the component impedances — do not change. RF and IF oscillations, however, usually vary in amplitude as operating frequency is changed.

Oscillation stops when the positive feedback is removed. Locating and replacing defective (or missing) bypass capacitor may effect an improvement. The defective oscillating stage can be found most reliably with an oscilloscope.

### 26.5.4 Amplitude Distortion

Amplitude distortion is the product of nonlinear operation. The resultant waveform contains not only the input signal, but also signals at other frequencies as well. All of the frequencies combine to produce the distorted waveform. Distortion in a transmitter gives rise to splatter, harmonics and interference.

**Figure 26.15** shows some typical cases of distortion. Clipping (also called flat-topping) is the consequence of excessive drive, change in bias, or insufficient supply voltage to the circuit. The corners on the waveform show that harmonics are present. (A square wave contains the fundamental and all odd harmonics.) If this was a transmitter circuit, these odd harmonics would be heard well away from the operating frequency, possibly outside of amateur bands.

Harmonic distortion produces radiation at frequencies far removed from the fundamental; it is a major cause of electromagnetic interference (EMI). Harmonics are generated

### Controlling Key Clicks

Key clicks are a special type of amplitude distortion caused by fast rising and falling edges of the output waveform or from abrupt disturbances in an otherwise smooth waveform. See the **Transmitting** chapter for more information about controlling key clicks. Most modern radios offer user configuration options to adjust keying rise and fall times. Older radios may require modification of a timing circuit that controls rise and fall time. Be a good neighbor to other operators and eliminate key clicks on your signal!

**Figure 26.15 — Examples of distorted waveforms. The result of clipping is shown in A. Nonlinear amplification is shown in B. A pure sine wave is shown in C for comparison.**

in nearly every amplifier. When they occur in a transmitter, they are usually caused by insufficient transmitter filtering (either by design, or because of filter component failure).

Anything that changes the proper bias of an amplifier can cause distortion. This includes failures in the bias components, leaky transistors or vacuum tubes with interelectrode shorts. In a receiver, these conditions may mimic AGC trouble. Improper bias of an analog circuit often results from a resistor that changed value or a leaky or shorted capacitor. RF feedback can also produce distortion by disturbing bias levels. Distortion is also caused by circuit imbalance in Class AB or B amplifiers.

Oscillations in an IF amplifier may produce distortion. They cause constant, full AGC action, or generate spurious signals that mix with the desired signal. IF oscillations

are usually evident on the S meter, which will show a strong signal even with the antenna disconnected.

### 26.5.5 Frequency Response

Every circuit, even a broadband circuit, has a desired frequency response. Audio amplifiers used in amateur SSB circuits, for example, typically are designed for signals between 300 and 3000 Hz, more or less. A tuned IF amplifier may have a bandwidth of 50 to 100 kHz around the stage's center frequency. Any change in the circuit's frequency response can alter its effect on the signals on which it operates.

Frequency response changes are almost always a consequence of a capacitor or inductor changing value. The easiest way to check frequency response is to either inject a signal

into the circuit and measure the output at several frequencies or use a spectrum analyzer or a signal generator's sweep function. In LC networks, it is relatively simple to lift one lead of the component and use a component checker to determine the value.

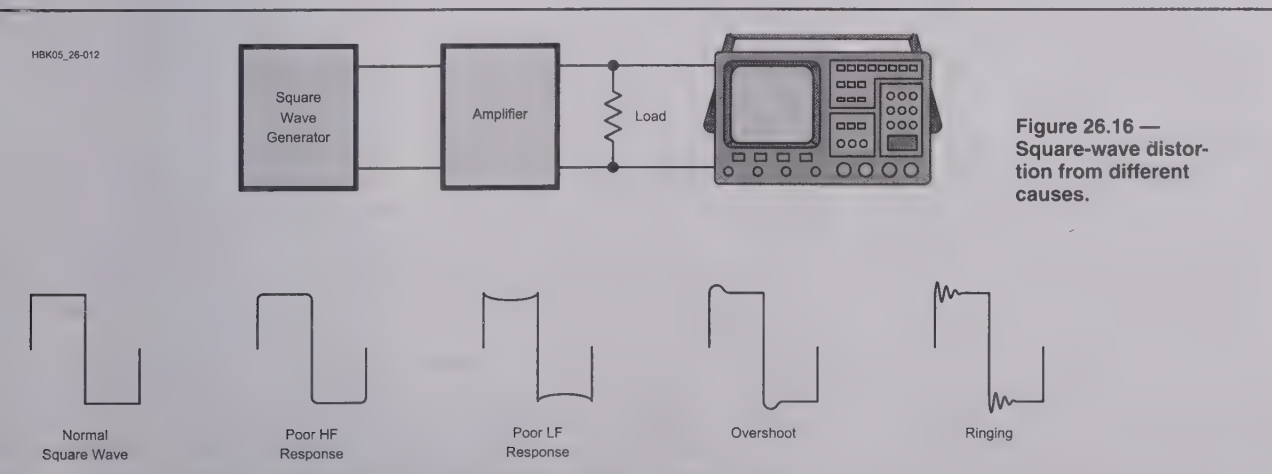

### 26.5.6 Distortion Measurement

A distortion meter is used to measure distortion of AF signals. A spectrum analyzer is the best piece of test gear to measure distortion of RF signals. If a distortion meter is not available, an estimation of AF distortion can sometimes be made with a function generator and an oscilloscope. Inject a square wave signal into the circuit with a fundamental frequency roughly in the middle of the expected frequency response.

Compare the input square wave to the output signal with an oscilloscope. **Figure 26.16** shows several effects on the square wave that are related to frequency response. These provide clues to what components or devices may be causing the problem. Severe distortion indicates some other problem besides frequency response changes.

### 26.5.7 Alignment

Alignment — the tuning or calibration of frequency sensitive circuits — is rarely the cause of an electronics problem with receiving or transmitting equipment, particularly modern equipment. Alignment does not shift suddenly and should be a last resort for treating sensitivity or frequency response problems. Do not attempt to adjust alignment without the proper equipment and alignment procedures. The process often requires steps to be performed exactly and in a specific order. Equipment misaligned in this way usually must be professionally repaired as a consequence.

**Figure 26.16 — Square-wave distortion from different causes.**

## 26.5.8 Contamination

Contamination is another common service problem. Soda or coffee spilled into a piece of electronics is an extreme example (but one that does actually happen).

Conductive contaminants range from water to metal filings. Most can be removed by a thorough cleaning. Any of the residue-free cleaners can be used, but remember that the cleaner may also be conductive. Do not apply power to the circuit until the area is completely dry.

Keep cleaners away from variable-capacitor plates, transformers and parts that may be harmed by the chemical. The most common conductive contaminant is solder, either from a printed-circuit board solder bridge or a loose piece of solder deciding to surface at the most inconvenient time.

High-voltage circuits attract significant amounts of dust as described in the section on high-power amplifier maintenance later in this chapter. Cooling fans and ventilation holes also allow dust to accumulate, creating conductive paths between components. If not removed, the conductive paths gradually become lower in resistance until they begin to affect equipment performance. Vacuuming or blowing out the equipment is usually sufficient to clear away dust, although a carbon track may require a more thorough cleaning.

## 26.5.9 Solder Bridges

In a typical PC-board solder bridge, the solder that is used to solder one component has formed a short circuit to another PC-board trace or component. Unfortunately, they are common in both new construction and repair work. Look carefully for them after you have completed any soldering, especially on a PC-board. It is even possible that a solder bridge may exist in equipment you have owned for a long time, unnoticed until it suddenly decided to become a short circuit.

Related items are loose solder blobs, loose hardware or small pieces of component leads that can show up in the most awkward and troublesome places.

## 26.5.10 Arcing

Arcing is a serious sign of trouble. It may also be a real fire hazard. Arc sites are usually easy to find because an arc that generates visible light or noticeable sound also pits and discolors conductors.

Arcing is caused by component failure, dampness, dirt or lead dress. If the dampness is temporary, dry the area thoroughly and resume operation. Dirt may be cleaned from the chassis with a residue-free cleaner. Arrange leads so high-voltage conductors are isolated. Keep them away from

sharp corners and screw points.

Arcing occurs in capacitors when the working voltage is exceeded. Air-dielectric variable capacitors can sustain occasional arcs without damage, but arcing indicates operation beyond circuit limits. Antenna tuners working beyond their ability may suffer from arcing. A failure or high SWR in an antenna circuit may also cause transmitter arcing. Prolonged, repeated, or high-power arcing can cause pits or deposits on capacitor plates that reduce capacitor voltage rating and lead to more arcing.

## 26.5.11 Digital Circuitry

Although every aspect of digital circuit operation may be resolved to a simple 1 or 0, or tristate (open circuit), the symptoms of their failure are far more complicated. The most common problems are false triggers or counts, digital inputs that do not respond to valid logic signals, and digital outputs stuck at ground or the supply voltage.

In most working digital circuitry the signals are constantly changing between low and high states, often at RF rates. Low-frequency or dc meters should not be used to check digital signal lines. A logic probe is often helpful in determining signal state and whether it is active or not. An oscilloscope or logic analyzer is usually needed to troubleshoot digital circuitry beyond simple go/no-go testing.

If you want to use an oscilloscope to give an accurate representation of digital signals, the scope bandwidth must be at least several times the highest clock frequency in the circuit in order to reproduce the fast rise and fall times of digital signals. Lower-bandwidth scopes can be useful in determining whether a signal is present or active but often miss short glitch signals (very fast transients) that are often associated with digital circuit malfunction.

## LOGIC LEVELS

Begin by checking for the correct voltages at the pins of each IC. The correct logic voltages are specified in the device's datasheet, which will also identify the power pins ( $V_{cc}$  and ground). The voltages on the other pins should be a logic high, a logic low, or tristate (more on this later).

Most digital circuit failures are caused by a failed logic IC. IC failures are almost always catastrophic. It is unlikely that an AND gate will suddenly start functioning like an OR gate. It is more likely that the gate will have a signal at its input, and no signal at the output. In a failed device, the output pin will have a steady voltage. In some cases, the voltage is steady because one of the input signals is missing. Look carefully at what is going into a digital IC to determine what should be coming out. Manufacturers' datasheets describe the

proper functioning of most digital devices.

## TRISTATE DEVICES

Many digital devices are designed with a third logic state, commonly called tristate. In this state, the output of the device acts as an open circuit so that several device outputs can be connected to a common bus. The outputs that are active at any given time are selected by software or hardware control signals. A computer's data and address busses are good examples of this. If any device output connected to the bus fails by becoming locked or stuck in a 0 or 1 logic state, the entire bus becomes nonfunctional. Tristate devices can also be locked on by a failure of the signal that controls the tristate output status.

## SIMPLE GATE TESTS

Most discrete logic ICs (collections of individual gates or other logic functions) can be easily tested by in-circuit inspection of the input and output signals. The device's truth table or other behavior description specifies what the proper input and output signals should be. Testing of more complicated devices requires the use of a logic analyzer, memory trace scope or a dedicated IC tester. If a single logic IC is found to be questionable, the easiest, usually easiest to simply substitute a known good device for it.

## CLOCK SIGNALS

In clocked circuits, check to see if the clock signal is active. If the signal is found at the clock chip, trace it to each of the other clock chips to be sure that the clock system is intact. Clock frequencies are rarely wrong but clock signals derived from a master clock can be missing or erratic if the circuitry that generates them is defective.

## RF INTERFERENCE

If digital circuitry interferes with other nearby equipment, it may be radiating or receiving spurious signals. These signals can interfere with your Amateur Radio operation or other services. Computer networking and microprocessor-controlled consumer equipment can generate a significant amount of noise, much of it to RF being radiated from cables and unshielded equipment.

Digital circuitry can also be subject to interference from strong RF fields. Erratic operation or a complete lock-up is often the result. Begin by removing the suspect equipment from RF fields. If the symptoms persist when there is no RF energy present, a common-mode choke as described in the **RF Interference** chapter.

The *ARRL RFI Book* has a chapter on computer and digital interference to and from digital devices and circuits. The subject is also covered in the **RF Interference** chapter of this book.

## 5.12 Replacing Parts

If you have located a defective component in a stage, you need to replace it. When replacing socket mounted components, be sure to align the replacement part correctly. Make sure that the pins of the device are properly inserted into the socket. See the **Instruction Techniques** chapter for guidance on working with SMT components.

## 5.6 After the Repairs

Once you have completed your troubleshooting and repairs, it is time to put the equipment back together. Take a little extra time to make sure you have done everything correctly.

### 26.6.1 All Units

Give the entire unit a complete visual inspection. Look for any loose ends left over from your troubleshooting procedures — you may have left a few components temporarily soldered in place, forgotten to reattach a wire, or overlooked some other repair. Look for cold solder joints and signs of damage incurred during the repair. Double-check the position, leads and polarity of components that were removed or replaced. Make sure that all ICs and connectors are properly oriented and inserted in their sockets. Test fuse continuity with an ohmmeter and verify that the current rating matches the unit specification.

Look at the position of all of the wires and components. Make sure that wires and leads will be clear of hot components, screw heads and other sharp edges. Make certain the wires and components will not be in a way and pinched or crimped when covers are installed and the unit is put back together. Separate the leads that carry dc, RF, input and output as much as possible. Plug-in circuit boards should be firmly seated with screws tightened and lock washers installed if specified. Shields and ground straps should be installed just as they were on the original.

### 26.6.2 Transmitter Checkout

Since the signal produced by an HF transmitter can be heard the world over, a thorough check is necessary after any service has been

performed. Do not exceed the transmitter duty cycle while testing. Limit transmissions to 10 to 20 seconds unless otherwise specified by the owner's manual.

1. Set all controls as specified in the operation manual, or at midscale.

2. Connect a dummy load and a power meter to the transmitter output.

3. Set the drive or carrier control for low output.

4. Switch the power on.

5. Transmit and quickly set the final-amplifier bias to specifications if necessary.

6. For vacuum tube final amplifiers, slowly tune the output network through resonance. The current dip should be smooth and repeatable. It should occur simultaneously with the maximum power output. Any sudden jumps or wiggles of the current meter indicate that the amplifier is unstable. Adjust the neutralization circuit (according to the manufacturer's instructions) if one is present or check for oscillation. An amplifier usually requires neutralization whenever active devices, components or lead dress (that affect the output/input capacitance) are changed.

7. Check to see that the output power is consistent with the amplifier class used in the PA (efficiency should be about 25% for Class A, 50 to 60% for Class AB or B, and 70 to 75% for Class C). Problems are indicated by the efficiency being significantly low.

8. Repeat steps 4 through 6 for each band of operation from lowest to highest frequency.

9. Check the carrier balance (in SSB transmitters only) and adjust for minimum power output with maximum RF drive and no microphone gain.

10. Adjust the VOX controls.

11. Measure the passband and distortion levels if equipment (wideband scope or spectrum analyzer) is available.

against the joint with a hot soldering iron.

Removing soldered ICs is a lot simpler if you simply clip its leads next to the IC body using fine-point wire cutters, although it does destroy the IC. Then melt the solder and lift out the pin with tweezers or the wire cutter. Use the desoldering pumps or wick to remove the solder. This works well for both through-hole and SMT components.

### 26.6.3 Other Repaired Circuits

After the preliminary checks, set the circuit controls per the manufacturer's specifications (or to midrange if specifications are not available) and switch the power on. Watch and smell for smoke, and listen for odd sounds such as arcing or hum. Operate the circuit for a few minutes, consistent with allowable duty cycle. Verify that all operating controls function properly.

Check for intermittent connections by subjecting the circuit to heat, cold and slight flexure. Also, tap or jiggle the chassis lightly with an alignment tool or other insulator.

If the equipment is meant for mobile or portable service, operate it through an appropriate temperature range. Many mobile radios do not work on cold mornings, or on hot afternoons, because a temperature-dependent intermittent was not found during repairs.

### 26.6.4 Close It Up

After you are convinced that you have repaired the circuit properly, put it all back together. If you followed the advice in this book, you have all the screws and assorted doodads in a secure container. Look at the notes you took while taking it apart; put it back together in the reverse order. Don't forget to reconnect all internal connections, such as ac power, speaker or antenna leads.

Once the case is closed, and all appears well, don't neglect the final, important step — make sure it still works. Many an experienced technician has forgotten this important step, only to discover that some minor error, such as a forgotten antenna cable, has left the equipment nonfunctional.

## 26.7 Professional Repairs

Repairs that deal with very complex and temperamental circuits, or that require sophisticated test equipment, should be passed on to a professional. Factory authorized service personnel have a lot of experience. What seems like a servicing nightmare to you is old hat to them. There is no one better qualified to service your equipment than the factory.

If the manufacturer is no longer in business, check with your local dealer or look through *Amateur Radio* magazines and websites. You can usually find one or more companies or repair services that handle all makes and models. Your local club or a user's group may also be able to make a recommendation.

If you are going to ship your equipment somewhere for repair, notify the repair center first. Get authorization for shipping and an identification name or number for the package.

### 26.7.1 Packing Equipment

You can always blame shipping damage on the shipper, but it is a lot easier for all concerned if you package your equipment properly for shipping in the first place.

- Take photos of the equipment before packing it to document its condition before shipping. Additional photos during the packing steps might also be useful to show that you took the proper care in packing the equipment.

Figure 26.17 — Ship equipment packed securely in a box within a box.

- Firmly secure all heavy components, either by tying them down or blocking them off with shipping foam.

- Large transformers, such as for RF power amplifiers, should probably be removed and shipped separately.

- Large vacuum tubes should be wrapped in packing material or shipped separately.

- Make sure that all circuit boards and parts are firmly attached.

If you have the original shipping container, including all of the packing material, you should use that if the repair facility approves doing so. Otherwise use a box within a box for shipping. (See **Figure 26.17**). Place the equipment and some packing material inside a box and seal it with tape. Place that box

inside another that is at least six inches large in each dimension.

Don't forget to enclose a statement of trouble, a short history of operation and a test results that may help the service technician. Include a good description of the thing you have tried. Be honest! At current rates you want to tell the technician everything to help ensure an efficient repair. Place the necessary correspondence, statement of symptoms, and your contact information in a mailing envelope and place it just inside the top covers of the outer box or tape it to the top of the inner box.

Fill any remaining gaps with packing material, seal, address and mark the outer box. Choose a good freight carrier and insure the package. If available, get a tracking number for the package so you can tell when it was delivered.

Even if you tried to fix it yourself but ended up sending it back to the factory, you can feel good about your experience. You learned a lot by trying, and you have sent it back knowing that it really did require the services of a professional. Each time you troubleshoot and repair a piece of electronic circuitry, you learn something new. The down side is that you may develop a reputation as a real electronics whiz. You may find yourself spending a lot of time at club meetings offering advice, or getting invited over to a lot of shacks for a late-evening pizza snack. There are worse fates.

## 26.8 Typical Symptoms and Faults

### 26.8.1 Power Supplies

Many equipment failures are caused by power supply trouble. Fortunately, most power supply problems are easy to find and repair. This section focuses on the common linear power supply. Some notes are also made about switchmode supplies. Both types are discussed in detail in the **Power Sources** chapter, including projects with typical schematics.

#### LINEAR POWER SUPPLIES

The block diagram for a linear power supply is shown in **Figure 26.18**. First, use a voltmeter to measure output. Complete loss of output voltage is usually caused by an open circuit. (A short circuit draws excessive current that opens the fuse, thus becoming an open circuit.) If output voltage appears normal, apply a small load (1/10th supply capacity or smaller) and test output voltage again. If the small load causes voltage to drop,

there is generally a problem in the regulator circuitry, often the pass transistors.

If the ac input circuit fuse is blown, that is usually caused by a shorted diode in the filter block, a failure of the output protection circuitry, or a short circuit in the device being powered by the supply. More rarely, one of the filter capacitors can short. If the fuse has opened, turn off the power, replace the fuse, and measure the load-circuit's dc resistance. The measured resistance should be consistent with the power-supply ratings. A short or open load circuit indicates a problem.

If the measured resistance is too low, troubleshoot the load circuit. (Nominal circuit resistances are included in some equipment manuals.) If the load circuit resistance is normal, suspect a defective regulator or problem in the rest of the unit.

IC regulators can oscillate, sometimes causing failure. The small-value capacitors on the input, output or adjustment pins of the regulator prevent oscillations. Check and replace these capacitors whenever a regulator has failed.

AC ripple (120 Hz buzz) is usually caused

Figure 26.18 — Block diagram of a typical linear power supply.

by low-value filter capacitors in the power supply. Ripple can also become excessive due to overload or regulation problems. Look for a defective filter capacitor (usually open or low-value), defective regulator, or shorted filter choke if chokes are used (not common in modern equipment). In older equipment, the defective filter capacitor will often have visible leaking electrolyte: Look for corrosion residue at the capacitor leads. In new construction projects make sure RF energy is not getting into the power supply.

Here's an easy filter capacitor test: Temporarily connect a replacement capacitor (about the same value and working voltage) across the suspect capacitor. If the hum goes away, replace the bad component permanently.

Once the faulty component is found, inspect the surrounding circuit and consider what may have caused the problem. Sometimes one bad component can cause another to fail. For example, a shorted filter capacitor increases current flow and burns out a rectifier diode. While the defective diode is easy to find, the capacitor may show no visible damage.

If none of these initial checks find the problem, here are the usual systematic steps to locate the part of the supply with a problem:

- Check the input ac through switches and fuses to the transformer primary.
- Verify that the transformer secondary outputs ac of the right voltage. Disconnect the output leads, if necessary.
- Check the rectifiers for shorted diodes. Disconnect the rectifier output and test for output with a resistor load.
- Reconnect the filter and disconnect the regulator. Verify that the right dc voltage is present at the filter output.
- Reconnect the regulator and in the regulator IC or circuit, test every pin or signal, especially enable/disable/soft-start and the voltage reference.

• Disconnect any output protective circuitry and verify that the pass transistors are working with a resistor load.

• Reconnect and test the output protective circuitry.

## SWITCHMODE POWER SUPPLIES

Switchmode or switching power supplies are quite different from conventional supplies. In a switcher, the regulator circuit is based on a switching transistor and energy storage inductor instead of a pass transistor to change power from one dc level to another that can be higher or lower than the input voltage. Switching frequencies range from 20-120 kHz for most supplies and up to the MHz range for miniature dc-dc converter modules.

Switchmode supplies operating from the

ac line have similar input circuits to linear supplies. The transformer that supplies isolation is then located in the low-voltage, high frequency section.

Apply the same input and output block-level tests as for linear supplies. The regulator circuitry in a switchmode supply is more complex than for a linear supply, but it usually is implemented in a single regulator IC. Failure of the regulator IC, transistor switch, or feedback path usually results in a completely dead supply. While active device failure is still the number one suspect, it pays to carefully test all components in the regulator subsystem.

## HIGH-VOLTAGE POWER SUPPLIES

Obviously, testing HV supplies requires extreme caution. See the safety discussion at the beginning of this chapter, the **Safety** chapter of this book, and the discussion of HV supplies in the **Power Sources** chapter. If you do not feel comfortable working on HV supplies, then don't. Ask for help or hire a professional repair service to do the job.

Most HV supplies used in amateur equipment are linear supplies with the same general structure as low voltage supplies. A typical supply is presented as a project in the **Power Sources** chapter and the same basic steps can be applied — just with a lot more caution.

Components in a string, such as rectifiers or filter capacitors, should all be tested if any are determined to have failed. This is particularly true for capacitors which can fail in sequence if one capacitor in the string shorts. Voltage equalizing resistors are not required for rectifier diodes available today such as the 1N5408. Consider replacing older rectifier strings with new rectifiers as a preventive maintenance step.

Interlocks rarely fail but verify that they are functioning properly before assuming they are in good working order.

## 26.8.2 Amplifier Circuits

Amplifiers are the most common circuits in electronics. The output of an ideal amplifier would match the input signal in every respect except magnitude: No distortion or noise would be added. Real amplifiers always add noise and distortion. Typical discrete and op-amp amplifier circuits are described in the **Analog Basics** chapter.

### AMPLIFIER GAIN

Amplifier failure usually results in a loss of gain or excessive distortion at the amplifier output. In either case, check external connections first. Is there power to the stage? Has the fuse opened? Check the speaker and leads in audio output stages, the microphone and push-to-talk (PTT) line in transmitter audio sections. Excess voltage, excess current or thermal runaway can cause sudden failure of

semiconductors. The failure may appear as either a short circuit or open circuit of one or more PN junctions.

Thermal runaway occurs most often in bipolar transistor circuits. If degenerative feedback (the emitter resistor reduces base-emitter voltage as conduction increases) is insufficient, thermal runaway will allow excessive current flow and device failure. Check transistors by substitution, if possible. If not, voltage checks as described below usually turn up the problem.

Faulty coupling components can reduce amplifier output. Look for component failures that would increase series impedance, or decrease shunt impedance, in the coupling network. Coupling faults can be located by signal tracing or parts substitution. Other passive component defects reduce amplifier output by shifting bias or causing active-device failure. These failures are evident when the dc operating voltages are measured.

If an amplifier is used inside a feedback loop, faults in the feedback loop can force a transistor into cutoff or saturation or force an op amp's output to either power supply rail. In a receiver, the AGC subsystem is such a feedback loop. Open the AGC line to the device and substitute a variable voltage for the AGC signal. If amplifier action varies with voltage, suspect the AGC-circuit components; otherwise, suspect the amplifier.

In an operating amplifier, check carefully for oscillations or noise. Oscillations are most likely to start with maximum gain and the amplifier input shorted. Any noise that is due to 60 Hz sources can be heard, or seen with an oscilloscope triggered by the ac line.

Unwanted amplifier RF oscillations should be cured with changes of lead dress or circuit components. Separate input leads from

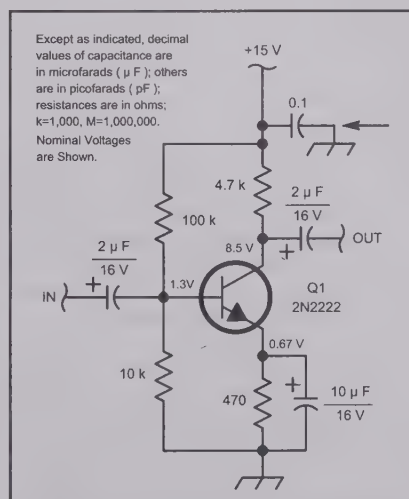

Figure 26.19 — The decoupling capacitor in this circuit is designated with an arrow.

output leads; use coaxial cable to carry RF between stages; neutralize inter-element or junction capacitance. Ferrite beads on the control element of the active device often stop unwanted oscillations.

Low-frequency oscillations (motorboating) indicate poor stage isolation or inadequate power supply filtering. Try a better lead-dress arrangement and/or check the capacitance of the decoupling network (see **Figure 26.19**). Use larger capacitors at the power supply leads; increase the number of capacitors or use separate decoupling capacitors at each stage. Coupling capacitors that are too low in value can also cause poor low-frequency response. Poor response to high frequencies is usually caused by circuit design.

### COMMON-EMITTER AMPLIFIER

The common-emitter circuit (or common-source using an FET) is the most widely used configuration. It can be used as an amplifier or as a switch. Both are analyzed here as an example of how to troubleshoot transistor amplifier circuits. Other types of circuit can be analyzed similarly.

**Figure 26.20** is a schematic of a common-emitter transistor amplifier. The emitter, base and collector leads are labeled e, b and c, respectively. Important dc voltages are measured at the emitter ( $V_e$ ), base ( $V_b$ ) and collector ( $V_c$ ) leads.  $V_+$  is the supply voltage.

First, analyze the voltages and signal levels in this circuit. The junction drop is the potential measured across a semiconductor junction that is conducting. It is typically 0.6 V for silicon and 0.2 V for germanium transistors.

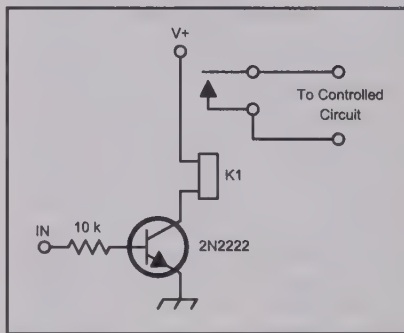

This is a Class-A linear circuit. In Class-A circuits, the transistor is always conducting some current. R1 and R2 form a voltage divider that supplies dc bias ( $V_b$ ) for the transistor. Normally,  $V_e$  is equal to  $V_b$  less the emitter-base junction drop. R4 provides degenerative dc bias, while C3 provides a low-impedance path for the signal. From this information, normal operating voltages can be estimated.

The bias and voltages will be set up so that the transistor collector voltage,  $V_c$ , is somewhere between  $V_+$  and ground potential. A good rule of thumb is that  $V_c$  should be about one-half of  $V_+$ , although this can vary quite a bit, depending on component tolerances. The emitter voltage is usually a small percentage of  $V_c$ , say about 10%.

Any circuit failure that changes collector current,  $I_c$ , (ranging from a shorted transistor or a failure in the bias circuit) changes  $V_c$  and  $V_e$  as well. An increase of  $I_c$  lowers  $V_c$  and raises  $V_e$ . If the transistor shorts from collector to emitter,  $V_c$  drops to about 1.2 V, as determined by the voltage divider formed by R3 and R4.

**Figure 26.20** — A typical common-emitter audio amplifier.

**Figure 26.21** — A typical common-emitter switch or driver.

You would see nearly the same effect if the transistor were biased into saturation by collector-to-base leakage, a reduction in R1's value or an increase in R2's value. All of these circuit failures have the same effect. In some cases, a short in C1 or C2 could cause the same symptoms.

To properly diagnose the specific cause of low  $V_c$ , consider and test all of these parts. It is even more complex; an increase in R3's value would also decrease  $V_c$ . There would be one valuable clue, however: if R3 increased in value,  $I_c$  would not increase;  $V_e$  would also be low.

Anything that decreases  $I_c$  increases  $V_c$ . If the transistor failed open, R1 increased in value, R2 were shorted to ground or R4 opened, then  $V_c$  would be high.

### COMMON-EMITTER SWITCH

A common-emitter transistor switching circuit is shown in **Figure 26.21**. This circuit functions differently from the circuit shown in **Figure 26.20**. A linear amplifier is designed so that the output signal is a faithful reproduction of the input signal. Its input and output

may have any value from  $V_+$  to ground.

The switching circuit of **Figure 26.21** however, is similar to a digital circuit. The active device is either on or off, 1 or 0, like digital logic. Its input signal level should either be 0 V or positive enough to switch the transistor on fully (saturate). Its output state should be either full off (with no current flowing through the relay), or full on (with the relay energized). A voltmeter placed at the collector will show either approximately +12 V or 0 V, depending on the input.

Understanding this difference in operation is crucial to troubleshooting the two circuits. If  $V_c$  were +12 V in the circuit in **Figure 26.21**, it would indicate a circuit failure. A  $V_c$  of +12 V in the switching circuit is normal when  $V_b$  is 0 V. (If  $V_b$  measured 0.8 V or higher,  $V_c$  should be low and the relay energized.)

### DC-COUPLED AMPLIFIERS

In dc-coupled amplifiers, the transistor are directly connected together without coupling capacitors. They comprise a unique troubleshooting case. Most often, when a device fails, it destroys one or more of the semiconductors in the circuit. If you do not find all of the bad parts, the remaining defective parts can cause the installed replacement to fail immediately. To reliably troubleshoot a dc-coupled circuit, you must test every semiconductor in the circuit and replace them all at once.

### 26.8.3 Oscillators

In many circuits, a failure of the oscillator will result in complete circuit failure. A transmitter will not transmit, and a superhetrodyne receiver will not receive if you have an internal oscillator failure. (These symptoms do not always mean oscillator failure, however.)

Whenever there is weakening or complete loss of signal from a radio, check oscillator operation and frequency. There are several methods:

- Use a receiver with a coaxial probe to listen for the oscillator signal.
- A dip meter can be used to check oscillators by tuning to within  $\pm 15$  kHz of the oscillator, couple it to the circuit, and listen for a beat note in the dip-meter headphones.
- Look at the oscillator waveform on an oscilloscope. The operating frequency can't be determined with great accuracy, but you can see if the oscillator is working at all. Use a low capacitance ( $10\times$ ) probe for oscillator observations.

Many modern oscillators are phase-locked loops (PLLs). Read the **Oscillators and Synthesizers** chapter of this book in order to learn how PLLs operate.

To test for a failed LC oscillator, use a voltmeter in the active mode. Set the dip meter

the oscillator frequency and couple it to the oscillator output circuit. If the oscillator is lead, the dip-meter signal will take its place and temporarily restore some semblance of normal operation.

### STABILITY

Drift is caused by variations in the oscillator. Poor voltage regulation and heat are the most common culprits. Check regulation with a voltmeter (use one that is not affected by RF). Voltage regulators are usually part of the oscillator circuit. Check them by substitution.

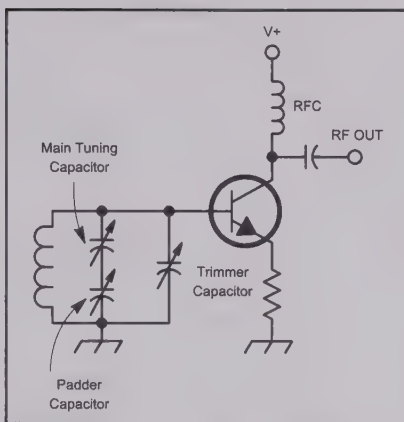

Chirp is a form of rapid drift that is usually caused by excessive oscillator loading or poor power-supply regulation. The most common cause of chirp is poor design. If chirp appears suddenly in a working circuit, look for component or design defects in the oscillator or its buffer amplifiers. (For example, a shorted coupling capacitor increases loading drastically.) Also check for new feedback paths from changes in wiring or component placement (feedback defeats buffer action).

Frequency instability may also result from defects in feedback components. Too much feedback may produce spurious signals, while too little makes oscillator start-up unreliable.

Sudden frequency changes are frequently the result of physical variations. Loose components or connections are probable causes. Check for arcing or dirt on printed-circuit boards, trimmers and variable capacitors, loose switch contacts, bad solder joints or loose connectors.

### FREQUENCY ACCURACY

In manually tuned LC oscillators, tracking

**Figure 26.22** — A partial schematic of a simple oscillator showing the locations of the trimmer and padder capacitors.

at the high-frequency end of the range is controlled by trimmer capacitors. A trimmer is a variable capacitor connected in parallel with the main tuning capacitor (see **Figure 26.22**). The trimmer represents a higher percentage of the total capacitance at the high end of the tuning range. It has relatively little effect on tuning characteristics at the low-frequency end of the range.

Low-end range is adjusted by a series trimmer capacitor called a *padder*. A padder is a variable capacitor that is connected in series with the main tuning capacitor. Padder capacitance has a greater effect at the low-frequency end of the range. The padder capacitor is often eliminated to save money. In that case, the low-frequency range is set by adjusting the main tuning coil.

## 26.8.4 Transmit Amplifier Modules

Most VHF/UHF mobile radios and many small HF radios use commercial amplifier modules as the final amplifier instead of discrete transistors. These modules are quite reliable and can withstand various stresses such as disconnected antennas. However, replacement units are rarely available more than a few years after a particular radio model goes out of production. You may be able to find a damaged radio of the same model to scavenge for parts, but once the modules fail, you are usually out of luck. User's groups are often good sources of information about common failure modes of certain radios and possibly even sources of replacement parts.

The usual failure mode of an amplifier module is caused by thermal cycling that eventually leads to an internal connection developing a crack. The module becomes intermittent and then eventually fails completely. If you can open the module, you can sometimes identify and repair such a problem by soldering over the crack.

When reinstalling or replacing an amplifier module, be very careful to attach it to the heat sink as it was at the factory. Do not use excessive amounts of thermal compound or grease and make sure the mounting screws are secure. If you can find a datasheet for the module, check to see if there are recommendations for mounting screw torque and any other installation procedures. (See the **RF Power Amplifiers** chapter for guidelines on mounting power transistors.)

## 26.9 Radio Troubleshooting Hints

**Tables 26.2, 26.3, 26.4 and 26.5** list some common problems and possible cures for older radios that are likely to have developed problems with some later-model equivalents. These tables are not all-inclusive. They are a collection of hints and shortcuts that may save you some troubleshooting time. If you don't find your problem listed, continue with systematic troubleshooting.

Remember that many problems are caused by improper setting of a switch, a control, or a configuration menu item. Before beginning a troubleshooting session, be sure you've checked the operating manual for proper control settings and checked through the manual's troubleshooting guide. If possible, obtain a service manual with its detailed

procedures, measurements, and schematics.

### 26.9.1 Receivers

A receiver can be diagnosed using any of the methods described earlier, but if there is not even a faint sound from the speaker, signal injection is not a good technique. If you lack troubleshooting experience, avoid following instinctive hunches. Begin with power supply tests and proceed to signal tracing.

### SELECTIVITY

Failure of control or switching circuits that determine the signal path and filters can cause selectivity problems. In older equipment, tuned transformers or the components

used in filter circuits may develop a shorted turn, capacitors can fail and alignment is required occasionally. Such defects are accompanied by a loss of sensitivity. Except in cases of catastrophic failure (where either the filter passes all signals, or none), it is difficult to spot a loss of selectivity. Bandwidth and insertion-loss measurements are necessary to judge filter performance.

### SENSITIVITY

A gradual loss of sensitivity results from gradual degradation of an active device or long-term changes in component values. Sudden partial sensitivity changes are usually the result of a component failure, usually in the RF or IF stages. Excessive signal levels

**Table 26.2**  
**Symptoms and Their Causes for All Electronic Equipment**

<i>Symptom</i>	<i>Cause</i>
<b>Power Supplies</b>	
No output voltage	Open circuit (usually a fuse, pass transistor, or transformer winding)
Hum or ripple	Faulty regulator, capacitor or rectifier, low-frequency oscillation
<b>Amplifiers</b>	
Low gain	Transistor, coupling capacitors, emitter-bypass capacitor, AGC component
Noise	Transistors, coupling capacitors, resistors
Oscillations	Dirt on variable capacitor or chassis, shorted op-amp input
Oscillations, untuned (oscillations do not change with frequency)	Audio stages
Oscillations, tuned	RF, IF and mixer stages
Static-like crashes	Arcing trimmer capacitors, poor connections
Static in FM receiver	Faulty limiter stage, open capacitor in ratio detector, weak RF stage, weak incoming signal
Intermittent noise	All components and connections, band-switch contacts, potentiometers (especially in dc circuits), trimmer capacitors, poor antenna connections
Distortion (constant)	Oscillation, overload, faulty AGC, leaky transistor, open lead in tab-mount transistor, dirty potentiometer, leaky coupling capacitor, open bypass capacitors, imbalance in tuned FM detector, IF oscillations, RF feedback (cables)
Distortion (strong signals only)	Open AGC loop
Frequency change	Physical or electrical variations, dirty or faulty variable capacitor, broken switch, loose compartment parts, poor voltage regulation, oscillator tuning (trouble when switching bands)
<b>No Signals</b>	
All bands	Dead VFO or LO, PLL won't lock
One band only	Defective crystal, oscillator out of tune, band switch
No function control	Faulty switch or control, poor connection to front panel subassembly

**Table 26.3**  
**Receiver Problems**

<i>Symptom</i>	<i>Cause</i>
Low sensitivity	Semiconductor degradation, circuit contamination, poor antenna connection
Signals and calibrator heard weakly (low S-meter readings)	RF chain
(strong S-meter readings)	AF chain, detector
No signals or calibrator heard, only hissing	RF oscillators
<b>Distortion</b>	
On strong signals only	AGC fault
AGC fault	Active device cut off or saturated
Difficult tuning	AGC fault
Inability to receive	Detector fault
AM weak and distorted	Poor detector, power or ground connection
CW/SSB unintelligible	BFO off frequency or dead
FM distorted	Open detector diode

or transients can damage input RF switching amplifier, or mixing circuits. Complete and sudden loss of sensitivity is caused by an open circuit anywhere in the signal path or by a dead oscillator.

**AGC**

AGC failure usually causes distortion that affects only strong signals. All stages operate at maximum gain when the AGC influence is removed. An S meter can help diagnose AGC failure because it is operated by the AGC loop. If the S meter does not move at all or remains at full scale, the AGC system has a problem.

In DSP radios, the AGC function is often controlled by software which you cannot troubleshoot but inputs to the software such as signal level detectors may be causing a problem instead.

In analog receivers, an open bypass capacitor in the AGC amplifier causes feedback through the loop. This often results in a receiver squeal (oscillation). Changes in the loop time constant affect tuning. If stations consistently blast, or are too weak for a brief time when first tuned in, the time constant is too fast. An excessively slow time constant makes tuning difficult, and stations fade after tuning. If the AGC is functioning, but the timing seems wrong, check the large-value capacitors found in the AGC circuit — they usually set the AGC time constants. If the AGC is not functioning, check the AGC detector circuit. There is often an AGC voltage that is used to control several stages. A failure in any one stage could affect the entire loop.

**DETECTOR PROBLEMS**

Detector trouble usually appears as complete loss or distortion of the received signal. AM, SSB and CW signals may be weak and unintelligible. FM signals will sound distorted. Look for an open circuit in the detector circuit. If tests of the detector parts indicate no trouble, look for a poor connection in the detector's power supply or ground connections. A BFO that is dead or off frequency prevents SSB and CW reception. In modern rigs, the BFO frequency is usually derived from the main VFO system.

**26.9.2 Transmitters**

Many potential transmitter faults are discussed in several different places in this chapter. There are, however, a few techniques used to ensure stable operation of RF amplifiers in transmitters that are not covered elsewhere.

RF final amplifiers often use parasitic chokes to prevent instability. Older parasitic chokes usually consist of a 51- to 100-Ω non-inductive resistor with a coil wound around the body and connected to the leads. It is

**Table 26.4**  
**Transmitter Problems**

<i>Symptom</i>	<i>Cause</i>
Key clicks	Keying filter, distortion in stages after keying, ALC overshoot or instability
<b>Modulation Problems</b>	
Loss of modulation	Broken cable (microphone, PTT, power), open circuit in audio chain, defective modulator
Distortion on transmit	Defective microphone, RF feedback, modulator imbalance, bypass capacitor, improper bias, excessive drive
Arcing	Dampness, dirt, improper lead dress
Low output	Incorrect control settings, improper carrier shift (CW signal outside of passband) audio oscillator failure, transistor or tube failure, SWR protection circuit
<b>Antenna Problems</b>	
Poor SWR	Damaged antenna element, matching network, feed line, balun failure (see below), resonant conductor near antenna, poor connection at antenna
Balun failure	Excessive SWR, weather or cold-flow damage in coil choke, broken wire or connection
RFI	Arcing or poor connections anywhere in antenna system or nearby conductors

**Table 26.5**  
**Transceiver Problems**

<i>Symptom</i>	<i>Cause</i>
Inoperative S meter	Faulty TR switching or relay
PA noise in receiver	Faulty TR switching or relay
Excessive current on receive	Faulty TR switching or relay
Arcing in PA	Faulty TR switching or relay
Reduced signal strength on transmit and receive	IF failure
Poor VOX operation	VOX amplifiers
Poor VOX timing	Adjustment, component failure in VOX timing circuits or amplifiers
VOX consistently tripped by receiver audio	AntiVOX circuits or adjustment

used to prevent VHF and UHF oscillations in a vacuum-tube amplifier. The suppressor is placed in the plate lead, close to the plate connection.

In recent years, problems with this style of suppressor have been discovered. See the **RF Power Amplifiers** chapter for information about suppressing parasitics. If parasitic suppressors are present in your transmitter, continue to use them as the exact layout and lead dress of the RF amplifier circuitry may require them to avoid oscillation. If they are not present, do not add them. When working on RF power amplifiers, take care to keep leads and components arranged just as they were when they left the factory.

Parasitic chokes often fail from excessive current flow. In these cases, the resistor is charred. Occasionally, physical shock or corrosion produces an open circuit in the coil. Test for continuity with an ohmmeter.

Transistor amplifiers are protected against parasitic oscillations by low-value resistors or ferrite beads in the base or collector leads. Resistors are used only at low power levels (about 0.5 W), and both methods work best when applied to the base lead. Negative feedback is used to prevent oscillations at lower frequencies. An open component in the feedback loop may cause low-frequency oscillation, especially in broadband amplifiers.

## KEYING

The simplest form of modulation is on/off keying. Although it may seem that there cannot be much trouble with such an elementary form of modulation, two very important transmitter faults are the result of keying problems.

Key clicks are produced by fast rise and times of the keying waveform (see the previous sidebar, “Controlling Key Clicks”). Most transmitters include components in the keying circuitry to prevent clicks. When clicks are experienced, check the keying filter components first, then the succeeding stages. An improperly biased power amplifier, or a Class C amplifier that is not keyed, may produce key clicks even though the keying waveform earlier in the circuit is correct. Clicks caused by a linear amplifier may be a sign of low-frequency parasitic oscillations. If they occur in an amplifier, suspect insufficient power-supply decoupling. Check the power-supply filter capacitors and all bypass capacitors.

The other modulation problem associated with on/off keying is called backwave. Backwave is a condition in which the signal is heard, at a reduced level, even when the key is up. This occurs when the oscillator signal feeds through a keyed amplifier. This usually indicates a design flaw, although in some cases a component failure or improper keyed-stage neutralization may be to blame.

## LOW OUTPUT POWER

Check the owner’s manual to see if the condition is normal for some modes or bands, or if there is a menu item to set RF output power. Check the control settings. Solid-state transmitters require so little effort from the operator that control settings are seldom noticed. The CARRIER (or DRIVE) control may have been bumped. Remember to adjust tuned vacuum tube amplifiers after a significant change in operating frequency (usually 50 to 100 kHz). Most modern transmitters are also designed to reduce power if there is high (say 2:1) SWR. Check these obvious external problems before you tear apart your rig.

Power transistors may fail if the SWR protection circuit malfunctions. Such failures occur at the weak link in the amplifier chain: It is possible for the drivers to fail without damaging the finals. An open circuit in the reflected side of the sensing circuit leaves the transistors unprotected; a short shuts them down.

Low power output in a transmitter may also spring from a misadjusted carrier oscillator or a defective SWR protection circuit. If the carrier oscillator is set to a frequency well outside the transmitter passband, there may be no measurable output. Output power will increase steadily as the frequency is moved into the passband.

## 26.9.3 Transceivers

### SWITCHING

Elaborate switching schemes are used in transceivers for signal control. Many transceiver malfunctions can be attributed to relay or switching problems. Suspect the switching controls when:

- The S meter is inoperative, but the unit otherwise functions. (This could also be a bad S meter or a consequence of a configuration menu item.)

- There is arcing in the tank circuit. (This could also be caused by a fault in the antenna system.)

- There is excessive broadband PA noise in the receiver.

Since transceiver circuits are shared, stage defects frequently affect both the transmit and receive modes, although the symptoms may change with mode. Oscillator problems usually affect both transmit and receive modes, but different oscillators, or frequencies, may be used for different emissions. Check the block diagram.

### VOX

Voice operated transmit (VOX) controls are another potential trouble area. If there is difficulty in switching to transmit in the VOX mode, check the VOX-SENSITIVITY and ANTI-VOX control settings. Next, see if the PTT and manual (MOX) transmitter controls work. If the PTT and MOX controls function, examine the VOX control circuits. Test the switches, control lines and control voltage if the transmitter does not respond to other TR controls.

VOX SENSITIVITY and ANTI-VOX settings should also be checked if the transmitter switches on in response to received audio. Suspect the ANTI-VOX circuitry next. Unacceptable VOX timing results from a poor VOX-delay adjustment, or a bad resistor or capacitor in the timing circuit or VOX amplifiers.

## 26.9.4 Amplifiers

While this section focuses on vacuum-tube amplifiers using high-voltage (HV) supplies, it also applies to solid-state amplifiers that operate at lower voltages and generally have fewer points of failure. Amplifiers are simple, reliable pieces of equipment that respond well to basic care, regular maintenance, and common sense. A well-maintained amplifier will provide reliable service and maximum tube lifetime. (The complete version of a *QST* article on amplifier repair is included with the downloadable supplemental content.)

The key to finding the trouble with your amplifier (or any piece of sophisticated equipment) is to be careful and methodical, and to avoid jumping to false conclusions or

making random tests. The manufacturer's customer service department will likely be helpful if you are considerate and have taken careful notes detailing the trouble symptoms and any differences from normal operation. There may be helpful guidelines on the manufacturer's web pages or from other Internet resources. Sometimes there is more than one problem — they work together to act like one very strange puzzle. Just remember that most problems can be isolated by careful, step-by-step tests.

### SAFETY FIRST

It is important to review good safety practices. (See the **Safe Practices** and **Power Sources** chapters for additional safety information.) Tube amplifiers use power supply voltages well in excess of 1 kV and the RF output can be hundreds of volts, as well. Almost every voltage in a vacuum-tube amplifier can be lethal! Take care of yourself and use caution!

**Power Control** — Know and control the state of both ac line voltage and dc power supplies. Physically disconnect line cords and other power cables when you are not working on live equipment. Use a lockout on circuit breakers. Double-check visually and with a meter to be absolutely sure power has been removed.

**Interlocks** — Unless specifically instructed by the manufacturer's procedures to do so, never bypass an interlock. This is rarely required except in troubleshooting and should only be done when absolutely necessary. Interlocks are there to protect you.

**The One-Hand Rule** — Keep one hand in your pocket while making any measurements on live equipment. The hand in your pocket removes a path for current to flow through you. It's also a good idea to wear shoes with insulating soles and work on dry surfaces. Current can be lethal even at levels of a few mA — don't tempt the laws of physics.

**Test Equipment Rating** — Be sure your test equipment is adequately rated for the voltages and power levels encountered in amplifiers! This is particularly important in handheld equipment in which there is no metal enclosure connected to an ac safety ground. Excessive voltage can result in a *flashover* to the user from the internal electronics, probes, or test leads, resulting in electric shock. Know and respect this rating.

If you are using an external high voltage probe, make sure it is in good condition with no cracks in the body. The test lead insulation should be in good condition — flexible and with no cracks or wire exposed. If practical, do not make measurements while holding the probe or meter. Attach the probe with the voltage discharged and then turn the power on. Turn power off and discharge the voltage

before touching the probe again. Treat high voltage with care and respect!

**Patience** — Repairing an amplifier isn't a race. Take your time. Don't work on equipment when you're tired or frustrated. Wait several minutes after turning the amplifier off to open the cabinet — capacitors can take several minutes to discharge through their bleeder resistors. On most amplifiers, the meter switch has a HV position — wait until it is at zero before opening the cabinet. Some amplifiers have a safety interlock that shorts the high voltage to ground — if the capacitor bank has not discharged, this can be quite spectacular — and destroy power supply components.

**A Grounding Stick** — Make the simple safety accessory shown in the High Voltage section of the **Power Sources** chapter and use it whenever you work on equipment in which hazardous voltages have been present. The ground wire should be heavy duty (#12 AWG or larger) due to the high peak currents (hundreds of amperes) present when discharging a capacitor or tripping a circuit breaker. When equipment is opened, touch the tip of the stick to every exposed component and connection that you might come in contact with. Assume nothing — accidental shorts and component failures can put voltage in places it shouldn't be.

**The Buddy System and CPR** — Use the buddy system when working around any equipment that has the potential for causing serious injury. The buddy needn't be a ham, just anyone who will be nearby in case of trouble. Your buddy should know how to remove power and administer basic first aid or CPR.

### CLEANLINESS

The first rule in taking good care of an amplifier is cleanliness. Amplifiers need not be kept sparkling new, but their worst enemy is heat. Excess heat accelerates component aging and increases stress during operation.

Outside the amplifier, prevent dust and obstructions from blocking the paths by which heat is removed. This means keeping all ventilation holes free of dust, pet hair and insects. Fan intakes are particularly susceptible to inhaling all sorts of debris. Use a vacuum cleaner to clean the amplifier and surrounding areas. Keep liquids well away from the amplifier.

Keep papers or magazines off the amplifier — even if the cover is solid metal. Paper acts as an insulator and keeps heat from being radiated through the cover. Amplifier heat sinks must have free air circulation to be effective. There should be at least a couple of inches of free space surrounding an amplifier on its sides and top. If the manufacturer recommends a certain clearance, mounting orientation or air flow, follow those recommendations.

**Figure 26.23** — A small paintbrush and a vacuum cleaner crevice attachment make dust removal easy.

Inside the amplifier, HV circuits attract dust that slows heat dissipation and will eventually build up to where it arcs or carbonizes. Use the vacuum cleaner to remove any dust or dirt. If you find insects (or worse) inside the amp, try to determine how they got in and plug that hole. Window screening works fine to allow airflow while keeping out insects. While you're cleaning the inside, perform a visual inspection as described in the next section.

Vacuuming works best with an attachment commonly known as a crevice cleaner. **Figure 26.23** shows a crevice cleaning attachment being used with a small paintbrush to dislodge and remove dust. The brush will root dust out of tight places and off components without damaging them or pulling on connecting wires. Don't use the vacuum cleaner brush attachment; they're designed for floors, not electronics. Some vacuums also have a blower mechanism, but these rarely have enough punch to clean as thoroughly as a brush. Blowing dust just pushes the dust around and into other equipment.

If you can't get a brush or attachment close enough, a spray can of compressed air will usually dislodge dust and dirt so you can vacuum it up. If you use a rag or towel to wipe down panels or large components, be sure not to leave threads or lint behind. Never use a solvent or spray cleaner to wash down components or flush out crevices

unless the manufacturer advises doing so — it might leave behind a residue or damage the component.

Cigarette smoke causes its own set of unique problems as tar and nicotine accumulate along with dust and dirt. Removal is difficult at best; commercial solvents such as *Krud Kutter* can be thinned 4-to-1 and will remove the gummy deposits. In extreme cases, disassemble the amplifier (remove tube(s), power transformer and meters), and wash it in a sink with soap and water. Be careful to protect or remove meters and other components that can be damaged by water. Thoroughly dry the amplifier in warm air. Re-lubricate variable capacitors, variable inductors, and any rotary controls.

## INSPECTION

Remove any internal covers or access panels and...stop! Get out the grounding stick (see the **Power Sources** chapter), clip its ground lead securely to the chassis, and touch every exposed connection. Now, using a strong light and possibly a magnifier, look over the components and connections. Use all of your senses to analyze the interior — smell, look, listen.

Amplifiers have far fewer components than transceivers, so look at every component and insulator. Look for cracks, signs of arcing, carbon traces (thin black lines), discoloration,

loose connections, melting of plastic, and anything else that doesn't look right. This is a great time to be sure that mounting and grounding screws are tight. Does anything smell burnt? Learn the smells of overheated components. Make a note of what you find, repair or replace — even if no action is required. If the amplifier was recently powered up, an infrared thermometer can spot components that were running hot. Or you may hear a crackling or sizzling noise from heat — not a good sign! Try to isolate the source of the noise.

## ELECTRICAL COMPONENTS

Let's start with the power supply. There are three basic parts to amplifier power supplies — the ac transformer and line devices, the rectifier/filter, and the metering/regulation circuitry. (See the **Power Sources** chapter for more information.) Transformers need little maintenance except to be kept cool and be mounted securely, but inspect for overheating, discoloration, or seepage from insulation or tar. Line components such as switches, circuit breakers and fuses, if mechanically sound and adequately rated, are usually electrically okay, as well. Check fuses and switches with a multimeter.

Rectifiers and HV filter capacitors require occasional cleaning. Look for discoloration around components mounted on a printed circuit board (PCB) and make sure that all wire connections are secure. HV capacitors are generally electrolytic or oil and should show no signs of leakage, swelling or outgassing around terminals.

Components that perform metering and regulation of voltage and current can be affected by heat or heavy dust. If there has been a failure of some other component in the amplifier — such as a tube — these circuits can be stressed severely. Resistors may survive substantial temporary overloads, but may show signs of overload such as discoloration or swelling — and change value. Verify the correct value with a multimeter against the color code; if it is not readable or reads erratically, replace the component.

Amplifiers contain two types of relays — control and RF. Control relays switch ac and dc voltages and do not handle input or output RF energy. The usual problem encountered with control relays is oxidation or pitting of their contacts. A burnishing tool can be used to clean relay contacts. In a pinch a strip of ordinary paper can be pulled between contacts gently held closed. Avoid the temptation to over-clean silver-plated relay and switch contacts. It is easy to remove contact plating with excessive polishing and while silver-plated relay and switch contacts may appear to be dark in color, oxidized silver (black) is still a good conductor. Once the silver's gone,

**Figure 26.24** — The band switch section on the left clearly shows the signs of destructive arcing.

it's gone; contact erosion will then be pervasive. If visual inspection shows heavy pitting or discoloration or resistance measurements show the relay to have intermittent contact quality, it should be replaced.

If the resting current is too high or intermittent, check power relays for good contact from the bias supply. On some older amplifiers, the relay coil is used as a resistor to create a voltage drop that cuts off the tube. If the relay coil covering is discolored, measure the resistance of the coil and possibly replace it.

RF relays are used to perform transmit/receive (TR) switching and routing of RF signals through or around the amplifier circuitry. Amplifiers designed for full break-in operation will usually use a high-speed vacuum TR relay. Vacuum relays are sealed and cannot be cleaned or maintained. When you replace RF relays, use a direct replacement part or one rated for RF service with the same characteristics as the original.

If the SWR measured between the transceiver and the amplifier suddenly increases, is erratic, or QSK (break-in) stays in the transmit state or is just open in receive, check the RF relay contacts.

Cables and connectors are subjected to heavy heat and electrical loads in amplifiers. Plastics may become brittle and connections may oxidize. Cables should remain flexible and not be crimped or pinched if clamped or tied down. Gently wiggle cables while watching the connections at each end for looseness or bending. Connectors can be unplugged

and resealed once or twice to clear oxide on contact surfaces.

Carefully inspect any connector that seems loose. Be especially careful with connectors and cables in amplifiers with power supplies in separate enclosures from the RF deck. Those interconnects are susceptible to both mechanical and electrical stress and you don't want an energized HV cable loose on the operating desk. Check the electrical integrity of those cables and make sure they are tightly fastened.

As with relays, switches found in amplifiers either perform control functions or route RF signals. Adequately rated control switches, if mechanically sound, are usually okay. Band switches are the most common RF switch—usually a rotary phenolic or ceramic type. A close visual inspection should show no pitting or oxidation on the wiper (the part of the switch that rotates between contacts) or the individual contacts. Arcing or overheating will quickly destroy rotary switches. **Figure 26.24** shows a heavy-duty band switch that has suffered severe damage from arcing.

Slight oxidation is acceptable on

## Wafer Switch Repair

Because they are often custom parts, replacements for individual wafers and contacts for rotary switches can be difficult or impossible to find. You may be able to find switches with the same size contacts, however. These can serve as replacements for contacts on the damaged switch. Save pieces of the damaged switch, since it can be used for parts.

Start by disassembling the damaged switch. If it is on a shaft there are usually two threaded rods holding it together. Save all pieces. Note the order in which flat and lock washers are used. Taking a close-up photo or making a careful drawing is a good idea. Take care to save all the parts. Place the damaged wafer on your work surface with the hollow-side of the rivet facing up. Use a drill bit just a bit larger than the rivet. Drill-out the rivet at low speed, using just enough pressure to cut off the lip of the rivet—do not drill into the contact itself. Remove the burned contacts first to get a “feel” for how to do it without damaging the contact.

Now disassemble the switch to be used for part replacement and once again, save all the parts for future use. Once the wafers are in-hand, inspect them and pick the best ones to be used as replacements. Remove the replacement contacts in the same way as the damaged contacts were removed.

Now replace the damaged contacts with the replacements using #2-56 screws and nuts (smaller switches may require even smaller hardware), being careful not to over-tighten the screws and crack the ceramic or phenolic wafer; “just tight” is good enough. Use a dab of LockTite Red (or paint or fingernail polish) to secure. **Figure 26.A1** shows a wafer that has been repaired using this technique.

**Figure 26.A1** — Five contacts starting at the 4:30 position on the wafer have been replaced using contacts removed from another switch and #2-56 hardware. [Photo courtesy of Matt Kastigar, W0MJ]

silver-plated switches. Phosphor-bronze contacts can sometimes be cleaned with a light scrub from a pencil eraser, but plating can be easily removed, so use caution with this method and be sure to remove any eraser crumbs. Rotary switch contacts cannot be replaced easily although individual wafer sections may be replaced if an exact matching part can be obtained. (See sidebar.) De-oxidation chemicals should be applied with a pen-type applicator and not sprayed to avoid absorption by porous phenolics or plastics that can create resistive paths.

When replacing capacitors and resistors, be sure to use adequately rated parts. Voltage and power-handling ratings are particularly important, especially for components handling high RF currents. An RF tank capacitor replacement should be checked carefully for adequate RF voltage and current ratings, not just dc. HV resistors are generally long and thin to prevent arcing across their surfaces. Even if a smaller (and cheaper) resistor has an equivalent power rating, resist the temptation to substitute it. In a pinch, a series string of resistors of the appropriate combined value can be used to replace one HV unit. Don't use carbon resistors for metering circuits, use metal or carbon film types. The carbon composition types are too unstable. Electrolytic capacitors also have a temperature rating, usually 85 or 105 °C; use the higher rating if available.

If you are repairing or maintaining an old amplifier and manufacturer-specific parts are no longer available, the ham community has many sources for RF and HV components. Fair Radio Sales ([www.fairradio.com](http://www.fairradio.com)) and Surplus Sales of Nebraska ([www.surplus-sales.com](http://www.surplus-sales.com)) are familiar names. Hamfests and websites often have amplifier components for sale. (See the **RF Power Amplifiers** chapter's sidebar on using surplus or used parts for amplifiers.) You might consider buying a non-working amplifier of the same model for parts. MFJ ([www.mfjenterprises.com](http://www.mfjenterprises.com)) sells some parts that are used in the Ameritron brand of amplifiers — you may be able to substitute.

## TUBES

Good maintenance starts with proper operation of the amplifier. Follow the manufacturer's instructions for input drive levels, duty cycles, tuning and output power level. Frequently check all metered voltages and current to be sure that the tubes are being operated properly and giving you maximum lifetime. The manufacturer spent time and effort to develop the manual — read it! If you do not have one, do a web search (or call the manufacturer) and get one. It is time well-spent.

The internal mechanical structures of tubes generally do not deal well with mechanical

shock and vibration, so treat them gently. The manufacturer may also specify how the amplifier is to be mounted, so read the operating manual. Tubes generate a lot of heat, so it's important that whatever cooling mechanism employed is kept at peak efficiency. Airways should be clean, including between the fins on metal tubes. All seals and chimneys should fit securely and be kept clean. Wipe the envelope of glass tubes clean after handling them — fingerprints should be removed to prevent baking them into the surface. On metal tubes that use finger-stock contacts, be sure the contacts are clean and make good contact all the way around the tube. Partial contact or dirty finger stock can cause asymmetric current and heating inside the tube, resulting in warping of internal grids and possibly cause harmonics or parasitics.

Plate cap connections and VHF parasitic suppressors should be secure and show no signs of heating. Overheated parasitic suppressors may indicate that the neutralization circuit is not adjusted properly. Inspect socket contacts and the tube pins to be sure all connections are secure, particularly high-current filament connections. Removing and inserting the tubes once or twice will clean the socket contacts.

While the tubes are removed, check the pins for melted solder — this is common on over-heated 3-500Z tubes. If needed, resolder with silver solder, and be careful not to use too much solder that might expand the diameter of the pin.

Adjustments to the neutralizing network, which suppresses VHF oscillations by negative feedback from the plate to grid circuit, are rarely required except when you are replacing a tube or after you do major rewiring or repair of the RF components. The manufacturer will provide instructions on making these adjustments. If symptoms of VHF oscillations occur without changing a tube, then perhaps the tube characteristics or associated components have changed. Parasitic oscillations in high-power amplifiers can be strong enough to cause arcing damage. Perform a visual inspection prior to readjusting the neutralizing circuit.

Metering circuits rarely fail on their own, but they play a key part in maintenance. By keeping a record of normal voltages and currents, you will have a valuable set of clues when things go wrong. Record tuning settings, drive levels, and tube voltages and currents on each band and with every antenna. When settings change, you can refer to the notebook instead of relying on memory.

## MECHANICAL

The most common faults appear with the moving parts: connectors, relays and switches. Thermal cycling and heat-related stresses can result in mechanical connections loosening

over time or material failures. Switch shafts, shaft couplings (especially if they are plastic) and panel bearings all need to be checked for tightness and proper alignment. All mounting hardware needs to be tight, particularly if it supplies a grounding path. Examine all panel-mounted components, particularly RF connectors, and be sure they're attached securely. BNC and UHF connectors mounted with a single nut in a round panel hole are notorious for loosening with repeated connect/disconnect cycles. Rubber and plastic parts are particularly stressed by heat. If there are any belts, gears or pulleys, make sure they're clean and that dust and lint are kept out of their lubricant. Loose or slipping belts should be replaced. Check O-rings, grommets and sleeves to be sure they are not brittle or cracked. If insulation sleeves or sheets are used, check to be sure they are covering what they're supposed to. Never discard them or replace them with improperly sized or rated materials.

Enclosures and internal shields should all be fastened securely with every required screw in place. Watch out for loosely overlapping metal covers. If a sheet metal screw has stripped out, either drill a new hole or replace the screw with a larger size, taking care to maintain adequate clearance around and behind the new screw. Or, if space permits, a "speed" or clip nut can sometimes be used. These are available from auto parts or home improvement stores, usually in the "specialty hardware" section.

Tip the amplifier from side to side while listening for loose hardware or metal fragments, all of which should be removed.

Clean the front and back panels to protect the finish. If the amplifier cabinet is missing a foot or an internal shock mount, replace it. A clean unit with a complete cabinet will have a significantly higher resale value, so it's in your interest to keep the equipment looking good.

## SHIPPING

When you are traveling with an amplifier or shipping it, some care in packing will prevent damage. Improper packing can also result in difficulty in collecting on an insurance claim, should damage occur. The original shipping cartons are a good method of protecting the amplifier for storage and sale, but they were not made to hold up to frequent shipping. If you travel frequently, it is best to get a sturdy shipping case made for electronic equipment. Pelican ([www.pelican-shipping-cases.com](http://www.pelican-shipping-cases.com)) and Anvil ([www.anvil-site.com](http://www.anvil-site.com)) make excellent shipping cases suitable for carrying amplifiers and radio equipment.

Some amplifiers require the power transformer to be removed before shipping. Check your owner's manual or contact the manufacturer to find out. Failure to remove it before

shipping can cause major structural damage to the amplifier's chassis and case.

Tubes should also be removed from their sockets for shipment. It may not be necessary to ship them separately if they can be packed in the amplifier's enclosure with adequate plastic foam packing material. If the manufacturer of the tube or amplifier recommends separate shipment, however, do it!

### CLEANING AND MAINTENANCE PLAN

For amateur use, there is little need for maintenance more frequently than once per year. Consider the maintenance requirements of the amplifier and what its manufacturer

recommends. Review the amplifier's manuals and make up a checklist of what major steps and tools are required.

### TROUBLESHOOTING

A benefit of regular maintenance will be familiarity with your amplifier should you ever need to repair it. Knowing what it looks (and smells) like inside will give you a head start on effecting a quick repair.

The following discussion is intended to illustrate the general flow of a troubleshooting effort, not be a step-by-step guide. Before starting on your own amplifier, review the amplifier manual's "Theory of Operation" section and familiarize yourself with the

schematic. If there is a troubleshooting procedure in the manual, follow it. **Figure 26.25** shows a general-purpose troubleshooting flow chart. Do not swap in a known-good tube or tubes until you are sure that a tube is actually defective. Installing a good tube in an amplifier with circuit problems can damage a good tube.

Many "amplifier is dead" problems turn out to be simply a lack of ac power. Before even opening the cabinet of an unresponsive amplifier, be sure that ac is really present at the wall socket and that the fuse or circuit breaker is really closed. If ac power is present at the wall socket, trace through any internal fuses, interlocks and relays all the way through to the transformer's primary terminals. If the amplifier operates from 240-V circuits, be sure you check both hot wires. (See the **Safety** chapter for more information about ac wiring practices.)

Hard failures in a high-voltage power supply are rarely subtle, so it's usually clear if there is a problem. When you repair a power supply, take the opportunity to check all related components. If all defective components are not replaced, the failures may be repeated when the circuit is re-energized.

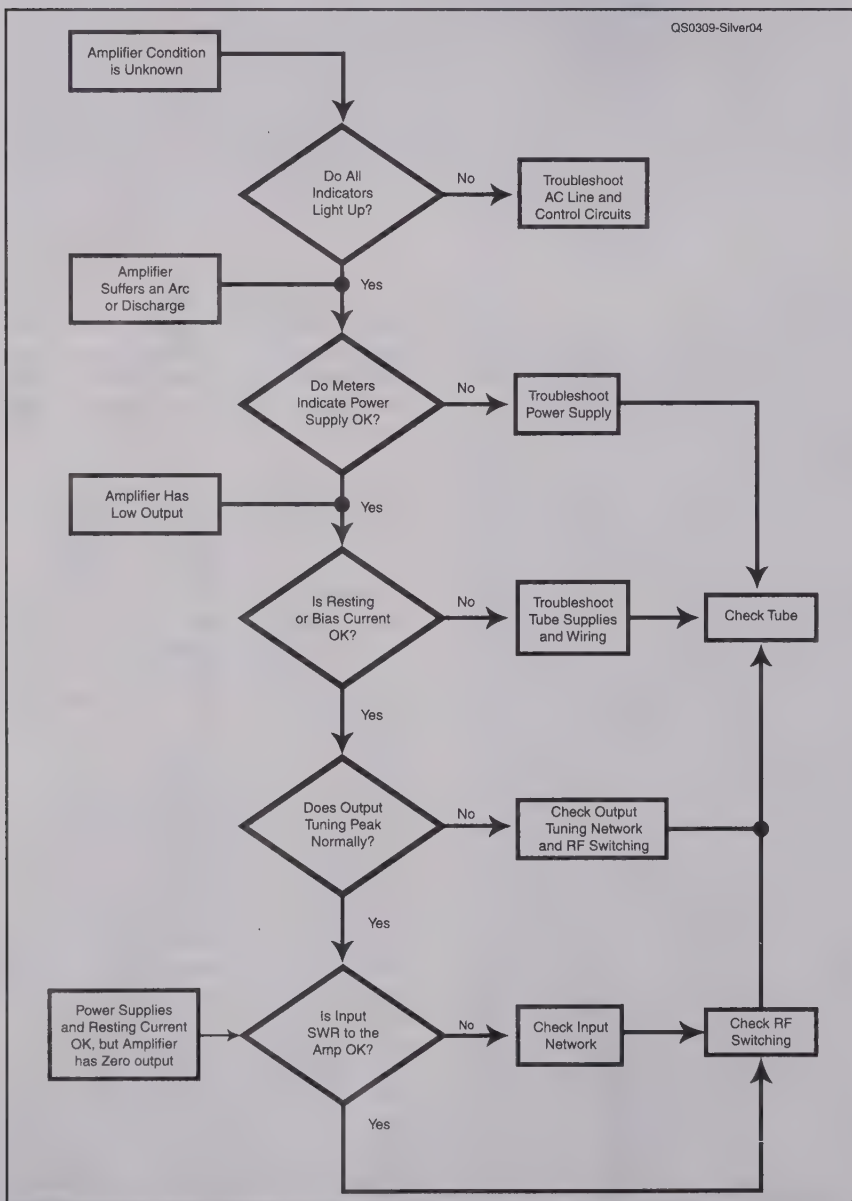

Rectifiers may fail open or shorted — test them using a DMM diode checker. An open rectifier will result in a drop in the high-voltage output of 50% or more but will probably not overheat or destroy itself. A shorted rectifier failure is usually more dramatic and may cause additional rectifiers or filter capacitors to fail. If one rectifier in a string has failed, it may be a good idea to replace the entire string as the remaining rectifiers have been subjected to a higher-than-normal voltage.

High-voltage filter capacitors usually fail shorted, although they will occasionally lose capacitance and show a rise in ESR (equivalent series resistance). Check the rectifiers and any metering components — they may have been damaged by the current surge caused from a short circuit.

Power transformer failures are usually due to arcing in the windings, insulation failures, or overheating. high-voltage transformers can be disassembled and rewound by a custom transformer manufacturer.

Along with the plate supply, tetrode screen supplies occasionally fail, too. The usual cause is the regulation circuit that drops the voltage from the plate level. Operating without a screen supply can be damaging to a tube, so be sure to check the tube carefully after repairs.

If the power supply checks out okay and the tube's filaments are not lit, check the tube socket and the pins on the tube itself — overheating can cause solder to flow and intermittent failure. If the tube's filament is lit, check the resting or bias current. If it is

**Figure 26.25** — This general-purpose flow chart will help identify amplifier problems. For solid-state units, substitute "Check Output Transistors" for "Check Tube."

excessive or very low, check all bias voltages and dc current paths to the tube, such as the plate choke, screen supply (for tetrodes) and grid or cathode circuits.

If you do not find power supply and dc problems, check the RF components or RF deck. Check the input SWR to the amplifier. If it has changed then you likely have a problem in the input circuitry (overheated coil, shorted capacitor or bad switch contact) or one or more tubes have failed. Perform a visual check of the input circuitry and the band switch, followed by an ohmmeter check of all input components. Use an SWR analyzer or a dip oscillator to see if the input tuning has changed, indicating a possible bad tuning network component in the input circuits. If input SWR is normal and applying drive does not result in any change in plate current, you may have a defective tube, tube socket or connection between the input circuits and the tube.

Check the TR control circuits and relay. If plate current changes, but not as much as normal, try adjusting the output tuning circuitry. If this has little or no effect, the tube may be defective or a connection between the tube and output circuitry may have opened. If retuning has an effect, but at different settings than usual, the tube may be defective or there may be a problem in the tuning circuitry. A visual inspection and an ohmmeter check are in order.

## SOLID STATE AMPLIFIERS

Almost all diagnostic techniques used for tube amplifiers are also applicable to solid state amplifiers. Input and output circuits are very similar. Power supplies are usually lower voltage (but high current).

Power supplies typically can be checked with a multimeter for voltage but current will require reading the voltage drop across a low-value, high-wattage resistor (this can cause problems from the voltage drop) or use a clamp-on current probe. Bias adjustments typically are made with a potentiometer on a voltage regulator circuit (you'll need the schematic or user's manual) and resting current needs to be checked and verified against the manufacturer's specifications.

As with tubes, heat is the enemy. Keep all ventilation openings clear and clean. Check fans for proper operating and speed. Remove any dust or dirt buildup, especially on heat sinks and transistor packages.

Bipolar transistors can be checked with a multimeter (see the **Component Data and References** chapter), as can MOSFETS which are now more common in RF amplifiers. Replacements will require de-soldering the old part, cleaning-up the PC board, and installation of the new part. If the transistors are mounted against a heat sink, use a thin, bubble-free film of heat sink compound

between the transistor and heat sink. Make sure all screws are in-place and tight. If shoulder washers are used to insulate screws, be sure they are used when the amplifier is reassembled.

## POWERING UP OLD AMPLIFIERS

When a piece of equipment has been idle for a long period of time, proper care must be taken to "revive" it. DO NOT just "plug it in" and "power it up" — the results will most likely be smoke and sparks! This is especially true for amplifiers with high-voltage power supplies. (See Powering Up the Equipment in the section Repair and Restoration of Vintage Equipment.)

First, examine the device for physical damage such as bent sheet metal or dents. Clean metal work and panels is usually a good sign. Assuming it is ac-powered, look at the line cord for cuts, scuffs, or cracks, then bend it between your fingers and listen for "cracking." If it is dried out or brittle, replace it before proceeding. If the line cord is okay, tie a piece of wire through the plug's pins so that it cannot be plugged-in to a receptacle. Make sure the plug is the right one for the input voltage (120 or 240 V). Check the fuses (if present) — a good indication of condition when last used.

Open the cabinet, remove the tube(s) and store in a safe place. Look closely for any irregularities such as dark PC board areas, discolored resistors, breached, swollen, or leaky capacitors, disconnected wires, loose components or screws, or cracked components or hardware. Begin with these and replace as required. Verify that all of the power supply connections are in order, including that power transformer connections are configured for the proper voltage.

Typically, old electrolytic capacitors, even if otherwise good, have dried-out and need attention. They can be tested with a multimeter for shorts (or open), or with an ESR meter if available. These are best replaced if the amplifier is really old or if they don't charge up properly in the power-up test (see below and this chapter's section on repairing vintage equipment.)

Use a multimeter to test for shorts to ground in the power supply section. With the power switch in the ON position (still not attached to ac power), measure resistance across the pins of the ac plug. It should read 4 to 5  $\Omega$  if it is connected to the primary of a transformer and open when the power switch is OFF. If you measure anything other than an open circuit, check for decoupling capacitors on the ac line that might be leaky. Check the secondary resistance of the transformer — it will be higher in resistance. Then work your way to the rectifier and filter capacitors and any chokes.

Check the resistance across the input and output RF connectors. They should be open or nearly open depending on the input or output network type. (Some amplifiers have an RF choke across the output connector which will present a low resistance.) Check the resistance of the HV plate connections of the tubes to ground — it should be open (the plate capacitors may be observed charging up).

If all looks good, and it is possible to do so, disconnect the rectifier board or assembly and check the transformer output windings. Then check any interlock components that might have to be closed or opened (depending on function).

Before starting power-up tests, *make sure* your multimeter is rated for the voltage. If not, don't use it as the meter could be destroyed or an arc through the meter or its leads (called *flashover*) can present a severe shock hazard.

Using a variable transformer (such as a Variac), bring up input power slowly to about 25% of rated input voltage. The secondary voltage of the transformer should be 25% of the recommended output. (Make high voltage measurements either hands-free or with one hand not touching anything.) Because full output voltage will exceed the maximum rating of most multimeters, disconnect the multimeter unless you are using a high-voltage probe. Increase the voltage slowly to full input while watching the transformer — it should not get hot or make noise. Use an infrared thermometer to avoid direct contact but verify the transformer does not get hot without a load.

Next, power down and reconnect the rectifier / filter board or assemblies. Using the variable transformer, start at 25% input voltage again. If the amplifier has a meter with an HV or B+ position, look for about 25% of the normal voltage reading. Dial lights might just barely light. Leave the power supply to "cook" for a few hours, monitoring it closely. Initially, there will be a high current surge that will slowly drop after the electrolytic filter capacitors start to reform their dielectric layer. When the current drops, bump the voltage up 10 to 20 V, wait a half hour, then turn it up again, monitoring the power supply with each increase. Continue until you have reached full input voltage.

When full power supply high voltage has been achieved, the electrolytic caps should be reformed and the dial lights should be at full brightness. If, at any time there is smoke, crackling noise or sparks, disconnect at once, discharge the capacitors, and investigate the issue(s).

Once the power supply is up and running, disconnect the plate B+ lead from the output of the rectifier / filter. In order to check filament voltage, solder temporary wires to the filament socket pins and route them out of

the amplifier cabinet. Insert the tube(s), close the cabinet (checking the interlock safety switches), and power up. Quickly verify the filament voltage — it should be within 5% of the specified voltage; if not, power off and investigate. Check the fan(s) for proper operation and air flow.

Tubes get gassy and may arc internally when first powered up after a long period of storage; leave the B+ disconnected and let the tubes “cook” for a few hours. If the tube has a “getter” this may activate it to remove gas. Not all power tubes have a getter — check the data sheet for your tube.

Using lots of caution and a high-voltage probe, check that there is no dc voltage at the

output RF connector — if the plate coupling capacitor is shorted, there may be full B+ on the amplifier output!

Power down, wait for the HV / B+ to read zero, and open the cabinet. Use a grounding stick to *be sure* the B+ is at zero, then reconnect it (see the **Power Sources** chapter for safety tips on working with high-voltage power supplies). Put the plate caps on, reattach the cover, and power it up. Listen and watch (if you can see the tubes) for any issues. If you notice anything unusual, stop at once and investigate (after discharging the high voltage, of course). If all is well, monitor the amp and let it cook for a few hours.

After a thorough test, power the amp off,

let it sit overnight, then power up the next day. Check the idling current for the recommended value once again.

Connect the amp to a dummy load that can handle full power output. Put the amp in transmit mode. The idling current should be the recommended value. Switch to standby. Connect a transmitter set for low output (about 20 W), and drive the amplifier. At low drive, the output should be proportional to the input times the gain. If all goes well, apply more drive until full output is achieved. At this point, if the tube is bad, it may fail to reach full power or it may arc. Listen and carefully verify all operations.

## 26.10 Antenna Systems

This section is an abbreviated version of the Antenna System Troubleshooting chapter of the *ARRL Antenna Book* that was added to the 22nd edition. Because of the enormous variety of antenna systems, general guidelines must be presented, but the successful troubleshooting process usually follows a systematic approach just as for any other radio system.

### 26.10.1 Basic Antenna Systems

Start with an inventory of the antenna system. Any of these can be the cause of your problem: supports, insulators, elements, feed point, balun (if any), feed line, grounding or transient protectors, impedance matching

and switching equipment, RF jumper cables at any point. As with any troubleshooting process, be alert for mistaken or loose connections, loose or disconnected power and control cables, wires touching each other that shouldn't be, and so forth. Reduce the antenna system to the simplest system with the problem and it will likely look something like the system in **Figure 26.26**.

It is particularly important to remember that your station ground is often part of the antenna system. The length of the connection between the equipment ground bus and the ground rod is usually several feet at minimum and that can be an appreciable fraction of a wavelength on the higher HF bands. This can greatly affect tuning if there is common-mode

current on the feed line or if a random-wire or end-fed type of antenna is being used. If touching equipment enclosures or the ground wire affects SWR or impedance readings, that will affect your antenna measurements as well.

### DUMMY-LOAD TESTING

Begin by replacing components of your antenna system with a dummy load, starting at the output of the radio using a known-good jumper cable. Verify that the radio works properly into a 50Ω load using a known-good directional wattmeter. Then move the dummy load to the output side of any antenna tuning or switching equipment, one component at a time until you have replaced the antenna

Figure 26.26 — A typical simple antenna system. An add-on antenna tuner is likely to be used if one is not built-in to the radio. More complex antenna systems have all of the same components plus some switching equipment.

feed line with the dummy load. If everything checks OK to this point, the problem is in the feed line or antenna. Don't forget to verify that the problem with the antenna is still present after each dummy load test. If the problem was a loose or intermittent connection, it is likely that swapping the dummy load in and out changed or eliminated the problem.

### ANTENNA VISUAL INSPECTION

Now it is time to perform a visual inspection of the feed line and antenna itself. Start with the feed line connector at the last point where the dummy load was swapped in. Disassemble the connector and inspect it for damage from water or corrosion. If either are present, replace the connector and check the condition of the cable before proceeding. Note that if water can get into the cable at the antenna's elevated feed point, it is not unknown for it to flow downward through the braid both by gravity and by capillary action all the way to the shack! If the cable braid is wet at both ends, the cable must be replaced.

If you have a wire antenna, lower it and make a visual inspection of all the pieces.

- Cut away the waterproofing around the

coax termination and inspect for water and/or corrosion.

- On the insulators at each end, there is no possibility of contact between the antenna wire and the supporting wire/ropes.
- If there are any splices in the wire elements, they are well crimped or soldered.
- At the center insulator, there is no possibility of contact between the element wires.
- At the balun or coax connection the element connections are soldered or firmly connected.

If you have a Yagi or vertical antenna, similar steps are required. Carefully check any feed point matching assembly, such as a gamma match, hairpin, or stub and make sure connections are clean and tight.

### ANTENNA TEST

Assuming any mechanical problems have been rectified, proceed to retest the antenna and feed line. Replace the antenna with a dummy load and check the feed line loss with a wattmeter or antenna analyzer at the antenna end of the feed line. If the feed line checks out OK, the problem must be in the antenna. Reattach the feed line to the antenna

and verify that the problem remains. Note that for wire antennas lowered to near ground level, the resonant point will change — this is to be expected.

If the problem is still present, repeat the visual inspection at a closer level of detail. Check all dimensions and connections. Double-check any telescoping sections of tubing, transmission line stubs, in-line coax connectors, clamped connections between wires and between wires and tubing. If possible, give joints and connections a good shake while watching for intermittent readings on the wattmeter or antenna analyzer. If you cannot see inside a component or assembly, perform resistance tests for continuity. Remember to identify your signals since you are testing on the air at this point in the process.

The next step is to reinstall or raise the antenna at least  $\frac{1}{4}$ -wavelength off the ground and verify that the problem remains. If you have repaired the antenna, perform a re-check at this point to be sure everything is in good working order before returning the antenna to full height. Once you have re-installed the antenna, including full weatherproofing of any coaxial cable terminations or connectors, record in the shack notebook your measurements of the antenna along with what the problem was discovered to be and how you repaired it.

## AM Broadcast Interference to Antenna Analyzers

Living or testing within a couple of miles of an AM broadcast station can create a lot of problems for the sensitive RF detectors in portable antenna analyzers. This type of RFI usually appears as values of SWR and impedance that don't change with frequency or that change in unexpected ways or an upscale meter reading that varies with the station modulation. The analyzer SWR reading will not agree with SWR measured by using a directional wattmeter and more than a few watts of power. The solution is sometimes to use a broadcast-rejection filter (available from analyzer manufacturers) although this tends to color measurements a bit and typically can't be used for measurements on 160 meters because it is so close to the AM broadcast band. In cases where the station is nearby or on 160 meters, directional wattmeters or analyzers with narrow-band tuned inputs must be used.

### 26.10.2 General Antenna Systems

Think of the following topics as a kind of toolbox for troubleshooting. Many of them assume you are testing some type of Yagi or other beam antenna, but the general guidelines apply to all types of antennas

It is important to remember this simple rule for adjustments and troubleshooting: Do the simplest and easiest adjustment or correction *first*, and only *one* at a time.

When making on-air comparisons, select signals that are at the margin and not pushing your receiver well over S9 where it can be difficult to measure differences of a few dB. Terrain has a lot to do with performance as well. If you are comparing with a large station, keep in mind that its location was probably selected carefully and the antennas were placed exactly where they should be for optimum performance on the property.

### TEST MEASUREMENTS

A) Test the antenna at a minimum height of 15 to 20 feet. (See **Figure 26.27**.) This will move the antenna far enough away from the ground (which acts to add capacitance to the antenna) and enable meaningful measurements. Use sawhorses *only* for construction purposes.

- 15 to 20 feet above ground does not mean 5 feet above a 10 to 15 foot high roof, it means

ANT1093

**Figure 26.27 —**  
When testing a Yagi or quad antenna, make sure it is at least 15 to 20 feet above ground. If oriented vertically, the reflector should be the closest to ground. Performance will still change as the antenna is raised.

above ground with nothing in between;

- Antenna resonant frequency will shift upward as it is raised;
- Feed point impedance will change with a change in height and this applies to both horizontal and vertical antennas;
- Some antennas are more sensitive to proximity to ground than others;
- Some antennas are more sensitive to nearby conductive objects (such as other antennas) than others.

B) Aiming the antenna upward with the reflector on the ground might coincide with some measurements on rare occasions, but there are no guarantees with this method. The reflector is literally touching a large capacitor (earth) and the driver element is very close, too. Raise the antenna at least 15 to 20 feet off the ground.

C) When using a hand-held SWR analyzer you are looking for the dip in SWR, not where the impedance or resistance meter indicates 50 Ω. (Dip = frequency of lowest SWR value, or lowest swing on the meter.) On the MFJ-259/269 series, the left-hand meter (SWR) is the one you want to watch, not the right-hand meter (Impedance).

D) Does the SWR and frequency of lowest dip change when the coax length is changed? If so, the balun might be faulty, as in not isolating the load from the coax feed line.

Additionally, with an added length of coax and its associated small (hopefully small) amount of loss :

- The value of SWR is expected to be lower with the additional coax and,
- The width of the SWR curve is expected to be wider with the additional coax , when measured at the transmitter end of the coax.

E) Be sure you are watching for the right dip, as some antennas can have a secondary resonance (another dip). It is quite possible to see a Yagi reflector's resonant frequency, or some other dip caused by interaction with adjacent antennas.

## MECHANICAL

A. Are the dimensions correct? Production units should match the documentation (within reason). When using tubing elements, measure each *exposed* element section during assembly and the element *half-length* (the total length of each half of the element) after assembly. Measuring the entire length is sometimes tricky, depending on the center attachment to the boom on Yagis, as the element can bow, or the tape might not lay flat along the tubing sections. Self-designed units might have a taper error.

B. Making the average taper diameter larger will make the equivalent electrical element longer. This makes the antenna act as if the physical element is too long.

C. Making the average taper diameter smaller will make the equivalent electrical

element shorter. This makes the antenna act as if the physical element is too short.

D. If the element is a mono-taper (tubing element is the same for the entire length), larger diameter elements will be physically shorter than smaller diameter mono-taper elements to give the same electrical performance at the same frequency.

E. The type of mounting of the element to the boom affects the element length, whether it is attached directly to the boom, or insulated from the boom. Incorrect mounting/mounting plate allocation will upset the antenna tuning:

- A mounting plate 4 × 8 inches has an equivalent diameter of approximately 2.5 inches and 4 inches in length for each element half.
- A mounting plate that is 3 × 6 inches has an equivalent diameter of about 1.8 inches and a length of 3 inches for each element half.
- The mounting plate equivalent will be the first section in a model of the element half.

F. In a Yagi, if the elements are designed to be touching, are the elements touching the boom in the correct locations?

G. In a Yagi, if the elements are designed to be insulated, are the elements insulated from the boom in the correct locations?

H. The center of hairpin matching devices (i.e. on a Yagi) can be grounded to the boom .

I. The boom is neutral, but it is still a conductor! The center of a dipole element is also neutral and can be touched while tuning without affecting the reading. With a hairpin match , the center of the hairpin can also be touched while tuning and touching the whole hairpin might not affect the readings much at all.

## PROXIMITY

A. What else is near-by (roof, wires, guy lines, gutters)? If it can conduct at all, it can and probably will couple to the antenna!

B. Does the SWR change when the antenna is rotated? If so, this indicates interaction. Note that in some combinations of antennas, there can be destructive interaction even if the SWR does not change. Computer models can be useful here.

C. What is within ¼ wavelength of the antenna? Imagine a sphere (like a big ball) with the antenna in question at the center of the sphere, with the following as a radius, depending on frequency. Think in three dimensions like a sphere — up and down and front and rear. Any resonant conductor (antenna or not) with the following radii will couple to and probably affect the antenna you are testing or installing.

160 meters = 140 feet

80 meters = 70 feet

40 meters = 35 feet

20 meters = 18 feet

15 meters = 12 feet

10 meters = 9 feet

D. Interaction occurs whether or not you

are transmitting on the adjacent antennas. When receiving, it simply is not as apparent as when transmitting.

E. Wire antennas under a Yagi can easily affect it. This includes inverted V dipoles for the low bands and multi-band dipoles. The wire antennas are typically for lower frequency band(s) and will not be affected by the Yagi(s), as the Yagis are for the higher bands.

## FEED SYSTEM

The feed system includes:

- the feed line,
- switching mechanisms,
- pigtails from the feed point on the antenna to the main feed line or switch and,
- all feed lines inside the radio room.

The feed system is the *entire connection* between the radio and the feed point of the antenna.

A. Is the feed line (coax) known to be good? (Start with the easiest first.) Check the dc resistance across the cable with the far end open and shorted. Is there water in the coax? This can give strange readings, even frequency-dependent ones. If there is any question, swap the feed line for a known good one and re-test.

B. Are the connectors installed properly? Has a connector been stressed (pulled)? Is the rotation loop done properly to not stress the coax? Is it an old existing loop or a new one? Usually it's alright if new. Type N connectors (especially the older type) are prone to having the center conductor pull out due to the weight of the coax pulling down on the connector. Connectors are easy to do, using the right technique.

C. Is there a barrel connector (a PL-258 dual-SO-239 adapter) in the feed line anywhere? Has a new or different barrel been inserted? These are a common failure point, even with new barrels. The failures range from micro-bridges across the face of the barrel shorting out the center and shield, to resistance between the two ends of the barrel. Have the new barrels been tested in a known feed system? Always test them before installing. Use only quality RF adapters as these are common system failure points.

D. Is the coax intact and not frayed such that the shield can come into contact with anything? This can cause intermittent problems as the coax shield touches the tower, such as on rotation loops and coax on telescoping towers.

E. Is the tuner OFF on the radio? This is often overlooked when adding a new antenna.

F. Are there any new devices in the line? It might be a good idea to remove everything but the essential items when troubleshooting.

G. Is there a remote antenna switch? Swap to another port.

H. Is there a low pass filter in the line? The filter can be defective, especially on 10 meters, causing strange SWR readings.

## 26:10.3 Antenna Tuners

Antenna tuners are usually well designed and built with adequately-rated parts. Most will last a lifetime, but even QRP power levels can result in arcing if the tuner is trying to match a very high impedance or is accidentally disconnected from an antenna. *Hot switching* can cause damage when contacts in the tuner are moved while transmitting. Lightning transients and excessive power beyond the tuner's ratings cause damage. Frequently adjusted components and contacts can wear out over time or just get dirty. Any of these can cause problems with normal operation.

For more information on the different types and circuits used in tuners, see the section on Matching Impedances in Antenna Systems in the chapter on **Transmission Lines**. Remember that “tuner” is the most common term, but ATU, transmatch, antenna coupler, impedance matching unit, matchbox, and other terms also refer to the same piece of equipment.

If you think your tuner is misbehaving, begin the process of troubleshooting according to the previous section on General Antenna System Troubleshooting. Make sure the problem really is in the tuner! Once you're sure the tuner has a problem, give it a good checkout to get an idea of what you're looking for. Keep notes as you test since these will provide clues to what the problem may be and also point to tests you should perform after repairs to be sure you've fixed the problem.

Whether the tuner is internal to your transmitter or an external unit, start with a close and detailed visual inspection. Are the connectors clean? Do any connectors look like there has been an arc or are they discolored from heat or corrosion? If there are multiple antenna connectors, does the unit perform differently when the antenna is connected to different connectors? Are there any loose parts inside that rattle when the unit is tipped or shaken? Smell the unit, too — if anything smells burned, you may have a damaged component inside. These are also excellent inspections to make before buying a used tuner.

Operate the tuner into a dummy load at low and high power. Does it behave the same way at both power levels? Does it operate erratically? Does wiggling any of the feed lines to or from the tuner cause SWR to change at the transmitter output? Operate the tuner into a known-good antenna and feed line, then repeat the tests.

T network tuners have a reputation of being able to “tune up into themselves” meaning they can match even an open circuit because they have such a wide tuning range. This results in very high voltages and currents

inside the tuner, creating all sorts of problems.

Once you've put the tuner through its paces, you'll have a better idea of what problems you're facing. It is also worth considering that there may be more than one problem. When you find something wrong and fix it, repeat your tests to see if the problem is still there or has changed.

### AUTOMATIC ANTENNA TUNERS

Most of the same components in a manual tuner are present in an automatic tuner along with sensing, selection, and indicating circuits. The most important new moving parts are relays. Automatic tuners are a bit more difficult to diagnose, but by breaking them down into functional parts troubleshooting is straightforward. (This section also applies to the internal antenna tuners common in HF transceivers.)

Typically, automatic tuners have fixed-value capacitors and inductors in an L network. A phase sensor and voltage detectors are read by a microprocessor, which switches in L and C based on an algorithm to arrive at the best SWR match. The inductors and capacitors are switched in or out by relays. In “zero-power” tuners (tuners that do not draw much, if any current once tuning is complete) latching relays are used. These remain open or closed once power is removed.

There are three usual symptoms for automatic tuner problems. The tuner may not be able to achieve a match at all and display some kind of error condition. The tuner can “hunt” without stopping for a match according to its control program — you'll hear the relays clicking or buzzing without stopping. Or the tuner will suddenly start re-tuning at higher power levels during transmission because a component or relay is failing.

If the tuner cannot find a match or keeps “hunting” to find a match, the issue is typically a bad relay contact. The controller “thinks” it has the correct L or C value switched-in, but the contact is not being made. A relay driver line can also be open. Also check for a bad interconnect cable between the external antenna connector and the main board.

The most common issue is relay failure. Relays have a coil that is energized to move an *armature* holding the contacts. The usual relay acts as a DPDT switch with a set of NC (*normally closed*) and NO (*normally open*) contacts. To test the relay, first measure the coil resistance. Then energize each relay one at a time and measure the resistance across the contacts with and without power. A coil failure (usually an open circuit) requires relay replacement.

If the coil is good and you can get to the relay contacts, a strip of bond paper and

cleaning solution can sometimes clean the contacts of corrosion or oxide. Carefully remove the cover using a hobby knife along the bottom edge, not poking too far into the relay — you do not want to cut the coil winding. In miniature relays in particular, be careful to avoid bending the armature while cleaning. Put some cleaning solution on the paper strip, slide the strip between one set of contacts, hold them together, and slide the strip back and forth. If there is a dark deposit on the paper, keep sliding it back and forth until no additional deposit is seen. Repeat with the other set of contacts. If the contacts are severely pitted or there is large buildup of material on the contact from arcing, the relay should be replaced. Filing the contacts should be avoided because it removes any plating from the contact surfaces.

If the relays are good, they may not be being actuated by the controller. Check the printed-circuit board traces for burned or open traces. Then work your way back to the driver ICs or transistors and test them; microcontrollers generally cannot drive relays directly. Typically, a transistor is used to energize the relay coils. There should be a suppressor diode across each coil, as well, that can be tested with a VOM. Replace components as necessary.

### MAINTENANCE AND OPERATION

Think of your antenna tuner as the output stage of an amplifier — it contains many of the same type of components, operates at the same power levels, and needs the same care to operate reliably.

In large manual tuners, keep air-variable capacitors, exposed inductors, and switches clean. Dirt and dust can form paths for arcing and cause heat buildup. Remove dust with a gentle brush and vacuum. If the tuner has been in a smoking environment, smoke deposits can accumulate. Clean with a brush first, then apply cleaning solution using a brush, and thoroughly dry before operation. Lightly re-oil any bearings in air-variable capacitors after using cleaning solution. Do not put oil on a roller inductor shaft or contact. Check for arcing, broken or heated connections and wires; repair or replace as needed. Use a high-quality cleaning solution on switch contacts, but not to excess, and remove any residue. Check connectors and the cables in and out of the tuner.

Check grounding and bonding. The cabinet of an (external) tuner should be bonded to the transceiver, and to any RF bonding bus or plane in the station. If common-mode RF current is upsetting SWR measurements, use ferrite beads or a toroid to block it.

## 26.11 Repair and Restoration of Vintage Equipment

When purchasing a classic receiver or transmitter, unless you absolutely know otherwise, assume the radio will need work. Often you can get a top-of-the-line radio needing a bit of repair or clean-up inexpensively. Don't worry — these radios were designed to be repaired by their owners — and curiously, except for cosmetic parts such as cabinets and knobs, parts are much easier to find for 60-year-old radios than a 20-year-old imported transceiver!

Chances are the radio has gone for years without use. Even if it has been recently used, don't completely trust components that might be 60 or more years old. Don't start by plugging in your new acquisition! To do so might damage a hard-to-replace power transformer, or cause a fire.

Instead, if the radio didn't come with its owner's manual, get one. Several *QST* vendors sell old manuals in good condition. K4XL's Boat Anchor Manual Archive ([www2.faculty.sbc.edu/kg Grimm/boat\\_anchor](http://www2.faculty.sbc.edu/kg Grimm/boat_anchor)) is probably *the* best free resource for these manuals. Armed with the manual, remove the radio from its cabinet. You very likely will find evidence of unsightly repairs, modifications, or even dangling wires. While modifications aren't necessarily bad, they can certainly add some drama to any necessary subsequent troubleshooting. It's up to you to reverse or remove them.

Another option for working with vintage equipment is to refer to editions of the *ARRL Handbook* published around the time that the equipment was in common use. The circuit design and construction practices described in the *Handbook* are likely to be representative of those in the radio and may provide guidance for troubleshooting, repair, and adjustment. Similarly, the troubleshooting sections and chapters in previous editions provide valuable guidance for working with equipment of the same or earlier vintages.

### 26.11.1 Component Replacement

Correct any obvious problems such as dangling components. Replace the line cord with a three-wire, grounded plug, if not a transformerless “ac/dc” type as discussed below. If the radio is one with a live chassis, you should operate it from an isolation transformer for safety. If you don't have an isolation transformer, use a voltmeter to determine the orientation of the ac plug that places the chassis at ground potential. Avoid touching the chassis and do not use knobs with set screws that contact metal control shafts. It's also a good idea to add a fuse, if the radio doesn't originally have

one. Are we ready to give it the smoke test? Not so fast!

### CAPACITOR RATINGS

Obviously, aged components deteriorate and capacitors are particularly prone to developing leakage or short-circuits with age. There are as many opinions on capacitor replacement as there are radio collectors, but *at the very least* you should replace the electrolytic filter capacitors. Here's why: they *will* short circuit sometime, and when they do, they'll probably take the rectifier tube and the power transformer with them. Modern high voltage electrolytic capacitors are reliable and much smaller than their classic counterparts. Old paper-wax and black plastic tubular capacitors should also be replaced. Again, a short circuit in one of them could take out other components, too. Modern film capacitors of the appropriate voltage are great replacements. Opinions vary as to whether all should be replaced, but replacements are cheap and you have the radio apart now, so why not? If keeping the original components is important, follow the procedure for using a variable transformer to reform electrolytics as described below.

You can mount the new capacitors under the chassis by mounting a new terminal strip (do *not* just wire them to the old capacitor terminals), you can re-stuff an old electrolytic capacitor's can with new capacitors, or you can buy a new can from places such as [www.hayseedhamfest.com](http://www.hayseedhamfest.com) or Antique Electronics Supply ([www.tubesandmore.com](http://www.tubesandmore.com)). In any event, follow the manufacturer's schematic — don't assume that the – (minus) end of the capacitor goes to ground, as in some radios the ground path is through a resistor so as to develop bias for the audio output stage

or RF gain circuit. Observe the polarity or you'll soon be cleaning up a stinky mess!

### TESTING OLD CAPACITORS

All capacitors have a voltage rating written on the side of the cap unless it is a small disc. Surplus stores often have bins full of capacitors of unmarked voltage rating. Don't assume they are a high enough voltage to use — check them with a capacitor checker. There are many models out there by Knight Kit, Lafayette, Sencore, and Eico, but the best were the Heathkit IT-11 or IT-28. They are basically the same model but different colors. Both use a 6E5 Magic Eye tube to indicate the status of the capacitor. A selectable voltage from 3 to 600 V dc can be applied to check for leakage and operation. These are good for small disc or paper caps and large electrolytics.

Take the unknown voltage cap and place it in the test terminals. Advance the voltage control from minimum until the eye tube shows it breaking down. You now know what voltage it is good to.

If the capacitor tests good through the 600 V dc range, it probably is a 1000 V dc capacitor. It is best, though, to know for sure the rating of the cap. In tube equipment, most capacitors should be 500 or 1000 V rated. Mouser ([www.mouser.com](http://www.mouser.com)) and Digikey ([www.digikey.com](http://www.digikey.com)) do still sell caps for those voltage ranges, but they have become very expensive. You could also find new old stock (NOS) capacitors of the correct voltage rating at surplus stores.

### REFORMING ELECTROLYTIC CAPACITORS

The best idea is to replace old electrolytic capacitors with a new unit. They are available cheaply in the voltage ranges required and

## Using a Tube Tester

Vacuum-tube testers are scarce but can be located through antique or vintage radio associations, audiophile groups, and sellers of tubes.

Most simple tube testers measure the cathode emission of a vacuum tube. Each grid is shorted to the plate through a switch and the current is observed while the tube operates as a diode. By opening the switches from each grid to the plate (one at a time), we can check for opens and shorts. If the plate current does not drop slightly as a switch is opened, the element connected to that switch is either open or shorted to another element. (We cannot tell an open from a short with this test.) The emission tester does not necessarily indicate the ability of a tube to amplify.

Other tube testers measure tube gain (transconductance). Some transconductance testers read plate current with a fixed bias network. Others use an ac signal to drive the tube while measuring plate current.

Most tube testers also check inter-element leakage. Contamination inside the tube envelope may result in current leakage and shorts between elements. The paths can have high resistance, and may be caused by gas or deposits inside the tube. Tube testers use a moderate voltage to check for leakage. Leakage can also be checked with an ohmmeter using the  $\times 1M$  range, depending on the actual spacing of tube elements.

more compact and reliable than the original electrolytic caps. If necessary, however, old electrolytics can often be revived by reforming the dielectric using a capacitor checker.

Disconnect the wires attached to the capacitor under test and connect it to the capacitor checker. Start at the lowest voltage rating and let it charge up the capacitor. You will know when it is charged by viewing the eye tube: if it is wide open, the cap is charged; if it is closed, the capacitor is either shorted or still charging. Advance gradually to the next voltage rating and wait until the eye fully opens—take plenty of time for the capacitor to stabilize. Continue on through the voltage ranges; each time it will take longer for the eye to open. The dielectric is being reformed. Finally, when you reach the voltage range of the capacitor and the eye is fully open, the cap has been fully revived and is ready for use.

The same process can be performed with a variable autotransformer (Variac) by advancing it a few volts at a time over several hours, but that is a coarse and unreliable process. A diode must be placed in series with the transformer to convert the ac voltage to dc. Monitor the voltage across the capacitor with a meter. If it suddenly jumps to zero, the capacitor has shorted and is now useless. Usually the capacitor can be revived successfully and will work just fine.

## RESISTORS

Over time, carbon resistors in older radios can change value significantly, which can affect circuit operation. Disconnect one end of the questionable resistor and measure it with an accurate ohmmeter. If it is out of tolerance, replace it. Most resistors in the tube era were  $\frac{1}{2}$  W or greater. Most circuits today use  $\frac{1}{4}$  W or smaller resistors, which will not dissipate the power tubes produce.

Carbon composition resistors are becoming rarer but there are still ample quantities of NOS in surplus stores. Be careful about power rating. Use metal oxide resistors if needed. Remember that wirewound resistors are very inductive and not good for RF circuits. They are excellent for power supply circuits and are usually found in the 1 to 25 W range.

## REPLACING DIODES

Many old tube radios use rectifier tubes. It is not a good idea to replace these with solid-state rectifiers, as a shorted diode can take out the transformer. Selenium rectifiers, however, are good candidates to replace with a silicon diode. The 1N400x series of diode are usually fine for use and very cheap. For higher voltage supplies, be sure to use 1N4007 or higher rated diodes. This may result in higher output voltage from the supply. Add a series dropping resistor if necessary to reduce voltage.

## TRANSFORMER REPLACEMENT

The best bet is to find another radio of the same variety from which you can harvest the transformer. This is especially common in transmitters like the Heathkit DX-35 and DX-40 which frequently had transformers fail. Replacement transformers are generally no longer available. Some companies will rewind transformers, but that is usually prohibitively expensive. Output voltages are quite critical in the design of tube radios, so it is not a good idea to replace a 400 V ac transformer with a 600 V ac unit. It may be best to find a donor radio for a replacement transformer.

## WIRE REPLACEMENT

Power cords should be replaced at the first sign of hardening and cracking. It is often a good idea to replace the two-wire power cords with three-wire cords, but this *cannot* be done on ac/dc transformerless radios in which one side of the ac line is connected directly to the chassis! Those must retain the two-wire cords. As noted previously, operating these radios with an isolation transformer is the safest option. If replacing the cord with a two-wire version, the neutral (larger blade) must be connected to the chassis.

Pre-WWII vintage radios often used a cotton covered power cord. To keep the radio as authentic as possible, cotton covered power cords and matching plugs can be found at suppliers such as Antique Radio Supply.

Many early radios had a two-pin power plug with fuses in the plug (the radio has no internal fusing). These are made by Elmeco and are still available (check eBay). Standard 3AG type fuses go in the power plug. Usually a 1 or 2 A fast-blow fuse will work fine except for a higher powered transmitter.

For using PVC-covered wire with terminal strips, solid wire is easier to attach before soldering than stranded wire, although stranded is very usable. You can also use Teflon covered wire that doesn't burn when the soldering iron hits the insulation.

## TUBE REPLACEMENT

The sidebar "Using a Tube Tester" explains what a tube tester does. Watch swap meets and garage sales for tube substitution books. Many tubes are interchangeable or similar in purpose. Be sure to document any tube substitutions you make on a vintage radio. Remember that a new tube in the circuit may require re-peaking of the tuned circuits associated with it.

If a tube has a loose tube cap on top, you can easily repair it. Unsolder the cap and make sure that ample wire is still coming from the tube glass envelope. The tube cap should have a tiny hole in the center of the top which the wire will pass through. Mix a small amount of JB Weld epoxy ([www.jbweld.com](http://www.jbweld.com)) and glue the tube cap back in place.

Make sure the wire is sticking out of the hole. After the epoxy has hardened, solder the wire back onto the tube top. Don't let a loose tube cap break it off.

One might be anxious to wipe off the tube and clean it up. Be careful, as you might wipe off the tube number, and then you won't have any idea what the tube is. Many tubes have been lost because they have become unidentifiable. If you do decide to clean up the tube, make sure you steer well clear of the tube number.

Tube sockets and tube pins easily become oxidized which result in radios not working or being intermittent. It is a good idea to pull each tube and spray the socket with DeoxIT or tuner cleaner. Re-insert the tube and wiggle it around in the socket to rub away any oxidation remaining.

## REMOVING AND REPLACING COMPONENTS

Replacing capacitors and/or other components isn't difficult, unless they are buried under other components. The Hallicrafters SX-28 and SX-42 receivers are examples of receivers that have extremely difficult-to-reach components. There are different schools of thought on the proper component replacement method. You can use solder wick and/or a desoldering tool to remove the solder from a terminal, unwrap the wires, and install the new component by wrapping the lead around the terminal and soldering it securely. The proponents of this method point out that this is the preferred military and commercial method. I find it often will needlessly damage other components such as tube sockets and create solder droplets inside of the radio.

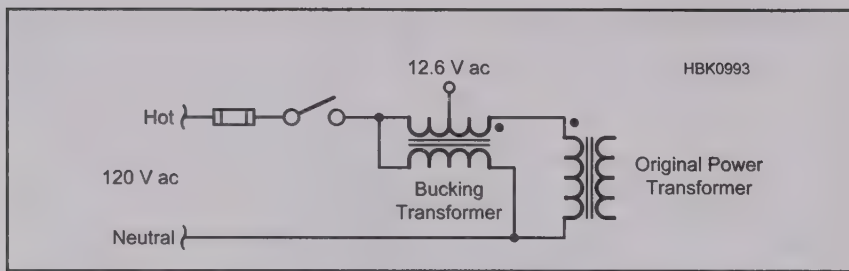

Back in the day, radio repairmen clipped out a component leaving a short stub of wire, made little coils in the new lead, then soldered the coiled lead to the old stub. This is a much faster, easier and neater method. Refer to books and websites on repairing vintage equipment for other useful tips and tricks.

## 26.11.2 Powering Up the Equipment

Before applying any power, use a VOM and measure the resistance from the B+ line to ground. Filter capacitors will cause an initial low resistance reading that increases as the capacitors charge. If the resistance stays low or does not increase beyond tens of k $\Omega$ , find the short circuit before you proceed.

## DETERMINING THE RIGHT INPUT AC VOLTAGE

Vintage radios were often designed for use with lower ac mains voltages than are the standard today. If they are powered from 120 V ac, the resulting higher voltages can

**Figure 26.28** — The bucking transformer secondary is connected out of phase with the radio's power transformer's primary. This reduces voltage output from the power transformer and avoids over-voltage stress on the radio's tubes and other components.

burn out filaments and overload the plate and screen circuits. Here's how to find out what voltage the radio was designed for:

- Remove all tubes and determine the proper filament voltage for one of them.
- Connect a voltmeter to the filament pins of the tube for which filament voltage is known.
- Using a Variac to power the radio, slowly increase voltage until the filament voltage matches the specified voltage for the tube.
- Measure the input voltage to the radio. That is the ac voltage from which the radio should be powered. If the input voltage is 115 V ac or lower, a bucking transformer can be used to reduce the input voltage.

Wiring for a bucking transformer is shown in **Figure 26.28**. The bucking transformer's primary is connected to the regular input ac voltage. Its secondary is connected in series and out of phase with the radio's power transformer primary. That reduces the input voltage to the power transformer primary so the output voltages are closer to what the components are rated for. Since phasing of a transformer secondary may not be obvious, hook the transformers up and measure output voltage from the radio's power transformer filament winding. If it has increased, reverse the connections for the bucking transformer secondary.

A small filament transformer with a secondary rating of 3 to 5 A will do for most radios. (Large radios may require transformers with higher current ratings.) To power a radio designed for 115 V ac from 120 V ac, use a 5 V or 6.3 V filament transformer. If the radio needs 110 V ac, use a 12.6 V filament transformer.

### INITIAL POWER-UP CHECKS

With the right input ac voltage determined, it's time to gradually power up the radio. DO NOT plug it in and turn it on "to see if it works!" Applying full voltage to a radio that has not been used for a long time can destroy it! It's best to use a variable transformer such as a Variac and ramp up the voltage slowly, or use a "dim bulb tester" (a 100 W light-bulb wired in series with one leg of the ac

power). Turn on the radio, and watch for any sparking, flashing or a red glow from the plates of the rectifier tube, or smoke. If any of these occur, immediately remove power and correct the problem. Observe that the tube filaments should light (although you won't see the glow from metal tubes, you should be able to feel them warm up). Again, any tubes that fail to light should be replaced before you continue.

Now hook up a speaker and antenna, and test the radio. With any luck you'll be greeted by a perfectly-performing radio. Seldom, however, is that the case. You may encounter any number of problems at this point. Dirty bandswitches and other controls manifest themselves by intermittently cutting out; they can be cleaned by DeoxIT contact cleaner applied with a cotton swab (don't spray the switch directly!). Scratchy volume or RF gain controls can be cleaned with some DeoxIT; in some cases you might need to remove the control and uncrimp the cover to reveal the carbon element inside.

If a receiver is totally dead at this point but the filaments and dial lights are lit, double-check to see that the Receive-Standby switch is in the receive position, and any battery plug or standby switch jumpers (as described in the manual) are in their correct place.

Although comprehensive troubleshooting is covered elsewhere in this chapter, the next step is comparing voltages with those stated in the user manual. If the manual doesn't have a voltage table denoting the expected voltage at each tube pin, expect between 200-350 V at the tube plate terminals, a few volts at the cathode (unless it's directly grounded), 70-200 V at the screen, and slightly negative voltage at the grid. If you're faced with this situation and a newcomer to troubleshooting vintage gear, help can be found at **amfone.net**, **www.antiqueradios.com**, or other forums that cater to boat-anchors and/or vintage radio repair and restoration.

### 26.11.3 Alignment

Over the years hams have been cautioned

that alignment is usually the *last* thing that should be attempted to repair a radio. In general this is true — but it's also a certainty that a 50 year old radio *will* need alignment in order for it to perform at its best. In any case, replace the capacitors and any other faulty components before you attempt alignment — it'll never be right if it still has bad parts! You'll need a good signal generator and a volt-ohm-meter or oscilloscope. Follow the manufacturer's instructions, and with care you'll be rewarded with a radio that performs as good as it did when it was new.

### RECEIVER ALIGNMENT

One last caution — alignment should not be attempted by the novice technician or if you do not have the proper equipment or experience. That said alignment may be justified under the following conditions:

- The set is very old and has not been adjusted in many years.
- The circuit has been subject to abusive treatment or environment.
- There is obvious misalignment from a previous repair.
- Tuned-circuit components or crystals have been replaced.
- An inexperienced technician attempted alignment without proper equipment.
- There is a malfunction, but all other circuit conditions are normal. (Faulty transformers can be located because they will not tune.)

Even if one of the above conditions is met, do not attempt alignment unless you have the proper equipment. Receiver alignment should progress from the detector to the antenna terminals. When working on an FM receiver, align the detector first, then the IF and limiter stages and finally the RF amplifier and local oscillator stages. For an AM receiver, align the IF stages first, then the RF amplifier and oscillator stages.

Both AM and FM receivers can be aligned in much the same manner. Always follow the manufacturer's recommended alignment procedure. If one is not available, follow these guidelines:

1. Set the receiver RF gain to maximum, BFO control to zero or center (if applicable to your receiver) and tune to the high end of the receiver passband.
2. Disable the AGC.
3. Set the signal source to the center of the IF passband, with no modulation and minimum signal level.
4. Connect the signal source to the input of the IF section.
5. Connect a voltmeter to the IF output.
6. Adjust the signal-source level for a slight indication on the voltmeter.
7. Peak each IF transformer in order, from the meter to the signal source. The adjustments interact; repeat steps 6 and 7 until adjustment brings no noticeable improvement.

8. Remove the signal source from the IF section input, reduce the level to minimum, set the frequency to that shown on the receiver dial and connect the source to the antenna terminals. If necessary, tune around for the signal — if the local oscillator is not tracking, it may be off.

9. Adjust the signal level to give a slight reading on the voltmeter.

10. Adjust the trimmer capacitor of the RF amplifier for a peak reading of the test signal. (Verify that you are reading the correct signal by switching the source on and off.)

11. Reset the signal source and the receiver tuning for the low end of the passband.

12. Adjust the local-oscillator padder for peak reading.

13. Steps 8 through 11 interact, so repeat them until the results are as good as you can get them.

## 26.11.4 Using Vintage Receivers

Connect a speaker, preferably the same impedance as the output impedance of the receiver. Some receivers have a 600  $\Omega$  and 3.2- or 4  $\Omega$  output. An 8  $\Omega$  speaker is fine — connect it to the low impedance output. Do not operate the receiver without a speaker, however, as the audio output transformer could be damaged by high voltage transients with no load. Alternatively, plug in a pair of headphones, keeping in mind that old receivers usually have high impedance headphone outputs and new headphones are usually low impedance. They'll work fine, but the volume may be considerably lower with the newer headphones.

If you're going to use the receiver in conjunction with a transmitter, you need to be able to mute the receiver while you're transmitting — otherwise, you'll end up with copious feedback from the receiver. Most receivers have mute terminals — some mute with a closed switch, others mute on open. Figure out which method your receiver and transmitter use. You'll need a relay if the receiver mute arrangement doesn't match that of the transmitter.

Some receivers — such as the older Hammarlund Super Pros and pre-WWII Hallicrafters models — use the mute terminals to open the B+ when putting the receiver in standby mode. This is extremely dangerous with 300 V or so on exposed terminals! An easy modification will save you from an almost certain shock. Open up the receiver and remove the wires from the standby terminals. Solder them together and insulate the connection with electrical tape or a wire nut. Better, solder them to an unused, ungrounded terminal if there's one handy. Next, examine the RF gain control and notice that one terminal is probably grounded. Cut this wire and solder

a 47 k $\Omega$  resistor between ground and the RF gain control terminal. Connect a pair of wires from the terminals of the mute connection across the 47 k $\Omega$  resistor just installed. Now, with the mute terminals open the RF gain is all the way down so the receiver is essentially muted. Short the terminals to receive. The voltage here is low and not dangerous.

Next, connect an antenna and antenna relay in the same manner and tune the bands. You'll find that the best fidelity from the receiver occurs at its maximum bandwidth. The crystal filter, if fitted, can help notch out heterodynes as can tuning the receiver slightly higher or lower. The bandspread control can be used to fine tune. Now, just enjoy using your classic, vintage equipment!

## 26.11.5 Plastic Restoration

Sometimes an old radio has a meter lens or dial face that is badly damaged. If it is cracked, there isn't much you can do but find a replacement. If it is just scratched, you have a good chance at fully restoring it.

First, remove the meter lens from the meter movement if possible. Most just snap on. To avoid damaging the very delicate needle and meter movement, place it in a protected area and be sure metal filings cannot get to the movement's magnet.

Make sure the scratch hasn't gone all the way through the plastic to become a crack, although even a deep scratch can be buffed out. You will need various grades of wet/dry sandpaper. Obtain sheets of 320, 400 and 600 grit (600 is the finest). One sheet will last a long time. Cut a piece about 1/2 inch by 2 inches and fold it in half. Start with 320 and gently sand in *one* direction only, over the scratch. This is very tedious and will take a while before you sand away enough plastic to get through the scratch.

Once the scratch is removed, it is time to start reconditioning the plastic. Again sanding in one direction, use the 400 and finally the 600 to completely remove all traces of the earlier sanding scratches. The 600 should leave almost a powdered effect but the plastic will still be hazy and opaque. Sand a little more with the 600 just to be sure all traces of any sanding scratches are gone completely.

To remove the haze you will need a polishing compound called Novus #2 ([www.novuspolish.com](http://www.novuspolish.com) or hobby stores) and another compound called Novus #1, which is a plastic shiner and static remover. This will be important to remove the static on the meter cases when you finish. Static causes the needle to react strangely and erratically.

Start with just a drop of NOVUS #2 and a soft cloth such as the disposable shop towels found at auto parts stores for polishing. Cut a 2 inch by 3 inch piece and start polishing. Continue for a long time and bit by bit the

haze will disappear — you will be left with a perfectly clear lens.

## FRONT PANEL RESTORATION

The most important part of a radio restoration, cosmetically, is the front panel. The case should also look good, but the front panel is the highlight of the radio and needs the most attention. Usually, paint on a radio from the 50s and 60s is well oxidized and there may be some fine scratches as well.

Scratches can be touched up by using enamel model car paint. Buy a bottle of gloss white, gloss black, and the color closest to the panel you have. Into a small paper cup put a drop or two of the stock color. Using the white or the black, stirring in a small drop at a time, lighten or darken the color until it most closely matches the panel. Use a model paint brush with the finest tip you can find to fill just the scratch and not get it on the rest of the paint. Remove excess with a Q-tip. Let it dry completely.

Remove the panel completely, if possible, or at least remove all the knobs. You will work on them individually later. If the panel was originally a gloss panel, you are in luck. If it is a wrinkle finish or flat, this technique might not work for you — those will be addressed later.

Use the Novus #2 compound to remove a few microns of paint — just the oxidized layer. Place a drop on the panel, and with a soft cloth or shop towel, start working the Novus into the paint. You just want to remove the oxidation, so don't rub too hard. Be careful when working on paint that is a second layer above a base paint. It can be very thin and removed with the Novus. After a small amount of gentle polishing, get another cloth or towel and wipe off the panel which should appear just as it did when it came from the factory.

If your panel is a wrinkle finish, you cannot use the Novus. Use a gentle soapy type cleaner and carefully brush the ridges and peaks of the finish to remove layers of dirt and smoke. Sometimes cleaners like 409 and Simple Green will work very well, but be cautious that it doesn't take off the lettering. Be very carefully around the lettering. One way to work it in is with a plumber's acid brush with the bristles cut very short. The bristles will get down into the crevices of the wrinkle finish and clean it. Once the panel is clean, it can be shined up a bit with some WD-40. This also works very well on wrinkle finish cabinets. Just lightly brush it on and remove it with a rag. This can collect dust but gives a nice wet finish to the wrinkle finish paints.

## KNOBS

Most knobs are plastic or have metal plates around the bottom. Use the Novus #2 to shine up the flat parts of the knob. Knobs with flutes on the sides are very tedious to clean,

but look beautiful once restored. Take a fine pick and drag it down each flute to scrape out the accumulated dirt. Once cleaned, the Novus can be used to shine up the flutes as well. On knobs with metalized bases, the bases are also shined up with the Novus. Make sure you don't polish off any markings on the trim bases. Sometimes the knobs will have white or red lines in the tops. Those can be filled with model paint to restore them to full beauty.

### HOLES IN FRONT PANELS

It may be most disconcerting to find someone has drilled a hole in the panel for one reason or another. Extra holes greatly devalue the rig because to properly restore it, you have to find a replacement panel. Panels with wrong holes can be salvaged with quite nice results by using JB Weld epoxy metal filler ([www.jbweld.com](http://www.jbweld.com)).

First remove the panel. If the hole is a considerable distance from the other knobs, repairs can be done on the radio but it is not advised. You will need a special tape called Kapton tape. This is a high temperature polyimide film tape that is widely available but not cheap. A little tape lasts a long time.

You will need a piece of tape slightly larger than the hole. Other types of tape may work but won't give as smooth a finish. If the panel is wrinkle finished, you may want a rough

finish tape such as masking tape. The key is a tight fit to the front of the panel. Place a piece of tape across the hole on the front of the panel and seal it securely all around the hole.

Lay the panel on a flat surface tape-down so the tape will be held flat and not bulge at all. Mix a suitable amount of the JB Weld epoxy and flow it into the hole from the rear of the panel. Stir it while it is still very wet and pliable to make sure no air bubbles are in the hole. Let it cure securely overnight so the hole will be filled and rock hard.

Flip the panel over and remove the tape. If you have secured the tape well enough, none of the epoxy will have been drawn out onto the front surface. There should be a flat filled area exactly level with the rest of the panel.

Now you can touch up the repaired hole with an exact match of spray paint. Mask off the rest of the panel so you don't get any on the lettering. You can also use the model paint method, described for scratch repair. Once painted, the offending hole should be virtually invisible.

### BROKEN PLASTIC

Sometimes a microphone or other item will have a chunk of the plastic broken out of it. It is most unsightly and usually is the reason for discarding the item. But, using our repair technology, it can be saved and fully restored as in this example of repairing a damaged

microphone case. This procedure will work well on broken Bakelite cases, too.

Once again, we will use JB Weld Epoxy and Kapton tape. Remove the microphone elements and switch from the case along with the cord and anything else not plastic. Clean the area around the broken part well. With the Kapton tape, make a backing area on the inside of the case to form a backing for the epoxy. The tape will hold it well and not deform.

Mix some JB Weld and pour it into the space around the break. Fill *higher* than the surrounding plastic. This will be difficult as the fill area will not be level. It may take a couple of fills to build up the area high enough to build up past the level of the surrounding plastic. Once cured and very hard (wait at least 24 hours), you now can begin to file the epoxy. File it down until it is nearly level with the plastic and then switch to sandpaper. Carefully sand the epoxy so it is exactly flush with the original plastic, and make sure the shape is correct. You can always add more JB Weld if too much is filed off.

Once sanded flush, finish the sanding with fine sandpaper (400 and 600 grade). The JB Weld will shine just like the original plastic, but will be the wrong color. Spray paint the entire case with a color close to the original. Once painted, the repair will be virtually undetectable!

Amateurs live in an increasingly crowded technological environment. As our lives become filled with technology, every lamp dimmer, garage-door opener or other new technical “toy” contributes to the electrical noise around us. Many of these devices also “listen” to that growing noise and may react to the presence of their electronic siblings. The more such devices there are, the higher the likelihood that the interactions will be undesirable.

What was once primarily a conversation about “interference” has expanded to include power systems, shielding, intentional and unintentional radiators, bonding and grounding, and many other related topics and phenomena. These are all grouped together under the general label of *electromagnetic compatibility (EMC)*. The scope of EMC includes all the ways in which electronic devices interact with each other and their environment.

The general term for interference caused by signals or fields is *electromagnetic interference* or *EMI*. This is the term you’ll encounter in the professional literature and standards. The most common term for EMI involving amateur signals is *radio frequency interference (RFI)* and when a television or video display is involved, *television interference (TVI)*. RFI is the term used most commonly by amateurs. Whether it’s called EMI, RFI or TVI, unwanted interaction between receivers and transmitters has stimulated vigorous growth in the field of electromagnetic compatibility! (This chapter will use the term RFI to refer to all types of interference to or from amateur signals, except where noted.)

This chapter begins with an overview of dealing with interference and includes relevant FCC regulations. This section is an excellent resource when you are confronted with an interference problem and are wondering “What do I do now?” The information here is based on the experiences of ARRL Lab staff in assisting amateurs with RFI problems.

The second part of this chapter is a discussion on identifying and locating RFI-related noise and signal sources then presents some effective ways of resolving the problem. A glossary of RFI terminology concludes the chapter.

The material in this chapter may provide enough information for you to solve your problem, but if not, the ARRL website offers extensive resources on RF interference at [www.arrl.org/radio-frequency-interference-rfi](http://www.arrl.org/radio-frequency-interference-rfi). Many topics covered in this chapter are covered in more detail in the *ARRL RFI Book* from a practical amateur perspective.

Throughout this chapter you’ll also find references to “Ott,” meaning the book *Electromagnetic Compatibility Engineering* by EMC consultant Henry Ott, WA2IRQ. EMC topics are treated in far greater depth in Ott’s book than is possible in this *Handbook*. Readers interested in the theory of EMC, analysis of EMC mechanisms, test methodology and EMC standards may be able to find a copy through a library or can purchase a copy through the ARRL Publication Sales department or the ARRL website.

## 27.1 Managing Radio Frequency Interference

Sooner or later, nearly every Amateur Radio operator will have a problem with RFI, but temper your dismay. Most cases of interference can be cured! Before diving into the technical aspects of interference resolution, consider the social aspects of the problem. A combination of “diplomacy” skills and standard technical solutions are the most effective way to manage the problem so that a solution can be found and applied. This section discusses the overall approach to solving RFI problems. Specific technical causes and solutions are described in subsequent sections.

### 27.1.1 Responsibility for Radio Frequency Interference

When an interference problem occurs, we may ask “Who is to blame?” The ham and the other party often have different opinions. It is natural (but unproductive) to assign blame instead of fixing the problem.

No amount of wishful thinking (or demands for the “other guy” to solve the problem) will result in a cure for interference. Each party has a unique perspective on the situation and a different degree of understanding of the personal and technical issues involved. On the other hand, each party has certain responsibilities and should be prepared to address them fairly. Given the realities of amateur operation, one of the parties is likely to be a neighbor to the amateur and so the term “neighbor” is used in this chapter, including businesses or other owners of equipment that might cause or experience RFI. The power utility is covered in a separate section dealing with power-line noise.

Always remember that every interference problem has two components — the equipment that is involved and the people who use it. A solution requires that we deal effectively with both the equipment and the people. The ARRL recommends that the hams and their neighbors cooperate to find solutions. The FCC also shares this view. It is important therefore to define the term “interference” without emotion.

### 27.1.2 Proper Station Operation

A radio operator is responsible for the proper operation of the radio station. This responsibility is spelled out clearly in Part 97 of the FCC regulations. If interference is caused by a spurious emission from your station, you must correct the problem there.

Fortunately, most cases of interference are not the fault of the transmitting station. If an amateur signal is the source of interference, the problem is usually caused by fundamental overload — a general term referring to interference caused by the intended, fundamental signal from a transmitter. If the amateur station is affected by interference, electrical noise is most often the culprit. Typical sources include power lines and consumer devices.

### 27.1.3 Personal Diplomacy

Whether the interference is to your station or from your station, what happens when you first talk to your neighbor (or the utility or business) sets the tone for all that follows. Any technical solutions cannot help, for example, if you are not allowed in your neighbor’s house to explain them! If the interference is not caused by spurious emissions from your

station, however, you should be a locator of solutions, not a provider of solutions.

Your neighbor will probably not understand all of the technical issues — at least not at first. Understand that, regardless of fault, interference is annoying whether your signals are causing interference to the neighbor or a device owned by the neighbor is causing interference to you.

Let your neighbor know that you want to help find a solution and that you want to begin by talking things over. Talk about some of the more important technical issues, in non-technical terms. Explain that you must also follow technical rules for your signal, such as for spurious emissions, and that you will check your station, as well.

### 27.1.4 Interference to Your Station

#### POWER-LINE NOISE (PLN)

A very common source of RFI to an amateur station is from ac power lines and associated equipment. It is so common that there is an entire section of this chapter devoted to identifying power-line noise (PLN), locating sources of it, and dealing with the utility to resolve it. Remember that you are not authorized to do any more than locate possible sources of PLN and refer them to the utility. See the section on PLN for further information on this common source of RFI.

#### RFI FROM A NEIGHBOR’S EQUIPMENT

Your neighbor is probably completely unaware that his or her equipment can interfere with your operation. You will have to explain that some home electronics equipment can generate radio signals many times stronger than the weak signals from a distant transmitter. Also explain that there are a number of ways to prevent those signals from being radiated and causing interference. If the

### Warning: Performing Repairs

You are the best judge of a local situation, but the ARRL strongly recommends that you do not work on your neighbor’s equipment. By opening a piece of equipment, you may become liable for problems. Internal modifications to your neighbor’s equipment may cure the interference problem, but if the equipment later develops some other problem, you may be blamed, rightly or wrongly. In some states, it is even *illegal* for you to do *any* work on electronic equipment other than your own.

equipment causing the problem can be identified, the owner’s manual or manufacturer of the device may provide information on the potential for RFI and for its elimination.

Explain that your intent is to help find a solution. Without further investigation it is premature to assume that the neighbor’s equipment is at fault or that FCC regulations require the neighbor to perform any corrective action. Working together to find a mutual, acceptable solution is the best strategy.

### 27.1.5 Interference to a Neighbor’s Equipment

Your transmitted signals can be the source of interference to a neighbor’s equipment. Assure your neighbor that you will check your station thoroughly and correct any problems. You should also discuss the possible susceptibility of consumer equipment. You may want to print a copy of the RFI information found on the ARRL website at [www.arrl.org/information-for-the-neighbors-of-hams](http://www.arrl.org/information-for-the-neighbors-of-hams) (This document, “What To Do if You Have an Electronic Interference Problem,” is also included in this book’s downloadable supplemental information.)

As with interference appearing to be caused by your station, your neighbor will probably feel much better if you explain that you will help find a solution, even if the interference is not your fault. This offer can change your image from neighborhood villain to hero, especially if the interference is not caused by your station. (This is often the case.)

Here is a good analogy: If you tune your TV to channel 3, and see channel 8 instead, you would likely decide that your TV set is broken. Now, if you tune your TV to channel 3, and see your local shortwave radio station (quite possibly Amateur Radio), you shouldn’t blame the shortwave station without some investigation. In fact, many televisions respond to strong signals outside the television bands. They may be working as designed, but require added filters and/or shields to work properly near a strong, local RF signal.

#### PREPARING TO TROUBLESHOOT RFI

In order to troubleshoot and cure RFI to someone else’s non-amateur equipment, you need to learn more than just the basics. This is especially important when dealing with your neighbor. If you visit your neighbor’s house and try a few dozen things that don’t work (or make things worse), your neighbor may lose confidence in your ability to help cure the problem. If that happens, you may be asked to leave.

Start by carefully studying the technical sources and cures for RFI in this book and in other references, such as the *ARRL RFI*

*Book.* Review some of the ARRL Technical Information Service and *QST* articles about interference. If you are unfamiliar with any of the terms in this chapter, refer to the glossary.

## LOCAL HELP

If you are not an expert (and even experts can use moral support), you should find some local help. Fortunately, such help is often available from your ARRL Section's Technical Coordinator (TC). The TC knows of any local RFI committees and may have valuable contacts in the local utility companies. Even an expert can benefit from a TC's help. The easiest way to find your TC is through your ARRL Section Manager (SM). There is a list of SMs on the ARRL website or in any recent *QST*. He or she can quickly put you in contact with the best source of local help.

Even if you can't secure the help of a local expert, a second ham can be a valuable asset. Often a second party can help defuse any hostility. When evaluating and solving RFI problems involving your station, it is very important for two hams to be part of the process. One can operate your station and the other can observe symptoms, and, when appropriate, try solutions.

## PREPARE YOUR HOME AND STATION

The first step toward curing the problem is to make sure your own signal is clean and that devices in your home are not causing any problems. Eliminate all interference issues in your own home to be sure your station is operating properly and that your own electronic equipment is not being interfered with or causing interference to your station!

This is also a valuable troubleshooting tool for situations in which your station is suspected of being the source of interference: If you know your signals are "clean," you have cut the size of the problem in half! If the FCC ever gets involved, you can demonstrate that you are not interfering with your own electronics.

Apply RFI cures to your own consumer electronics and computer equipment. What you learn by identifying and eliminating interference in your own home will make you better prepared to do so in your neighbor's home. When your neighbor sees your equipment working well, it also demonstrates that filters work and cause no harm.

To help build a better relationship, you may want to show your station to your neighbor. A well-organized and neatly-wired station inspires confidence in your ability to solve the RFI problem. Clean up your station and clean up the mess! A rat's nest of cables, unsoldered connections and so on can contribute to RFI.

Grounding and bonding in your station is also important for lightning safety and to help

manage RF currents and voltages picked up by the wiring and cables. This is typically not a cure for RFI, but proper grounding will improve lightning safety. Bonding and proper cable management can greatly reduce hum and buzz from power systems. Make sure cable shields are connected properly and that RF current picked up from your transmitted signal by audio and power wiring is minimized.

Install a low-pass or band-pass transmit filter. (In the unlikely event that the FCC becomes involved, they will ask you about filtering.) Show your neighbor that you have installed the necessary filter on your transmitter. Explain that if there is still interference, it is necessary to try filters on the neighbor's equipment, too.

Operating practices and station-design considerations can cause interference to TV and FM receivers. Don't overdrive a transmitter or amplifier; that can increase its harmonic output. Make sure an amplifier or impedance-matching unit is tuned properly.

Along with applying some of the interference-reducing solutions in this chapter, you can also consider steps to reduce the strength of your signal at the victim equipment. This includes raising, moving, or re-orienting the antenna, or reducing transmit power. The use of a balun and properly balanced feed line will minimize radiation from your station feed line. (See the **Transmission Lines** chapter.) Changing antenna polarization may help, such as if a horizontal dipole is coupling to a cable TV service drop. Using different modes, such as CW or FM, may also change the effects of the interference. Although the goal should be for you to operate as you wish with no interference, be flexible in applying possible solutions.

## CONTACTING YOUR NEIGHBOR

Now that you have learned more about RFI, located some local help (we'll assume it's the TC) and done all of your homework, make contact with your neighbor. First, arrange an appointment convenient for you, the TC and your neighbor. After you introduce the TC, allow him or her to explain the issues to your neighbor. Your TC will be able to answer most questions, but be prepared to assist with support and additional information as required.

Invite the neighbor to visit your station. Show your neighbor some of the things you do with your radio equipment. Point out any test equipment you use to keep your station in good working order. Of course, you want to show the filter you have installed on your transmitter's output.

Next, have the TC operate your station on several different bands while you show your neighbor that your home electronics

equipment is working properly when your station is transmitting. Point out the filters or chokes you have installed to correct any RF susceptibility problems. If the interference is coming from the neighbor's home, show it to the neighbor and explain why it is a problem for you.

At this point, tell your neighbor that the next step is to try some of the cures seen in your home and station on his or her equipment. This is a good time to emphasize that the problem is probably not your fault, but that you and the TC will try to help find a solution anyway.

Study the section on Troubleshooting RFI before deciding what materials and techniques are likely to be required. You and the TC should now visit the neighbor's home and inspect the equipment installation.

## AT YOUR NEIGHBOR'S HOME

Begin by asking when the interference occurs, what equipment is involved, and what frequencies or channels are affected, if appropriate. The answers are valuable clues.

The next step should be opening the neighbor's home's main breaker to test whether the RFI is coming from equipment in the neighbor's home. Have the neighbor open their main breaker to see if the noise goes away - then further isolate the source by having them open individual circuit breakers. The ARRL references two downloadable resources that a ham can provide his or her neighbor to help explain the process. The first on opening the breaker is available at [www.rfiservices.com/tips.doc](http://www.rfiservices.com/tips.doc) and the second explaining RFI in layman's term for the neighbor is available at [www.arrl.org/information-for-the-neighbors-of-hams](http://www.arrl.org/information-for-the-neighbors-of-hams).

Next, the TC should operate your station while you observe the effects. Try all bands and modes that you use. Ask the neighbor to demonstrate the problem. Seeing your neighbor's interference firsthand will help all parties feel more comfortable with the outcome of the investigation.

If it appears that your station is involved, note all conditions that produce interference. If no transmissions produce the problem, your station *may* not be the source. (It's possible that some contributing factor may have been missing in the test.) Have your neighbor keep notes of when and how the interference appears: what time of day, what channels or device was being interfered with, what other equipment was in use, what was the weather? You should do the same whenever you operate. If you can readily reproduce the problem, you can start to troubleshoot the problem. This process can yield important clues about the nature of the problem.

The tests may show that your station isn't involved at all. A variety of equipment

## Product Review Testing and RFI

The ARRL Laboratory mostly considers RFI as an outside source interfering with the desired operation of radio reception. Power line noise, power supplies, motor controls and light dimmers are all *outside* a radio receiver and antenna system and can be a major annoyance that distracts from the pleasure of operating. Have you ever considered RFI generated *inside* your own receiver or by another legally operating Amateur Radio station?

### Harmonics

RFI is just that: radio frequency interference. For instance, a harmonic from another radio amateur's transmitter could be interfering with the desired signal you're tuned to. One might think in this day and age, harmonics are minimal and do not cause interference. I ask you to reconsider.

The maximum spurious output of a modern amateur transmitter must be 43 dB lower than the output on the carrier frequency at frequencies below 30 MHz. While that figure may be "good enough" for an FCC standard, it's not good enough to eliminate the possibility of causing interference to other radio amateurs or possibly other services. Here at the ARRL Laboratory, the measurement of harmonic emission level is a measurement I make of RFI generated *outside* your receiver.

A radio amateur contacted me, concerned about a report that he was causing interference to operators on the 80 meter CW band while operating at full legal limit power during a 160 meter CW contest. Knowing FCC rule part 97.307, he made the effort to measure his 80 meter harmonic. Easily meeting FCC standards at 50 dB below carrier output on 160, he wondered how his transmitter could cause interference.

Here's a breakdown of power output and signal reduction:

0 dB down from 1500 W = 1500 W  
10 dB down from 1500 W = 150 W  
20 dB down from 1500 W = 15 W  
30 dB down from 1500 W = 1.5 W  
40 dB down from 1500 W = 150 mW  
43 dB down from 1500 W = 75.2 mW (this is the FCC legal limit)

50 dB down from 1500 W = 15 mW

While 15 mW may seem too low of a power to cause interference, it wasn't in this case; the interfering signal was reported to be S9. QRP enthusiasts know that at 15 mW, signals can propagate well with the right conditions. Using a single band, resonant antenna will reduce interference caused by harmonics located on other bands, but today many stations employ antennas resonant on more than one ham band. (In this case, the use of a bandpass filter designed for 160 meters would significantly attenuate the harmonic on 80 meters, eliminating the interference.)

### Signals Generated in the Receiver

What about RFI generated *inside* the receiver you're operating? You're tuning across the 15 meter band when, all of a sudden, you hear what seems to be an AM broadcast station. Is it a jammer? It is definitely interference — radio frequency interference — caused by two strong shortwave stations! In this particular case, a Midwest radio amateur experienced interference on 15 meters and figured out what was happening. One station was transmitting near 6 MHz and another transmitting above 15 MHz. These two strong stations added up to created a second order IMD (intermodulation distortion) product at the 1st IF stage, and this unwanted signal was passed along to subsequent stages and to the speaker. The RFI in this case was caused by insufficient receiver performance (second order IMD dynamic range) where the frequencies of the two stations added up to exactly the frequency that the operator was tuned to. Third-order IMD products from strong in-band signals are another form of RFI created within a radio receiver.

Nearby stations transmitting at or near the IF frequency will cause interference not because the transmitter is at fault, but because of a receiver's insufficient IF rejection. The same interference will be heard if a nearby transmitter is operating at an image frequency.

### Power Supplies

RFI can also be created from another part of a radio system, such as an external power supply. In addition to transmitter and receiver testing, the Lab also measures the conducted emission levels of power supplies. This is an indication of the amount of RF at given frequencies conducted onto power lines from a power supply as described in this chapter.

Through our published Product Review test results in *QST* magazine, readers can compare the above figures of modern HF transceivers when considering the purchase of a new or used transceiver. Our published data tables spawn friendly competition between radio manufacturers who in turn, strive to perfect their circuit designs. The result is a better product for the manufacturer and a better product for you, the radio amateur. —

malfunctions or external noise can look like interference. Some other nearby transmitter or noise source may be causing the problem. You may recognize electrical noise or some kind of equipment malfunction. If so, explain your findings to the neighbor and suggest that he or she contact appropriate service personnel.

If the interference is to your station from equipment that may be in the neighbor's home, take along a portable receiver. A familiar AM broadcast band receiver is a good choice. You will need to visit when the noise is occurring. Show that the noise is present but there is no need to make it so loud as to be offensive. Describe when you are receiving the interference and what pattern it seems to have (continuous, pulsed, intermittent, certain times of day, and so on). Show that the problem is what you are experiencing and that you need the neighbor's help.

Begin with the main breaker test as described earlier in this section. Then proceed to individual circuits. Once you have identified the circuit powering the equipment, physically unplug it, turn it off, or remove the batteries as required while you or the TC observe at your station. (Remember that turning a piece of equipment OFF with its ON/OFF switch may not cause the equipment to completely power down.) Removing cables from a powered-up piece of equipment may serve to further isolate the problem.

At this point, the action you take will depend on the nature of the problem and its source. Techniques for dealing with specific interference issues are discussed in the following sections of the chapter. If you are unable to determine the exact nature of the problem, develop a plan for continuing to work with the neighbor and continue to collect information about the behavior of the interference.

## Some Common Reported Problems — A Few Statistics

The ARRL has nearly 20 years of RFI complaint data. During that time we've found that the vast majority of reported sources are either power line noise or a consumer device. They fall within one of three categories under the FCC rules. Although a small percentage of reports may come from other sources it is generally recommended to start a typical RFI search with the assumption that it probably falls into one of these categories. Excluding unknown sources, here is a rough breakdown:

### Part 15 Incidental Radiators

These sources do not intentionally create or radiate RF energy but do so as an incidental part of their intended operation. Typically these are non-electronic sources and the RF is generated by sparking or arcing. Excluding unknown source complaints, approximately one third of the interference reports received by the ARRL are power line noise. This is by far the most common RFI problem caused by incidental radiators. Other common sources in this category include bad doorbell transformers and arcing electric fences.

### Part 15 Unintentional Radiators

These sources intentionally create RF energy but do not intentionally radiate it. (RF in this case is defined as a frequency above 9 kHz.) These are typically electronic consumer devices such as computers, televisions and radio receiving equipment. By far the most common unintentional radiator at the heart of an RFI problem is the ubiquitous switching mode power supply. Switchers are in many consumer devices these days, including lighting devices and battery chargers. They are often easy to identify by their regular and repeating pattern of noise peaks and nulls as you tune across the spectrum. The peaks are usually around 50 kHz apart, but a spacing anywhere between 40 and 80 kHz is common. Less common are lower and higher spacings ranging from 20 to 120 kHz. The peaks will often drift with respect to time.

### Part 18 RF Lighting Devices

Part 18 of the FCC rules covers Industrial, Medical and Industrial (ISM) devices. Some consumer devices, however, also fall under Part 18. These devices convert RF directly into some other form of energy such as heat or light. Devices in this category include microwave ovens, some ultrasonic jewelry cleaners and lighting devices that use RF to ionize gas molecules. Once again, the RF must be greater than 9 kHz. Part 18 also prohibits the RF from being used to communicate intelligence or data of any kind.

So far, the only problematic Part 18 consumer devices at the heart of an RFI problem have been lighting devices, including CFLs, electronic fluorescent light ballasts, and grow lights. Particularly noteworthy have been grow lights which have been measured to be as much as 58 dB over the applicable FCC limits.  
— Mike Gruber, W1MG (ARRL EMC Engineering, [rfti@arrl.org](mailto:rfti@arrl.org))

## 27.2 FCC Rules and Regulations

In the United States most unlicensed electrical and electronic devices are regulated by Part 15 of the FCC's rules. These are referred to as "Part 15 devices." Most RFI issues reported to the ARRL involve a Part 15 device. Some consumer equipment, such as certain wireless and lighting devices, is covered under FCC Part 18 which pertains to ISM (Industrial, Scientific and Medical) devices.

The Amateur service is regulated by FCC Part 97. (Part 97 rules are available downloadable at [www.arrl.org/part-97-amateur-radio](http://www.arrl.org/part-97-amateur-radio). See also the sidebar "RFI-related FCC Rules and Definitions.") To be legal, the amateur station's signal must meet all Part 97 technical requirements, such as for spectral purity and power output.

As a result, it isn't surprising that most interference complaints involve multiple parts of the FCC rules. (The FCC's jurisdiction does have limits, though — ending below 9 kHz.) It is also important to note that each of the three parts (15, 18 and 97) specifies different requirements with respect to interference, including absolute emissions limits and spectral purity requirements. The FCC does not specify *any* RFI immunity requirements. Most consumer devices therefore receive no FCC protection from a legally licensed transmitter, including an amateur transmitter operating legally according to Part 97.

Licensed services are protected from interference to their signals, even if the interference is generated by another licensed service transmitter. For example, consider TVI from an amateur transmitter's spurious emissions, such as harmonics, that meet the requirements of Part 97 but are still strong enough to be received by nearby TV receivers. The TV receiver itself is not protected from interference under the FCC rules. However, within its service area the licensed TV broadcast signal is protected from harmful interference caused by spurious emissions from other licensed transmitters. In this case, the amateur transmitter's interfering spurious emission would have to be eliminated or reduced to a level at which harmful interference has been eliminated.

### 27.2.1 FCC Part 97 Rules

While most interference to consumer devices may be caused by a problem associated with the consumer device as opposed to the signal source, all amateurs must still comply with Part 97 rules. Regardless of who is at fault, strict conformance to FCC requirements, coupled with a neat and orderly station appearance, will go far toward creating a good and positive impression in the event of an FCC field investigation. Make sure your

**Figure 27.1 — An illustration of out-of-band versus spurious emissions. Some of the modulation sidebands are outside the necessary bandwidth. These are considered out-of-band emissions, not spurious emissions. The harmonic and parasitic emissions shown here are considered spurious emissions; these must be reduced to comply with §97.307.**

### What If the Police Are Called?

Many amateurs have had a similar experience. You are enjoying some time in front of the radio when the doorbell rings. When you answer the door, you find an irate neighbor has called the police about your transmissions interfering with their stereo (or cordless telephone or other home electronics). The officer tells you that you are interfering with your neighbor and orders you to stop transmissions immediately.

The bad news is you are in the middle of a bad situation. The good news is that most cases of interference can be cured! The proper use of "diplomacy" skills to communicate with a neighbor and standard technical cures will usually solve the problem. Even more good news is that if you are operating in accordance with your license and employing good engineering practices, the law and FCC rules are on your side.

Most RFI is caused by the unfortunate fact that most consumer equipment lacks the necessary filtering and shielding to allow it to work well near a radio transmitter. The FCC does not regulate the immunity of equipment, however, so when interference is caused by consumer-equipment fundamental overload, there is no FCC rules violation, and licensed stations have no regulatory responsibility to correct interference that may result.

Further, in 1982, Congress passed Public Law 97-259. This law is specific and reserves exclusive jurisdiction over RFI matters to the Federal Communications Commission. This national law preempts any state or local regulations or ordinances that attempt to regulate or resolve RFI matter. This is a victory for amateurs (and other services operating with the legal and technical provisions of their licenses).

Simply put, 97-259 says that cities and towns may not pass ordinances or regulations that would prohibit someone from making legal radio transmissions. But what do you do when your neighbor (or the police) confront you about RFI to their consumer electronics? First and foremost, remain calm. In all likelihood the officer or your neighbor has probably never heard of 97-259. Don't get defensive and get drawn into an argument. Don't make comments that the problem is with the neighbor's "cheap" equipment. While inexpensive radios are usually big culprits, any home electronics are potential problems due to inadequate technical designs.

Begin by listening to the complaint. Explain that while you understand, you are operating your equipment within its technical specifications. If your equipment doesn't interfere with your own home electronics, offer to demonstrate that to the officer. Also explain the basics of PL 97-259. If the officer (or neighbor) continues to insist that regardless of the law that you cease, consider temporarily complying with his or her request, with the understanding that you are doing so until the matter is resolved.

Work with your neighbors to understand that steps can be taken that should help resolve the problems (for example, placing toroids and filters on the consumer electronics). The ARRL website has lots of helpful information as you work to resolve the problems. If your club has a local RFI committee or ARRL Technical Specialist, get them involved — their expertise can really be helpful. But above all, remember that when you practice easy, level-headed "diplomacy" you can usually keep the situation from escalating. — Dan Henderson, N1ND, ARRL Regulatory Information

station and signal exhibit good engineering and operating practices.

The bandwidth of a signal is defined by §97.3(a)(8) while the paragraphs of §97.307 define the technical standards amateur transmissions must meet. Paragraph (c) defines the rules for interference caused by spurious emissions. As illustrated in **Figure 27.1**, modulation sidebands outside the necessary bandwidth are considered *out-of-band* emissions, while harmonics and parasitic signals are considered *spurious emissions*. Paragraphs (d) and (e) specify absolute limits on spurious emissions, illustrated in **Figure 27.2**. Spurious emissions must not exceed these levels, whether or not the emissions are causing interference. If spurious emissions from your transmitter are causing interference, it's your responsibility to clean them up.

Strict observance of these rules can not only help minimize interference to the amateur service, but other radio services and consumer devices as well.

### 27.2.2 FCC Part 15 Rules

In the United States, most unlicensed devices are regulated by Part 15 of the FCC's rules. While understanding these rules doesn't necessarily solve an RFI problem, they do provide some important insight and background on interference to and from a Part 15 device. (Part 18 devices and rules are similar in some respects) and will not be discussed separately — see the sidebar.)

There are literally thousands of Part 15 devices with the potential to be at the heart of an RFI problem. A Part 15 device can be almost anything not already covered in another

## FCC Part 18, Consumer Devices

Some consumer devices are regulated by Part 18 of the FCC Rules which pertains to the Industrial, Scientific and Medical (ISM) bands. These devices convert RF energy directly into some other form of energy, such as heat, light or ultrasonic sound energy. Some common household Part 18 devices therefore include microwave ovens, electronic fluorescent light ballasts, CFLs, and ultrasonic jewelry cleaners. (Note that LED bulbs are covered under Part 15 because of the process by which they generate light.) Recently, indoor grow light ballasts and related equipment have been causing a lot of RFI. Those sold to consumers are required to be certified under Part 18 rules, while those sold to industrial and commercial customers are not. There have been reports of non-Part 18 devices being sold at home-improvement and other consumer outlets. The ARRL is working with the FCC and manufacturers to resolve this issue.

Consumer Part 18 devices are generators of RF — but not for communications purposes — and can cause interference in some cases. However, there are no rules that protect them from interference. The purpose of Part 18 is to permit those devices to operate and to establish rules prohibiting interference.

From the standpoint of an RFI problem, Part 18 rules aren't much different from Part 15. As with a Part 15 device, a Part 18 device is required to meet specified emissions limits. Furthermore, it must not cause harmful interference to a licensed radio service.

### Part 18 Rules and the 33 cm Band

Part 18 specifies a number of bands for ISM (industrial, scientific, and medical) devices. The so-called ISM bands in some cases overlap amateur spectrum. For example, the entire 33 cm band from 902 to 928 MHz is both an amateur and ISM band. And, as the following rule from Part 97 indicates, the amateur service is not protected from ISM devices operating in this or any other ISM band:

§97.303 (e) Amateur stations receiving in the 33 cm band, the 2400-2450 MHz segment, the 5.725-5.875 GHz segment, the 1.2 cm band, the 2.5 mm band, or the 244-246 GHz segment must accept interference from industrial, scientific, and medical (ISM) equipment.

Additional restrictions apply in some areas of the country when using the 33 cm band.

- Amateurs located in some parts of Colorado and Wyoming may not transmit in some parts of this band.
- Amateurs located in some parts of Texas and New Mexico are prohibited from using this band.
- Amateurs located within 150 miles of White Sands Missile Range are limited to 150 W PEP.

Amateurs in these areas are responsible for knowing the boundaries of these areas and observing all applicable rules. See the latest edition of the *ARRL Repeater Directory* for more information and boundary details.

**Figure 27.2** — Required attenuation of spurious outputs, 30-225 MHz. Below 30 MHz, spurious emissions must be suppressed by 43 dB for amateur transmitters installed after January 1, 2003.

Part of the FCC rules. In fact, many Part 15 devices may not normally even be associated with electronics, RF or in some cases, electricity. While televisions, radios, telephones and even computers obviously constitute a Part 15 device, the rules extend to anything that is capable of generating RF, including electric motors and consumer devices such as baby monitors, wireless microphones and intercoms, RF remote controls, garage door

openers, etc. With so many Part 15 consumer devices capable of generating and responding to RF, it isn't surprising therefore that most reported RFI problems involving Amateur Radio also involve a Part 15 device.

## TYPES OF PART 15 DEVICES

Part 15 describes three different types of devices that typically might be associated with an RFI problem. A fourth type of de-

vice, called a *carrier current device*, uses power lines and wiring for communications purposes. As we'll see, the rules are different for each type.

**Intentional Emitters** — Intentionally generate RF energy and radiate it. Examples include garage door openers, cordless phones and baby monitors.

**Unintentional Emitters** — Intentionally generate RF energy internally, but do not intentionally radiate it. Examples include computers and network equipment, superheterodyne receivers, switchmode power supplies and TV receivers.

**Incidental Emitters** — Generate RF energy only as an incidental part of their normal operation. Examples include power lines, arcing electric fence, arcing switch contacts, dc motors and mechanical light switches.

**Carrier Current Devices** — Intentionally generate RF and conduct it on power lines and/or house wiring for communications purposes. Examples include Powerline and X.10 networks, Access or In-House Broadband-Over-Power-Line (BPL), campus radio-broadcast systems, and other power-line communications devices.

## PART 15 SUMMARY

FCC's Part 15 rules pertain to unlicensed devices and cover a lot of territory. Although reading and understanding Part 15 can appear rather formidable — especially at first glance — the rules pertaining to RFI can be roughly summarized as follows:

- Part 15 devices operate under an unconditional requirement to not cause harmful interference to a licensed radio service, such as Amateur Radio. If such interference occurs, the operator of the Part 15 device is responsible for eliminating the interference.

- Part 15 devices receive no protection from interference from a licensed radio service. There are no FCC rules or limits with regard to Part 15 device RFI immunity.

When is the operator of a licensed transmitter responsible for interference to a Part 15 device?

- The rules hold the transmitter operator responsible if interference is caused by spurious emissions such as a harmonic. An example would be a harmonic from an amateur's transmitter interfering with a cordless telephone. In this case, the transmitter is generating harmful RF energy beyond its permitted bandwidth. A cure must be installed at the transmitter.

- The transmitter operator is not responsible when a Part 15 device is improperly responding to a legal and intentional output of the transmitter. An example of this case would be interference to a cordless telephone operation by the strong-but-legal signal from a nearby amateur transmitter. In this case, the Part 15 device is at fault and the cure must be installed there. It is important to note that

## RFI-Related FCC Rules and Definitions

Here are some of the most important rules and definitions pertaining to RFI and the Amateur Radio Service. Definitions in Part 2 are used in regulations that apply to all radio services.

### §2.1 Definitions

**Harmful Interference.** Interference which endangers the functioning of a radionavigation service or of other safety services or seriously degrades, obstructs, or repeatedly interrupts a radiocommunication service operating in accordance with [the ITU] Radio Regulations.

**Interference.** The effect of unwanted energy due to one or a combination of emissions, radiations, or inductions upon reception in a radiocommunication system, manifested by any performance degradation, misinterpretation, or loss of information which could be extracted in the absence of such unwanted energy.

**Out-of-band Emission.** Emission on a frequency or frequencies immediately outside the necessary bandwidth which results from the modulation process, but excluding spurious emissions. Band does not mean "amateur band" here.

### §97.3 Definitions

(a) The definitions of terms used in Part 97 are:

(8) **Bandwidth.** The width of a frequency band outside of which the mean power of the transmitted signal is attenuated at least 26 dB below the mean power of the transmitted signal within the band.

(23) **Harmful interference.** (see the previous Part 2 definition)

(42) **Spurious emission.** An emission, on frequencies outside the necessary bandwidth of a transmission, the level of which may be reduced without affecting the information being transmitted.

### §97.307 Emission standards

(a) No amateur station transmission shall occupy more bandwidth than necessary for the information rate and emission type being transmitted, in accordance with good amateur practice.

(b) Emissions resulting from modulation must be confined to the band or segment available to the control operator. Emissions outside the necessary bandwidth must not cause splatter or key-click interference to operations on adjacent frequencies.

(c) All spurious emissions from a station transmitter must be reduced to the greatest extent practicable. If any spurious emission, including chassis or power line radiation, causes harmful interference to the reception of another radio station, the licensee of the interfering amateur station is required to take steps to eliminate the interference, in accordance with good engineering practice.

(d) For transmitters installed after January 1, 2003, the mean power of any spurious emission from a station transmitter or external RF amplifier transmitting on a frequency below 30 MHz must be at least 43 dB below the mean power of the fundamental emission. For transmitters installed on or before January 1, 2003, the mean power of any spurious emission from a station transmitter or external RF power amplifier transmitting on a frequency below 30 MHz must not exceed 50 mW and must be at least 40 dB below the mean power of the fundamental emission. For a transmitter of mean power less than 5 W installed on or before January 1, 2003, the attenuation must be at least 30 dB. A transmitter built before April 15, 1977, or first marketed before January 1, 1978, is exempt from this requirement.

(e) The mean power of any spurious emission from a station transmitter or external RF power amplifier transmitting on a frequency between 30-225 MHz must be at least 60 dB below the mean power of the fundamental. For a transmitter having a mean power of 25 W or less, the mean power of any spurious emission supplied to the antenna transmission line must not exceed 25  $\mu$ W and must be at least 40 dB below the mean power of the fundamental emission, but need not be reduced below the power of 10  $\mu$ W. A transmitter built before April 15, 1977, or first marketed before January 1, 1978, is exempt from this requirement.

this situation is typical of most interference to Part 15 devices.

Even though the causes and cures for these situations are different, the common element for all three situations is the need for personal diplomacy in resolving the problem.

## PART 15 MANUFACTURER REQUIREMENTS

Under FCC rules, both device manufac-

tures and operators of those devices share responsibility for addressing an RFI problem. The rules for manufacturers are primarily designed to reduce the possibility of harmful interference. They do not however completely eliminate the possibility of an RFI problem. If and when interference does occur, the rules are designed to minimize and confine the scope of problems such that they can be addressed on a case by case basis. Responsibility

then falls on the device operator to correct the problem or cease using the device.

Manufacturers are subject to requirements that they use good engineering practice to help minimize the potential for interference. In addition, they must meet certain absolute conducted and radiated emissions limits for intentional and unintentional emitters. (See the sidebar for limits on conducted and radiated emissions.) These limits are high enough

## Part 15 Absolute Emissions Limits for Unintentional Emitters

### §15.107 Conducted limits

(a) Except for Class A digital devices, for equipment that is designed to be connected to the public utility (ac) power line, the radio frequency voltage that is conducted back onto the ac power line on any frequency or frequencies within the band 150 kHz to 30 MHz shall not exceed the limits in the following table, as measured using a 50  $\mu$ H/50 ohms line impedance stabilization network (LISN). Compliance with the provisions of this paragraph shall be based on the measurement of the radio frequency voltage between each power line and ground at the power terminal. The lower limit applies at the band edges.

#### Conducted Limits — Non Class-A Digital Devices

Frequency of emission (MHz)	Conducted limit (dB $\mu$ V) Quasi-peak	Average
0.15–0.5	66 to 56*	56 to 46*
0.5–5	56	46
5–30	60	50

\*Decreases with the logarithm of the frequency.

(b) For a Class A digital device that is designed to be connected to the public utility (ac) power line, the radio frequency voltage that is conducted back onto the ac power line on any frequency or frequencies within the band 150 kHz to 30 MHz shall not exceed the limits in the following table, as measured using a 50  $\mu$ H/50 ohms LISN. Compliance with the provisions of this paragraph shall be based on the measurement of the radio frequency voltage between each power line and ground at the power terminal. The lower limit applies at the boundary between the frequency ranges.

#### Conducted Limits — Class-A Digital Devices

Frequency of emission (MHz)	Conducted limit (dB $\mu$ V) Quasi-peak	Average
0.15–0.5	79	66
0.5–30	73	60

(c) The limits shown in paragraphs (a) and (b) of this section shall not apply to carrier current systems operating as unintentional radiators on frequencies below 30 MHz. In lieu thereof, these carrier current systems shall be subject to the following standards:

(1) For carrier current systems containing their fundamental emission within the frequency band 535-1705 kHz and intended to be received using a standard AM broadcast receiver: no limit on conducted emissions.

(2) For all other carrier current systems: 1000  $\mu$ V within the frequency band 535–1705 kHz, as measured using a 50  $\mu$ H/50 ohms LISN.

(3) Carrier current systems operating below 30 MHz are also subject to the radiated emission limits in §15.109(e).

(d) Measurements to demonstrate compliance with the conducted limits are not required for devices which only employ battery power for operation and which do not operate from the ac power lines or contain provisions for operation while connected to the ac power lines. Devices that include, or make provision

for, the use of battery chargers which permit operating while charging, ac adaptors or battery eliminators or that connect to the ac power lines indirectly, obtaining their power through another device which is connected to the ac power lines, shall be tested to demonstrate compliance with the conducted limits.

### § 15.109 Radiated emission limits

(a) Except for Class A digital devices, the field strength of radiated emissions from unintentional radiators at a distance of 3 meters shall not exceed the following values:

#### Radiated Limits — Non Class-A Digital Devices

Frequency of emission (MHz)	Field Strength ( $\mu$ V/meter)
30–88	100
88–216	150
216–960	200
Above 960	500

(b) The field strength of radiated emissions from a Class A digital device, as determined at a distance of 10 meters, shall not exceed the following:

#### Radiated Limits — Class-A Digital Devices

Frequency of emission (MHz)	Field Strength ( $\mu$ V/meter)
30–88	90
88–216	150
216–960	210
Above 960	300

(c) In the emission tables above, the tighter limit applies at the band edges. Sections 15.33 and 15.35 which specify the frequency range over which radiated emissions are to be measured and the detector functions and other measurement standards apply.

(d) For CB receivers, the field strength of radiated emissions within the frequency range of 25–30 MHz shall not exceed 40 microvolts/meter at a distance of 3 meters. The field strength of radiated emissions above 30 MHz from such devices shall comply with the limits in paragraph (a) of this section.

(e) Carrier current systems used as unintentional radiators or other unintentional radiators that are designed to conduct their radio frequency emissions via connecting wires or cables and that operate in the frequency range of 9 kHz to 30 MHz, including devices that deliver the radio frequency energy to transducers, such as ultrasonic devices not covered under part 18 of this chapter, shall comply with the radiated emission limits for intentional radiators provided in §15.209 for the frequency range of 9 kHz to 30 MHz. As an alternative, carrier current systems used as unintentional radiators and operating in the frequency range of 525 kHz to 1705 kHz may comply with the radiated emission limits provided in §15.221(a). At frequencies above 30 MHz, the limits in paragraph (a), (b), or (g) of this section, as appropriate, apply.

## RFI-related Part 15 FCC Rules and Definitions

The FCC's Part 15 rules are found in Title 47 section of the Code of Federal Regulations (CFR). They pertain to unlicensed devices. Here are some of the more important Part 15 rules and definitions pertaining to RFI.

### §15.3 Definitions.

(m) **Harmful interference.** Any emission, radiation or induction that endangers the functioning of a radionavigation service or of other safety services or seriously degrades, obstructs or repeatedly interrupts a radio communications service operating in accordance with this chapter.

(n) **Incidental radiator.** A device that generates radio frequency energy during the course of its operation although the device is not intentionally designed to generate or emit radio frequency energy.

(o) **Intentional radiator.** A device that intentionally generates and emits radio frequency energy by radiation or induction.

(z) **Unintentional radiator.** A device that intentionally generates radio frequency energy for use within the device, or that sends radio frequency signals by conduction to associated equipment via connecting wiring, but which is not intended to emit RF energy by radiation or induction.

(t) **Power line carrier systems.** An unintentional radiator employed as a carrier current system used by an electric power utility entity on transmission lines for protective relaying, telemetry, etc. for general supervision of the power system. The system operates by the transmission of radio frequency energy by conduction over the electric power transmission lines of the system. The system does not include those electric lines which connect the distribution substation to the customer or house wiring.

(ff) **Access Broadband over Power Line (Access BPL).** A carrier current system installed and operated on an electric utility service as an unintentional radiator that sends radio frequency energy on frequencies between 1.705 MHz and 80 MHz over medium voltage lines or over low voltage lines to provide broadband communications and is located on the supply side of the utility service's points of interconnection with customer premises. Access BPL does not include power line carrier systems as defined in §15.3(t) or In-House BPL as defined in §15.3(gg).

(gg) **In-House Broadband over Power Line (In-House BPL).** A carrier current system, operating as an unintentional radiator, that sends radio frequency energy by conduction over electric power lines that are not owned, operated or controlled by an electric service provider. The electric power lines may be aerial (overhead), underground, or inside the walls, floors or ceilings of user premises. In-House BPL devices may establish closed networks within a user's premises or provide connections to Access BPL networks, or both.

Some of the most important Part 15 rules pertaining to radio and television interference from unintentional and incidental radiators include:

### §15.5 General conditions of operation.

(b) Operation of an intentional, unintentional, or incidental radiator is subject to the conditions that no harmful interference is caused and that interference must be accepted that may be caused by the operation of an authorized radio station, by another intentional or unintentional radiator, by industrial, scientific and medical (ISM) equipment, or by an incidental radiator.

(c) The operator of the radio frequency device shall be required to cease operating the device upon notification

by a Commission representative that the device is causing harmful interference. Operation shall not resume until the condition causing the harmful interference has been corrected.

### §15.13 Incidental radiators.

Manufacturers of these devices shall employ good engineering practices to minimize the risk of harmful interference.

### §15.15 General technical requirements.

(c) Parties responsible for equipment compliance should note that the limits specified in this part will not prevent harmful interference under all circumstances. Since the operators of Part 15 devices are required to cease operation should harmful interference occur to authorized users of the radio frequency spectrum, the parties responsible for equipment compliance are encouraged to employ the minimum field strength necessary for communications, to provide greater attenuation of unwanted emissions than required by these regulations, and to advise the user as to how to resolve harmful interference problems (for example, see Sec. 15.105(b)).

### §15.19 Labeling requirements.

(a) In addition to the requirements in part 2 of this chapter, a device subject to certification, notification, or verification shall be labeled as follows:

(3) All other devices shall bear the following statement in a conspicuous location on the device:

*This device complies with part 15 of the FCC Rules. Operation is subject to the following two conditions: (1) This device may not cause harmful interference, and (2) this device must accept any interference received, including interference that may cause undesired operation.*

And the following requirements apply for consumer and residential Class B digital devices. Different requirements apply for Class A digital devices which can only be used in industrial and similar environments:

### §15.105 Information to the user.

(b) For a Class B digital device or peripheral, the instructions furnished the user shall include the following or similar statement, placed in a prominent location in the text of the manual:

*This equipment has been tested and found to comply with the limits for a Class B digital device, pursuant to part 15 of the FCC Rules. These limits are designed to provide reasonable protection against harmful interference in a residential installation. This equipment generates, uses and can radiate radio frequency energy and, if not installed and used in accordance with the instructions, may cause harmful interference to radio communications. However, there is no guarantee that interference will not occur in a particular installation. If this equipment does cause harmful interference to radio or television reception, which can be determined by turning the equipment off and on, the user is encouraged to try to correct the interference by one or more of the following measures:*

*Reorient or relocate the receiving antenna.*

*Increase the separation between the equipment and receiver.*

*Connect the equipment into an outlet on a circuit different from that to which the receiver is connected.*

*Consult the dealer or an experienced radio/TV technician for help.*

at S9+ interference levels can occur nearby, depending on frequency, distance and other factors. In fact, most reported Part 15 consumer products causing harmful interference are Amateur Radio and meet these required limits. Therefore, the fact that a particular device is causing harmful interference is not in itself evidence or proof of a rules violation with regard to emissions limits.

With the exception of intentional emitters and carrier-current devices, there are no absolute radiated emissions limits below 30 MHz. The size of a Part 15 device is usually small relative to the wavelength at these frequencies. It is typically too small to be an effective antenna at these longer wavelengths. Therefore, under the FCC rules, only conducted emissions are specified below 30 MHz. (Note that cables and wiring connected to the devices are often effective at radiating signals and are frequent sources of radiated RFI.)

In general, radiated emissions limits are specified only at frequencies above 30 MHz. The shorter wavelengths above 30 MHz, the device itself is large enough to be a radiator. Wiring connected to it can also be an effective antenna for radiating noise.

Although incidental radiators do not have any absolute emissions limits, as for all Part 15 devices, manufacturers must still employ good engineering practice to minimize the potential for interference.

The FCC also requires manufacturers to provide information as a label to most Part 15 devices or as text in the device's operating manual. This information attests to the potential for interference and to the responsibility of the device operator. It must be placed in a conspicuous location on the device or in the manual and contain the following statement: "This device complies with part 15 of the FCC Rules. Operation is subject to the following two conditions: (1) This device may not cause harmful interference, and (2) this device must accept any interference received, including interference that may cause undesired operation."

Owners of Part 15 devices are frequently unaware of this information and surprised to find it on the device or in its manual. Reading this label can be an important step in resolving RFI issues. Additional details regarding labeling requirements can be found in the sidebar on Part 15 Rules.

## FCC EMISSION LIMITS

While the FCC's rules impose absolute emissions limits for most electronic consumer devices, it is a common misconception that they will protect nearby receivers from interference. The reality is that these limits are high—high enough to cause harmful interference to a ham even if the source is in a nearby residence. Once manufacturers meet these

limits, the device can be legally marketed and sold in the United States as described in the next section. However, if and when harmful interference occurs from an otherwise legal device, the burden to correct it falls on the operator of the device causing it. In most cases, this is either the ham or a neighbor.

The rules for unintentional radiators are summarized by the ubiquitous Part 15 label that follows. It should also be noted that Part 18 devices such as electronic fluorescent light ballasts and CFLs have a similar provision:

*This device complies with part 15 of the FCC Rules. Operation is subject to the following two conditions: (1) This device may not cause harmful interference, and (2) this device must accept any interference received, including interference that may cause undesired operation.*

In addition, many non-electronic sources are classified as "incidental radiators" under Part 15. These devices typically generate RF by a spark or arcing and are classified as "incidental radiators." There are no emissions limits for incidental radiators—only a provision that they not cause harmful interference to licensed radio services. Once again, the burden to correct any harmful interference caused by these devices falls on the operator of the device.

## EQUIPMENT AUTHORIZATION

FCC regulations do not require Part 15 devices to be tested by the FCC. In fact, very few devices must actually undergo FCC testing. In most cases, the requirements are met by the manufacturer testing the device and the test results either kept on file or sent to the FCC, depending on the type of device involved. Here is some general information concerning various FCC approval processes for RF devices:

- **Certification:** Requires submittal of an application that includes a complete technical description of the product and a measurement report showing compliance with the FCC technical standards. Certification procedures have now largely replaced the once familiar Type Acceptance, which is no longer used by the FCC. Devices subject to certification include: low-power transmitters such as cordless telephones, security alarm systems, scanning receivers, super-regenerative receivers, Amateur Radio external HF amplifiers and amplifier kits, and TV interface devices such as DVD players.

- **Declaration of Conformity (DoC):** Is a declaration that the equipment complies with FCC requirements. A DoC is an alternative to certification since no application to FCC is required, but the applicant must have the device tested at an accredited laboratory. A Declaration of Conformity is the usual approval procedure for Class B personal com-

puters and personal computer peripherals.

- **Notification:** Requires submittal to the FCC of an abbreviated application for equipment authorization which does not include a measurement report. However, a measurement report showing compliance of the product with the FCC technical standards must be retained by the applicant and must be submitted upon request by the Commission. Devices subject to notification include: point-to-point microwave transmitters, AM, FM and TV broadcast transmitters and other receivers (except as noted elsewhere).

- **Verification:** Verification is a self-approval process where the applicant performs the necessary tests and verifies that they have been done on the device to be authorized and that the device is in compliance with the technical standards. Verified equipment requires that a compliance label be affixed to the device as well as information included in the operating manual regarding the interference potential of the device. Devices subject to verification include: business computer equipment (Class A); TV and FM receivers; and non-consumer Industrial, Scientific and Medical Equipment.

## PART 15 OPERATOR REQUIREMENTS

All Part 15 devices are prohibited from causing harmful interference to a licensed radio service—including the Amateur Radio Service. This is an absolute requirement without regard to the emitter type or a manufacturer's conformance to emissions limits or other FCC technical standards. It is important to note that the manufacturer's requirements are not sufficient to prevent harmful interference from occurring under all circumstances. If and when a Part 15 device generates harmful interference, it becomes the responsibility of the device operator to correct the problem. Upon notice from the FCC, the device operator may also be required to cease using the device until such time as the interference has been corrected.

## PART 15 INTERFERENCE IMMUNITY

Licensed radio services, including Amateur Radio, are guaranteed absolute protection from harmful interference caused by Part 15 devices. There is a similar provision for Part 18 devices unless the affected amateur frequency happens to also be an ISM band (such as the 902 MHz band.) So what's the problem?

First, the emissions limits for most electronic consumer equipment are not low enough to protect nearby radio receivers from harmful interference. The only way to know for sure is to test the device that is causing the problem, which is expensive and not practical. Even then, most of the reported interference sources tested at the ARRL Laboratory actu-

ally meet the emissions limits.

As a result, most RFI cases are actually argued on basis of harmful interference as opposed to exceeding the specified emission limits. The rules place the burden to correct the interference on device operator — not manufacturer. Typically the operator is either the ham or a neighbor.

So, if the source is found to be in the ham's residence, he or she is responsible for fixing the problem. (The FCC historically is not sympathetic if you own the device.) And if the operator proves to be a neighbor, the problem can become even worse. The ham is now confronted with a potentially awkward and difficult situation with his neighbor, often stretching his or her diplomacy skills to their limit. Should the neighbor refuse to cooperate, the case can drag on for a considerable period of time, even with FCC intervention.

Another potential issue for the ham centers on the meaning of "harmful interference." Paraphrasing, the FCC rules (both Parts 2 and 15) define harmful interference as a repeated disruption of intended radio communications. If and when an RFI complaint results in an FCC field investigation, this determination is made by the agent conducting the investigation. The ham and agent may not agree as to whether or not his or her problem meets the FCC's definition to be considered harmful. (In fact, the ARRL has seen one case in which a particular case in which it went both ways for the ham. There were two investigations about a year apart. Each investigator came to a different conclusion concerning the same case — and both were from the same field office.)

Finally, it is important to emphasize that the rules don't specify who must actually find the noise source(s). The FCC doesn't have the resources to do RFI locating, at least in a timely and consistent fashion. The reality in the case of consumer a device is that the burden to find it falls on the affected ham. In the case of power line noise, the utility is responsible for finding and fixing the problem. However, many utilities lack the necessary personnel and equipment to locate noise sources in a timely manner. The ARRL has seen cases some such cases drag on for years.

## RF Interference and the FCC

by Riley Hollingsworth, K4ZDH (retired Special Counsel to the FCC Enforcement Bureau)

Since 1999, the FCC has worked with the ARRL in a cooperative agreement whereby the staff at the ARRL Lab takes the first cut at resolving RFI. The lab works with the complainant to make sure that the noise is narrowed down to the most probable source. The success rate with this program has been very high, and in many cases — perhaps most — the ARRL and the complainant solve the problem without any FCC involvement.

The lab can help you with the proper testing you need to do in your shack and with the documentation you need in the event the matter is referred to the FCC. I was always amazed at the number of situations in which noise that at first seemed to be power line related, was in fact (these are real examples) a nearby electric fence, a battery charger for a golf cart, an Ethernet adapter, a paper shredder or a circuit board in a brand new clothes washer in a room adjacent to the radio shack.

Don't assume anything. Test every possibility and document your testing. Not only will you learn a lot about the devices in your house and what causes noise and what doesn't, but good documentation will make your case stronger and easier to work. Follow to the letter the ARRL articles and website tutorials on tracking down noise in and around your shack. You can even hear noise samples on the website.

The documentation requirement is especially important if it is power line related and you have to start dealing with the power company. Take notes of every call you make, who you talked to and when. This helps not only the power company but also the FCC in the unfortunate event that FCC action is required. In many cases, power company staff has a lot of experience running down such noise and they take pride in locating it. In other cases, the power company has been bought, sold, merged or whatever and does not have staff with a lot of experience in these matters. Sometimes its staff has no experience.

The cost of the equipment required to track down power line noise is less than that of two employees and a bucket truck for a day. Often the source of power line noise is a simple piece of equipment that is loose or about to fail, so finding the source helps the power company maintain its system. Keep in mind, though, that some areas are just not suitable for Amateur Radio. If you live next to an old substation, or a conglomeration of old poles and transformers, or an industrial area, your situation is tenuous. Whether it's our roads or power grids, lots of the infrastructure in this country is just plain old and out of date.

You must test diligently and document thoroughly. Never go to the FCC with a situation when you have not already worked with the ARRL and the power company.

# 27.3 Elements of RFI

## 27.3.1 Source-Path-Victim

All cases of RFI involve a *source* of radio frequency energy, a device that responds to the electromagnetic energy (*victim*), and a transmission *path* that allows energy to flow from the source to the victim. Sources include radio transmitters, receiver local oscillators, computing devices, electrical noise, lightning and other natural sources. Note that receiving unwanted electromagnetic energy does not necessarily cause the victim to function improperly.

A device is said to be *immune* to a specific source if it functions properly in the presence of electromagnetic energy from the source. In fact, designing devices for various levels of immunity is one aspect of electromagnetic compatibility engineering. Only when the victim experiences a *disturbance* in its function as a consequence of the received electromagnetic energy does RFI exist. In this case, the victim device is *susceptible* to RFI from that source.

There are several ways that RFI can travel from the source to the victim: *radiation*, *conduction*, *inductive coupling* and *capacitive coupling*. *Radiated RFI* propagates by electromagnetic radiation from the source through space to the victim. *Conducted RFI* travels over a physical conducting path between the source and the victim, such as wires, enclosures, ground planes, and so forth. Inductive coupling occurs when two circuits are magnetically coupled. Capacitive coupling occurs when two circuits are coupled electrically through capacitance. Typical RFI problems you are likely to encounter often include multiple paths, such as conduction and radiation. (See the section Shields and Filters, also Ott, sections 2.1-2.3.)

Many instances of RFI are a combination of radiated and conducted RFI. Conducted RFI exits the source as current on one or more conductors connected to the source. The conductors act as transmitting antennas for the common-mode current which creates radiated signals. A conductor connected to the victim then picks up the radiated signal where the resulting common-mode current is conducted to the victim.

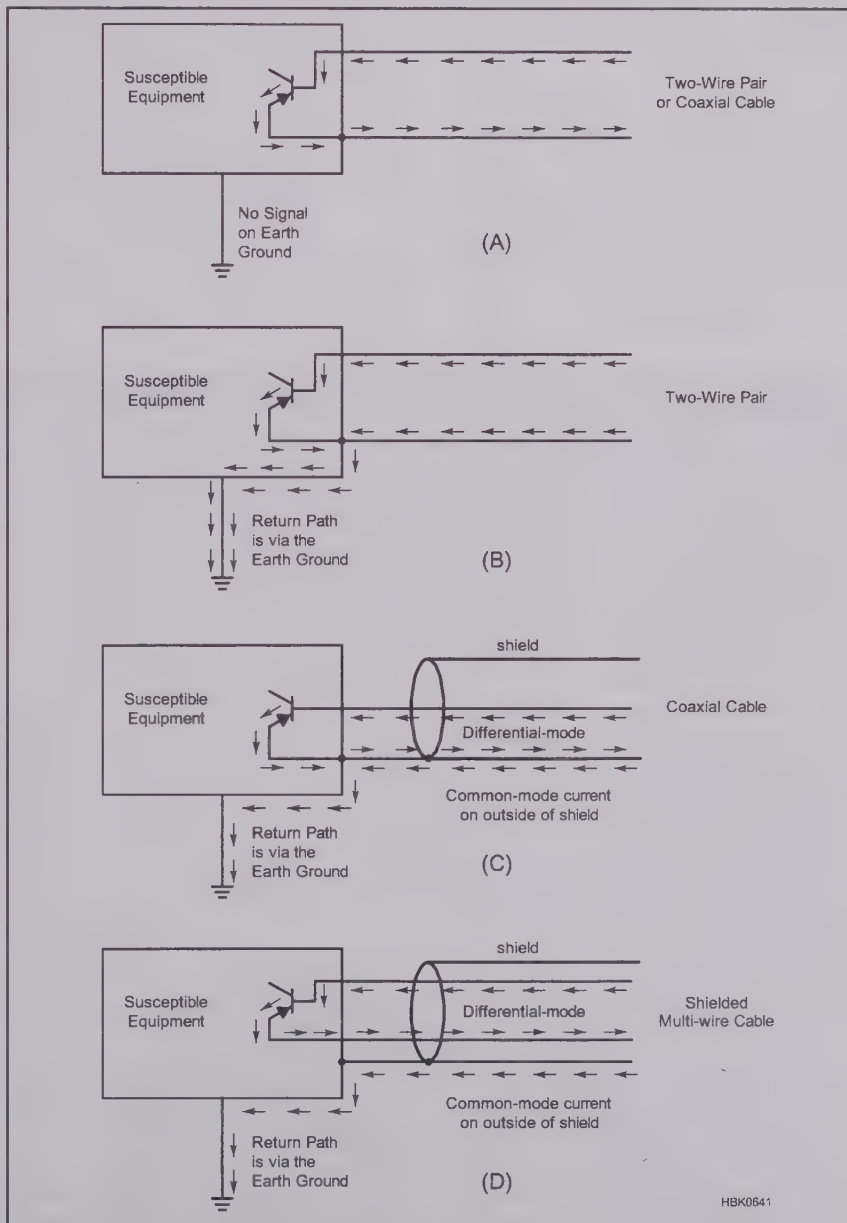

## 27.3.2 Differential-Mode vs Common-Mode Signals

The path from source to victim almost always includes some conducting portion, such as wires or cables. RF energy can be conducted directly from source to victim, be conducted onto a wire or cable that acts as an antenna where it is radiated, or be picked up by a conductor connected to the victim that acts like an antenna. When the noise signal is travel-

ing along the conducted portion of the path, it is important to understand the differences between *differential-mode* and *common-mode* conducted signals (see **Figure 27.3**).

Differential-mode signals usually have two easily identified conductors. In a two-wire transmission line, for example, the signal leaves the generator on one wire and

returns on the other. When the two conductors are in close proximity, they form a transmission line and the two signals have opposite polarities as shown in Figure 27.3A. Most desired signals, such as the TV signal inside a coaxial cable or an Ethernet signal carried on CAT5 network cable, are conducted as differential-mode signals.

**Figure 27.3** — Typical configurations of common-mode and differential-mode current. The drawing in A shows the currents of a differential-mode signal while B shows a common-mode signal with currents flowing equally on all of the source wires. In C, a common-mode signal flows on the outside of a coaxial cable shield with a differential-mode signal inside the cable. In D, the differential-mode signal, such as a data signal with a dedicated return circuit, flows on the internal wires while a common-mode signal flows on the outside of the cable shield.

A common-mode circuit consists of two or more wires in a multi-wire cable acting as if they were a single signal path as in Figure 27.3B. Common-mode circuits also exist when the outside surface of a cable's shield acts as a conductor as in Figures 27.3C and 27.3D. (See the chapter on **Transmission Lines** for a discussion about isolation between the shield's inner and outer surfaces for RF signals.) The return path for a common-mode signal often involves earth ground. Common-mode currents are the net result of currents for which there is not an equal-and-opposite current in the same conductors or group of conductors

Figure 27.3D illustrates the case for a signal and its return path both enclosed in a separate shield. This is a common arrangement for digital data or control signals in a multiconductor cable with a dedicated signal return or signal ground wire. The cable shield should be kept separate from all data and data return connections.

External noise generated by electronic equipment and RFI caused to electronic equipment is often associated with common-mode current on a cable shield that is improperly connected. For example, consider what happens when the cable shield in Figures 27.3C and 27.3D is not connected to the enclosure but enters the device before connecting to a circuit's common or ground connection. In this case, any noise generated by the circuit has a path out of the enclosure and on to the surface of the cable shield where it is then radiated. Similarly, any noise or signals picked up by the cable shield are conducted into the equipment where it is connected to the circuit and can disrupt normal operation or interfere with the desired signals. This is discussed more in this chapter's section Elements of RFI Control.

### COMMON-MODE AND POWER WIRING

There is an important difference between the preceding definition and what ac power companies consider common-mode. Corcom

is a major manufacturer of power line RFI filters and related components. (See [www.te.com/usa-en/products/emi-filters/power-line-filters.html](http://www.te.com/usa-en/products/emi-filters/power-line-filters.html).) Common-mode is defined in their Product Guide's appendix on "Understanding Insertion Loss," as "signals present on both sides of the line (hot and neutral) referenced to ground." The RF definition of common-mode in this book includes signals on the ground conductor, as well.

What this means is that a typical ac-line filter may be ineffective against common-mode RF flowing on the ground conductor. The ground connection is typically carried through a power-line RFI filter as a direct connection. To block RF on the ground conductor of a three-wire ac power cord or cable, the usual remedy is to wind the cord on a ferrite core. This places an impedance in all three conductors, not just hot and neutral. (See the sidebar "Differential-Mode and Common-Mode Current and RFI Filtering" by W1RFL in the section Elements of RFI Control.)

## Power Inverters and Conducted Emissions Limits

Some electronic devices intentionally generate internal RF but do not intentionally radiate it. For example, the RF generated by computers, televisions, radio receivers, and switch-mode power supplies (SMPS) is intentional and necessary for such devices to function. Although the RF is intentionally generated by these devices, they do *not* intentionally radiate it. Under Part 15 of the FCC rules, these are defined as *unintentional emitters*.

Like all Part 15 devices, unintentional emitters must not cause harmful interference to a licensed radio service. In addition, Part 15 rules further establish the following two types of absolute limits for unintentional emitters:

- *Conducted emissions* — emissions conducted onto the house wiring and power lines via the device power cord. Part 15 provides absolute limits for conducted emissions from 150 kHz to 30 MHz. There are no conducted emissions limits above 30 MHz, in part because power lines are not particularly good transmission lines at these higher frequencies. In addition, most Part 15 devices are small relative to the longer wavelengths below 30 MHz. Conducted emissions therefore become the primary problem when a physically larger RFI "antenna" is required at HF and lower frequencies.

- *Radiated emissions* — emissions radiated by the device itself. The absolute limits in this case are specified at 30 MHz and higher frequencies. It's important to note that there are no radiated emissions limits below 30 MHz. Since power lines are relatively inefficient "transmission lines" at VHF and higher frequencies, radiated emissions now become the primary problem. The relatively shorter wavelengths now start to approach the physical size of a typical Part 15 device at 30 MHz.

Conducted emissions rules and limits normally only apply to devices that plug into house wiring. Inverters, however, convert dc power from batteries and solar panels into ac power. In this case, inverters are the ac power source, and as such, not connected to house wiring and power lines. Emissions from power inverters are therefore not considered "conducted emissions" as defined by the FCC rules.

Although the usual limits don't apply in this case, they are conducted emissions in every other respect. Fortunately the shorter power lines typically associated with inverters reduce

the potential for interference from conducted emissions. Using one to power an amateur station, however, can be a particularly demanding application. For this reason, the ARRL Lab staff felt typical Part 15 conducted emissions testing, using standard procedures and instruments, would be useful when evaluating inverters. The data correlates directly with other unintentional emitters and the FCC limits.

At the ARRL Laboratory we use a LISN (Line Impedance Stabilization Network) and a calibrated Rohde & Schwarz ESH-3 EMC receiver to measure conducted emissions. Normally, the device under test is plugged into the LISN, which separates the unwanted RF from the desired 60 Hz ac power. The conducted emissions are then measured by the special Rohde & Schwarz receiver using quasi-peak detection (AM, 9 kHz bandwidth, designed to access the effect of interference of a received signal to the human ear). In the case of power inverters, however, the LISN is plugged into the power inverter. In order to accomplish this, we used a set of adapter cables to reverse the LISN input and output. In the case of the power inverter test, we used the LISN as described in ANSI Standard C63.4-2003, page 10, Figure 2.

The table below lists the Part 15 conducted emissions limits. Note that the limits are expressed in dB $\mu$ V, or dB relative to a microvolt. In this case, 1000  $\mu$ V of signal equals +60 dB $\mu$ V.

Frequency	dB $\mu$ V, quasi-peak detection
0.150 – 0.5 MHz	66 to 56*
0.5 – 5.0	56
5.0 – 30.0	60
>30.0	None

\*Decreases with the logarithm of the frequency.

It is important to note that these limits are not low enough to eliminate the possibility of interference but rather localize it. With power inverters, one may hear a buzzing sound across the LF, MF and HF spectrum. Besides conducted emissions levels, the severity of the interference can also depend upon such things as the placement and characteristics of the power cords and distance from the antenna. The lower the conducted emissions level, the better. — Bob Allison, WB1GCM, ARRL Laboratory Assistant Manager

### 27.3.3 Types of RFI

There are four basic types of RFI that apply to Amateur Radio. The first two occur in the following order of likelihood when the interfering source is the transmitted signal from an amateur transmitter:

1) **Fundamental Overload** — Disruption or degradation of a device's function in the presence of a transmitter's fundamental signal (the intended signal from the transmitter). This can happen because the fundamental is simply too strong for the victim device's circuitry to reject — a true overload situation. It can also happen because of *common-mode ingress* in which the strong signal is picked up as common-mode current on an external cable which is then conducted into the victim device's circuitry. A third variation is *direct pickup* or *direct detection* in which the interfering signal is picked up by the victim device's internal wiring. The appropriate remedy must be used for each mechanism.

2) **Spurious Emissions** — Reception of a radio signal interfered with by spurious emissions from the transmitter as defined in the previous section on Part 97 definitions and Figure 27.1.

The second two types of RFI occur, again in order of likelihood, when the reception of a desired signal is interfered with by RF energy received along with the desired signal.

3) **External Noise Sources** — Reception of a radio signal interfered with by RF energy transmitted incidentally or unintentionally by a device that is not a licensed transmitter

4) **Intermodulation** — Reception of a radio signal interfered with by intermodulation distortion (IMD) products generated inside or outside of the receiver

As an RFI troubleshooter, start by determining which of these is involved in your interference problem. Once you know the type of RFI, selecting the most appropriate cure for the problem becomes much easier.

### 27.3.4 Fundamental Overload

Most cases of interference caused by an amateur transmission are due to *fundamental overload*. The world is filled with RF signals. Properly designed radio receivers of any sort should be able to select the desired signal, while rejecting all others. Unfortunately, because of design deficiencies such as inadequate shields or filters, some radio receivers are unable to reject strong out-of-band signals. Electronic equipment that is not a radio receiver can also suffer from fundamental overload from similar design shortcomings. Both types of fundamental overload are common in consumer electronics.

A strong signal can enter equipment in several different ways. Most commonly, it is conducted into the equipment by connecting

wires and cables. Possible RFI conductors include antennas and feed lines, interconnecting cables, power cords, and ground wires. TV antennas and feed lines, telephone or speaker wiring and ac power cords are the most common points of entry.

If the problem is a case of fundamental overload, significant improvement can often be observed just by moving the victim equipment's antenna and the signal source farther away from each other. The effect of an interfering signal is directly related to its strength, diminishing with the square of the distance from the source. If the distance from the source doubles, the strength of the electromagnetic field decreases to one-fourth of its power density at the original distance from the source. An attenuator is often a weapon of choice when encountering this type of problem. Reducing the level of the offending strong signal returns the receiver to normal operation and causes the undesirable effects to disappear. This characteristic can often be used to help identify an RFI problem as fundamental overload. If reducing the strength of the signal source causes the same effect that is also a signature of fundamental overload.

### 27.3.5 Spurious Emissions

All transmitters generate some (hopefully few) RF signals that are outside their intended transmission bandwidth — out-of-band emissions and spurious emissions as illustrated in Figure 27.1. Out-of-band signals result from distortion in the modulation process or consist of broadband noise generated by the transmitter's oscillators that is radiated along with the intended signal. Harmonics, the most common spurious emissions, are signals at integer multiples of the operating (or fundamental) frequency.

Transmitters may also produce broadband noise and/or parasitic oscillations as spurious emissions. (Parasitic oscillations are discussed in the **RF Power Amplifiers** chapter.) Overdriving an amplifier often creates spurious emissions. Amplifiers not meeting FCC certification standards but sold illegally are frequent sources of spurious emissions.

Regardless of how the unwanted signals are created, if they cause interference, FCC regulations require the operator of the transmitter to correct the problem. The usual cure is to adjust or repair the transmitter or use filters at the transmitter output to block the spurious emissions from being radiated by the antenna.

### 27.3.6 External Noise Sources

Most cases of interference to the Amateur Service reported to the FCC are eventually determined to involve some sort of external

noise source, rather than signals from a radio transmitter. Noise in this sense means an RF signal that is not essential to the generating device's operation.

The most common external noise sources are electrical, primarily power lines. Motors and switching equipment can also generate electrical noise. Noise radiated by switch-mode systems such as power supplies, digital equipment, and variable-speed drives is increasingly common.

External noise can also come from unlicensed Part 15 RF sources such as computers and networking equipment, video games, appliances, and other types of consumer electronics.

Regardless of the source, if you determine the problem to be caused by external noise, elimination of the noise must take place at the source. As an alternative, several manufacturers also make noise canceling devices that can help in some circumstances.

### 27.3.7 Intermodulation Distortion

As discussed in the chapter on **Receiving**, intermodulation distortion (IMD) is caused by two signals combining in such a way as to create *intermodulation products* — signals at various combinations of the two original frequencies. The two original signals may be perfectly legal, but the resulting *intermodulation distortion products* may occur on the frequencies used by other signals and cause interference in the same way as a spurious signal from a transmitter. Depending on the nature of the generating signals, "intermod" can be intermittent or continuous. IMD can be generated inside a receiver by large signals or externally by signals mixing together in non-linear junctions or connections.

### 27.3.8 Ground Connections

An electrical ground is not a huge sink that somehow swallows noise and unwanted signals. Ground is a *circuit* concept, whether the circuit is small, like a radio receiver, or large, like the propagation path between a transmitter and AM/FM receiver. Ground forms a universal reference point between circuits.

While grounding is not a cure-all for RFI problems, ground is an important safety component of any electronics installation. It is part of the lightning protection system in your station and a critical safety component of your house wiring. Any changes made to a grounding system must not compromise these important safety considerations. Refer to the **Safety** chapter for important information about grounding. The ARRL book *Grounding and Bonding for the Radio Amateur* also goes into detail about ground systems for electrical safety, lightning protection, and managing RF

voltages and currents.

Many amateur stations have several connections referred to as “grounds”; the required safety ground that is part of the ac wiring system, another required connection to earth for lightning protection, and perhaps another shared connection between equipment for RFI control. These connections can interact with each other in ways that are difficult to predict. Rearranging the station ground connections may cure some RFI problems in the station by changing the RF current distribution so that the affected equipment is at a low-impedance point and away from RF “hot spots.” It is better to address the problem by implementing proper bonding within the station and to the station’s ground system.

## BONDING

Bonding refers to a connection intended to minimize potential (voltage) differences. The purpose of bonding in the amateur station is to minimize the potential difference between equipment and all elements of the ground system — ground rods, entry wiring for electrical power, telephone or data systems, cable or satellite TV systems, and amateur antennas. This minimizes voltage differences in the event of lightning surges. It also minimizes hum and buzz and reduces RFI resulting from voltage differences between pieces of equipment.

Creating a low-impedance connection between your station’s equipment is easy to do and will help reduce voltage differences (and current flow) between pieces of equipment. Bonding is also discussed in this book’s **Safety** chapter.

Bonding also reduces voltage differences between the ends of cable shields that are connected to different pieces of equipment. This voltage difference is effectively in series with the cable shield and can be added to the desired signals carried by the cable. The voltage difference can be at ac power, audio, or RF so bonding helps reduce RFI across a wide frequency range.

The conductors used for bonding should be heavy enough to have low inductance and resistance. The standard for commercial and military facilities is solid copper strap but heavy stranded or solid wire (bare or insulated) works well. Flat woven braid will also work if kept dry. Braid removed from coaxial cable is not recommended but is often used with good results.

Equipment enclosures should be connected either directly together as in **Figure 27.5** or by using a bonding bus or ground reference plane as shown in the chapter on **Assembling a Station**. Amateur Radio and home entertainment equipment usually has a ground screw or terminal. Chassis connections for many computers can be found at the shell of video or data connectors.

## LENGTH OF GROUND CONNECTIONS

The required ground connection for lightning protection between the station equipment and an outside ground rod is at least several feet long in most practical installations. (See the **Safety** chapter for safety and lightning protection ground requirements.)

In general, however, a long connection to earth should be considered as part of an RFI problem only to the extent that it is part of the

**Figure 27.4** — An earth ground connection can radiate signals that might cause RFI to nearby equipment. This can happen if the ground connection is part of an antenna system or if it is connected to a coaxial feed line carrying RF current on the outside of the shield.

antenna system. For example, should a long-wire HF antenna end in the station, a ground connection of *any* length is a necessary and useful part of that antenna and will radiate RF.

At VHF a ground wire can be several wavelengths long — a very effective antenna for any harmonics that could cause RFI! For example, in **Figure 27.4**, signals radiated from the required safety ground wire could very easily create an interference problem in the downstairs electronic equipment.

## GROUND LOOPS, HUM, AND BUZZ

A *ground loop* is created by a continuous conductive path around a series of equipment enclosures. While this does create an opportunity for lightning and RFI susceptibility, the ground loop itself is rarely a cause of problems at RF. Problems created by loops

## RFI and End-Fed Antennas

An end-fed antenna brought directly into the station is often adjusted to produce a current-maximum (low-impedance point) at the feed point. The feed point is often the output of an antenna tuner so the feed point is actually *in* the station. If a resonant counterpoise is not attached to the tuner, the resulting current will couple to and flow on whatever conductors happen to be connected to or close to the enclosures of the transmitter and tuner, including ground system and signal connections. Common-mode current on the outside of an antenna feed line can act in the same way. To address this situation, make sure equipment is bonded together properly, as well as the ground system, and provide the necessary counterpoise for the end-fed wire or a common-mode choke for the antenna feed line (see the **Transmission Lines** chapter).

**Figure 27.5** — Direct equipment-to-equipment bonding. Use heavy wire or strap connected to a single ground terminal or enclosure screw on each piece of equipment, including computers and related gear. The same approach can be used in home entertainment systems or with computers and accessories.

picking up RF signals are addressed by proper bonding of equipment and by minimizing the loop area formed by cables and wiring.

Ground loops are usually associated with audio hum caused by coupling to power-frequency magnetic fields from transformers or motors and sometimes from coupling to high-current power wiring. The hum appears as a nearly-pure sine wave at the frequency

of the ac power system, 50 or 60 Hz. To avoid low-frequency ground-loop issues, use short cables that are the minimum length required to connect the equipment and bundle them together to minimize the area of any enclosed loop. Moving the cables away from the source of the magnetic field or reorienting the source or cables can reduce hum. Bonding equipment together to short-circuit a loop is sometimes effective.

Audio “buzz” is caused primarily by currents at harmonics of the ac power frequency. The current results from leakage in ac-powered equipment with rectifiers or switching circuits that conduct during parts of the ac power waveform. Buzz is addressed by bonding and by insuring the ac power ground connections have a minimum of these voltages on them.

## 27.4 Identifying the Type of RFI Source

It is useful to recognize an offending noise source as one of several broad categories at the early stages of any RFI investigation. Since locating and resolution techniques can vary somewhat for each type of noise, the process of locating and resolving RFI problems begins with identifying the *general* type of RFI source. It is not useful, however, to go farther and attempt to identify a particular type of equipment or device at the beginning of the search. The purpose of this section is to help you determine the general category of the noise being received and choose the right set of tools and methods to locate the source of the noise.

It is often impossible to identify the exact type of device generating the RFI from the sound of the interference. Because there are many potential sources of RFI, it is often more important to obtain and interpret clues from the general noise characteristics and the patterns in which it appears.

A source that exhibits a repeatable pattern during the course of a day or week, for example, suggests something associated with human activity. A sound that varies with or is affected by weather suggests an outdoor source. Noise that occurs in a regular and repeating pattern of peaks and nulls as you tune across the spectrum, every 50 kHz for example, is often associated with a switch-mode power supply or similar pulsed-current devices. A source that exhibits fading or other sky wave characteristics suggests something that is not local. A good ear and careful attention to detail will often turn up some important clues. A detailed RFI log can often help, especially if maintained over time.

### BROADBAND AND NARROWBAND NOISE

Noise can be characterized as broadband or narrowband — another important clue. *Broadband noise* is defined as noise having

### Common Mistake — What Is It?

When someone has an unusual RFI problem, the first question he or she almost always asks is: What is it? That's an interesting question, and you may need to ask it during the troubleshooting process, but it is not the first question you should ask. Even if someone were to say that it's a Model XYZ Panasonic switching power supply, what would that tell you? You would still have to go into the world and find it. It could be useful, though, to know whether you are searching for a switching power supply, DSL or cable leakage, or a plasma TV. But be general, not specific, because you don't want to be misled. — *Ed Hare, W1RFI, ARRL Lab Manager* (An extended version of this sidebar is available on this book's supplemental material online.)

### Keeping an RFI Log

The importance of maintaining a good and accurate RFI log cannot be overstated. Be sure to record time and weather conditions. Correlating the presence of the noise with periods of human activity and weather often provide very important clues when trying to identify power-line noise. It can also be helpful in identifying noise that is being propagated to your station via sky wave. A log showing the history of the noise can also be of great value should professional services or FCC involvement become necessary at some point.

a bandwidth much greater than the affected receiver's operating bandwidth and is reasonably uniform across a wide frequency range. Noise from arcs and sparks, such as power-line noise, tend to be broadband. *Narrowband noise* is defined as noise having a bandwidth less than the affected receiver's bandwidth. Narrowband noise is present on specific, discrete frequencies or groups of frequencies, with or without additional modulation. In other words, if you listened to the noise on an SSB receiver, tuning would cause its sound to vary, just like a regular signal. Narrowband noise often sounds like an unmodulated carrier with a frequency that may drift or suddenly change. Microprocessor clock harmonics, oscillators and transmitter harmonics are all examples of narrowband noise.

### 27.4.1 Identifying Noise from Part 15 Devices

The most common RFI problem reported to the ARRL comes from an unknown and unidentified source. Part 15 devices and other consumer equipment noise sources are ubiquitous. Although the absolute signal level from an individual noise source may be small, their increasing numbers makes this type of noise a serious problem in many suburban and urban areas. The following paragraphs describe several common types of electronic noise sources.

Electronic devices containing oscillators, microprocessors, or digital circuitry produce RF signals as a byproduct of their operation. The RF noise they produce may be radiated from internal wiring as a result of poor shielding. The noise may also be conducted to external, unshielded or improperly shielded wiring as a common-mode signal where it radiates noise. Noise from these devices is usually narrowband that changes characteristics (frequency, modulation, on-off pattern) as the device is used in different ways. HF and lower frequency

problems are typically caused by conducted emissions although they may travel to the victim as radiated signals. As we'll see, the cure in these cases usually involves common-mode chokes and filters. At VHF and higher frequencies, the probable cause is radiated emissions from the source device. In these cases, shielding is often the solution of choice.

Another major class of noise source is equipment or systems that control or switch large currents. Among them are variable-speed motors in products as diverse as washing machines, elevators, and heating and cooling systems. Charging regulators and control circuitry for battery and solar power systems are a prolific source of RF noise. So are switchmode power supplies for computers and low-voltage lighting. This type of noise is only present when the equipment is operating.

Switchmode supplies, solar controllers and inverters often produce noise signals every N kHz, with N typically being from 5 to 50 or more kHz, the frequency at which current is switched. This is different from noise produced by spark or arc sources that is uniform across a wide bandwidth. This pattern is often an important clue in distinguishing switching noise from power-line or electrical noise.

Wired computer networks radiate noise directly from their unshielded circuitry and from network and power supply cables. The noise takes two forms — broadband noise and modulated carriers at multiple frequencies within the amateur bands. As an example, Ethernet network interfaces often radiate signals heard on a receiver in CW mode. 10.120, 14.030, 21.052 and 28.016 MHz have been reported as frequencies of RFI from Ethernet networks. Each network interface uses its own clock, so if you have neighbors with networks you'll hear a cluster of carriers around these frequencies,  $\pm 500$  Hz or so.

In cable TV systems video signals are converted to RF across a wide spectrum and distributed by coaxial cable into the home. Some cable channels overlap with amateur bands, but the signals should be confined within the cable system. No system is perfect, and it is common for a defective coax connection to allow leakage to and from the cable. When this happens, a receiver outside the cable will hear RF from the cable and the TV receiver may experience interference from local transmissions. Interference to and from cable TV signals is discussed in detail later in this chapter.

## 27.4.2 Identifying Power-line and Electrical Noise

### POWER-LINE NOISE

Next to external noise from an unknown source, the most frequent cause of an RFI

Figure 27.6 — The gap noise circuit on a power line — simplified. (From Loftness, *AC Power Interference Handbook*)

problem reported to the ARRL involving a known source is power-line noise. (For more information on power-line noise, see the book *AC Power Interference Handbook*, by Marv Loftness, KB7KK.) Virtually all power-line noise originating from utility equipment is caused by spark or arcing across some hardware connected to or near a power line. A breakdown and ionization of air occurs and current flows across a gap between two conductors, creating RF noise as shown in Figure 27.6. Such noise is often referred to as “gap noise” in the utility power industry. The gap may be caused by broken, improperly installed or loose hardware. Typical culprits include insufficient and inadequate hardware spacing such as a gap between a ground wire and a staple. Contrary to common misconception, corona discharge is almost never a source of power-line noise.

While there may not be one single conclusive test for power-line noise, there are a number of important tell-tale signs. On an AM or SSB receiver, the characteristic raspy buzz or frying sound, sometimes changing in intensity as the arc or spark sputters a bit, is often the first and most obvious clue.

Power-line noise is typically a broadband type of interference, relatively constant across a wide spectrum. Since it is broadband noise, you simply can't change frequency to eliminate it. Power-line noise is usually, but not always, stronger on lower frequencies. It occurs continuously across each band and up through the spectrum. It can cause interference from below the AM broadcast band through UHF, gradually tapering off as frequency increases. If the noise is not continuous across all of an amateur band, exhibits a pattern of peaks and nulls at different frequencies, or repeats

at some frequency interval, you probably do not have power-line noise.

The frequency at which power-line noise diminishes can also provide an important clue as to its proximity. The closer the source, the higher the frequency at which it can be received. If it affects VHF and UHF, the source is relatively close by. If it drops off just above or within the AM broadcast band, it may be located some distance away — up to several miles.

Power-line noise is often affected by weather if the source is outdoors. It frequently changes during rain or humid conditions, for example, either increasing or decreasing in response to moisture. Wind may also create fluctuations or interruptions as a result of line and hardware movement. Temperature effects can also result from thermal expansion and contraction.

Another good test for power-line noise requires an oscilloscope. Remember that power-line noise occurs in bursts most frequently at a rate of 120 bursts per second and sometimes at 60 bursts per second. Observe the suspect noise from your radio's audio output. (Note: The record output jack works best if available.) Use the AM mode with wide filter settings and tune to a frequency without a station so the noise can be heard clearly. Use the LINE setting of the oscilloscope's trigger subsystem to synchronize the sweep to the line. Power-line noise bursts will remain stable on the display and should repeat every 8.33 ms (a 120-Hz repetition rate) or less commonly, 16.67 ms (60 Hz), if the gap is only arcing once per cycle. (This assumes the North American power-line frequency of 60 Hz.) See Figure 27.7 for an explanation. If a noise does not exhibit either of these charac-

## ELECTRICAL NOISE

Electrical noise sounds like power-line noise, but is generally only present in short bursts or during periods when the generating equipment or machinery is in use. Noise that varies with the time of day, such as daytime-only or weekends-only, usually indicates some electrical device or appliance being used on a regular basis and not power-line noise. Unless it is associated with climate control or HVAC system, an indoor RFI source of electrical noise less likely to be affected by weather than power-line noise.

## ELECTRIC FENCES

A special type of electrical noise that is easy to identify is the “pop...pop...pop” of an electric fence. High voltage is applied to the fence about once a second by a charging unit. Arcs will occur at corroded connections in the fence, such as at a gate hook or splice. If brush or weeds touch the fence, the high-voltage will cause an arc at those points until the vegetation burns away (the arc will return when the vegetation re-grows). Each arc results in a short burst of broadband noise, received as a “tick” or “pop” in an HF receiver.

### 27.4.3 Identifying Intermodulation Distortion (IMD)

IMD products generated from the mixing of two strong signals in a non-linear junction or circuit appear at frequencies that are combinations of the two signal frequencies. The process of combination can occur outside or inside the receiver. The resulting IMD product signals include the modulation of both signals. For example, intermodulation from two SSB or FM voice signals produces somewhat distorted signals with the modulating signals of both stations. Since the two signals are not synchronized, the intermodulation products come and go unpredictably, existing only when both of the external signals are present.

#### IMD GENERATED OUTSIDE A RECEIVER

Mixing of signals can occur in any non-linear junction where the original signals are both strong enough to cause current to flow in the junction. This is a particular problem at multi-transmitter sites, such as broadcast facilities and industrial or commercial communications sites. Non-linear junctions can be formed by loose mechanical contacts in metal hardware, corroded metal junctions, and by semiconductor junctions connected to wires that act as antennas for the strong signals. Non-linear junctions also detect or demodulate RF signals to varying degrees, creating interfering audio or dc signals in some cases. IMD products generated externally cannot be filtered out at the receiver and

## Common Mistake — The Source Must Be Illegal Because It's So Loud

The FCC limits for consumer electronics are not sufficient to protect against interference to nearby receivers. In a typical suburban neighborhood, the interference can be loud even from a neighboring residence. Proving they meet the applicable limits, these devices can be legally marketed and sold. If and when interference occurs, the burden then fall on the operator of the device to correct the problem.

Conclusion: Don't automatically assume that the device illegally exceeds the FCC limits just because it is causing harmful interference, even if it seems excessive. — Mike Gruber, W1MG (ARRL EMC Engineering, [rfi@arrl.org](mailto:rfi@arrl.org))

must be eliminated where the original signals are being combined.

An intermodulation product generated externally to a receiver often appears as an intermittent transmission, similar to a spurious emission. (See the **Receiving** chapter for more information on intermodulation.) It is common for strong signals from commercial paging or dispatch transmitters sharing a common antenna installation to combine and generate short bursts of voice or data signals. AM broadcast transmissions can combine to produce AM signals with the modulation from both stations audible.

An amateur station itself can be the source of strong signals that are picked up on various cables and wiring. The RF is then conducted into the station where it can encounter many types of diodes and transistors that act as the non-linear junctions. The resulting IMD product signals can then be conducted and radiated by the same cables and wiring that picked up the RF in the first place.

IMD can also be created in a broadcast FM or TV receiver or preamplifier. The solution is to add suitable filters or reduce overall signal levels and gain so that the strong interfering signal or signals can be processed linearly.

#### IMD GENERATED INSIDE A RECEIVER

Since the products are generated internally to the receiver, the strong signals must be filtered out or attenuated before they can enter the receiver circuits in which IMD products are generated. Like external intermodulation products, those generated by a receiver acting non-linearly appear as combinations of two or more strong external signals. Intermodulation generated within a receiver can often be

**Figure 27.7** — The 60-Hz signal found on quiet power lines is almost a pure sine wave, as shown in A. If the line, or a device connected to it, is noisy, this will often add visible noise to the power-line signal, as shown in B. This noise is usually strongest at the positive and negative peaks of the sine wave where line voltage is highest. If the radiated noise is observed on an oscilloscope, the noise will be present during the peaks, as shown in C.

teristics, it is probably not power-line noise.

If a local TV station is transmitting analog TV signals on a lower VHF channel (very few remain as of early 2018), additional clues may be obtained by viewing the noise pattern on an analog TV set (if you still have one) using an antenna (not a cable TV connection). Power-line noise usually appears as two horizontal bars that drift slowly upward on the screen through the picture. (This is due to the difference between the NTSC signal's 59.94 Hz field rate and the 60 Hz power-line frequency.) As one bar rolls off the screen at the top of the display, a new one simultaneously forms at the bottom. In cases where the noise is occurring at 60 bursts per second, there will be only one bar on the display. In addition, the power-line noise bursts may have slightly different characteristics at the positive and negative peaks. This can cause each half of the cycle to have a slightly different pattern on the screen.

detected simply by activating the receiver's incoming signal attenuator. If attenuating the incoming signals causes the intermodulation product to be reduced in strength by a greater amount than that of the applied attenuation, intermodulation in the receiver is a strong possibility. Since receivers vary in their IMD performance, differences in the interfering signal strength between receivers is also an indication of intermodulation.

The following simple "attenuator test" can be used to identify an IMD product, even in cases where it appears similarly in multiple receivers. This procedure applies mainly to superheterodyne receivers with analog circuitry in the sensitive front-end stages. SDR receivers respond to strong signals somewhat differently, with a more abrupt transition between linear and non-linear operation.

- If your receiver does not have one, install a step attenuator at its RF input. If you use an attenuator internal to your receiver, it must attenuate the RF at the receiver's input.
- Tune the receiver to the suspected intermod product with the step attenuator set to 0 dB. Note the signal level.
- Add a known amount of attenuation to the signal. Typically 10 or 20 dB makes a good starting point for this test.
- If the suspect signal drops by more than the amount of added attenuation, the suspect signal is an IMD product. For example, if you add 10 dB of attenuation, and the signal drops

## Common Mistake — Radiated vs. Conducted Emissions

The FCC does not impose radiated emissions limits below 30 MHz. There are only conducted emissions below 30 MHz. Specifically, the FCC requirements are for the RF conducted on the ac power connection, a power cord for most consumer devices. The limits in the case are expressed in terms of a voltage from both the phase (or "hot") conductor and neutral conductor to the ground conductor.

Note: Typical consumer devices are too small to be an effective antenna at HF. While the device may generate the RF, it doesn't radiate it. The actual radiation takes place from the wires and cables connected to the source device. The FCC rules in this regard only address the connection to ac power.

Above 30 MHz, the situation is reversed. There are no limits for conducted emissions — only for radiated emissions. The limits in this case are expressed as a field strength at a specified distance from the device. — Mike Gruber, W1MG (ARRL EMC Engineering, [rfi@arri.org](mailto:rfi@arri.org))

by 30 dB, you have identified an IMD product.

- You can also compare the reduction in signal level between the suspect IMD product and a known genuine signal with and without the added attenuation. Use a known genuine signal that is about the same strength as the suspect signal with no added attenuation. If the suspect signal drops by the same as the added attenuation, it is not an IMD product.

Intermodulation distortion can be cured in a number of ways. The goal is to reduce the strength of the signals causing IMD so that the receiver circuits can process them linearly and without distortion.

If IMD is occurring in your receiver, filters

that remove the strong unwanted signals causing the IMD while passing the desired signal are generally the best approach since they do not compromise receiver sensitivity. (The chapter on **Receiving** discusses how to add additional filtering to your receiver.) Turning off preamplifiers, adding or increasing the receiver's attenuation, and reducing its RF gain will reduce the signal strength in your receiver. Antenna tuners and external band-pass filters can also act as a filter to reduce IMD from out-of-band signals. Directional beams and antennas with a narrower bandwidth can also help, depending on the circumstances of your particular problem.

## 27.5 Locating Sources of RFI

Once you have determined the *general* nature of the noise, it's time to find out where it's coming from. "Pinpoint the source precisely and you will know what it is." Good advice! There is no need to know exactly what the source is until it is found or narrowed down to a few possibilities. So the proper first question is, "How do I locate the source?"

Along with the material in this chapter, the Radio Direction Finding chapter of *The ARRL RFI Book*, describes the many methods available to locate sources. There are numerous websites with information about direction finding at all frequencies. This information helps educate the amateur that locating the source is the first step rather than speculating about what it might be.

Locating an offending device or noise source might sometimes seem like trying to find a needle in a haystack. With a little patience and know-how, it is often possible to find the source of a problem in relatively short order. RF detective work is often re-

quired and some cases require a little more perseverance than others. In any case, armed with some background and technique, it is often easier to find an offending source than the first-time RFI investigator might expect. Once the source is pinpointed and its exact nature is known, proper treatment can be applied to eliminate the RFI.

### PREPARING TO FIND A SOURCE OF RFI

Consider the following questions:

- 1) First and foremost, does the searcher have an open mind? This kind of search is not a visual search until the structure containing the source is located. Even then, equipment must still be relied upon to pinpoint the source. An open mind means a willingness to trust the equipment and not waste time guessing or deviating from the search path to pursue something seen or guessed at.
- 2) Is the searcher equipped to produce useful results? A battery operated AM-

FM-SW-VHF receiver with a useful signal strength indicator and a directional antenna suitable for a walking search that receives fairly well at the highest relevant frequency is essential. See the Power-line Noise section for examples of what works for that type of source. Handheld SDR receivers are now available that can act as a portable spectrum analyzer, as well.

3) Does the searcher know how to direction-find? The type of power lines or potential sources in the area is irrelevant at this point. Finding the structure that contains the source is the only objective. Only by trusting your equipment and using it correctly to lead you to the source will the job get done with a minimum of wasted time and effort.

4) Has the searcher done enough listening and record keeping to have a good idea when the source is active, the best (highest?) frequency at which to listen to hear and track the source. Information includes:

- Signal strength

## Prospecting for RFI

By using several types of radios at the same time, you can characterize a wide area. For example, RFI professional KB4T uses the following radios when driving: the vehicle AM/FM radio tuned to 1710 kHz AM, an IC-7000 mobile HF transceiver tuned to 15 MHz AM (WWV), and an IC-2820 VHF receiver tuned to 121.500 MHz in AM mode. All three are operated un-squelched with the volume turned down so only a slight hiss is heard. A noise source will be very apparent on one or more of the radios when approached or passed.

- Highest frequency at which each source can be heard
- A simple description of each source's character
- Any other descriptive data
- Brief notes about weather conditions

If you can record the noise for a long period of time that shows the time as well as the noise, that will provide a lot of information about the source, as well.

5). Can it be decided what tools are best to locate the source? (Receiver, antenna, attenuator) Even if the right tools are in hand, mastery of them is essential. Make sure you know how to interpret the measurements or work with an experienced user to learn how.

### NOISE SOURCE SIGNATURES

Be wary of assuming too much about a source based on what the interference “sounds like” on a receiver or even “looks like” on an oscilloscope or spectrum analyzer. At the beginning of the search, “keep it simple” by not making too many assumptions about the nature of the source. Once the location of a source has been determined, then you can begin to narrow the search based on the source's “fingerprint” or signature.

Keep an open mind, be deliberate in your search, and don't act on assumptions about what a source is or isn't until you have exhausted the search techniques. Much time has been wasted in looking for sources of RFI because of assuming a location or type of source at the beginning.

### MULTIPLE NOISE SOURCES

Consider that the source may be more than single piece of equipment! You might have power-line noise combined with switchmode power supply noise, for example. Trying to find the source based on the combination of noise signatures will be frustrating at best. Most suburban and urban locations have multiple noises active at any time. Survey the area to see if different sources are stronger in different areas.

Take careful notes about the nature and behavior of the source, then let your location-finding equipment lead you to each source in turn. It is often most productive to work on the strongest noise source first. Be prepared to discover there are multiple levels of noise sources — after dealing with the top-level source, you may find additional (and equally objectionable) sources remain. Be patient!

### VERIFY NOISE IS EXTERNAL TO THE RADIO

Whenever an unknown source of interference becomes an issue, you can begin the process of identifying the source by verifying that the problem is external to your radio. This advice might not sound very useful but it can save you a lot of wasted time. Start by removing the antenna connection. If the noise disappears, the source is external to your radio and you are ready to begin hunting for the noise source.

#### 27.5.1 Locating Noise Sources Inside Your Home

Professional RFI investigators and the experiences of the ARRL RFI desk confirm that most RFI sources are ultimately found to be in the complainant's home. Furthermore, locating an in-house source of RFI is so simple that it makes sense to start an investigation by simply turning off your home's main circuit breaker while listening to the noise with a battery-powered portable radio.

Remember that battery-powered equipment may also be a noise source — turn off or disable battery-powered consumer devices, as well. If you have a UPS (uninterruptible power supply) it will continue to operate with ac power removed. It may be necessary to actually disconnect the UPS battery to shut it completely down.

If the noise goes away, you know the source is in your residence. After resetting the breaker, you can further isolate the source by turning off individual breakers one at a time. Once you know the source circuit, you can then unplug devices on that circuit to find it.

**CAUTION:** *Do not attempt to remove cartridge fuses or operate exposed or open-type disconnects if it is possible to make physical contact with exposed electrical circuits.*

#### 27.5.2 Locating Noise Sources Outside Your Home

It is often possible to locate a noise source outside your home with a minimum of equipment and effort. The following process will help you determine whether the noise is radiated directly to your equipment or conducted, most frequently by power lines or wiring which then radiate the noise signal themselves.

## Hunting Noise with an SDR

SDR receivers are increasingly common and can be very good tools for locating noise sources and characterizing them. Portable SDRs are also available, potentially replacing the time-honored battery-powered AM radio. Dave Cole, NK7Z uses the SDRPlay (10 kHz – 2 GHz) with SDR software on a PC to characterize noise. ([nk7z.net/sdr-for-rfi-survey-p1](http://nk7z.net/sdr-for-rfi-survey-p1)) The PC can also store data over an extended period — he captures 24 hours of noise across multiple bands as a “site survey.” This provides information about when the noise source is active, which is often key to locating and identifying one source of many possibilities.

## Common Mistake — It's Everywhere, Joe Even Hears It Across Town!

RFI from a typical otherwise legal consumer device usually only propagates for a few hundred feet or less. However, the ARRL often receives reports of non-power line noise RFI covering an extraordinarily wide area. In this case — multiple hams hear a noise at opposite ends of a town, across a state wide area, or in some cases, even a multi-state region.

The fact of the matter is that RFI is a very common problem. And if you look hard enough, noise from a consumer device can probably be heard in most suburban neighborhoods these days. Many of them sound alike, so much so that they can easily be mistaken for each other.

Conclusion: Don't rely on RFI reported by hams in other locations as being the same RFI at your location. Before concluding that the RFI covers a widespread area, always make sure that an RFI source is not local and nearby.

Note: While power-line noise at 80 or 40 meters can propagate for miles, it won't propagate much more than that. Most power-line noise sources can sound alike so beware. Power-line noise will not propagate across state or multi-state-wide regions. In this case, the ARRL recommends the use of signature analysis to determine which source or sources are contributing to an RFI problem before making unnecessary repairs. See the section on Power-Line Noise for more information on signature analysis. — Mike Gruber, W1MG (ARRL EMC Engineering, [rfi@arrl.org](mailto:rfi@arrl.org))

Because of Part 15's absolute emissions limits, most noise sources that are compliant with Part 15 are within a few hundred feet of the complainant's antenna. They are also often on the same power transformer secondary system as the complainant if the noise is conducted. This typically reduces the number of possible residences to relatively few.

If the noise source is not compliant with Part 15 limits, it may be blocks, or in some rare cases, even thousands of feet from your station. The ballasts of grow lights, for example, have been known to exceed the FCC limits by a considerable margin and have been heard for over ½ mile. Some Part 15 devices, battery chargers for electric scooters and wheelchairs, for example, are well-known for exceeding Part 15 absolute emissions limits on conducted noise.

Electrical noise sources in a home, such as an arcing thermostat or a noisy washing machine controller, can also be tracked down in the same way as noise from consumer electronic devices. Electrical noise from an incidental emitter, such as a power line, can propagate much farther than noise from an otherwise legal unintentional emitter.

The following procedure can be used to trace a noise source to a private home, town house, apartment, or condominium. The number of homes that could be host to a source generating noise could make searching house by house impractical. In such cases, use noise tracking techniques discussed in the following sections to narrow the search to a more reasonable area.

1) Verify that the noise is active before attempting to locate it. Don't forget this all-important first step. You cannot find the source when it's not present.

2) If possible, use a beam to record bearings to the noise before leaving your residence. Walk or drive through the neighborhood with particular emphasis in the direction of the noise, if known. Try to determine the rough geographic area over which the noise can be heard. If the geographic area over which you can hear the noise is confined to a radius of several hundred feet or less, or it diminishes quickly as you leave your neighborhood, this confirms you are most likely dealing with a Part 15 consumer device.

3) Since the noise will be strongest at an electrical device connected to the residence containing the source, you want to measure the noise at a device common to the exterior of all the potential homes. Suitable devices include electric meters, main service breakers (whether outside or in a utility room), front porch lights, electric lamp posts, outside air conditioner units, or doorbell buttons. Whatever radiator you choose, it should be accessible at each home. The device you select to test as the noise radiator will be referred to in these instructions as the "radiator." Using

## Common Mistake — It's Not Me, I've Already Eliminated My House as the Source

Consumer devices are by far one of the most common sources of RFI. And once found, a surprisingly high percentage of them are actually in the complainant's home. For this reason, that we recommend that hams affected by noise open the main breaker to their residence while listening with a battery-powered radio. (See the text's caution about making sure battery-powered devices are off, as well.) If the noise goes away, you can further isolate the source by tripping the individual circuit breakers.

While all this sounds simple enough, many hams actually skip this step. Unplugging or turning off suspect sources is not the same as tripping the main breaker. Another mistake is to conclude that the source could not be in your home because you haven't bought or changed anything. Even though quiet when new, devices that fail or otherwise break down can become a source of RFI.

Conclusion: When it comes to consumer devices, do not assume that a noise source is not in your home until you open the main breaker. This is a simple and easy test to perform. Many hams have spent months – even years – searching for a noise that they could have easily found with simple breaker test. Why skip it?

— Mike Gruber, W1MG (ARRL EMC Engineering, [rfi@arrl.org](mailto:rfi@arrl.org))

## Common Mistake — Nothing In My Home Could Cause Noise Like That

One of the most common sources of RFI is the ubiquitous switching mode power supply. They are found in almost everything these days. Devices such as "wall warts," many light bulbs, computers, battery chargers, televisions and various other appliances all may and probably do include switchers capable of causing RFI. In addition, many other electronic devices have clocks and other oscillators that can cause RFI.

Despite this reality, it is surprising how many hams are convinced that the source of an RFI problem could not possibly be located in their home. They are often proven wrong.

Conclusion: Do not automatically that nothing in your home could cause an RFI problem. Almost every electronic device in a home can be suspect. Furthermore, a typical home these days can contain hundreds of potential RFI sources.— Mike Gruber, W1MG (ARRL EMC Engineering, [rfi@arrl.org](mailto:rfi@arrl.org))

## Common Mistake — I Don't Have the Equipment

Most consumer devices actually meet the FCC emission limits so the RFI problem is usually limited to about 300 feet or less. They are also often in the complainant's residence, and if not, frequently in a home connected to the same power transformer secondary system as the complainant.

With this in mind, a simple portable (battery powered) shortwave radio capable of hearing the noise is all you typical need to find it. Opening the main breaker of your home will locate many of the problems. And if it's not in your home, it's likely in an adjacent or nearby residence. By collapsing or removing the antenna, adding a step attenuator, or reducing the RF gain of the locating receiver, you can often reduce the area in which you search for the source. Reducing the signal level to something at or below the receiver's AGC threshold (or turning AGC off) can often help.

An approach that often works is to find the loudest power pole. Next, look to see what houses are connected to that pole. And finally, if possible, hold the radio a short distance from the power meters at each house. Always be sure to minimize signal levels but do not make any adjustments when making comparisons between the different meters. If access to the power meters is not possible, you can use lawn lights or similar for this. The house with the highest noise level will be the one containing the source.

Please note that spectrum analyzers are not needed. In fact, in many cases, a spectrum analyzer can add to confusion, especially if there are other sources at other frequencies.

Conclusion: Finding noisy consumer devices is often easier than most people think. Furthermore, it does not require specialized equipment. A cheap battery powered shortwave radio will often do the job. — Mike Gruber, W1MG (ARRL EMC Engineering, [rfi@arrl.org](mailto:rfi@arrl.org))

the same type of device as a test point at each time helps obtain consistent results.

4) You are now ready to compare the relative signal strengths at the radiator on each of the potential source residences. Use a detector suitable to receive the noise, typically a battery-powered receiver. Preferably, the receiver should have a variable RF gain control. An external step attenuator will also work if the antenna is external to the radio. If the antenna can be removed, a probe can also be made from a small piece of wire or paper clip to reduce the receiver's sensitivity. Start by holding the detector about two inches from the radiator at the residence where the noise source may be located. Turn the detector's RF gain control down to a point where you can just barely hear the noise. Alternately, increase the attenuation if using an external step attenuator. Record the RF gain or attenuator

## Common Mistake — It Must Be The XYZ Company — They Were Just Here

Many hams might notice activity in their neighborhood by a cable, power or telephone company. Other variations include an installation of something electrical at an adjacent or nearby residence. Typical examples might include a swimming pool pump, broadband, satellite TV or an alarm system. So far, so good...

The problem, however, will become apparent a few days later when he or she turns on their radio. Interference now plagues the amateur bands! The ham may now erroneously conclude that the interference is a result of the activity he saw in his neighborhood several days prior. In some cases, the ham is so convinced of the source that they fail to take even the most rudimentary steps to confirm their suspicions. This often leads to significant delays in resolving their problem.

The reality in a typical suburban neighborhood is that there could easily be over a thousand devices in the range of an amateur's antenna if those sources are all at the legal limit. This RFI environment is also constantly in transition as family members and nearby neighbors buy or turn on electronic devices and other appliances.

Conclusion: Do not automatically assume that you know what the source of an interference problem is based on activity that you've seen in the neighborhood. Always verify the source to the best extent possible.

— Mike Gruber, W1MG (ARRL EMC Engineering, rfi@arrl.org)

setting for each test. Because any wiring connected to a portable receiver becomes part of the receiver's antenna, including headphones, external battery, even the operator's hands and body, keep the configuration the same as you evaluate each potential source.

5) Proceed to the next residence. Again hold the detector approximately two inches from the radiator. (The detector should be placed at the same location at each residence, as much as is practical.) Since you had previously set the detector to just barely hear the noise at the residence having the interference problem, you can move on to the next residence if you do not hear the noise. Remember, in order for your detector to hear the noise at the next house, the noise level will have to be the same or higher than the previous location. If you need to increase the detector's sensitivity to be able to hear the noise, you are moving away from the noise source.

6) When you reach the next residence, if the level is lower or not heard, you're moving further from the source. Continue your search to residences in other directions or across the street. If the level is higher, then you're headed in the right direction. Be sure to turn the gain control down to the point of just barely hearing the noise as its strength increases.

7) Continue on to the next house, repeating the previous steps as necessary. The residence with the source will be the one with the strongest noise at the radiator.

Depending on the circumstances of a particular situation, it may be possible to first isolate the power pole to which the source residence is connected. Walk or drive along the power lines in the affected area while listening to the noise with a battery-powered radio. Continue to decrease the receiver's RF gain as the noise gets louder, thus reducing the area over which you can hear it. Finally, isolate the loudest pole by reducing the RF gain to a point at which you can hear it at only one pole. Once the pole has been isolated, look to see which houses are connected to its transformer. Typically this will reduce the number of potential residences to a very small number.

Be aware that not all power poles have a grounding conductor (a wire running down the side of the pole into the ground). This wire will carry currents from the entire section of the power system for that pole. A receiver held close to that wire will hear more noise than at poles without a ground wire. This may create a "false positive" with respect to homes fed from that pole — the actual noise source may be in any home connected to that section of the power system. Follow up by checking the power drop to the home and, if possible, at the meter before identifying that residence as the source of the noise. Noise on power lines can travel a long way and it is easy to be fooled by where it is heard.

**CAUTION:** *Always observe good safety practices! Only qualified people familiar with the hazards of working around energized electrical equipment should inspect power-line or other energized circuitry.*

When attempting to isolate the pole, it is often best to use the highest frequency at which you can hear the noise. Noise can exhibit peaks and nulls along a power line that are a function of its wavelength. Longer wavelengths can therefore make it difficult to pinpoint a particular point along a line. Furthermore, longer wavelength signals typically propagate further along power lines. You can often reduce your search area by simply increasing the frequency at which you look for the noise.

In some cases, tuning upward in frequency can also be used to attenuate noise. This can be especially helpful in cases where your receiver does not have an RF gain control. As mentioned previously, switchmode power supplies typically generate noise that exhibits a regular and repeating pattern of peaks and nulls across the spectrum. While a typical interval might be every 50 kHz or so, the noise will often start to diminish at the highest frequencies. The peaks in some cases might drift over time, but tuning to the highest frequency at which you can hear the noise will often attenuate it enough to help locate it. If the peak drifts however, be sure to keep your receiver set on the peak as you attempt to locate the source.

Under FCC rules, the involved utility is responsible for finding and correcting harmful interference that is being generated by its own equipment. In cases where a utility customer is using an appliance or device that generates noise, the operator of the device is responsible for fixing it — even if the noise is conducted and radiated by the power company's power lines.

### 27.5.3 Approaching Your Neighbor

Once you identify the source residence and approach your neighbor, the importance of personal diplomacy simply cannot be overstated. The first contact regarding an RFI problem between a ham and a neighbor is often the most important; it is the start of all future relations between the parties. The way you react and behave when you first discuss the problem can set the tone for everything that follows. It is important, therefore, to use a diplomatic path from the very start. A successful outcome can depend upon it!

A self-help guide for the consumer published jointly by the ARRL and the Consumer Electronics Association (CEA) often proves helpful when discussing an interference problem with a neighbor. Entitled *What To Do if You Have an Electronic Interference Problem*,

it may be printed and distributed freely. It is available on the ARRL website at [www.arrl.org/information-for-the-neighbors-of-hams](http://www.arrl.org/information-for-the-neighbors-of-hams) and also in the downloadable supplemental information accompanying this book. Be sure to download and print a copy for your neighbor before you approach him or her.

With the noise active and with a copy of the pamphlet handy, approach your neighbor with a radio in hand, preferably an ordinary AM broadcast or short-wave receiver. Let them hear it but not so loud that it will be offensive. Tell them this is the problem you are experiencing and you believe the source may be in their home. Don't suggest what you think the cause is. If you're wrong, it often makes matters worse. Give them the pamphlet and tell them it will only take a minute to determine whether the source is in their home. Most neighbors will agree to help find the source, and if they agree to turn off circuit breakers, it can be found very quickly. Start with the main breaker to verify you have the correct residence, then the individual breakers to find the circuit. The procedure then becomes the same as described for your own residence.

#### **27.5.4 Radio Direction Finding**

Radio direction finding (RDF) can be a highly effective method to locate an RFI source although it requires more specialized equipment than other methods. RDF techniques can be used to find both broadband and single-signal, narrowband noise sources. Professional interference investigators almost always use radio direction finding techniques to locate power-line noise sources. See the **Antennas** chapter for more information on direction finding antennas. The following

recommendations are most effective in locating noise from a broadband source. For narrow-band, single-signal sources, regular RDF techniques are the most effective way to determine a source's location.

A good place to start, whenever possible, is at the affected station. Use an AM receiver, preferably one with a wide IF bandwidth. An RF gain control is particularly helpful but an outboard step attenuator can be a good substitute. If there is a directional beam capable of receiving the noise, use it on highest frequency band at which the noise can be heard using the antenna. If you can hear the noise at VHF or UHF, you'll typically want to use those frequencies for RDF.

Select a frequency at which no other stations or signals are present and the antenna can discern a directional peak in the noise. Rotate the beam as required to get a bearing on the noise, keeping the RF gain at a minimum. Repeat with a complete 360° sweep using the minimum RF gain possible to hear the noise in its loudest direction. Try to decrease the RF gain to a point at which the noise clearly comes from one and only one direction. You can simultaneously increase the AF gain as desired to hear the noise.

Distant sources, including power-line noise, are generally easier to RDF at HF than nearby sources. Whenever possible, it's almost always better to use VHF or UHF when in close proximity to a source. Tracking a source to a specific residence by RDF at HF is sometimes possible. Such factors as balance and geometry of a home's internal wiring, open switch circuits and distance, may cause the residence to appear somewhat as a point source.

If the search is being conducted while mobile or portable, VHF and UHF are typi-

cally the easiest and most practical antennas. Small handheld Yagi antennas for 2 meters and 440 MHz are readily available and can serve double duty when operating portable. Many handheld receivers can be configured to receive AM on the VHF bands. Be sure to check your manual for this feature. VHF Aircraft band or "Air band" receivers are also a popular choice since they receive AM signals.

Using RDF to locate an HF noise source while in motion presents significant challenges. Conducted emissions are typical from a consumer device or appliance. In this case, the emissions can be conducted outside the residence and on to the power line. The noise can then propagate along neighborhood distribution lines, which in turn acts as an antenna. The noise can often exhibit confusing peaks and nulls along the line, and if in the vicinity of a power line radiating it, RDF can be extremely difficult, if not impossible. Depending on the circumstances, you could literally be surrounded by the near field of an antenna! You would generally want to stay away from power lines and other potential radiators when searching at HF.

Antennas for HF RDF while walking typically include small loops and ferrite rod antennas. In some cases, a portable AM broadcast radio with a ferrite rod antenna can be used for direction finding. An HF dipole made from a pair of whip antennas may be able to be used to get an approximate bearing toward the noise. Mount the dipole about 12 feet above ground (remembering to watch out for overhead conductors!) and rotate to null out the noise. For all three types of antenna, there will be two nulls in opposite directions. Note the direction of the null. Repeat this procedure from another location then triangulate to determine the bearing to the noise.

## 27.6 Power-Line Noise

This chapter's section "Identifying RFI Source Types" describes power-line noise, its causes, and methods to identify it. Power-line noise is a unique problem in several respects. First and foremost, the offending source is never under your direct control. You can't just simply "turn it off" or unplug the offending device. Nor will the source be under the direct control of a neighbor or someone you are likely to know. In the case of power-line noise, the source is usually operated by a company, municipality, or in some cases, a cooperative. Furthermore, shutting down a power line is obviously not a practical option.

Another unique aspect of power-line noise is that it almost always involves a defect of some sort. The cure for power-line noise is to fix the defect. This is almost always a utility implemented repair and one over which you do not have any direct control.

FCC rules specify that that the operator of a device causing interference is responsible for fixing it. Whenever encountering a power-line noise problem, you will be dealing with a utility and won't have the option of applying a relatively simple technical solution to facilitate a cure, as you would if the device were located in your home. Utilities have a mixed record when it comes to dealing with power-line noise complaints. In some cases, a utility will have a budget, well-trained personnel, and equipment to quickly locate and address the problem. In other cases, however, the utility is simply unable to effectively deal with power-line noise complaints or even denies their equipment can cause RFI.

What does this mean for an amateur with a power-line noise complaint? Utilities can be of any size from large corporations to local cooperatives or city-owned systems. Regardless of the category in which your utility may fall, it must follow Part 15 of the FCC rules. Dealing with a company, coop or municipality, however, as opposed to a device in your home, or a nearby neighbor that you know personally, can present its own set of unique challenges. Multiple parties and individuals are often involved, including an RFI investigator, a line crew and associated management. In some cases, the utility may never have received an RFI complaint before yours.

### 27.6.1 Before Filing a Complaint

Obviously, before filing a complaint with your local utility, it is important to verify the problem as power-line noise as best as possible and verify that it is not caused by a problem with electrical equipment in your home. Other sources, such as lighting devices and motors, can mimic power-line noise, especially to an

untrained ear. Don't overlook these important steps. Attempting to engage your utility in the resolution of an RFI problem can not only waste time but can be embarrassing if the source is right in your own home!

Utilities are not responsible for noise generated by customer-operated devices — *even if the noise is being radiated by the power lines*. They are responsible for fixing only that noise which is being generated by their equipment.

### 27.6.2 Filing a Complaint

Once you have verified the problem to be power-line noise (see this chapter's section on Identifying Power-line and Electrical Noise) and that it is not coming from a source in your home or a nearby residence, contact your utility's customer service department. In addition to your local phone book, customer service phone numbers are included on most power company websites.

**It is important to maintain a log during this part of the process.** Be sure to record any "help ticket" numbers that may be assigned to your complaint as well as names, dates and a brief description of each conversation you have with electric company personnel. If you identify specific equipment or power poles as a possible noise source, record the address and any identifying numbers on it.

Hopefully, your complaint will be addressed in a timely and professional manner. Once a noise source has been identified, it is up to the utility to repair it within a reasonable period. You and the utility may not agree on what constitutes a reasonable period, but attempt to be patient. If no action is taken after repeated requests, reporting the complaint to the ARRL and requesting assistance may be in order. (Before contacting the ARRL review The Cooperative Agreement, a section of this chapter.)

It is also important to cooperate with utility personnel and treat them with respect. Hostile and inappropriate behavior is almost always counter-productive in these situations. Remember, you want utility and other related personnel to help you — not avoid you. Even if the utility personnel working on your case seem unqualified, hostile behavior has historically never been a particularly good motivator in these situations. In fact, most protracted power-line noise cases reported to the ARRL began with an altercation in the early stages of the resolution process. In no case did it help or expedite correction of the problem.

### 27.6.3 Techniques for Locating Power-line Noise Sources

Radio direction finding (RDF) techniques

## Common Mistake — It's Coming From That Pole!

RFI problems from consumer devices, especially below 30 MHz, frequently involve conducted emissions. The RF in this case is generated by a consumer device in a home. It is then conducted by the house wiring, where it is radiated. In some cases, the RF can also be conducted to the service entrance of the home and out to a utility pole. In this case, the noise will peak at the pole and appear to be the source of the interference. It is not. The real source of the problem is in a residence connected to the pole.

Always verify that the actual source is not in a home connected to that pole. Frequently, the source residence will be connected to the power transformer secondary system on that pole. Also keep in mind that the hardware on a pole can also make for a better "antenna." This means that noise tends to peak at poles in general. Noise also tends to peak at about every half wavelength as you traverse along a power line. Be sure to use higher frequencies (i.e., shorter wavelengths) whenever possible.

**Conclusion:** Don't automatically assume that the source of an RFI problem is on a pole where the noise peaks. This is a common mistake made by many beginners!  
— Mike Gruber, W1MG (ARRL EMC Engineering, [rfl@arri.org](mailto:rfl@arri.org))

typically offer the best and most efficient approach to locating most power-line noise sources. It is the primary method of choice used by professionals. While RDF is usually the most effective method, it also requires some specialized equipment, such as a hand-held beam antenna. Although specialized professional equipment is available for RDF, hams can also use readily available amateur and homebrew equipment successfully. The downloadable supplemental information for this *Handbook* includes some power-line noise locating equipment projects you can build. This includes a simple and easy to build RDFing antenna, an ultrasonic dish, and attenuators.

Although it is the utility's responsibility to locate a source of noise emanating from its equipment, many companies simply do not possess the necessary expertise or equipment to do so. As a practical matter, many hams have assisted their utility in locating noise sources. In some cases, this can help expedite a speedy resolution.

There is a significant caveat to this approach however. Should you mislead the power company into making unnecessary repairs, they will become frustrated. This expense and time will be added to their repair list. Do not make a guess or suggestions if you don't know what is causing the noise. While some power companies might know less about the locating process than the affected ham, indiscriminate replacement of hardware almost always makes the problem worse. Nonetheless, depending on your level of expertise and the specifics of your situation, you may be able to facilitate a speedy resolution by locating the RFI source for the utility.

## 27.6.4 Amateur Power-line Noise Locating Equipment

Additional information on the equipment, antennas, and techniques used to locate power line noise are also discussed in the *ARRL Antenna Book's* material on Direction Finding. Before discussing how to locate power-line noise sources, here are a few additional equipment guidelines.

**Receiver** — You'll need a battery-operated portable radio capable of receiving VHF or UHF in the AM mode. Ideally, it should also be capable of receiving HF frequencies, especially if the interference is a problem at HF and not VHF. Some amateurs also use the aircraft band from 108 to 137 MHz. The lower frequencies of this band can sometimes enable an RFI investigator to hear the noise at greater distances than on 2 meters or 70 cm. An RF gain control is essential but an outboard step attenuator can be used as a substitute. A good S-meter is also required.

**Attenuator** — Even if your receiver has an RF gain control, an additional outboard step attenuator can often be helpful. It can not only minimize the area of a noise search but also provide added range for the RF gain control. As with other RFI sources — you'll need to add more and more attenuation as you approach the source.

**VHF/UHF Antennas** — You'll need a hand-held directional beam antenna. A popular professional noise-locating antenna is an eight-element Yagi tuned for 400 MHz. Since power-line noise is a broadband phenomenon, the exact frequency is not important. Either a 2 meter or 70 cm Yagi are capable of locating a power-line noise source on a specific power pole.

Although professional grade antennas can cost several hundred dollars, some hams can build their own for a lot less. See this book's downloadable supplemental information for the article, "Adapting a Three-Element Tape Measure Beam for Power-line Noise Hunting," by Jim Hanson, W1TRC. This low cost and easy to build antenna for locating power-line noise can be adapted for a variety of fre-

quencies and receivers. Commercial 2 meter and 70 cm antennas for portable use are also suitable if a handle is added, such as a short length of PVC pipe.

Before using an antenna for power-line noise locating, determine its peak response frequency. Start by aiming the antenna at a known power-line noise source. Tune across its range and just beyond. Using minimum RF gain control, find its peak response. Label the antenna with this frequency using a piece of tape or marking pen. When using this antenna for noise locating, tune the receiver to this peak response frequency.

If you don't have a VHF or UHF receiver that can receive AM signals, see the downloadable supplemental content for the article, "A Simple TRF Receiver for Tracking RFI," by Rick Littlefield, K1BQT. It describes the combination of a simple 136 MHz beam and receiver for portable RFI tracking.

**HF Antennas** — Depending on the circumstances of a particular case, a mobile HF whip such as a 7 or 14 MHz model can be helpful. Magnet-mount models are acceptable for temporary use. An RFI investigator can typically get within VHF range by observing the relative strength of the noise from different locations. Driving in a circle centered on the affected station will typically indicate the general direction in which the noise is strongest. As with beam antennas, determine the peak response frequency for best results.

**Ultrasonic Pinpointer** — Although an ultrasonic pinpointer is not necessary to locate the pole or structure containing the source, some hams prefer to go one more step by finding the offending noise source on that structure. Guidelines for the use of an ultrasonic device are described later in this section.

Professional-grade ultrasonic locators are often beyond the budget of the average ham. Home brewing options however, can make a practical ultrasonic locator affordable in most situations — and make a great weekend project too. See the downloadable supplemental information accompanying this book for "A Home-made Ultrasonic Power Line Arc Detector" by Jim Hanson, W1TRC.

**Oscilloscope** — A battery-powered portable oscilloscope is only required for signature analysis. See the next section, Signature or Fingerprint Method, for details.

**Thermal/Infrared Detectors and Corona Cameras** — This equipment is not recommended for the sole purpose of locating power-line noise sources. It is rare that an RFI source is even detectable using infrared techniques. Although these are not useful tools for locating noise sources, many utilities still use them for such purposes with minimal or no results. Not surprisingly, ARRL experience has shown that these utilities are typically unable to resolve interference complaints in a timely fashion.

## 27.6.5 Signature or Fingerprint Method

Each sparking interference source exhibits a unique pattern. By comparing the characteristics between the patterns taken at the affected station with those observed in the field, it becomes possible to conclusively identify the offending source or sources from the many that one might encounter. It therefore isn't surprising that a pattern's unique characteristic is often called its "fingerprint" or "signature." See **Figure 27.8** for an example.

This is a very powerful technique and a real money saver for the utility. Even though there may be several different noise sources in the field, this method helps identify only those sources that are actually causing the interference problem. The utility need only correct the problem(s) matching the pattern of noise affecting your equipment.

You as a ham can use the signature method by observing the noise from your radio's audio output with an oscilloscope. Record the pattern by drawing it on a notepad or taking a photograph of the screen. Take the sketch or photograph with you as you hunt for the source and compare it to signatures you might observe in the field.

Professional interference-locating receivers, such as the Radar Engineers Model 243 shown in **Figure 27.8**, have a built in time-domain display and waveform memory similar to a digital oscilloscope. This is the preferred method used by professional interference investigators. These receivers provide the ability to switch between the patterns saved at the affected station and those from sources located in the field.

Once armed with the noise fingerprint taken at the affected station, you are ready to begin the hunt. If you have a directional beam, use it to obtain a bearing to the noise. If multiple sources are involved, you'll need to record the bearings to each one. Knowing how high in frequency a particular noise can be heard also provides a clue to its proximity. If the noise can be heard at 440 MHz, for example, the source will typically be within walking distance. If it diminishes beginning 75 or 40 meters, it can be up to several miles away.

Since each noise source will exhibit unique characteristics, you can now match this noise "signature" with one from the many sources you may encounter in the investigation. Compare such characteristics as the duration of each noise burst, pulse shape, and number of pulses. Be wary of assuming that all devices have similar signatures when arcing. The fingerprint of a particular piece of hardware arcing may be quite different even for the same device on another pole.

If you have a non-portable oscilloscope,

(A)

(B)

Figure 27.8 — The spectrum of an unknown noise source is shown on the display of a Model 243 RFI locating receiver (A) along with a typical noise receiving antenna (B). During the RFI investigation, noise signatures not matching this pattern can be ignored. Once the matching signature originally shown in A is found, the offending noise source has been located.

Figure 27.9 — Listening for noise signals on a power distribution line at 1 MHz vs 200 MHz can result in identification of the wrong power pole as the noise source. (From Loftness, *AC Power Interference Handbook*)

you may still be able to perform signature matching by using an audio recorder. Make a high quality recording of the noise source at your station and at each suspected noise source in the field, using the same receiver if possible. Replay the sounds for signature analysis.

### 27.6.6 Locating the Source's Power Pole or Structure

Start your search in front of the affected station. If you can hear the noise at VHF or UHF, begin with a handheld beam suitable for these frequencies. As discussed previously, the longer wavelengths associated with the AM broadcast band and even HF, can create misleading "hotspots" along a line when searching for a noise source as shown in Figure 27.9.

As a general rule, only use lower frequencies when you are too far away from the source to hear it at VHF or UHF. Generally work with the highest frequency at which the noise can be heard. As you approach the source, keep increasing the frequency to VHF or UHF, depending on your available antennas. Typically, 2 meters and 70 cm are both suitable for isolating a source down to the pole level.

If you do not have an initial bearing to the noise and are unable to hear it with your portable or mobile equipment, start traveling in a circular pattern around the affected station, block-by-block, street-by-street, until you find the noise pattern matching the one recorded at the affected station.

Once in range of the noise at VHF or UHF, start using a handheld beam. You're well on your way to locating the structure contain-

ing the source. In many cases, you can now continue your search on foot. *Again, maintain minimum RF gain to just barely hear the noise over a minimum area.* This is important step is crucial for success. If the RF gain is too high, it will be difficult to obtain accurate bearings with the beam.

Power-line noise will often be neither vertically nor horizontally polarized but somewhere in between. Be sure to rotate the beam's polarization for maximum noise response. Maintain this same polarization when comparing poles and other hardware.

### 27.6.7 Pinpointing the Source on a Pole or Structure

Once the source pole has been identified, the next step becomes pinpointing the offending hardware on that pole. A pair of binoculars

Figure 27.10 — The clear plastic parabolic dish is an “ear” connected to an ultrasonic detector that lets utility personnel listen for the sound of arcs.

Figure 27.11 — The Radar Engineers Model 247 Hotstick Line Sniffer is an RF and ultrasonic locator. It is used by utility workers to pinpoint the exact piece of hardware causing a noise problem. Mounted on a hotstick, the sniffer is used from the ground or from a bucket.

on a dark night may reveal visible signs of arcing and in some cases you may be able to see other evidence of the problem from the ground. These cases are rare. More than likely, a better approach will be required. Professional and utility interference investigators typically have two types of specialized equipment for this purpose:

- An ultrasonic dish or pinpointer. The RFI investigator, even if not a lineman, can pinpoint sources on the structure down to a component level from the ground using this instrument. See **Figure 27.10**.

- An investigator can instruct the lineman on the use of a hot stick-mounted device used to find the source. This method is restricted to only qualified utility personnel, typically from a bucket truck. See **Figure 27.11**.

Both methods are similar but hams only have one option — the ultrasonic pinpointer.

**CAUTION** — *Hot sticks and hot stick mounted devices are not for hams! Do not use them. Proper and safe use of a hot stick requires specialized training. In most localities, it is generally unlawful for anyone unqualified by a utility to come within 10 feet of an energized line or hardware. This includes hot sticks.*

Remember that it may be interesting to you to determine what piece of equipment is generating noise but it is the utility’s job to positively complete the identification and then work on the equipment. Once you have identified the noise as coming from a particular location, be prepared to step back and let the professionals do their job.

### ULTRASONIC PINPOINTER TIPS

An ultrasonic dish is the tool of choice for pinpointing the source of an arc from the ground. While no hot stick is required, an unobstructed direct line-of-sight path is required between the arc and the dish. This is not a suitable tool for locating the structure containing the source. It is only useful for pinpointing a source once its pole or structure has been determined.

**Caveat:** Corona discharge, while typically not a source of RF power-line noise, can and often is a significant source of ultrasonic sound. It can often be difficult to distinguish between the sound created by an arc and corona discharge. This can lead to mistakes when trying to pinpoint the source of an RFI problem with an ultrasonic device.

The key to success, just as with locating the structure, is using gain control effectively. Use minimum gain after initially detecting the noise. If the source appears to be at more than one location on the structure, reduce the gain. In part, this will eliminate any weaker noise signals from hardware not causing the problem.

## 27.6.8 Common Causes of Power-line Noise

The following are some of the more common power-line noise sources. They’re listed in order from most common to least common. Note that some of the most common sources are not connected to a primary conductor. This in part is due to the care most utilities take to ensure sufficient primary conductor clearance from surrounding hardware. Note, too, that power transformers do not appear on this list:

- Loose staples on ground conductor
- Loose pole-top pin
- Ground conductor touching nearby hardware
- Corroded slack span insulators
- Guy wire touching neutral
- Loose hardware
- Bare tie wire used with insulated conductor
- Insulated tie wire on bare conductor
- Loose cross-arm braces
- Lightning arrestors

## 27.6.9 The Cooperative Agreement

While some cases of power-line noise are resolved in a timely fashion, the reality is that many cases can linger for an extended period of time. Many utilities simply do not have the expertise, equipment or motivation to properly address a power-line noise complaint. There are often no quick solutions. Patience can often be at a premium in these situations. Fortunately, the ARRL has a Cooperative Agreement with the FCC that can help. While the program is not a quick or easy solution, it does offer an opportunity and step-by-step course of action for relief. It emphasizes and provides for voluntary cooperation without FCC intervention.

Under the terms of the Cooperative Agreement, the ARRL provides technical help and information to utilities in order to help them resolve power-line noise complaints. It must be emphasized that the ARRL’s role in this process is strictly a technical one — it is not in the enforcement business. In order to participate, complainants are required to treat utility personnel with respect, refrain from hostile behavior, and reasonably cooperate with any reasonable utility request. This includes making his or her station available for purposes of observing and recording noise signatures. The intent of the Cooperative Agreement is to solve as many cases as possible before they go to the FCC. In this way, the FCC’s limited resources can be allocated where they are needed the most — enforcement.

As the first step in the process, the ARRL sends the utility a letter advising of pertinent Part 15 rules and offering assistance. The FCC then requires a 60-day waiting period before

the next step. If by the end of 60 days the utility has failed to demonstrate a good faith effort to correct the problem, the FCC then issues an advisory letter. This letter allows the utility another 60-day window to correct the problem.

A second FCC advisory letter, if necessary, is the next step. Typically, this letter provides another 20- or 30-day window for the utility

to respond. If the problem still persists, a field investigation would follow. At the discretion of the Field Investigator, he or she may issue an FCC Citation or Notice of Apparent Liability (NAL). In the case of an NAL, a forfeiture or fine can result.

It is important to emphasize that the ARRL Cooperative Agreement Program does not offer a quick fix. There are several built-in wait-

ing periods and a number of requirements that a ham must follow precisely. It does however provide a step-by-step and systematic course of action under the auspices of the FCC in cases where a utility does not comply with Part 15. Look for complete details, including how to file a complaint, in the ARRL's Powerline Noise FAQ web page at [www.arrrl.org/power-line-noise-faq-page](http://www.arrrl.org/power-line-noise-faq-page).

## 27.7 Elements of RFI Control

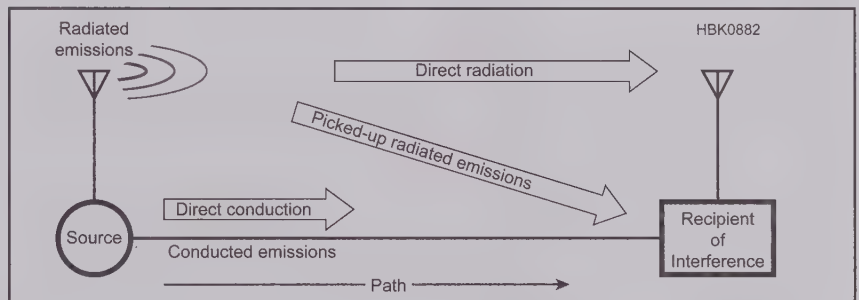

### 27.7.1 Differential- and Common-Mode Signal Control

As shown in **Figure 27.12**, the path from source to victim almost always includes some conducting portion, such as wires or cables. RF energy can be conducted directly from source to victim, be conducted onto a wire or cable that acts as an antenna where it is radiated, or be picked up by a conductor connected to the victim that acts like an antenna. When the energy is traveling along the conducting portion of its path, it is important to understand whether it is a differential- or common-mode signal.

Removing unwanted signals that cause RFI is different for each of these conduction modes. Differential-mode cures (a high-pass filter, low-pass filter, or a capacitor across the ac power line, for example) do not attenuate common-mode signals. Similarly, a common-mode choke will not affect interference resulting from a differential-mode signal.

It's relatively simple to build a differential-mode filter that passes desired signals and blocks unwanted signals with a high series impedance or presents a low-impedance to a signal return line or path. The return path for common-mode signals often involves earth ground, or even the chassis of equipment if it is large enough to form part of an antenna at the frequency of the RFI. A differential-mode filter is not part of this current path, so it can have no effect on common-mode RFI. Note that in practice, conducted emissions problems are more likely to be the result of common-mode than differential-mode signals.

In either case, an exposed shield surface is a potential antenna for RFI, either radiating or receiving unwanted energy, regardless of the shield's quality. In this way, a coaxial cable can act as an antenna for RFI if the victim device is unable to reject common-mode signals on the cable's shield. This is why it is important to connect cable shields

**Figure 27.12** — A block diagram showing every RFI problem involves three elements — a source, path and a victim. Fixing the problem requires removing one or more of them.

### RFI Email Reflector

A good source of information and help is the RFI email reflector maintained on the [contesting.com](http://contesting.com) website lists. [contesting.com/mailman/listinfo/RFI](http://contesting.com/mailman/listinfo/RFI)). Simply subscribing in digest form provides a daily dose of RFI discussion. Before asking your question, however, be sure to check the reflector's searchable archives to see if your topic has been covered recently.

in such a way that common-mode currents flowing on the shields are not allowed to enter the victim device. (See the section below on Cable Shield Connections.)

### 27.7.2 Shields and Filters

Breaking the path between source and victim is often an attractive option, especially if either is a consumer electronics device. Remember, the path will involve one or more of three possibilities — radiation, conduction, and inductive or capacitive coupling. Breaking the path of an RFI problem can require

analysis and experimentation in some cases. Obviously you must know what the path is before you can break it. While the path may be readily apparent in some cases, more complex situations may not be so clear. Multiple attempts at finding a solution may be required.

### ENCLOSURE SHIELDING

Shielding can be used to control radiated emissions — that is, signals radiated by wiring inside the device — or to prevent radiated signals from being picked up by signal leads in cables or inside a piece of equipment. Shielding can also be used to reduce inductive or capacitive coupling, usually by acting as an intervening conductor between the source and victim.

Shields are used to set boundaries for radiated energy and to contain electric and magnetic fields. Thin conductive films, copper braid and sheet metal are the most common shield materials for the electric field (capacitive coupling), and for electromagnetic fields (radio waves). At RF, the small skin depth allows thin shields to be effective at these frequencies. Thicker shielding material is needed for magnetic field (inductive coupling) to minimize the voltage caused by

induced current. At audio frequencies and below, the higher skin depth of common shield materials is large enough (at 60 Hz, the skin depth for aluminum is 0.43 inches) that high-permeability materials such as steel or mu-metal (a nickel-iron alloy that exhibits high magnetic permeability) are required.

Maximum shield effectiveness usually requires solid sheet metal that completely encloses the source or susceptible circuitry or equipment. While electrically small holes generally do not affect shield effectiveness (fine-mesh screening makes good shielding at VHF and below, for example) seams can act as a slot antenna if they are a significant fraction of a wavelength long. In addition, mating surfaces between different parts of a shield must be conductive. To ensure conductivity, file or sand off paint or other nonconductive coatings on mating surfaces.

The effectiveness of a shield is determined by its ability to reflect or absorb the undesired energy. Reflection occurs at a shield's surface. In this case, the shield's effectiveness is independent of its thickness. Reflection is typically the dominant means of shielding for radio waves and capacitive coupling, but is ineffective against magnetic coupling. Most RFI shielding works, therefore, by reflection. Any good conductor will serve in this case, even thin plating.

Magnetic material is required when attempting to break a low-frequency inductive coupling path by shielding. A thick layer of high permeability material is ideal in this case. Although the near field of low frequency magnetic fields can extend for long distances, magnetic fields generally have their greatest effect at relatively short range. Simply increasing the distance between the source and victim may help avoid the expense and difficulty of implementing a shield.

Adding shielding may not be practical in many situations, especially with many consumer products, such as a television. Adding a shield to a cable can minimize capacitive coupling and RF pickup, but it has no effect on magnetic coupling. Replacing parallel-conductor cables (such as zip cord) with twisted-pair is quite effective against magnetic coupling and also reduces electromagnetic coupling.

Additional material on shielding may be found in Chapter 2 of Ott (see the References).

## FILTERS

Many RFI problems are caused by conducted emissions which leave the noise source as common-mode signals on wiring connected to the source. The noise may travel directly from the source to the victim or it might be radiated by the wiring and picked up by wiring connected to the victim. The same design or production problems that enable conducted emissions can also work in reverse, allow-

ing the noise that has been picked up to be conducted into the victim where it causes the interference.

Filters and chokes can be very effective in dealing with a conducted emissions problem by blocking or suppressing the noise. Fortunately, filters and chokes are simple, economical and easy to try. As we'll see, use of common-mode chokes alone can often solve many RFI problems, especially at HF when common-mode current is more likely to be the culprit. In many cases, filters and chokes can also be applied externally to the victim device, avoiding the need to open an enclosure. Solving an RFI problem without having to alter a device's internal wiring is almost always preferable to the alternative.

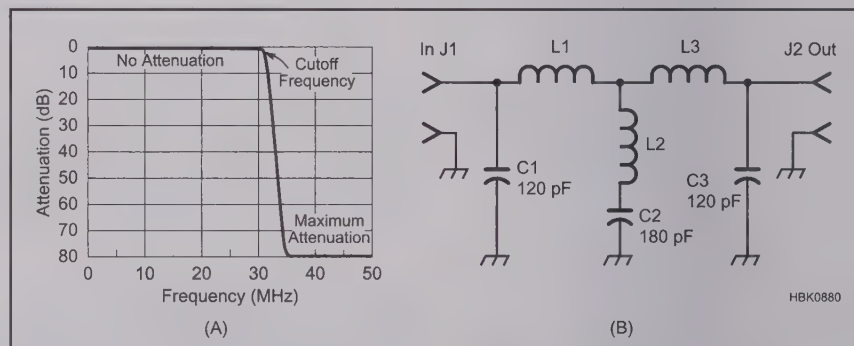

A primary means of separating signals relies on their frequency difference. Filters offer little opposition to signals with certain frequencies while blocking or shunting others. Filters vary in attenuation characteristics, frequency characteristics and power-handling capabilities. The names given to various filters are based on their uses. (More information

on filters may be found in the **Analog and Digital Filtering** chapter.)

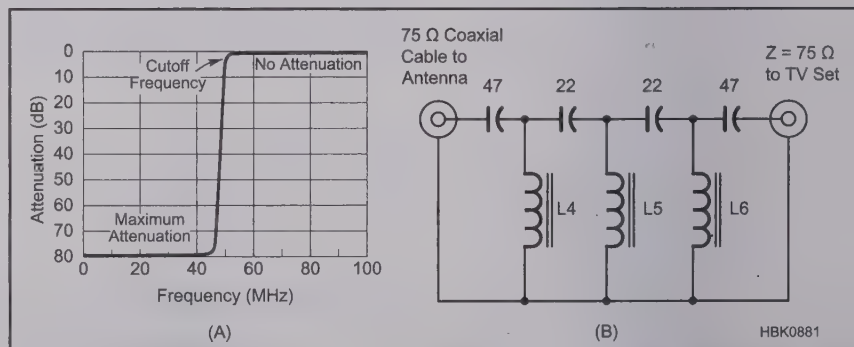

**Low-pass filters** pass frequencies below some cutoff frequency, while attenuating frequencies above that cutoff frequency. A typical low-pass filter curve is shown in **Figure 27.13A**. A schematic is shown in **Figure 27.13B**. These filters are can be difficult to construct properly so many hams choose to buy them. Many retail Amateur Radio stores that advertise in *QST* stock low-pass filters.

**High-pass filters** pass frequencies above some cutoff frequency while attenuating frequencies below that cutoff frequency. A typical high-pass filter curve is shown in **Figure 27.14A**. **Figure 27.14B** shows a schematic of a typical high-pass filter. Again, it is best to buy one of the commercially available filters.

**Bypass capacitors** can be used to cure differential-mode RFI problems by providing a low-impedance path for RF signals away from the affected lead or cable. A bypass capacitor is usually placed between a signal or power lead and the equipment chassis. If the bypass capacitor is attached to a shielded cable, the

The inductors are all #24 AWG enameled wire on T-44-0 toroid cores. L4 and L6 are each 12 turns (0.157 μH) and L5 is 11 turns (0.135 μH).

**Figure 27.15** — A “brute-force” ac-line filter. Note there is no filtering on the chassis ground connections. See the sidebar “Differential-Mode and Common-Mode Currents and RFI.”

shield should also be connected to the chassis. Bypass capacitors for HF signals are usually 0.01  $\mu\text{F}$ , while VHF bypass capacitors are usually 0.001  $\mu\text{F}$ . Leads of bypass capacitors should be kept short, particularly when dealing with VHF or UHF signals.

**AC-line filters**, sometimes called “brute-force” filters, are used to remove RF energy from ac power lines. A typical schematic is shown in **Figure 27.15**. Note that no filtering is performed on the ground or common connection. (See the Elements of RFI section for the definition for common-mode by utilities and ac power systems.)

Products from Corcom ([www.corcom.com](http://www.corcom.com)) and Delta Electronics ([www.deltaww.com](http://www.deltaww.com)) are widely available and well documented on their websites. Morgan Manufacturing ([www.morganmfg.us](http://www.morganmfg.us)) sells stand-alone ac-line filters with ac plugs and sockets, such as the M-473 and M-475 series of AC Line Protectors. SMT EMI filters are now available for brush DC motors, as well, which are increasingly common in consumer appliances. See the *Microwaves & RF* article by Jeff Elliott in the References section for more information.

AC-line filters come in a wide variety of sizes, current ratings, and attenuation. In general, a filter must be physically larger to handle higher currents at lower frequencies. The Corcom 1VB1, a compact filter small enough to fit in the junction box for many low voltage lighting fixtures, provides good common-mode attenuation at MF and HF (only on the hot and neutral lines) and its 1 A at 250 V ac rating is sufficient for many LV lighting fixtures. In general, you will get more performance from a filter that is physically small if you choose the filter with the lowest current rating sufficient for your application. (Section 13.3 of Ott covers ac-line filters.)

The best location for an ac line filter is at the enclosure of the equipment. Filter modules can be bonded to the enclosure through the case of the filter (best) or via a bonding jumper to the enclosure. Bond the enclosure of the filter to the enclosure of the equipment by the shortest possible path. Many enclosures are painted which defeats the bonding of either a filter case, terminal, or solder lug. Clean the

paint off the enclosure wherever a bonding connection is made.

Some commercial filters are built with an integral IEC power socket, and can replace a standard IEC connector if there is sufficient space behind the panel. (IEC is the International Electrotechnical Commission, an international standards organization that has created specifications for power plugs and sockets. See the **Safety** chapter for a drawing of an IEC connector.) The case of such a filter is bonded to the enclosure and interconnecting leads are shielded by the enclosure, optimizing its performance.

AC-line filters connected externally to equipment through a cord require extra attention. Any wiring between a filter and the equipment being filtered acts as an antenna and forms an inductive loop that degrades the performance of the filter. All such wiring should be as short as possible, and should be

twisted. As described above, they do not apply filtering to the ground conductor which remains active for RFI. Wind several turns of the wiring on a ferrite core to block common-mode RF current on the ground conductor.

**AC-line capacitors** — A capacitor between line and neutral or between line and ground at the noise source or at victim equipment can solve some RFI problems. (“Ground” in this sense is not “earth,” it is the power system equipment ground — the green wire — at the equipment.) Power lines, cords, and cables are often subjected to short-duration spikes of very high voltage (4 kV). Ordinary capacitors are likely to fail when subjected to these voltages, and the failure could cause a fire. Only Type X1, X2, Y1 and Y2 capacitors should be used on power wiring. AC-rated capacitors can safely handle being placed across an ac line along with the typical voltage surges that occur from time to time. Type X1 and X2

## Differential-Mode and Common-Mode Currents and RFI

*Ed Hare, ARRL Lab Manager*

Most RFI problems involve a combination of differential-mode and common-mode signals or noise. (See the definition of these terms in the section Elements of RFI and Figures 27.3 and 27.16.) It is important to understand the difference between these two types of signals because generally, a filter designed to filter one type of signal will not be effective against the other type.

A common-mode filter is designed to not affect the differential-mode signals inside of the wiring being filtered. The result is that a common-mode choke would not attenuate any differential-mode noise carried by the wires being filtered. As another example, a differential-mode filter does not usually filter the ground lead in a 3-wire ac cord or cable (see **Figure 27.15**), so any common-mode signals or noise present on the ground conductor of the ac wiring would be coupled directly through the filter.

In many cases, a noisy device creates both differential-mode and common-mode currents, due to various imbalances in the device and the wiring it is connected to. A susceptible device experiencing interference from a nearby transmitter can be the result of both common-mode and differential-mode signals being picked up on its wiring. Imbalance in ac or signal wiring usually results in both types of signals being created and coupled into and out of devices. For this reason, in many cases, both common-mode and differential-mode filtering may be required.

If an amateur decides on filtering the ac line supplying equipment belonging to a neighbor, it is often best to resolve that problem as quickly and efficiently as possible. Experimenting to find out which type of filter is needed often leads to frustration on the part of the neighbor, who may quickly lose confidence in the ham’s ability to resolve the problem. For this reason, it is usually advisable to install both common-mode and differential-mode filtering on a neighbor’s device as shown in **Figure 27.A1**, resolving the interference that is present and making future interference less likely.

**Figure 27.A1** — An ac line filter and a ferrite RF choke combined in the ac line to the affected equipment block both differential- and common-mode current. The line filter can be a standalone model with plugs and receptacles or a module in a grounded metal enclosure. The ferrite mix should be type 31 (for HF) or type 43 (for middle HF through VHF). Either a toroid or clamp-on core can be used if multiple turns can be wound on the core to create sufficient choking impedance.

capacitors are rated for use between line and neutral, and are available in values between 0.1  $\mu\text{F}$  and 1  $\mu\text{F}$ . Type X2 capacitors are tested to withstand 2.5 kV, type X1 capacitors are tested to 4 kV. Type Y1 and Y2 capacitors are rated for use between line and ground; Y1 capacitors are impulse tested to 8 kV; Type Y2 to 5 kV. Note that 4700 pF is the largest value permitted to be used between line and ground — larger values can result in excessive leakage currents.

### CABLE SHIELD CONNECTIONS

In this chapter's prior discussion of common-mode and differential-mode signals, the need for proper connection of cable shields was introduced. Improperly connected shields

on audio, RF, and data cables are an important source of radiated and conducted emissions. In addition, they provide a path into equipment for common-mode RF that has been picked up on a cable shield as common-mode current. Either way, an improperly connected shield is a likely cause of RFI.

Figure 27.16 describes the basic reasoning as to how cable shields should be connected. This is a very simplified overview to illustrate the basic concepts. Figure 27.16A shows a metal enclosure and an internal circuit, usually on a PC board. In the circuit itself, there is a common connection that could be a ground plane or point-to-point wiring or traces. Either way, there is some small impedance between any two points in the circuit's ground system.

This is shown by the resistor symbols. Current flowing in the ground system is shown as  $i_G$ . The usual practice is to connect the ground system to the enclosure (chassis ground) through a wire or hardware. That, too, has some impedance, shown as a resistor.

The actual voltage applied to the cable connection,  $V_{DM}$ , is not equal to  $V_{OUT}$ . The ground currents flowing through the ground system impedances create small voltages. So does the ground current flowing through the connection between the circuit ground system and the enclosure. All of these voltages combine to create  $V_G$ , which then combines with the amplifier output voltage,  $V_{OUT}$ , to create  $V_{DM}$ .

Outside the enclosure, a coaxial cable is terminated in an RF connector, such as a PL-259, BNC, Type N, or even a shielded, metal phono plug. The differential-mode signal currents inside the cable (shown as  $i_{DM}$ ) flow on the cable's center conductor and the *inside* of the cable shield. If a signal is picked up by the cable the resulting common-mode current (shown as  $i_{CM}$ ) flows on the *outside* of the cable shield. Due to the skin effect, the inside and outside of the cable shield are independent conductors for RF currents.

On the inside of the mating connector (such as an SO-239) a cable or wire pair connect the  $i_{DM}$  currents to the circuit. In Figure 27.16A, the center conductor in the cable is connected to some kind of amplifier output ( $V_{OUT}$ ) and the enclosure-connected part of the connector to the circuit's common or ground terminal. If the connector and shield are attached properly, there is no path between the circuit's differential-mode common terminal and the outside, common-mode surface of the cable shield. Similarly, whatever current  $i_{DM}$  is flowing inside the cable, it cannot flow to the outside of the cable where it would become common-mode current and radiate an unwanted signal — a radiated emission.

Figure 27.16B shows what happens when the shield connection goes through the enclosure and is connected directly to the inner circuit ground system. The common-mode current path is now open to  $i_G$  that flows in the connection from the circuit ground system to

Figure 27.16 — Properly (A) and improperly (B,C) connected shields showing undesired paths for common-mode current into and out of equipment. Improperly connected shields create an ingress and egress path for RF common-mode current. See the text for discussion.

### Warning: Bypassing Speaker Leads

Older amateur literature might suggest connecting a 0.01- $\mu\text{F}$  capacitor across an amplifier's speaker output terminals to cure RFI from common mode signals on speaker cables. Don't do this! Doing so can cause some modern solid-state amplifiers to break into a destructive, full-power, sometimes ultrasonic oscillation if they are connected to a highly capacitive load. Use common-mode chokes and twisted-pair speaker cables instead.

**Figure 27.17** — A common-mode RF choke wound on a toroid core is shown at top left. Several styles of ferrite cores for common-mode chokes are also shown.

the enclosure. This allows noise and signals from the circuit to escape the enclosure as a radiated emission. The path is also open for  $i_{CM}$  to flow in the enclosure connection and add to the voltage that makes up  $V_G$ . Depending on the ground system impedance, some of  $i_{CM}$  can add to  $i_G$ , as well. This allows external noise and signals to get into the circuit's ground system and disrupt its operation.

Figure 27.16C illustrates the situation when the differential-mode signal is an input to the circuit. Noise and signals on the circuit ground system can still escape the enclosure. In addition, the common-mode current  $i_{CM}$  combines with  $i_G$  which modifies  $V_G$  and  $V_{IN}$ . This can easily cause a lot of problems if the circuit is a receiver front end or other sensitive function.

Figure 27.3D showed a similar situation with two wires inside a shield. This is common for data or control connections where there might be several data lines and a dedicated signal return or signal ground circuit that is separate from the overall shield. Treat the signal return circuit as an independent circuit and do not connect it to the enclosure. Most shielded data cables have separate signal ground and shield connections. Only the shield should connect to the enclosure.

Not connecting the shield at all breaks the path for the desired differential-mode current on the inside of the shield. This forces it to find another return path, often through ground systems or power wiring. The gap in the shield creates an antenna similar to a magnetic loop that not only radiates the differential-mode signal but allows the undesired common-mode current to combine with the differential-mode signals. The whole system acts as if it were unshielded.

The need to connect the shields of cables to a shielding enclosure is clear whether they are coaxial cables, shielded twisted-pair, or multiconductor data cables. If the shield connection penetrates the enclosure and is connected directly to the circuit's ground system, both radiated emissions and incoming RFI are the likely result. In addition, the unintended current path can affect the impedance of the con-

nection to the cable as discussed in the material on common-mode chokes later in this section and in the **Transmission Lines** chapter. It is possible to devise alternate connections, such as for transceiver microphone cables, but RF filtering or chokes and careful circuit ground system design and construction are required.

### 27.7.3 Common-Mode Chokes

Common-mode chokes on ferrite cores are the most effective answer to RFI from a common-mode signal. Differential-mode filters are *not* effective against common-mode signals. (AC-line filters usually only perform differential-mode filtering as described in the preceding section.) Common-mode chokes work differently, but equally well, with coaxial cable and paired conductors. (Additional material on common-mode chokes is found in sections 3.5 and 3.6 of Ott.)

The most common form of common-mode choke is multiple turns of cable wound on a ferrite toroid core as shown in **Figure 27.17**. The following explanation applies to chokes wound on rods as well as toroids, but avoid rod cores since they may couple to nearby circuits at HF. At HF, toroid cores are recommended — beads and clamp-on ferrite cores are usually adequate.

Most of the time, a common-mode signal on a coaxial cable or a shielded, multi-wire cable is a current flowing on the outside of the cable's shield. By wrapping the cable around a magnetic core the current creates a flux in the core, creating a high imped-

ance in series with the outside of the shield. (An impedance of a few hundred to several thousand ohms are required for an effective choke.) The impedance then blocks or reduces the common-mode current. Because equal-and-opposite fields are coupled to the core from each of the differential-mode currents, the common-mode choke has no effect on differential-mode signals inside the cable.

When the cable consists of two-wire, unshielded conductors such as zip cord or twisted-pair, the equal-and-opposite differential currents each create a magnetic flux in the core. The equal-and-opposite fluxes cancel each other and the differential-mode signal experiences zero net effect. To common-mode signals, however, the choke appears as a high impedance in series with the signal: the higher the impedance, the lower the common-mode current.

It is important to note that common-mode currents on a transmission line will result in radiation of a signal from the feed line. (See the sidebar for an explanation of balanced vs unbalanced transmission lines.) The radiated signal can then cause RFI in nearby circuits. This is most common when using coaxial cable as a feed line to a balanced load, such as the dipole in the sidebar. Reducing common-mode current with a common-mode choke at the antenna feed point and where the feed line enters the residence can help reduce RFI caused by signals radiated from the feed line's shield.

Common-mode noise is also picked up by feed lines. If it is allowed to flow into the

**Figure 27.18** — Impedance vs. frequency plots for "101" size ferrite beads illustrate the effect of various ferrite materials across different frequency ranges. A 3.50 mm × 1.30 mm × 6.00 mm bead (Fair-Rite 301 size) was used for the above curve for material comparison, however all materials are not available in all shapes and sizes. Type 73 material is only available in smaller cores, type 31 is only available in larger cores, and type 75 is currently only available as a toroid core. [Graph courtesy of the Fair-Rite Corporation]

station, it can also be converted to differential-mode signals at connectors and by coupling to other cables and wiring in the station. Chokes can block this current and eliminate this source of received noise and unwanted signals which can contribute to the noise level considerably.

Common-mode chokes using ferrite cores are discussed at length in the **RF Techniques** and **Transmission Lines** chapters. They block common-mode RF current by adding a large value of resistive impedance in series with the common-mode circuit. The choke actually behaves as a parallel-self-resonant circuit that includes the winding inductance and stray capacitance along with the resistance of the core material at that frequency. (The electrical characteristics of ferrite at RF are discussed in the **RF Techniques** chapter.)

The self-resonance of a conductor passing once through most ferrite cores (considered to be one turn) used for suppression is in the range of 150 MHz, and this is where a core simply clamped around a cable will be effective. To obtain good suppression in the range of 1-50 MHz, we must wind multiple turns through the ferrite core to lower the resonant frequency. Common-mode chokes are typically wound on toroid cores with a 1-inch or greater inside diameter or a split-core clamp-on core.

**Figure 27.18** is a combined graph of the impedance of single turns through a ferrite bead of different mixes. It gives an idea of the range of ferrites that are available. By using the right material and the right number of turns through the core, choke impedance can be optimized for resistance and for the frequency range desired. Resistive impedance is desired to avoid interacting with the conductor's reactance at the frequency of use. The right material to use is specified for "suppression" over the frequency range required. (Fair-Rite mixes #31, #43, #44, and #61 are of the most use to amateurs.) This means the core's impedance is primarily resistive in that range. Chokes wound on these cores have a very low Q (because they are dissipating energy instead of storing it) so the choke's bandwidth can be as much as an octave. Chokes can be designed to work over different frequency ranges ~ placing chokes optimized for different ranges in series works over the combined frequency range.

Type 31 material is a good all-purpose material for HF and low-VHF applications, especially at low HF frequencies. Type 43 is widely used for HF through VHF and UHF. The **Component Data and References** chapter includes a table of ferrite materials and characteristics. This discussion only touches on the basic characteristics of ferrite-core common-mode chokes as they apply to dealing with RFI.

## Warning: Surplus Ferrite Cores

Don't use a core to make a common-mode choke if you don't know what type of material it is made of. Such cores may not be effective in the frequency range you are working with. This may lead to the erroneous conclusion that a common-mode choke doesn't work when a core with the correct material would have done the job.

## Feed Line Radiation — The Difference Between Balanced and Unbalanced Transmission Lines

The physical differences between balanced and unbalanced feed lines are obvious. Balanced lines are parallel-type transmission lines, such as ladder line or twin lead. The two conductors that make up a balanced line run side-by-side, separated by an insulating material (plastic, air, whatever). Unbalanced lines, on the other hand, are coaxial-type feed lines. One of the conductors (the shield) completely surrounds the other (the center).

In an ideal world, both types of transmission lines would deliver RF power to the load (typically your antenna) without radiating any energy along the way. It is important to understand, however, that both types of transmission lines require a balanced condition in order to accomplish this feat. That is, the currents in each conductor must be equal in magnitude, but opposite in polarity.

The classic definition of a balanced transmission line tells us that both conductors must be symmetrical (same length and separation distance) relative to a common reference point, usually ground. It's fairly easy to imagine the equal and opposite currents flowing through this type of feeder. When such a condition occurs, the fields generated by the currents cancel each other hence, no radiation. An imbalance occurs when one of the conductors carries more current than the other. This additional "imbalance current" causes the feed line to radiate.

Things are a bit different when we consider a coaxial cable. Instead of its being a symmetrical line, one of its conductors (usually the shield), is grounded. In addition, the currents flowing in the coax are confined to the outside portion of the center conductor and the inside portion of the shield.

When a balanced load, such as a resonant dipole antenna, is connected to unbalanced coax, the outside of the shield can act as an electrical third conductor (see **Figure 27.A**). This phantom third conductor can provide an alternate path for the imbalance current to flow. Whether the small amount of stray radiation that occurs is important or not is subject to debate. In fact, one of the purposes of a balun (a contraction of balanced to unbalanced) is to reduce or eliminate imbalance current flowing on the outside of the shield. See the **Transmission Lines** chapter of this book for more information on baluns.

**Fig 27.A** — Various current paths are present at the feed point of a balanced dipole fed with unbalanced coaxial cable. The diameter of the coax is exaggerated to show the currents clearly.

## 27.8 Troubleshooting RFI

Troubleshooting an RFI problem is a multi-step process, and all steps are equally important. First you must determine the type(s) of noise source(s) that are involved. Next, diagnose the problem by locating the noise source and the means by which it creates the noise. The final step is to identify the path by which the noise or signals reach the victim device. Only then can you cure the problem by breaking the path from source to victim.

Each step in troubleshooting an RFI problem involves asking and answering several questions: Is the problem caused by harmonics, fundamental overload, conducted emissions, radiated emissions or a combination of all of these factors? Should it be fixed with a low-pass filter, high-pass filter, common-mode chokes or ac-line filter? How about shielding, isolation transformers, a different ground or antenna configuration? By the time you finish with these questions, the possibilities could number in the millions. You probably will not see your exact problem and cure listed in this book or any other. You must not only diagnose the problem but find a cure as well!

Now that you have learned some RFI fundamentals, you can work on specific technical solutions. A systematic approach will identify the problem and suggest a cure. Most RFI problems can be solved in this way by the application of standard techniques. The following sections suggest specific approaches for different types of common interference problems. This advice is based on the experience of the ARRL RFI Desk, but is not guaranteed to provide a solution to your particular problem. Armed with your RFI knowledge, a kit of filters and tools, your local TC and a determination to solve the problem, it is time to begin. You should also get a copy of the *ARRL RFI Book*. It's comprehensive and picks up where this chapter leaves off.

### 27.8.1 General RFI Troubleshooting Guidelines

Before diving into the problem, take a step back and consider some of these "pre-troubleshooting steps."

**Is It Really EMI?** — Before trying to solve a suspected case of EMI, verify that the symptoms actually result from external causes. A variety of equipment malfunctions or external noise can look like interference.

**Is It Your Station?** — "Your" EMI problem might be caused by another ham or a radio transmitter of another radio service, such as a local CB or police transmitter. If it appears that your station is involved, operate your station on each band, mode and power level that you use. Note all conditions that produce

interference. If no transmissions produce the problem, your station *may* not be the cause. (Although some contributing factor may have been missing in the test.) Have your neighbor keep notes of when and how the interference appears: what time of day, what station, what other appliances were in use, what was the weather? You should do the same whenever you operate. If you can readily reproduce the problem with your station, you can start to troubleshoot the problem.

**Take One Away** — Can you remove the source or victim entirely? The best cure for an RFI problem is often removing the source of the noise. If the source is something broken, for example, the usual solution is to repair it. Power-line noise and an arcing electric fence

### Dummy Detectives

One particularly useful troubleshooting tool for determining where RFI is entering a victim device is called a "dummy" — a short test cable that can be inserted in a signal path. The dummy's cable shield is connected on each end of the cable but the center conductor is not connected. The dummy will allow common-mode current to flow on the shield, but will not pass a differential-mode signal. This technique was devised by Bill Whitlock of Jensen Transformers.

Dummies are quite useful in identifying where RFI is being introduced in a signal path. If the interference goes away when the dummy is inserted, the RFI is being introduced upstream of the dummy. If the interference is common-mode, it will still be present when the dummy is inserted upstream of the victim equipment that is detecting it because the dummy's shield passes common-mode noise to the victim.

An F connector dummy is easily made with two F plugs installed on a short length of coax. A double-receptacle F "barrel" adaptor can be attached to one of the plugs to create an extension cable. At one or both of the plugs, the center conductor is snipped flush with the shield so that it does not make contact with the mating connector.

Dummies made with RCA and 1/8-in connectors (mono and stereo) are also useful for the same purpose in home entertainment systems and other consumer electronics. Use high-quality connectors, such as those made by Switchcraft and Neutrik, and use good shielded cable that fits the connector, such as RG-174 subminiature coax. Cut the center conductor of the coaxial cable so that it does not make contact with the connector pins.

usually fall into this category. If a switchmode power supply is radiating noise, replace it with a linear supply. Victim devices can sometimes be replaced with a more robust piece of equipment, as well.

**Look Around** — Aside from the brain, the eyes are a troubleshooter's best tool. Installation defects contribute to many RFI problems. Look for loose connections, shield breaks in a cable-TV installation or corroded contacts in a telephone installation. Have these fixed these first. Look for wiring connected to the victim equipment that might be long enough to be resonant on one or more amateur bands. If so, a common-mode choke may be an easy cure. Ideally you'll generally want place the choke as close to the victim device as practical. If this placement proves too difficult or additional suppression is required, chokes placed at the middle of the wiring may help break up resonances. These are just a few of the possible deficiencies in a home installation.

**At Your Station** — Make sure that your own station and consumer equipment are clean. This cuts the size of a possible interference problem from your station in half! Once this is done, you won't need to diagnose or troubleshoot your station later. Also, any cures successful at your house may work at your neighbor's as well. If you do have problems in your own home, continue through the troubleshooting steps and specific cures and take care of your own problem first.

**Simplify the Problem** — Don't tackle a complex system — such as a telephone system in which there are two lines running to 14 rooms — all at once. You could spend the rest of your life running in circles and never find the true cause of the problem.

There's a better way. In our hypothetical telephone system, first locate the telephone jack closest to the telephone service entrance. Disconnect the lines to more remote jacks and connect one RFI-resistant telephone at the remaining jack. (Old-style rotary-dial phones are often quite immune to RF.) If the interference remains, try cures until the problem is solved, then start adding lines and equipment back one at a time, fixing the problems as you go along. If you are lucky, you will solve all of the problems in one pass. If not, at least you can point to one piece of equipment as the source of the problem.

**Multiple Causes** — Many RFI problems have multiple causes. These are usually the ones that give new RFI troubleshooters the most trouble. For example, consider a TVI problem caused by the combination of harmonics from the transmitter due to an arc in the transmitting antenna, an overloaded TV preamplifier, fundamental overload generat-

ing harmonics in the TV tuner, induced and conducted RF on the ac-power connections, and a common-mode signal picked up on the shield of the TV's coaxial feed line. You would never find a cure for this multiple-cause problem by trying only one cure at a time.

In this case, the solution requires that all of the cures be present at the same time. When troubleshooting, if you try a cure, leave it in place even if it doesn't solve the problem. When you add a cure that finally solves the problem entirely, start removing the "temporary" attempts one at a time. If the interference returns, you know that there were multiple causes.

**Take Notes** — In the process of troubleshooting an RFI problem, it's easy to lose track of what remedies were applied, to what equipment, and in what order. Configurations of equipment can change rapidly when you're experimenting. To minimize the chances of going around in circles or getting confused, take lots of notes as you proceed. Sketches and drawings can be very useful. When you do find the cause of a problem and a cure for it, be sure to write all that down so you can refer to it in the future.

**RFI Survival Kit** — **Table 27.1** is a list of the material needed to troubleshoot and solve most RFI problems. Having all of these materials in one container, such as a small tackle or craft box, makes the troubleshooting process go a lot smoother.

## 27.8.2 Transmitters

We start with transmitters not because most interference comes from transmitters, but because your station transmitter is under your direct control. Many of the troubleshooting steps in other parts of this chapter assume that your transmitter is "clean" (free of unwanted RF output).

Start by looking for patterns in the interference. Problems that occur only on harmonics of a fundamental signal usually indicate the transmitter is the source of the interference. Harmonics can also be generated in nearby semiconductors, such as an unpowered VHF receiver left connected to an antenna, rectifiers in a rotator control box, or a corroded connection in a tower guy wire. Harmonics can also be generated in the front-end components of the TV or radio experiencing interference.

If HF transmitter spurs at VHF are causing interference, a low-pass filter at the transmitter output will usually cure the problem. If an amplifier is used, be sure it is adjusted properly and not mistuned. If a filter at the transmitter is insufficient either the amplifier or transmitter may need repair or something else may be creating the harmonics. Transmitting filters are generally designed for 50  $\Omega$  input and output impedances, so install any filters on the input side of an antenna tuner, if one is used. Install a low-pass filter as your first step in any in-

terference problem that involves another radio service at VHF or higher frequencies.

Interference from non-harmonic spurious emissions is extremely rare in commercial radios. Any such problem indicates a malfunction that should be repaired.

### 27.8.3 Television Interference (TVI)

Digital TV has somewhat better immu-

nity than the obsolete analog system but for both formats, clear reception requires a strong signal at the TV antenna-input connector so the receiver must be in what is known as a *strong-signal area*.

TVI to a TV receiver (or a video monitor) normally has one of the following causes:

- Spurious signals within the TV channel coming from your transmitter or station.
- The TV set may be overloaded by your transmitter's fundamental signal.

## "Keeping It Simple"

Filters and chokes are the number one weapons of choice for many RFI problems whether the device is the source or the victim. They are relatively inexpensive, easy to install, and do not require permanently modifying the device.

**Common-mode choke** — Making a common-mode choke is simple. Select the type of core and ferrite material for the frequency range of the interference. (Type 31 is a good HF/low-VHF material, type #43 from 5 MHz through VHF) Wrap several turns of the cable or wire pairs around the toroid. Six to 8 turns is a good start at 10-30 MHz and 10 to 15 turns from 1.8 to 7 MHz. (Ten to 15 turns is probably the practical limit for most cables.) Ferrite clamp-on split cores and beads that slide over the cable or wire are not as effective as toroid-core chokes at HF but are the right solution at VHF and higher frequencies. For a clamp-on core, the cable doesn't even need to be disconnected from its end. Use type 31 or type 43 material at VHF, type 61 at UHF. At 50 MHz, use two turns through type 31 or 43 cores.

**"Brute-Force" ac-line filters** — RF signals often enter and exit a device via an ac power connection. "Brute-force" ac-line filters are simple and easy to install. Most ac filters only provide differential-mode suppression as described in the text. It is essential to use a filter rated to handle the device's required current.

### General installation guidelines for using chokes and filters

1. If you have a brute-force ac-line filter, put one on the device or power cord. If RFI persists, add a common-mode choke to the power cord at the device.
2. Simplify the problem by removing cables one at a time until you no longer detect RFI. Start with cables longer than 1/10th-wavelength at the highest frequency of concern. If the equipment can't operate without a particular cable, add common-mode chokes at the affected or source device.
3. Add a common-mode choke to the last cable removed and verify its effect on the RFI. Some cables may require several chokes in difficult cases.
4. Begin reconnecting cables one at a time. If RFI reappears, add a common-mode choke to that cable. Repeat for each cable.
5. Once the RFI goes away, remove the common-mode chokes you added one at a time. If the RFI does not return, you do not need to reinstall the choke. If the RFI returns after removing a choke, reinstall it. Keep only those chokes required to fix the problem.

- Signals within the TV channel from some source other than your station, such as electrical noise, an overloaded mast-mounted TV preamplifier or a transmitter in another service.
- The TV set might be defective or mis-adjusted, making it look like there is an interference problem.
- One or more connecting cables is loose or

defective. Be sure cables are of good-quality and that connectors are installed properly, especially older crimp-type F connectors.

All of these problems are made potentially more severe because TV receiving equipment is hooked up to *two* antenna systems: (1) the incoming antenna or cable feed line and (2) the ac power line and interconnecting cables. These two antenna systems can couple sig-

nificant levels of fundamental or harmonic energy into the TV set or video display! The *TVI Troubleshooting Flowchart* in **Figure 27.19** is a good starting point.

The problem could also be caused by direct pickup of the transmitted signal by an unshielded TV or device connected to the TV.

Certain types of television receivers and video monitors are reported to cause broadband RF interference to amateur signals — large-screen plasma display models were at one time reported to be the most frequent offender — and this may be difficult to cure due to the nature of the display technology. Fortunately, less-expensive, more power-efficient, and RF-quieter LCD technology has displaced plasma technology for current models.

The manufacturer of the TV or video equipment can sometimes help with an interference problem. The Consumer Electronics Association (CEA) can also help you contact equipment manufacturers. Contact them directly for assistance in locating help at [www.ce.org](http://www.ce.org).

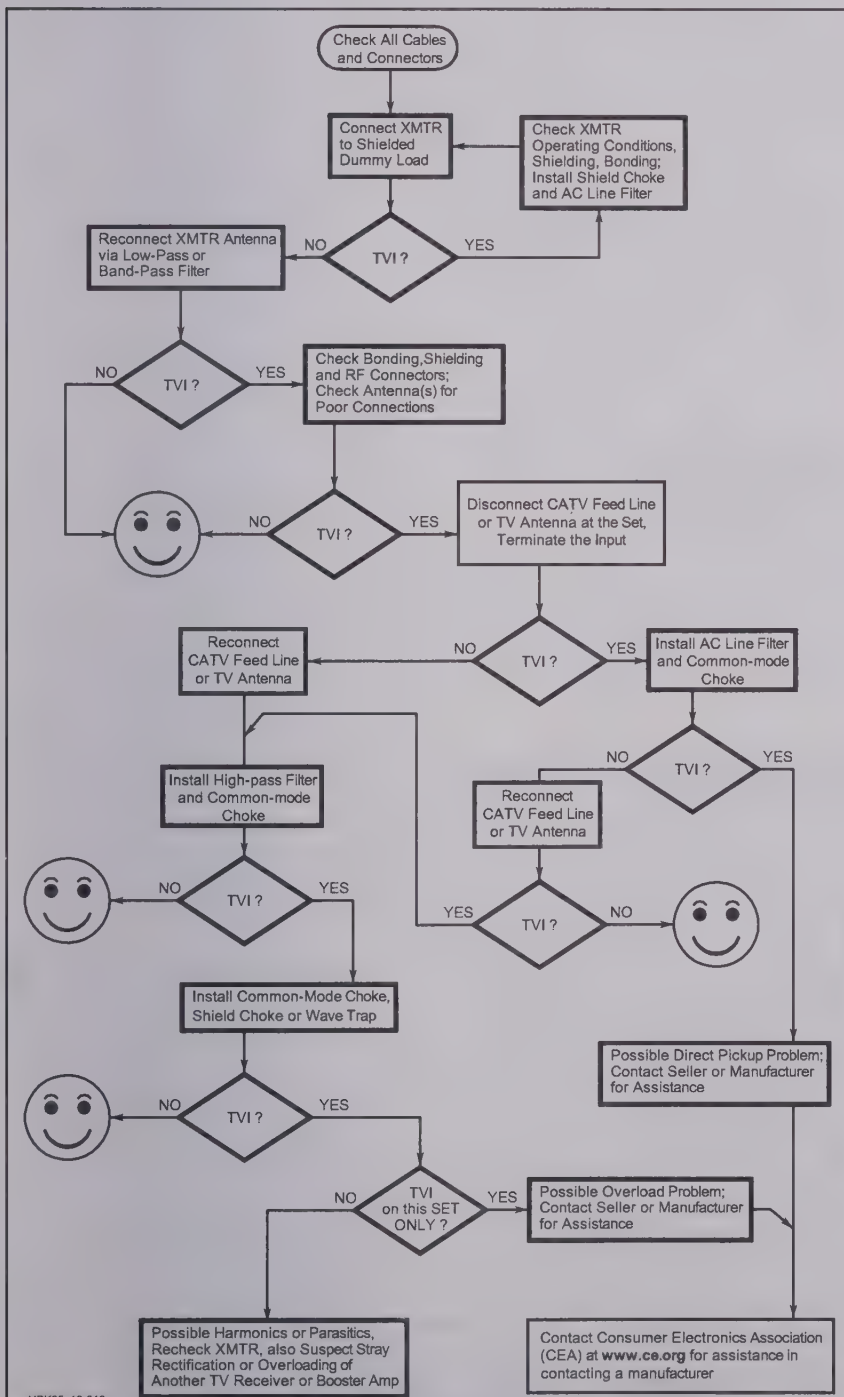

### COMMON SOURCES OF TVI

**HF transmitters** — A nearby HF transmitter is most likely to cause fundamental overload. This is usually indicated by interference to all channels, or at least all VHF channels. To cure fundamental overload from an HF transmitter to an antenna-connected TV, install a high-pass filter directly at the TV set's antenna input. (Do not use a high-pass filter on a cable-TV input because the HF range is used for data and other system signals.)

A strong HF signal can also result in a strong common-mode signal on the TV's feed line. A common-mode choke will block signals on the outside of the feed line shield, leaving the desired signals inside the feed line unaffected. **Figure 27.20** shows how a common-mode choke is constructed for a coaxial feed line. The same choke can be applied

**Figure 27.20** — To eliminate HF and VHF signals on the outside of a coaxial cable, use an 1- to 2-inch OD toroid core and wind as many turns of the cable on the core as practical.

to audio, control, and power cables, as well, to prevent RFI caused by common-mode ingress via these non-RF paths.

These filters and chokes can probably cure most cases of TVI! **Figure 27.21** shows a “bulletproof” installation for both over-the-air and cable TV receivers. If one of these methods doesn’t cure the problem, the problem is likely direct pickup in which a signal is received by the TV set’s circuitry without any conducting path being required. In that case, don’t try to fix it yourself — it is a problem for the TV manufacturer.

High-pass filters *should not* be used in a cable TV feed line (Figure 27.21A) with two-way cable devices such as cable modems, set-top boxes, and newer two-way CableCARD-equipped TVs. The high-pass filter may prevent the device from communicating via the cable network’s upstream signal path.

**VHF Transmitters** — Most TV tuners are not very selective and a strong VHF or UHF signal, including those from nearby FM and

TV transmitters, can overload the tuner easily, particularly when receiving VHF or UHF broadcasts over the air and not via a cable or satellite system. In this case, a notch or stop-band filter at the TV can help by attenuating the fundamental signal that overloads the TV tuner. Channel Plus ([www.solidsignal.com](http://www.solidsignal.com)), PAR Electronics ([www.parelectronics.com](http://www.parelectronics.com)), and Scannermaster ([www.scannermaster.com](http://www.scannermaster.com)) sell notch filters. A common-mode choke may also be necessary if the TV is responding to the common-mode fundamental signal present on the TV’s feed line. Note that most TV broadcasts are now in the UHF spectrum, regardless of what channel number they use in their identification. You can find the actual channel used by a TV station at [transition.fcc.gov/dtv/markets](http://transition.fcc.gov/dtv/markets) and [www.fcc.gov/media/engineering/dtvmaps](http://www.fcc.gov/media/engineering/dtvmaps) provides coverage maps based on Zip code.

If the VHF transmitter is generating a harmonic or other spurious emission causing RFI, a transmission line stub filter may be a good

solution. The stub can be designed to remove a signal at the transmitter. If the transmitter’s fundamental signal is overloading the receiver, a notch filter stub can also be applied at the receiver. See the **Transmission Lines** chapter for more information about these filters.

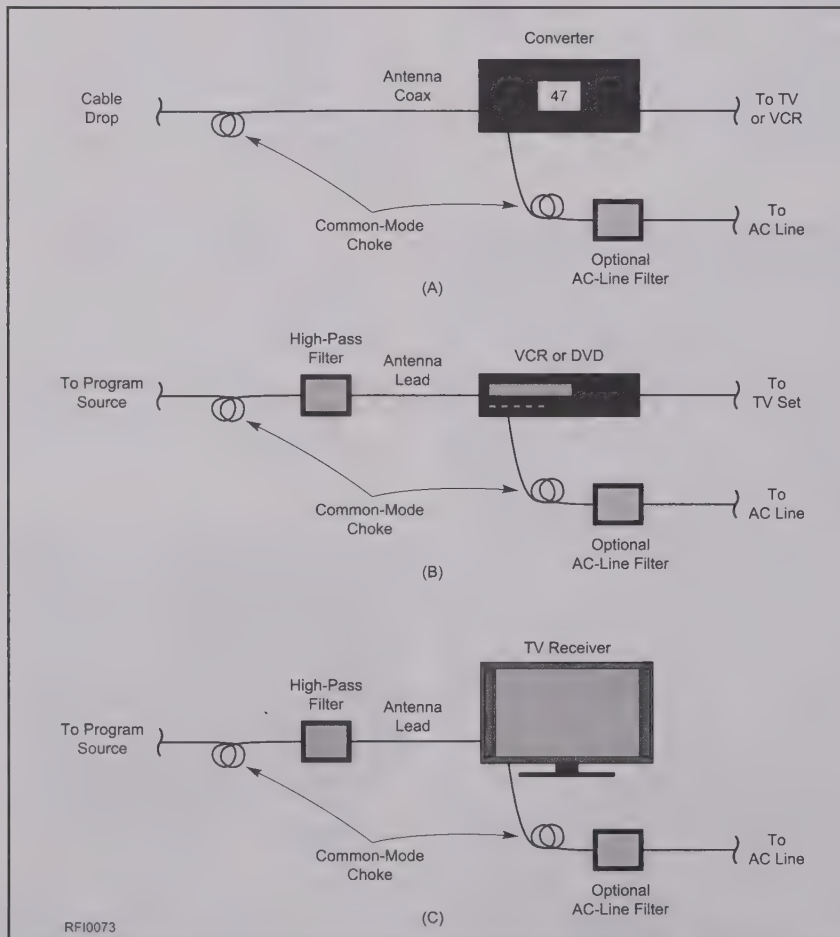

**TV Preamplifiers** — Preamplifiers are only needed in weak-signal areas and they often cause trouble, particularly when used unnecessarily in strong-signal areas. They are subject to the same overload problems as TVs and when located on the antenna mast it can be difficult to install the appropriate cures. You may need to install a high-pass notch filter at the input of the preamplifier as well as a common-mode choke on the input and power-supply wiring (if separate) to effect a complete cure. All filters, connections, and chokes must be weatherproofed. A common-mode choke will reduce RF current on the feed line’s shield.

For a common-mode feed line choke, use two 1-inch long type 43 clamp-on ferrite cores if VHF signals are causing the interference and type 61 material for UHF. HF choke design is discussed in the section on Common Mode Chokes.

**Spurious Emissions** — You are responsible for spurious emissions produced by your station. If your station is generating any interfering spurious signals, the problem may be cured there. Start by analyzing which channels are affected. A TV Channel Chart showing the relationship of the amateur band locations and their harmonics to over-the-air and cable channels is provided in this book as downloadable supplemental material. Each channel is 6 MHz wide. If the interference is only on channels that are multiples of your transmitting frequency, you probably have interference caused by harmonics of your transmitted signal. Harmonics from commercial transceivers, however, are quite rare. As mentioned earlier, significant harmonics from such equipment probably indicates a fault that needs to be repaired.

It is not certain that these harmonics are coming from your station, however. Harmonics can be generated by overloaded preamplifiers or tuner input circuits. Harmonics can also be generated like IMD products by nonlinear junctions near your station transmitter or very near the TV receiver antenna. (See the section on Intermodulation Distortion.) Your transmitter and station check “clean” — check to see if you have interference on a TV set in your own home — then you must look elsewhere for the source of the harmonics.

An inexpensive SDR receiver is a good way to see if spurious emissions of any sort — not necessarily just harmonics — are present. Several QST vendors sell complete SDR packages and SDR projects are available as well. An online survey of SDR receivers, including portable models, is available at

**Figure 27.21** — Installing common-mode chokes and high-pass filters will cure most fundamental overload interference from HF sources. Apply common-mode chokes in the ac power cord before adding ac-line filters. This technique does not address direct pickup or spurious emission problems.

**Electrical Noise** — Digital TV signals are fairly resistant to electrical noise, but in extreme cases can cause the picture to freeze or fail to be displayed as discussed in the following section on Digital TV Receivers.

On an AM receiver (including SSB or CW receivers), electrical noise usually sounds like a buzz, sometimes changing in intensity as the arc or spark sputters a bit. If you have a problem with electrical noise, refer to the section on Electrical Noise.

## DIGITAL TV (DTV) RECEIVERS

Nearly all over-the-air TV broadcasters in the US, with the exception of low-power TV stations and translators, are using the DTV (digital TV) format. Digital TV signals can cooperate with much lower signal-to-noise ratios, but are still susceptible to interference.

Interference to digital TV signals from amateur signals — narrowband interference, for instance, a CW carrier — to a 6 MHz-wide digital TV signal generally has two effects. If the interfering signal is strong enough, it will cause degraded *modulation error ratio* (MER) and degraded *bit error rate* (BER) in the digital video signal. If the amplitude of the interference is sufficient, the digital receiver's *forward error correction* (FEC) circuitry will be unable to fix the broken bits, and the digital video signal will "crash." (See the **Digital Modes** chapter for more information on coding and error correction in digital protocols.)

TV viewers watching any of the multiple video streams that may be contained within the digital video signal won't see any problems in the picture (or hear anything wrong in the sound), until the so-called "crash point" is reached. At that point, the picture will begin to show intermittent "tiling" (the picture breaking up into small squares) or blocking (freezing) in the image. As the amplitude of the interfering signal increases perhaps another 0.5 dB to 1 dB, the crash point or "digital cliff" is reached, and the picture and sound are gone! As you can see, there is a tiny window between receiving a perfect picture and receiving no picture. The same effect is produced by signal fading and may be difficult to distinguish from RFI.

Interference to the digital signal does not make its presence known through visual or audible artifacts such as streaks, lines, or tearing in the picture, or garbled audio. This means that a viewer experiencing interference may not be able to identify its source, but troubleshooting interference may also become more difficult. Nevertheless, the more robust digital modulation is often less susceptible to interference from narrowband amateur signals. A clue to the source of the interference is that interference caused by an amateur signal will occur in sync with the amateur's transmis-

sions while other types of interference will have no correlation.

The techniques for curing interference between amateur and digital TV signals are largely the same as they were for analog TV. Fundamental overload generally responds well to filters in the antenna or RF inputs. Interference caused by spurious emissions from the amateur station can be eliminated by filtering at the amateur transmitter. Common-mode problems in which RF signals are conducted into the television receiver's circuitry by external audio, video, and power cables are no more or less likely than for analog TV sets and can be addressed as described elsewhere in this chapter.

## ANALOG TV RECEIVERS

Even though over-the-air TV broadcasting largely switched to a digital format in 2009, many analog TV receivers are still in use for cable TV, satellite TV, with converter boxes for digital broadcast signals, and for displaying video from DVDs and other video sources. Older VCR and DVD players may also include an analog TV tuner to receive analog TV signals.

Interference to video displays and monitors that do not receive RF signals from an antenna or RF modulator should be assumed to be common-mode interference or direct pickup. The same applies to interference to a TV set displaying video signals (not through the antenna input). Interference that is present only on the audio is probably a case of common-mode RFI. (See the Stereos and Home Entertainment Systems section of this chapter.)

## 27.8.4 Cable TV

Cable TV has generally benefited Amateur Radio with respect to TVI. The cable system delivers a strong, consistent signal to the TV receiver, reducing susceptibility to interference from amateur signals. It is also a shielded system so an external signal shouldn't be able to cause interference. Most cable companies are responsible about keeping signal leakage (*egress*) and *ingress* — the opposite of leakage — under control, but problems do happen. Cable companies are not responsible for direct pickup or common-mode interference problems, but are responsible for leakage, ingress, and any noise radiated by common-mode currents from their equipment.

Cable companies are able to take advantage of something known as frequency reuse. That is, all radio frequencies higher than 5 MHz are used to transmit TV signals. The latter is possible because the cables and components used to transport signals to and from paying subscribers comprise what is known as a closed network. In other words, a cable company can use frequencies inside of its cables that may be used for entirely different purposes in the over-the-air environment. As long as the shielding integrity of the cable network is maintained, the cable company's signals won't interfere with over-the-air services, and vice-versa.

The reality is that the shielding integrity of a cable network is sometimes compromised, perhaps because of a loose or damaged connector, a cracked cable shield, rodent damage, poorly shielded customer premises equipment (CPE) such as cable-ready TVs and

### Common Mistake — It's the Cable System

The cable company is often incorrectly blamed for causing interference that is actually generated by consumer devices. Remember that all the individual circuit grounds in your home are bonded at the service entrance panel. The National Electrical Code also requires the cable TV ground to be bonded to this same ground system.

When you now consider that most RFI problems, especially at HF, involve conducted emissions, it's easy to see what can happen. Conducted emissions from a consumer device can propagate along ground conductors and wind up on the shield of the cable TV coax. The cable (and possibly other components of the cable TV system) can then radiate the noise.

Ron Hranac, NØIVN, also adds the following from an industry point of view: "A key point that needs to be emphasized related to this topic is that in many cases wideband noise from consumer devices that is being coupled to and radiated from the cable TV network is often assumed to be leaking cable modem digital signals. The cable company channelizes its digital signals (downstream channel bandwidths are 6 MHz, and upstream channel bandwidths are typically either 3.2 MHz or 6.4 MHz). The cable company generally does not use upstream frequencies below about 15 MHz for cable modem data transmission, although there might be a narrowband data carrier from set-top boxes in the roughly 8 MHz to 12 MHz range. Cable modem upstream signals are generally found in the 20 MHz to 42 MHz range, sometimes as low as 15 MHz or so. The cable company does not transmit signals in the diplex filter cutoff region of about 42 MHz to 50 MHz, nor does it transmit signals below about the previously mentioned 8 MHz or so."

Conclusion: Don't automatically assume that the cable TV system is the cause of an RFI problem just because it is radiating the noise. — Mike Gruber, W1MG (ARRL EMC Engineering, [rfi@arrl.org](mailto:rfi@arrl.org))

DVD and Blu-Ray players, and problems that may happen when someone tries to steal cable service! §76.605(a)(12) of the FCC Rules defines the maximum allowable signal leakage (*egress*) field strength at specified measurement distances, and §76.613 covers harmful interference. FCC Rules also mandate that cable operators "...shall provide for a program of regular monitoring for signal leakage by substantially covering the plant every three months," and leaks greater than 20 microvolts per meter ( $\mu\text{V}/\text{m}$ ) at a 10 ft. measurement distance repaired in a reasonable period of time. As well, an annual "snapshot" of leakage performance must be characterized via a flyover measurement of the cable system, or a ground-based measurement of 75% of the network.

### CABLE TV FREQUENCY USAGE

A typical modern North American cable network is designed to use frequencies in the 5 to 1002 MHz spectrum. Signals that travel from the cable company to the subscriber occupy frequencies from just above 50 MHz to as high as 1002 MHz range (this is the downstream or forward spectrum), and signals that travel from the subscriber to the cable company are carried in the 5 to as high as 42 MHz range, known as the upstream or return spectrum. The downstream is divided into 6 MHz-wide channel slots, which carry 64- or 256-QAM digitally modulated signals used for digital video, high-speed data, and telephone services. (Analog cable service has been phased out.) Upstream signals from cable modems and two-way set-top boxes are generally carried on specific frequencies chosen by the cable company. **Table 27.2** summarizes cable downstream channel allocations that overlap Amateur Radio bands. The complete North American channel plan is controlled by EIA standard 542-B. A summary of the channel structure for North America is maintained at [en.wikipedia.org/wiki/North\\_American\\_television\\_frequencies#cite\\_note-14](http://en.wikipedia.org/wiki/North_American_television_frequencies#cite_note-14).

### COMMON MECHANISMS FOR LEAKAGE AND INGRESS

As noted previously, cable TV leakage and ingress occur when the shielding integrity of the cable network is compromised. A large cable system that serves a major metropolitan area has literally millions of connectors, tens of thousands of miles of coaxial cable, thousands of amplifiers, hundreds of thousands of passives (splitters, directional couplers, and similar devices), and uncountable customer premises equipment connected to the cable network! Any of these may be a source of leakage and ingress.

### DIGITAL SIGNAL LEAKAGE

The digitally modulated signals carried in a

cable TV network use 64-QAM or 256-QAM, the latter more common. (See the **Modulation** chapter for more information on Digital TV modulation.) If a QAM signal were to leak from a cable TV network, it is possible for interference to an over-the-air service to occur, but very unlikely to be identified as from a digital TV signal. The reason for this is that a QAM signal is noise-like, and sounds like normal background noise or hiss on a typical amateur receiver. The QAM signal's digital channel power — its average power over the entire occupied bandwidth — is typically 6 to 10 dB lower than what an analog TV signal's visual carrier peak envelope power (PEP) would be on the same channel. As well, a QAM signal occupies most of the 6 MHz channel slot, and there are no carriers *per se* within that channel bandwidth. Note that over-the-air 8-VSB digital TV broadcast signals transmit a pilot carrier near the lower end of the digital "haystack," but the QAM format used by cable operators has no comparable pilot carrier.

What makes the likelihood of interference occurring (or not occurring) has in large part to do with the behavior of a receiver in the presence of broadband noise. While each downstream cable TV QAM signal occupies close to 6 MHz of RF bandwidth, the IF

bandwidth of a typical amateur FM receiver might be approximately 20 kHz. Thus, the noise power in the receiver will be reduced by  $10 \log_{10} (6,000,000/20,000) = 24.77$  dB because of the receiver's much narrower IF bandwidth compared to the QAM signal's occupied bandwidth. In addition, there is the 6 to 10 dB reduction of the digital signal's average signal PEP.

Field tests during 2009 confirmed this behavior, finding that a leaking QAM signal would not budge the S meter of a Yaesu FT-736R at low to moderate field strength leaks, even when the receiver's antenna — a resonant half-wave dipole — was located just 10 feet from a calibrated leak. In contrast, a CW carrier that produced a  $20 \mu\text{V}/\text{m}$  leak resulted in an S meter reading of S9 +15 dB, definitely harmful interference! When the CW carrier was replaced by a QAM signal whose digital channel power was equal to the CW carrier's PEP and which produced the same leakage field strength (the latter integrated over the full 6 MHz channel bandwidth), the S-meter read <S1. When the leakage field strength was increased to  $100 \mu\text{V}/\text{m}$ , the CW carrier pegged the S meter at S9 +60 dB, while the QAM signal was S3 in FM mode and between S1 and S2 in USB mode. It wasn't until the leaking QAM signal's field strength reached

several hundred  $\mu\text{V}/\text{m}$  that the “noise” (and it literally sounded like typical white noise) could be construed to be harmful interference.

One of the most common signs of possible leakage is interference to the 2 meter amateur band, especially in the vicinity of standard (STD) cable channel 18’s visual carrier on 145.25 MHz. If you suspect cable leakage, listen for the telltale broadband noise from the digital video signal over the 144-150 MHz range, and check other STD, incrementally related carrier (IRC), and harmonically related carrier (HRC) visual carrier frequencies on nearby channels listed in **Table 27.3** using a wide range receiver or scanner. (Leakage of an analog TV signal on cable channel 18 sounds like buzzing at the carrier frequencies in the table on or near 145.25 MHz. Also listen for TV channel sound on the FM aural carriers 4.5 MHz above the visual carriers.)

### LOCATING LEAKAGE SOURCES

When a cable company technician troubleshoots signal leakage, the process is similar to Amateur Radio fox hunting. The technician uses radio direction finding techniques that may include equipment such as handheld dipole or Yagi antennas, Doppler antenna arrays on vehicles, near-field probes, and commercially manufactured signal leakage detectors. Many leakage detectors incorporate what is known as “tagging” technology to differentiate a leaking cable signal from an over-the-air signal or electrical noise that may exist on or near the same frequency. Most leakage detection is done on a dedicated cable channel in the 108-138 MHz frequency range.

### ELIMINATING LEAKAGE

A large percentage of leakage and ingress problems are not the result of a single shielding defect, although this does happen. For example, a squirrel might chew a hardline feeder cable, or a radial crack might develop in the shield as a consequence of environmental or mechanical damage. Most often, leakage and ingress are caused by several small shielding defects in an area: loose or corroded hardline connectors and splices, old copper braid subscriber drop cabling, improperly installed F connectors, subscriber-installed standard “do-it-yourself” components, and the previously mentioned poorly shielded cable-ready TVs and other *customer premises equipment (CPE)*.

Other leakage and ingress problems can be caused by improper shield connections at the cable TV set-top box. The return data signal in the low HF region (3.7-5.5 MHz) can be radiated in this way, as well. Common-mode chokes at the equipment with the poor shield connection can block the RF current.

After the cable technician locates the source(s) of the leakage, it is necessary to

repair or replace the culprit components or cabling. In the case of poorly shielded TVs or DVD players, the cable technician cannot repair those devices, only recommend that they be fixed by a qualified service shop. Often the installation of a set-top box will take care of a cable-ready CPE problem because the subscriber drop cabling is no longer connected directly to the offending device.

It is important to note that interference from leakage that is received over the air cannot be eliminated at the receiver. It is an “in-band” signal just like the desired signal and can’t be filtered out or suppressed with chokes. It must be eliminated at the source of the leakage.

Similarly, RFI from cable ingress — where a clean, transmitted signal gets into the cable system signals through similar defects to those that cause leakage — must also be eliminated at the point at which the transmitted signal enters the cable system.

In both cases, a little RFI detective work may be necessary. Refer to the various RFI troubleshooting sections of this chapter and radio direction finding techniques may come in handy, as well. Once the source of leakage or point of ingress is determined, like power-line noise, it becomes the job of the cable company to repair.

### VERIFYING AN RFI SOURCE TO BE LEAKAGE

Spurious signals, birdies, harmonics, intermodulation, electrical noise, and even interference from Part 15 devices are sometimes mistaken for cable signal leakage. One of the most common is emissions from Part 15 devices that become coupled to the cable TV coax shield in some way. Non-leakage noise or spurious signals may radiate from the cable TV lines or an amplifier location, but only because the outer surface of the cable shield is carrying the coupled interference as a common-mode current.

A common non-leakage interference that may radiate from a cable network is broadband electrical interference or other noise in the MF and lower end of the HF spectrum. A common misconception is that since cable companies carry digital signals on frequencies that overlap portions of the over-the-air spectrum below 30 MHz, any “noise” that radiates from the cable plant must be leaking digital signals. This type of interference is almost always power-line electrical interference or other noise that is coupled to the cable network’s shield as a common-mode signal.

Leakage of downstream digital signals sound like broadband noise as described above, over a range of frequencies given in the channels of Table 27.3. Upstream digital signals from cable modems, which have channel bandwidths of 1.6, 3.2 or 6.4 MHz, are

typically transmitted in the roughly 20 to 40 MHz range, and are bursty in nature rather than continuous like downstream digital signals. Set-top box upstream telemetry carriers are narrowband frequency shift keying (FSK) or quadrature phase shift keying (QPSK) carriers usually in the approximately 8 to 11 MHz range.

If normal leakage troubleshooting techniques do not clearly identify the source of the interference, sometimes the cable company may temporarily shut off its network in the affected neighborhood. If the interference remains after the cable network is turned off, it is not leakage, and the cable company is not responsible for that type of interference. If the interference disappears when the cable network is turned off, then it most likely is leakage or something related to the cable network. Turning off even a small portion of the cable network is a last resort and may not be practical because of the service disruption to subscribers. It may be easier for the cable company to temporarily shut off a suspect cable channel briefly. Here, too, if the interference remains after the channel is turned off, the interference is not leakage.

### HOW TO REPORT LEAKAGE

If you suspect cable signal leakage is causing interference to your amateur station, *never attempt your own repairs to any part of the cable network, even the cabling in your own home!* Document what you have observed. For instance, note the frequency or frequencies involved, the nature of the interference, any changes to the interference with time of day, how long it has been occurring, and so forth. If you have fox-hunting skills and equipment, you might note the probable source(s) of the interference or at least the direction from which it appears to be originating.

Next, contact the cable company. You will most likely reach the cable company’s customer service department, but ask to speak with the local cable system’s Plant Manager (may also be called Chief Engineer, Director of Engineering, Chief Tech, VP of Engineering, or similar), and explain to him or her that you are experiencing what you believe to be signal leakage-related interference. If you cannot reach this individual, ask that a service ticket be created, and a technician familiar with leakage and ingress issues be dispatched. Share the information you have gathered about the interference. And as with all RFI issues, remember diplomacy!

In the vast majority of cases when cable leakage interference to Amateur Radio occurs, it is able to be taken care of by working with local cable system personnel. Every now and then for whatever reason, the affected ham is unable to get the interference resolved locally. Contact the ARRL for help in these cases.

## 27.8.5 DVD and Video Players

A DVD or similar video player usually contains a television tuner. Older models may have an analog TV channel output. (Newer models typically have an HDMI digital video interface which is less susceptible to RFI.) It is also connected to an antenna or cable system and the ac line, so it is subject to all of the interference problems of a TV receiver. Start by proving that the video player is the susceptible device. Temporarily disconnect the device from the television or video monitor. If there is no interference to the TV, then the video player is the most likely culprit. (Cables between the video player and monitor can also be the means by which RF is getting into the monitor, so a cable dummy (see the sidebar) may be a useful way to determine if that is the case and which cable or cable(s) are the problem.)

Next, find out how the interfering signal is getting into the video player. Temporarily disconnect the antenna or cable feed line from the video player. If the interference goes away, then the antenna line is involved. In this case, you can probably fix the problem with a common-mode choke or high-pass filter.

Figure 27.21 shows a bulletproof video player installation. If you have tried all of

the cures shown and still have a problem, the player is probably subject to direct pickup. In this case, you can replace it or contact the manufacturer through the CEA.

Older analog-type VCRs are quite susceptible to RFI from HF signals. The video baseband signal extends from 30 Hz to 3.5 MHz, with color information centered around 3.5 MHz and the FM sound subcarrier at 4.5 MHz. The entire video baseband is frequency modulated onto the tape at frequencies up to 10 MHz. Direct pickup of strong signals by VCRs is a common problem and may not be easily solved, short of replacing the VCR with a better-shielded model or a modern DVD player.

## 27.8.6 Non-Radio Devices

Interference to non-radio devices is not the fault of the transmitter. (A portion of the *FCC Interference Handbook*, 1990 Edition, is shown in **Figure 27.22**. Although the FCC no longer offers this *Handbook*, an electronic version is available in this book's downloadable supplemental information, from the ARRL at [www.arrl.org/fcc-rfi-information](http://www.arrl.org/fcc-rfi-information) or search the ARRL website for "cib interference handbook".) In essence, the FCC views non-radio devices that pick up nearby radio signals as improperly functioning; contact the

manufacturer and return the equipment. The FCC does not require that non-radio devices include RFI protection and they don't offer legal protection to users of these devices that are susceptible to interference.

## TELEPHONES

Landline or "wired" telephones present a very common non-TVI interference problem to Amateur Radio. As more people switch over to mobile telephone service instead of landline, this problem is gradually diminishing. Nevertheless, landline and cordless phones which are connected to the landline will continue to be with us for many years. Most cases of telephone interference to these phones can be cured by correcting any installation defects and installing telephone RFI filters where needed. The remainder of this section assumes the telephone is connected to landline service.

Telephones can improperly function as radio receivers. Semiconductor devices inside many telephones act like diodes. When such a telephone is connected to the telephone wiring (a large antenna) an AM radio receiver can be formed. When a nearby transmitter goes on the air, these telephones can be affected.

Troubleshooting techniques were discussed earlier in the chapter. The suggestion to simplify the problem applies especially to telephone interference. Disconnect all telephones except one, right at the service entrance if possible, and start troubleshooting the problem there.

If any single device or bad connection in the phone system detects RF and puts the detected signal back onto the phone line as audio, that audio cannot be removed with filters. Once the RF has been detected and turned into audio, it cannot be filtered out because the interference is at the same frequency as the desired audio signal. To effect a cure, you must locate the detection point and correct the problem there.

Defective telephone company lightning arrestors can act like diodes, rectifying any nearby RF energy. Telephone-line amplifiers or other electronic equipment may also be at fault. Do not attempt to diagnose or repair any telephone company wiring or devices on the "telco" side of your service box or that were installed by the phone company. Request a service call from your phone company.

Inspect the telephone system installation. Years of exposure in damp basements, walls or crawl spaces may have caused deterioration. Be suspicious of anything that is corroded or discolored. In many cases, homeowners have installed their own telephone wiring, often using substandard wiring. If you find sections of telephone wiring made from nonstandard cable, replace it with standard twisted-pair telephone or CAT5 cable. If you

## PART II

# INTERFERENCE TO OTHER EQUIPMENT

## CHAPTER 6

### TELEPHONES, ELECTRONIC ORGANS, AM/FM RADIOS, STEREO AND HI-FI EQUIPMENT

Telephones, stereos, computers, electronic organs and home intercom devices can receive interference from nearby radio transmitters. When this happens, the device improperly functions as a radio receiver. Proper shielding or filtering can eliminate such interference. The device receiving interference should be modified in your home while it is being affected by interference. This will enable the service technician to determine where the interfering signal is entering your device.

The device's response will vary according to the interference source. If, for example, your equipment is picking up the signal of a nearby two-way radio transmitter, you likely will hear the radio operator's voice. Electrical interference can cause sizzling, popping or humming sounds.

Figure 27.22 — Part of page 18 from the *FCC Interference Handbook* (1990 edition) explains the facts and places responsibility for interference to non-radio equipment.

do use telephone cable, be sure it is high-quality twisted-pair to minimize differential-mode pickup of RF signals.

Next, evaluate each of the telephone instruments. If you find a susceptible telephone, install a telephone RFI filter on that telephone, such as those sold by K-Y Filters. ([www.ky-filters.com](http://www.ky-filters.com)) or use DSL filters that keep the DSL data signals out of the telephones. If the home uses a DSL broadband data service, be sure that the filters do not affect DSL performance by testing online data rates with and without a filter installed at the telephone instrument.

If you determine that you have interference only when you operate on one particular ham band, the telephone wiring system either has an "RF hot spot" at that point when excited on that band or some cable in the system could be resonant and thus especially responsive on that band. Install common-mode chokes on the wiring to add a high impedance in series with the "antenna." A telephone RFI filter may also be needed. (See the section on DSL Equipment for filtering suggestions.)

**Telephone Accessories** — Answering machines and fax machines (two more telephone-related instruments that are slowly disappearing) are also prone to interference problems. All of the troubleshooting techniques and cures that apply to telephones also apply to these telephone devices. In addition, many of these devices connect to the ac mains. Try a common-mode choke and/or ac-line filter on the power cord (which may be an ac cord set, a small transformer or power supply).

**Cordless Telephones** — A cordless telephone is an unlicensed radio device that is manufactured and used under Part 15 of the FCC regulations. The FCC does not intend Part 15 devices to be protected from interference. These devices usually have receivers with very wide front-end filters, which make them very susceptible to interference.

A likely path for interference to cordless phones is as common-mode current on the base unit's connecting cables that will respond to common-mode chokes. In addition, a telephone filter on the base unit and an ac line filter may help. The best source of help is the manufacturer but they may point out that the Part 15 device is not protected from interference.

Newer cordless phone systems operating at 900 MHz and higher frequencies are often less susceptible to interference than older models are less susceptible to interference.

## AUDIO EQUIPMENT

Consumer and commercial audio equipment such as stereos, home entertainment systems, intercoms and public-address systems can also pick up and detect strong nearby transmitters. The FCC considers these non-radio devices and does not protect them from

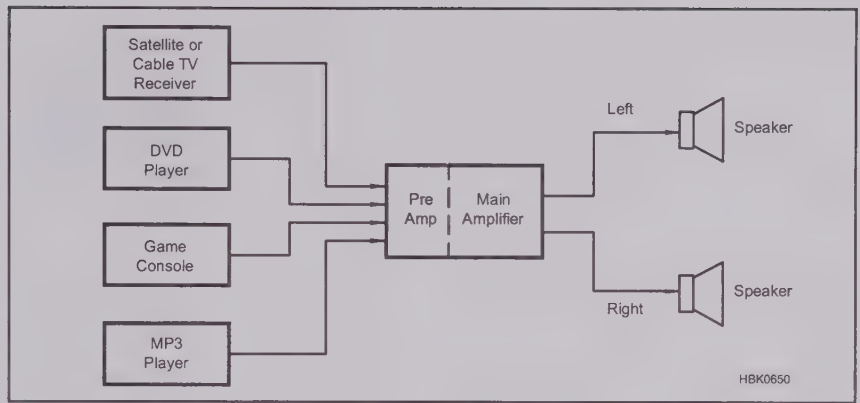

Figure 27.23 — A typical modern home-entertainment system.

licensed radio transmitters that may interfere with their operation. The RFI can be caused by one of several things: pickup on speaker leads or interconnecting cables, pickup by the ac mains wiring or direct pickup. If the interference involves wiring connected to the affected device, common-mode chokes are the most likely solution.

Use the standard troubleshooting techniques discussed earlier in this chapter to isolate problems. In a multi-component home entertainment system (as in Figure 27.23), for example, you must determine what combination of components is involved with the problem. First, disconnect all auxiliary components to determine if there is a problem with the main receiver/amplifier. Long speaker or interconnect cables are prime suspects.

**Stereos and Home Entertainment Systems** — If the problem remains with the main amplifier isolated, determine if the interference level is affected by the volume control. If so, the interference is getting into the circuit before the volume control, usually through accessory wiring. If the volume control has no effect on the level of the interfering sound, the interference is getting in after the control, usually through speaker wires.

Speaker wires are often effective antennas on HF and sometimes into VHF and above. The speaker terminals are often connected directly to the output amplifier transistors. Modern amplifier designs use a negative feedback loop to improve fidelity. This loop can conduct the detected RF signal back to the high-gain stages of the amplifier. The combination of all of these factors often makes the speaker cables the dominant receiving antenna for RFI.

There is a simple test that will help determine if the interfering signal is being coupled into the amplifier by the speaker leads. Temporarily disconnect the speaker leads from the amplifier, and plug in a test set of headphones with short leads. If there is no interference with the headphones, filtering the speaker

Figure 27.24 — Making a speaker-lead common-mode choke. Use ferrite material appropriate for the frequency of the RF interference.

leads will likely cure the problem.

Start by applying common-mode chokes. Figure 27.24 shows how to wrap speaker wires around a large (2-inch O.D. or larger) ferrite core to cure speaker-lead RFI. Type 31 material is preferred at HF. (See the section on Common-Mode Chokes in this chapter.)

In some cases, the speaker wires may be picking up RF as a differential-mode signal. To reduce differential-mode pickup, replace the zip cord speaker wire with twisted-pair wire. (#16 AWG will work for most systems with higher-power systems requiring #12 AWG.)

**Powered Speakers** — A powered speaker is one that has its own built-in power amplifier. Powered subwoofers are common in home entertainment systems and small powered speakers are often used with computer and gaming systems. If a speaker runs on batteries and/or an external power supply, or is plugged into mains power, it is a powered loudspeaker. Powered loudspeakers are notoriously susceptible to common-mode interference from internally misconnected cable shields and poor shielding. Apply suitable common-mode chokes to all wiring, including power wiring. If the RFI persists, try an RF filter

Figure 27.25 — A low-pass LC filter.

at the input to the speaker, such as the LC low-pass filter in **Figure 27.25**. Unshielded speakers may not be curable, however.

**Intercoms and Security Systems** — RFI to these systems is nearly always caused by common-mode current on interconnect wiring. Common-mode chokes are the most likely cure, but you may also need to contact the manufacturer to see if they have any additional, specific information. Twisted-pair wiring (CAT5 network cable contains four such pairs) should be used, including for audio output wiring. Wiring can often be complex, so any work on these systems should be done by a qualified sound contractor.

**Public-Address Systems** — Common-mode current is also the culprit here. Powered speakers are increasingly used and can be treated as described above. Work to remove interference should be done by the installing contractor and may require coordination between the amateur and contractor to characterize the interference and provide test assistance while the work is being done.

### COMPUTERS AND OTHER UNLICENSED RF SOURCES

Computers and microprocessor-based devices such as video games or audio players can be sources or victims of interference. These devices contain oscillators that can and do radiate RF energy. In addition, the internal functions of a computer generate different frequencies, based on the various data signals. All of these signals are digital — with fast rise and fall times that are rich in harmonics.

Computing devices are covered under Part 15 of the FCC regulations as unintentional emitters. As for any other unintentional emitter, the FCC has set absolute radiation limits for these devices. As previously discussed in this chapter, FCC regulations state that the operator or owner of Part 15 devices must take whatever steps are necessary to reduce or eliminate any interference they cause to a licensed radio service. This means that if your neighbor's video game interferes with your radio, the neighbor is responsible for correcting the problem. (Of course, your neighbor may appreciate your help in locating a solution!)

The FCC has set up two tiers of limits for computing devices. Class A is for computers used in a commercial environment. FCC Class B requirements are more stringent — for computers used in residential environ-

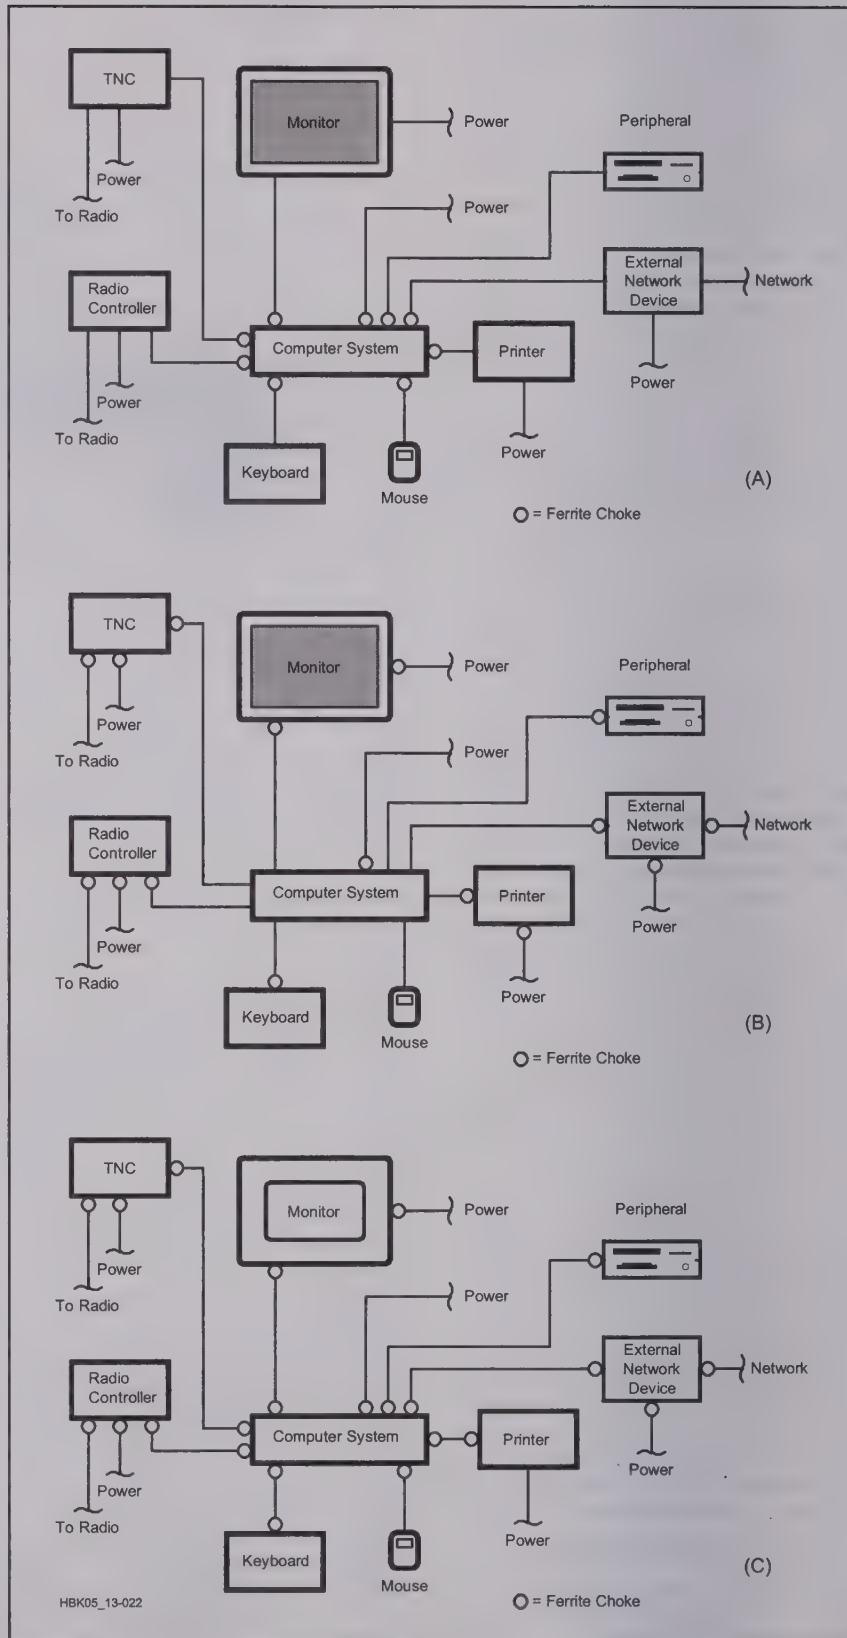

Figure 27.26 — Where to locate ferrite chokes in a computer system. At A, the computer is noisy, but the peripherals are quiet. At B, the computer is quiet, but external devices are noisy. At C, both the computer and externals are noisy.

ments. If you buy a computer or peripheral, be sure that it is Class B certified or it will probably generate interference to your amateur station or home-electronics equipment.

If you find that your computer system is interfering with your radio (not uncommon in this digital-radio age), start by simplifying the problem. Temporarily remove power from as many peripheral devices as possible and disconnect their cables from the back of the computer. (It is necessary to physically remove the power cable from the device, since many devices remain in a low-power state when turned off from the front panel or by a software command.) If possible, use just the computer, keyboard and monitor. This test may identify specific peripherals as the source of the interference.

It can be difficult to determine whether peripheral connecting cables are shielded. If possible, use shielded cables for all peripherals. Replace any unshielded cables with shielded ones; this often significantly reduces RF noise from computer systems. The second line of defense is the common-mode choke. The choke should be installed as close to the computer and/or peripheral device as practical. **Figure 27.26** shows the location of common-mode chokes in a complete computer system where both the computer and peripherals are noisy. USB-power devices can also create noise from internal power supplies and are discussed in K9YC's *National Contest Journal* paper, "Killing Receive Noise – Part 1 and 2," included in the downloadable supplemental information for this chapter.

A multi-turn common-mode choke wound for the HF bands is often ineffective at VHF. When VHF antennas are located close to these devices (or if a more distant beam is pointed at them), it may also be necessary to add one or two 2-turn chokes to suppress noise on 6 meters and multiple, single-turn, clamp-on cores for 2 meter noise. The cores for the higher frequencies should always be placed closest to the noise source, and when two pieces of digital equipment are connected, each should be considered a potential source, so VHF cores may be needed on both ends.

Switchmode power supplies in computers are often sources of interference. A common-mode choke and/or ac-line filter may cure this problem. In extreme cases of computer interference you may need to improve the shielding of the computer. (Refer to the *ARRL*

*RFI Book* for more information about this.) Don't forget that some peripherals (such as modems) are connected to the phone line, so you may need to treat them like telephones.

### GROUND-FAULT AND ARC-FAULT CIRCUIT INTERRUPTORS (GFCI AND AFCI)

GFCIs are occasionally reported to "trip" (open the circuit) when a strong RF signal, such as an amateur's HF transmission, is present. GFCI circuit breakers operate by sensing unbalanced currents in the hot and neutral conductors of an ac circuit. In the absence of RF interference, such an imbalance indicates the presence of a fault somewhere in the circuit, creating a shock hazard. The breaker then trips (opens) to remove the shock hazard.

An Arc Fault Circuit Interrupter (AFCI) circuit breaker is similar in that it monitors current to watch for a fault condition. Instead of current imbalances, the AFCI detects patterns of current that indicate an arc — one of the leading causes of home fires. The AFCI is not supposed to trip because of "normal" arcs that occur when a switch is opened or a plug is removed.

Under current codes, GFCI protection is required for all basement outlets, outdoor outlets, and for outlets in kitchens and bathrooms. AFCI protection is now required for all circuits that supply bedrooms and other areas of a home as well. Code requirements can vary so be sure to check with your local building inspector for those that apply in a specific case.

RF interference to GFCI breakers is caused by RF current or voltage upsetting normal operation of the imbalance detection circuit, resulting in the false detection of a fault. Similarly, RF current or voltage could upset the arc detection circuitry of an AFCI breaker. Some early GFCI breakers were susceptible to RFI, but as the technology has improved, fewer and fewer such reports have been received. While it is possible to add filtering or RF suppression to the breaker wiring, a simpler and less expensive solution is to replace the GFCI breaker with a new unit less susceptible to RF.

The ARRL Lab has received favorable reports on the following GFCI products:

- Leviton ([www.leviton.com](http://www.leviton.com)) GFCI outlets which are available in both 15 and 20 A versions for 120 V ac circuits as well as cord sets and user-attachable plugs and receptacles.

- Bryant ([www.bryant-electric.com](http://www.bryant-electric.com)) ground fault receptacles which feature published 0.5 V immunity from 150 kHz to 230 MHz.

- Cooper ([www.cooperindustries.com](http://www.cooperindustries.com)) GFCI products that are labeled "UL 943 compliant" on the package.

A web page on the ARRL website is maintained on GFCI/AFCI technology ([www.arrl.org/gfci-and-afci-devices](http://www.arrl.org/gfci-and-afci-devices)). Reports have not been received on AFCI products as of early 2013. Although there have been numerous reported immunity problems with AFCI products, they are now greatly reduced. Manufacturers seem to have largely fixed these issues. See [www.arrl.org/afci-devices](http://www.arrl.org/afci-devices) for more information.

### WALL TRANSFORMER SWITCHING SUPPLIES

While small, low-current linear power supplies known as "wall warts" have been widely used for many years, it is now becoming common for these devices to contain switchmode or "switcher" supplies. Because they must be manufactured very inexpensively, these supplies often have little or no RF filtering at either the ac input or dc output, frequently creating significant RFI to nearby amateurs.

The least expensive course of action may be to simply replace the switchmode supply with a linear model. If the system in which the supply is used is still under warranty, the distributor or manufacturer may be able to replace it. Otherwise, a third-party linear replacement may be available with the same voltage rating and current output equal to or higher than the original supply. Adapters may be available to convert output connector styles where necessary or new connectors installed. Older linear-style supplies can be re-used if you are willing to splice them in to replace the switchmode model.

If replacing the supply with a linear model is not an option, you will have to apply RF filters to the supply. These supplies are rarely serviceable, so filters must be installed externally. Noise is usually radiated from the output cable so winding the cable onto a ferrite core creates a common-mode RF choke as described in this chapter's Elements of RFI Control section. Since the wall-wart style supply plugs directly into a wall-mounted receptacle, a short ac extension cord or power strip cord can be made into a common-mode choke, as well.

## 27.9 Automotive RFI

Automobiles have evolved from a limited number of primitive electrical components to high technology, multi-computer systems on-wheels. Every new technology deployed can potentially interfere with amateur equipment.

Successful mobile operation depends on a multitude of factors such as choosing the right vehicle, following installation guidelines, troubleshooting and deploying the appropriate RFI fixes as needed.

A number of these factors will be covered in this section. Additionally, newly emerging electrical and hybrid-electric vehicles will be discussed, which pose unique challenges to amateur equipment installations and operation.

### 27.9.1 Before Purchasing a Vehicle

When shopping for a new vehicle intended for a mobile amateur installation, begin with research. A wealth of information is available on the Internet, and specifically at [www.arrl.org/automotive](http://www.arrl.org/automotive), where the ARRL has compiled years of data from automotive manufacturers and other hams. Email reflectors and websites may provide information from hams willing to share their experiences concerning mobile communications in their own vehicles that may be the very make and model you were considering.

Armed with research, your next step is your dealer. The manufacturer of each vehicle is the expert on how that vehicle will perform. The dealer should have good communication with the manufacturer and should be able to answer your questions. Ask about service bulletins and installation guidelines. You can also ask your dealer about fleet models of their vehicles. Some manufacturers offer special modifications for vehicles intended for sale to police, taxicabs and other users who will be installing radios (usually operating at VHF and UHF) in their cars.

When shopping for a vehicle, it is useful to take along some portable (preferably battery operated) receivers or scanners and have a friend tune through your intended operating frequencies while you drive the vehicle. This will help identify any radiated noise issues associated with that model vehicle, which can be more difficult to resolve than conducted noise. If you intend to make a permanent transceiver installation, give some consideration to how you will mount the transceiver and route the power and/or antenna cables. While looking for ways to route the wiring, keep in mind that some newer cars have the battery located in the trunk or under the rear seat, and that may make power wire routing easier.

Test the car before you buy it. A dealer

expects you to take the car for a test ride; a cooperative dealer may let you test it for radio operation, too. A fair amount of checking can easily be performed without digging too deeply into the car. Check the vehicle for noise with a portable receiver on VHF, where your handheld transceiver will do the job nicely. On HF, you can usually locate noise with a portable short-wave receiver, or operate your HF transceiver with a portable antenna and cigarette-lighter plug. With the engine running, tune across the bands of interest. You may hear some noise, or a few birdies, but if the birdies don't fall on your favorite frequency, this is an encouraging sign! Check with the vehicle completely off, with the key in the ignition, and with the vehicle running — electronic subsystems operate in different ways with the vehicle running or not running.

To test the vehicle for susceptibility to your transmitted signal, you must transmit. It is important to note that without a full and complete installation, you will not be able to fully assess the effects of full-power transmissions on a vehicle. Any testing done with temporary equipment installations cannot be considered an absolute guarantee because an installed transmitter connected directly to the vehicle's power source may cause the vehicle to act differently.

To perform transmit tests, bring your radio and a separate battery (if permitted by dealer) so you can transmit at full power while in motion without having to run cables to the vehicle battery. Use a magnet-mount antenna (several *QST* advertisers sell mounts suitable for HF) for temporary testing. (Use the magnet-mount carefully; it is possible to scratch paint if any particles of dirt get on the bottom of the magnets.) Transmit on each band you will use to see if the RF has any effect on the vehicle. Lack of response to your transmissions is a good sign, but does not mean the vehicle is immune to RF as a permanent installation will result in different (likely stronger) field strengths and distributions in and around the vehicle and a permanent antenna more effectively coupled to the vehicle.

On both transmit and receive, you may want to experiment with the placement of the antenna. Antenna placement plays an important role in operation, and you may be able to find an optimal location for the antenna that predicts good performance with a permanent installation.

### 27.9.2 Transceiver Installation Guidelines

While most amateurs are familiar with the process of installing a transceiver, there are preferred practices that will help minimize

potential problems. These include support from the automotive dealer, typical “best practices” installations, and consideration of special situations.

The first step is to ensure that your installation complies with both the vehicle manufacturer's and radio transceiver manufacturer's installation guidelines. Links to domestic automotive manufacturer installation guidelines are found at [www.arrl.org/automotive](http://www.arrl.org/automotive). Automotive manufacturers that import vehicles for sale here do not publish installation guidelines because their vehicles are not typically used in police, fire and taxicab applications within the US.

The installation guidelines of different manufacturers vary as to how to install a radio transceiver's power leads. Most manufacturers recommend that the positive and negative leads from the radio be run directly to the battery. This minimizes the potential for the interaction between the radio's negative lead currents and vehicle electronics. If the manufacturer recommends that both wires be connected to the battery, they will also require that both wires be fused. This is necessary because, in the unlikely event that the connection between the battery and the engine block were to fail, excessive current could be drawn on the radio's negative lead when the vehicle starter is engaged.

Some vehicles provide a “ground block” near the battery for a negative cable to be connected. On these vehicles, run the negative power lead, un-fused, to the “ground block.” When this technique is recommended by the manufacturer, the interaction between the power return currents and vehicle electronics has been evaluated by the manufacturer. In all cases, the most important rule to remember is this: If you want the manufacturer to support your installation, do it exactly the way the installation guidelines tell you to do it.

If no installation guidelines are available for your vehicle, the practices outlined below will improve compatibility between in-vehicle transceivers and vehicle electronics:

#### 1) Transceivers

- Transceivers should be mounted in a location that does not interfere with vehicle operator controls and visibility, provides transceiver ventilation, and be securely mounted.

- Ensure all equipment and accessories are removed from the deployment path of the airbag and safety harness systems.

#### 2) Power Leads

- The power leads should be twisted together from the back of the rig all the way to the battery. This minimizes the area formed by the power leads, reducing susceptibility to transients and RFI.

- Do not use the vehicle chassis as a power return.

- The power leads should be routed along the body structure, away from vehicle wiring harnesses and electronics.

- Any wires connected to the battery should be fused at the battery using fuses appropriate for the required current.

- Use pass-through grommets when routing wiring between passenger and engine compartments.

- Route and secure all under hood wiring away from mechanical hazards.

### 3) Coaxial Feed Lines

- The coaxial feed line should have at least 95% braided coverage. The cable shield should be connected to every coaxial connector for the entire circumference (no “pigtailed”).

- Keep antenna feed lines as short as practical and avoid routing the cables parallel to vehicle wiring.

### 4) Antennas

- Antenna(s) should be mounted as far from the engine and the vehicle electronics as practical. Typical locations would be the rear deck lid or roof. Metal tape can be used to provide an antenna ground plane on non-metallic body panels.

- Care should be used in mounting antennas with magnetic bases, since magnets may affect the accuracy or operation of the compass in vehicles, if equipped.

- Since the small magnet surface results in low coupling to the vehicle at HF, it is likely that the feed line shield will carry substantial RF currents. A large (2-inch OD or larger toroid) common-mode choke at the antenna will help reduce this current, but will also reduce any radiation produced by that current.

- Adjust the antenna for a low SWR.

## 27.9.3 Diagnosing Automotive RFI

Most VHF/UHF radio installations should result in no problems to either the vehicle systems or the transceiver, while HF installations are more likely to experience problems. In those situations where issues do occur, the vast majority are interference to the receiver from vehicle on-board sources of energy that are creating emissions within the frequency bands used by the receiver. Interference to one of the on-board electronic systems can be trivial or it can cause major problems with an engine control system.

The dealer should be the first point of contact when a problem surfaces, because the dealer should have access to information and factory help that may solve your problem. The manufacturer may have already found a fix for your problem and may be able to save your mechanic a lot of time (saving you money in the process). If the process works properly, the dealer/customer-service network can be helpful. In the event the dealer is unable to solve your problem, the next section includes

general troubleshooting techniques you can perform independently.

## GENERAL TROUBLESHOOTING TECHNIQUES

An important aspect is to use the source-path-victim model presented earlier in this chapter. The path from the source to the receiver may be via radiation or conduction. If the path is radiation, the electric field strength (in V/m) received is reduced as a function of the distance from the source to the receiver. In most cases, susceptible vehicle electronics is in the near-field region of the radiating source, where the electric and magnetic fields can behave in complex ways. In general, however, the strength of radiated signals falls off with distance.

The best part of all this is that with a general-coverage receiver or spectrum analyzer, a fuse puller and a shop manual, the vehicle component needing attention may be identified using a few basic techniques. The only equipment needed could be as simple as:

- A mobile rig, scanner or handheld transceiver, or
- Any other receiver with good stability and an accurate readout, and
- An oscilloscope for viewing interference waveforms

## BROADBAND NOISE

Automotive broadband noise sources include:

- Electric motors such as those that operate fans, windows, sunroof, AM/FM antenna deployment, fuel pumps, etc.
- Ignition spark

If you suspect electric motor noise is the cause of the problem, obtain a portable AM or SSB receiver to check for this condition. Switch on the receiver and then activate the electric motors one at a time. When a noisy motor is switched on, the background noise increases. It may be necessary to rotate the radio, since portable AM radios use a directional ferrite rod antenna.

To check whether fuel pumps, cooling fans, and other vehicle-controlled motors are the source of noise, pull the appropriate fuse and see whether the noise disappears.

A note concerning fuel pumps: virtually every vehicle made since the 1980s has an electric fuel pump, powered by long wires. It may be located inside the fuel tank. Don't overlook this motor as a source of interference just because it may not be visible. Electric fuel-pump noise often exhibits a characteristic time pattern. When the vehicle ignition switch is first turned on, without engaging the starter, the fuel pump will run for a few seconds, and then shut off when the fuel system is pressurized. At idle, the noise will generally follow the pattern of being present for a few seconds before stopping, although in

some vehicles the fuel pump will run almost continuously if the engine is running.

## NARROWBAND NOISE

Automotive narrowband noise sources include:

- Microprocessor based engine control systems
- Instrument panel
- RADAR obstacle detection

Start by moving the antenna to different locations. Antenna placement is often key to resolving narrowband RFI problems. However, if antenna location is not the solution, consider pulling fuses. Tune in and stabilize the noise, then find the vehicle fuse panels and pull one fuse at a time until the noise disappears. If more than one module is fed by one fuse, locate each module and unplug it separately. Some modules may have a “keep-alive” memory that is not disabled by pulling the fuse. These modules may need to be unplugged to determine whether they are the noise source. Consult the shop manual for fuse location, module location, and any information concerning special procedures for disconnecting power.

A listening test may verify alternator noise, but if an oscilloscope is available, monitor the power line feeding the affected radio. Alternator whine appears as full-wave rectified ac ripple and rectifier switching transients superimposed on the power system's dc power voltage (see **Figure 27.27**).

Alternators rely on the low impedance of the battery for filtering. Check the wiring from the alternator output to the battery for corroded contacts and loose connectors when alternator noise is a problem.

Receivers may allow conducted harness noise to enter the RF, IF or audio sections (usually through the power leads), and interfere with desired signals. Check whether the

**Figure 27.27** — Alternator whine consists of full-wave rectified ac, along with pulses from rectifier switching, superimposed on the vehicle's dc power voltage.

interference is still present with the receiver powered from a battery or power supply instead of from the vehicle. If the interference is no longer present when the receiver is operating from a battery or external supply, the interference is conducted via the radio power lead. Power line filters installed at the radio may resolve this problem.

### 27.9.4 Eliminating Automotive RFI

The next section includes various techniques to resolve the more common RFI problems. As a caveat, performing your own RFI work, in or out of warranty, you assume the same risks as you do when you perform any other type of automotive repair. Most state laws (and common sense) say that those who work on cars should be qualified to do so. In most cases, this means that work should be done either by a licensed dealer or automotive repair facility.

#### CONDUCTED INTERFERENCE

To reduce common-mode current, impedance can be inserted in series with the wiring in the form of common-mode chokes. (See this chapter's section on Common-Mode Chokes.) Wire bundles may also be wound around large toroids for the same effect.

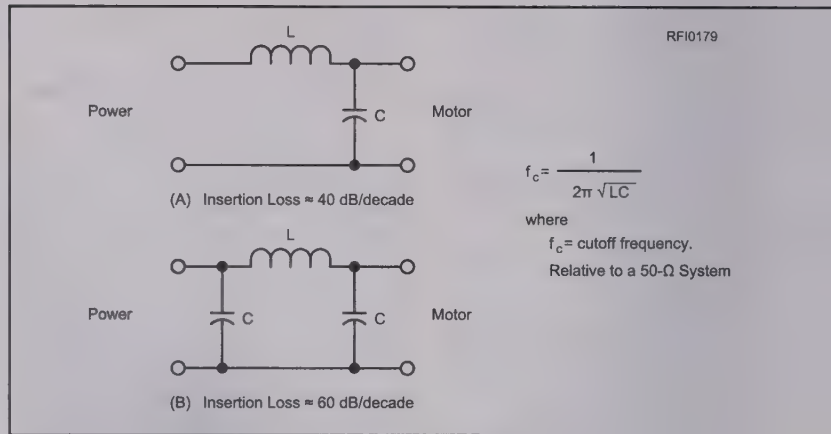

Mechanical considerations are important in mobile installations. A motor vehicle is subject to a lot of vibration. If a choke is installed on a wire, this vibration may cause the choke to flex the wire, which may ultimately fail. It is critical that any additional shielding and/or chokes placed on wiring have been installed by qualified personnel who have considered these factors. These must be properly secured, and sometimes cable extenders are required to implement this fix.

#### RFI TO ON-BOARD CONTROL SYSTEMS

RFI to a vehicle's on-board control and electronic modules should be treated with common-mode chokes at the connection to the module. Some success has been reported by using braid or metal foil to cover a wire bundle as a shield and connecting the shield to the vehicle chassis near the affected module. Vehicle electronic units should not be modified except by trained service personnel according to the manufacturer's recommendations. The manufacturer may also have specific information available in the form of service bulletins.

#### FILTERS FOR DC MOTORS

If the motor is a conventional brush- or commutator-type dc motor, the following cures shown in **Figure 27.28** are those generally used. As always, the mechanic should consult with the vehicle manufacturer. To

**Figure 27.28** — Filters for reducing noise from dc motors

diagnose motor noise, obtain an AM or SSB receiver to check the frequency or band of interest. Switch on the receiver, and then activate the electric motors one at a time. When a noisy motor is switched on, the background noise increases as well.

The pulses of current drawn by a brush-commutator motor generate broadband RFI that is similar to ignition noise. However, the receiver audio sounds more like bacon frying rather than popping. With an oscilloscope displaying receiver audio, the noise appears as a series of pulses with random space between the pulses. Such broadband noise generally has a more pronounced effect on AM receivers than on FM. Unfortunately, the pulses may affect FM receivers by increasing the “background noise level” and will reduce perceived receiver sensitivity because of the degraded signal-to-noise ratio.

#### ALTERNATOR AND GENERATOR NOISE

As mentioned previously, brush-type motors employ sliding contacts which can generate noise. The resulting spark is primarily responsible for the “hash” noise associated with these devices. Hash noise appears as overlapping pulses on an oscilloscope connected to the receiver audio output. An alternator also has brushes, but they do not interrupt current. They ride on slip rings and supply a modest current, typically 4 A to the field winding. Hence, the hash noise produced by alternators is relatively minimal.

Generators use a relay regulator to control field current and thus output voltage. The voltage regulator's continuous sparking creates broadband noise pulses that do not overlap in time. They are rarely found in modern automobiles.

Alternator or generator noise may be conducted through the vehicle wiring to the power input of mobile receivers and transmitters and may then be heard in the audio output. If

alternator or generator noise is suspected and an oscilloscope is not available, temporarily remove the alternator belt as a test. (This may not be possible in vehicles with a serpentine belt.)

#### IGNITION NOISE

Ignition noise is created by fast-rise-time pulses of coil current discharging across air gaps (distributor and spark plug). The theoretical models (zero rise time) of such pulses are called impulse functions in the time domain. When viewed in the frequency domain, the yield is a constant spectral energy level starting nearly at 0 Hz and theoretically extending up in frequency to infinity. In practical real ignition pulses have a finite rise time, so the spectral-energy envelope decreases above some frequency.

It turns out that noise generated by ignition sparks and fuel injector activation manifests themselves as a regular, periodic “ticking” in the receiver audio output, which varies with engine RPM. If an oscilloscope were connected to the audio output, a series of distinct, separate pulses would appear. At higher speeds it sounds somewhat musical like alternator whine, but with a harsher note (more harmonic content).

A distinguishing feature of ignition noise is that it increases in amplitude under acceleration. This results from the increase in the required firing voltage with higher cylinder pressure. (Noise at higher frequencies may also be reproduced better by the audio circuits.) Since ignition noise is usually radiated noise, it should disappear when the antenna element is disconnected from the antenna mount. The radiation may be from either the secondary parts of the system or it may couple from the secondary to the primary of the coil and be conducted for some distance along the primary wiring to the ignition system, then radiated from the primary wiring.

Two main methods are employed to sup-

press this noise — one involves adding an inductance, and the other involves adding resistance — both in the secondary (high voltage) wiring. This is shown in **Figure 27.29**. The addition of these elements does not have a measurable effect on the engine operation, because the time constants involved in the combustion process are much longer than those associated with the suppression components. (Note that modifying your vehicle's ignition system may be considered as tampering with your vehicle's emission control system and may affect your warranty coverage — work with your dealer or limit your efforts to changing spark plug wires or possibly shielding them.)

The resistance method suppresses RFI by dissipating energy that would have been radiated and/or conducted. Even though the amount of energy dissipated is small, it is still enough to cause interference to sensitive amateur installations. The other method uses inductance and even though the energy is not dissipated, suppression occurs because the inductor will store the pulse energy for a short time. It then releases it into the ignition return event, which is a low impedance path, reducing the RFI.

For traditional “Kettering” inductive discharge ignition systems, a value of about 5  $\Omega$  impedance (either real and/or reactive) in the spark plug circuit provides effective suppression and, with this value, there is no detectable engine operation degradation. (Capacitor discharge systems, in comparison, are required to have very low impedance on the order of tens of ohms in order to not reduce spark energy, so they are not tolerant of series impedance). Most spark plug resistances are designed to operate with several kV across the plug gap, so a low-voltage ohmmeter may not

give proper resistance measurement results.

The term “resistor wire” is somewhat misleading. High-voltage ignition wires usually contain both resistance and inductance. The resistance is usually built into suppressor spark plugs and wires, while there is some inductance and resistance in wires, rotors and connectors. The elements can be either distributed or lumped, depending on the brand, and each technique has its own merit. A side benefit of resistance in the spark plug is reduced electrode wear.

### COIL-ON-PLUG IGNITION NOISE

Many newer spark-ignition systems incorporate a “coil on plug” (COP) or “coil near plug” (CNP) approach. There are advantages to this from an engine operation standpoint, and this approach may actually reduce some of the traditional sources of ignition system RFI. This is because of the very short secondary wires that are employed (or perhaps there are no wires — the coil is directly attached to the spark plug). This reduces the likelihood of coupling from the secondary circuit to other wires or vehicle/engine conductive structures.

There will always be some amount of energy from the spark event that will be conducted along the lowest impedance path. It may mean that the energy that would have been in the secondary circuit will be coupled back on the primary wiring harness attached to the coils. This means that the problem may go from a radiated to a conducted phenomenon.

The fix for this in some cases may actually be easier or harder than one might think. Two approaches that have been used with success are ferrite cores and bypass capacitors.

Ferrite cores are recommended as the first choice, since they require no electrical modification to the vehicle. Ferrite clamp-on split

cores are added to the 12-V primary harness attached to the coils. Depending on the frequency of the noise and selection of the ferrite material, there can be significant improvement (as much as 10 dB). Key to optimizing the amount of suppression is to determine where the noise “peaks” and selecting the correct ferrite material for that frequency range (see this chapter's section Using Ferrite for RFI Suppression).

The second method is to add a bypass capacitor between the primary wire of the 12-V coil and ground in the harness near the coil assemblies (there may be 2, 3 or 4 coils). This must be done carefully because it could affect the functionality of the ignition system and — perhaps most importantly — may void the vehicle warranty. This “bypass” capacitor performs the same function that bypass capacitors in any other application perform — separating the noise from the intended signal/power.

### 27.9.5 Electric and Hybrid-Electric Vehicles

Electric vehicles (EV) and hybrid-electric vehicles (HEV) are quickly becoming a practical means of transportation. EV/HEVs are advanced vehicles that pose unique challenges for amateur equipment. While EV/HEVs provide improved emissions and fuel economy, EV/HEVs utilize switched high voltage and high current to control propulsion. The switching techniques used generate RFI within much of our frequency bands — a cause for concern, particularly for HF operation.

This section is designed to enlighten vehicle owners to the challenges and to make suggestions when installing mobile amateur equipments in an EV/HEV.

Figure 27.29 — Ignition noise suppression methods.

## EV AND HEV ARCHITECTURE

Most EVs and HEVs have similar electrical traction system (ETS) architectures consisting of a high voltage battery supplying energy to an inverter which controls an electric motor within a transmission connected to the drive wheels. The main difference between the two is that an HEV includes an internal combustion engine to aid in propulsion and a pure EV is strictly electrically powered.

The heart of the ETS is a device called an inverter. It simply converts dc voltage from the high voltage battery (typical voltage range from 42 to 350 V dc) to an ac waveform supplying the electric motor. This dc-to-ac conversion is performed by a matrix of six transistor switches. The switches chop the dc voltage into systematically varying pulses called pulse-width-modulation (PWM) to form an adjustable frequency and RMS voltage suitable to power electric motor.

In most cases, the ac voltage from the inverter is a three-phase waveform similar to industrial applications because three-phase motors can be smaller, more efficient, and provide greater torque than single-phase motors.

**IMPORTANT** — Bright orange cables connect the battery pack to the inverter and the inverter to the drive motor, transferring voltage and current to and from the inverter. Because of the non-sinusoidal waveforms being transferred, these cables are shielded and terminated at each end. Under no condition should these cables be disconnected or modified, because the high voltage system depends on a delicate balance of sensors and safety mechanisms. Possible malfunction and damage to the ETS may occur if modified.

### EV AND HEV RFI CONCERNS

The inverter uses PWM to convert dc battery voltage to an ac waveform. The phase-to-phase terminal voltage appears in **Figure 27.30** as rectangular blocks with positive and

negative amplitude equal to the battery voltage. For example, a 300 V dc battery pack will provide 600 V peak-to-peak at the motor terminals. In **Figure 27.30**, the same terminal voltage signal is sent through a low pass filter to show how PWM forms a sinusoidal waveform. Each pulse is essentially a square wave. Harmonics from these pulses fall within most of our amateur HF bands, affecting radio performance. Because EV/HEV systems are evolving rapidly, check the ARRL's Automotive RFI web page ([www.arrl.org/automotive](http://www.arrl.org/automotive)) for more information.

### EV AND HEV RFI REMEDIES

Troubleshooting techniques described earlier apply in diagnosing RFI from EV/HEV systems. Limited RFI remedies are available associated to components within the ETS. Work with your dealer when you suspect the ETS as the RFI source. Do not attempt to modify or repair your ETS; the dealer's service center is most qualified to inspect and repair your EV/HEV electrical traction system.

During installation, mobile equipment power cables and antenna coaxial cables should be routed as far as possible from the bright orange cables. Common-mode chokes can decrease noise on 12-V dc power cables. Additionally, antenna placement plays a critical role in mobile equipment performance. Areas such as the top of a roof or trunk sometimes provide additional shielding.

### 27.9.6 Automotive RFI Summary

Most radio installations should result in no problems to either the vehicle systems or any issues with the transceiver. However, manufacturer, make and models differ, thus introducing challenges during amateur equipment installations.

Begin by researching your vehicle of interest

**Figure 27.30** — Phase-to-phase motor terminal voltage.

and visiting the dealer. Insist on transmitting and receiving your favorite frequencies as you test drive. Request information pertaining to the manufacturer's transceiver installation guidelines. If manufacturer information is not available, follow the guidelines described earlier.

After installation, RFI problems may appear. Report you problem to the dealer, because they have access to manufacturer service bulletins which may describe a repair solution. Additional troubleshooting and remedies are also described previously to assist in successful communication.

Limited RFI remedies are available associated to components within the ETS. Work with your dealer when you suspect the ETS is the RFI source. Do not attempt to modify or repair your ETS; the dealer's service center is most qualified to inspect and repair your EV/HEV electrical traction system.

Lastly, the latest version of the *ARRL RFI Book* contains additional information on RFI in automobiles. More details are given about noise sources, troubleshooting techniques, a troubleshooting flow chart, additional filtering techniques, and information on EV/HEVs.

# 27.10 RFI Projects

Note: Additional RFI projects are included in the downloadable supplemental information accompanying this book.

## 27.10.1 Project: RF Sniffer

Every home is full of electrical equipment capable of emitting electromagnetic radiation to interfere with radio amateurs trying to listen to signals on the bands. This project detects the radiation that causes problems to the amateur, and the noise can be heard. This device will allow you to demonstrate the “noise” with which we have to contend.

An article by AC9PR detailing the entire

construction process, including an improved RF pickup coil, is available in the downloadable supplemental information.

### CONSTRUCTION

The circuit (Figure 27.31) uses a telephone pick-up coil as a detector, the output of which is fed into a LM741 IC preamplifier, followed by a LM386 IC power amplifier. See Table 27.4 for the complete component list. An article by AC9PR detailing the entire construction process including an improved RF pickup coil is available in the downloadable supplemental information.

The project is built on a perforated board

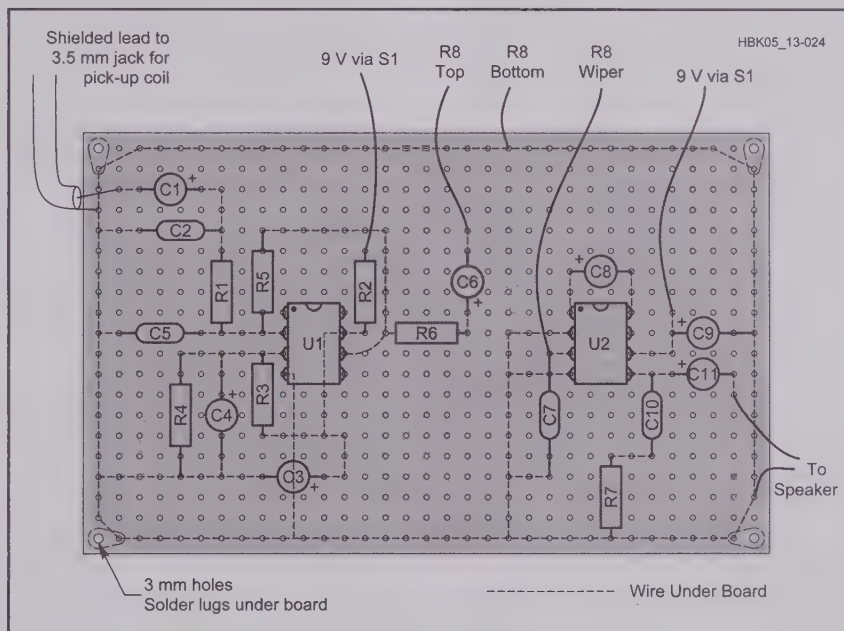

(Figure 27.32), with the component leads pushed through the holes and joined with hook-up wire underneath. There is a wire running around the perimeter of the board to form an earth bus.

Build from the loudspeaker backwards to R8, apply power and touch the wiper of R8. If everything is OK you should hear a loud buzz from the speaker. Too much gain may cause a feedback howl, in which case you will need to adjust R8 to reduce the gain. Complete the rest of the wiring and test with a finger on the input, which should produce a click and a buzz. The pick-up coil comes with a lead and 3.5 mm jack, so you will need a suitable socket.

## 27.11 RFI Glossary

**Balanced circuit** — A circuit whose two conductors have equal impedance to a common reference, such as a reference plane or circuit common.

**Bond** — (noun) A low-impedance, mechanically robust, electrical connection.

**Common-mode** — In a group of conductors, such as multi-conductor cable, voltage or current that is present with the same amplitude, phase and polarity on all conductors in a group, such as multi-conductor cable. AC current flowing on the outside of a coaxial cable shield is also considered to be common-mode current.

**Conducted RFI** — RFI received via a conducting path.

**Coupled RFI** — RFI received via inductive or capacitive coupling between conductors.

**Differential mode** — A signal that that exists and is transmitted as a voltage *between* two conductors of a cable. At any instant, signal current on one conductor is equal to but of the opposite polarity to the current on the other conductor. Ordinary connections between equipment in systems are differential mode signals.

**Disturbance** — The improper operation of a device as a result of interference.

**Electric field** — The field present between two or more conductive objects as a result of potential difference (voltage) between those objects.

**Electromagnetic field** — The combination of a magnetic field and electric field in which the fields are directly related to each other, are at right angles to each other, and move through space as radio waves in a direction that is mutually

perpendicular to both fields. An electrical conductor designed to produce electromagnetic fields when carrying an RF current is called an antenna.

**Equipment ground** — The connection of all exposed parts of electrical equipment to earth, or to a body that serves in place of earth.

**Fundamental overload** — 1. (Receiver Performance) Interference to a receiver caused by a signal at its input whose amplitude exceeds the maximum signal-handling capabilities of one or more receiver stages. 2. (RF interference) — Any disruption to the function of any RFI victim caused by the fundamental component of a transmitted signal or intended in-band output of a transmitter.

**Ground** — 1. A low impedance electrical connection to earth, or to a body that serves in place of earth. 2. A common signal connection in an electrical circuit.

**Immunity** — The ability of a device to function properly in the presence of unwanted electromagnetic energy. (After Ott, section 1.3)

**Intentional radiator** — A device that uses radio waves to transmit information by antenna action. A radio transmitter, with its associated antenna, is an intentional radiator.

**Interference** — 1. Disruption of a device's normal function as a result of an electromagnetic field, voltage, or current. 2. Disruption by a signal or noise of a receiver's ability to acquire and process a desired signal.

**Magnetic field** — The field produced by a permanent magnet or current flow through a conductor.

**Path** — The route by which

electromagnetic energy is transferred from a transmitter to a receiver or from a source to a victim.

**Radiated RFI** — RFI received through radiation.

**Shielding** — A conductive barrier or enclosure interposed between two regions of space with the intent of preventing a field in one region from reaching the other region.

**Source** — A device that produces an electromagnetic, electric, or magnetic field, voltage, or current. If RFI is the result, the source is an *RFI source*.

**Spurious emission** — An emission outside the bandwidth needed for transmission of the mode being employed, the level of which may be reduced without reducing the quality of information being transmitted. Spurious emissions are most commonly the products of distortion (harmonics, intermodulation), of circuit instability (oscillation, including RF feedback), or of digital transmission with excessively fast rise times (including key clicks). Phase noise, such as that produced by a frequency synthesizer is also a spurious emission.

**Susceptibility** — The capability of a device to respond to unwanted electromagnetic energy. (After Ott, section 1.3)

**System ground** — A bond between one current-carrying conductor of the power system and earth.

**Unintentional radiator** — A device that produces RF as part of its normal operation but does not intentionally radiate it.

**Victim** — A device that receives interference from a *source*.

# Safe Practices

Previously named “Safety,” this chapter focuses on safe practices to avoid common hazards associated with ac electrical power, antennas and towers, and RF exposure. The first section, updated from material originally written by Jim Lux, W6RMK, and updated by Ward Silver, N0AX, details electrical safety, grounding, bonding, and related issues in the station. The following section on antenna and tower safety was written by Steve Morris, K7LXC, and updated by Don Daso, K4ZA both professional tower climbers and antenna installers with many years of experience. Finally, the ARRL RF Safety Committee explains good amateur practices, standards and FCC regulations as they apply to RF exposure.

## Safety First — Always

We need to learn as much as possible about what could go wrong so we can avoid factors that might result in accidents. Amateur Radio activities are not inherently hazardous, but like many things in modern life, it pays to be informed. Stated another way, while we long to be creative and innovative, there is still the need to act responsibly. Safety begins with our attitude. Make it a habit to plan work carefully. Don't be the one to say, “I didn't think it could happen to me.”

Having a good attitude about safety is not enough, however. We must be knowledgeable about common safety guidelines and follow them faithfully. Safety guidelines cannot possibly cover all situations, but if we approach each task with a measure of common sense, we should be able to work safely.

Involve your family in Amateur Radio. Having other people close by is always beneficial in the event that you need immediate assistance. Take the valuable step of showing family members how to turn off the electrical power to your equipment safely. Additionally, cardiopulmonary resuscitation (CPR) training can save lives in the event of electrical shock. Classes are offered in most communities. Take the time to plan with your family members exactly what action should be taken in the event of an emergency, such as electrical shock, equipment fire or power outage. Practice your plan!

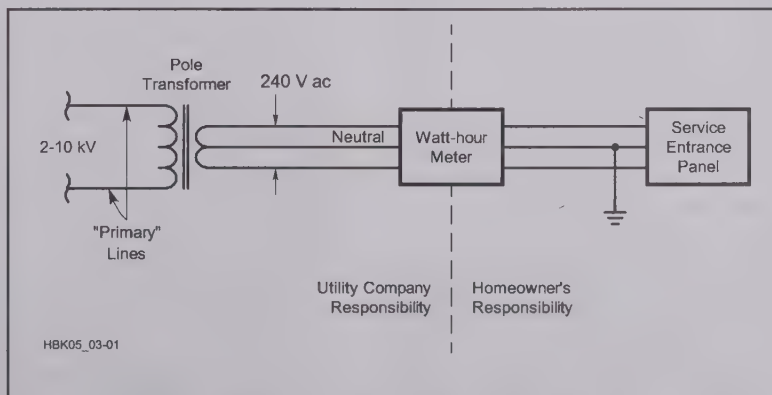

## 28.1 Electrical Safety

The standard power available from commercial mains in the United States for residential service is 120/240-V ac. The “primary” voltages that feed transformers in our neighborhoods may range from 1300 to more than 10,000 V. Generally, the responsibility for maintaining the power distribution system belongs to a utility company, electric cooperative or city. The “ownership” of conductors usually transfers from the electric utility supplier to the homeowner where the power connects to the meter or weather head. If you are unsure of where the division of responsibility falls in your community, a call to your electrical utility will provide the answer. **Figure 28.1** shows the typical division of responsibility between the utility company and the homeowner. This section is concerned more with wiring practices in the shack, as opposed to within the equipment in the shack.

There are two facets to success with electrical power: safety and performance. Since we are not professionals, we need to pursue safety first and consult professionals for alternative solutions if performance is unacceptable. The ARRL's Volunteer Consulting Engineers program involves professional engineers who may be able to provide advice or direction on difficult problems.

### 28.1.1 Station Concerns

There never seem to be enough power outlets in your shack. A good solution for small scale power distribution is a switched power strip with multiple outlets. The strip should be listed by a nationally recognized testing laboratory (NRTL) such as Underwriters Lab, UL, and should incorporate a circuit breaker. See the sidebars “What Does UL Listing Mean?” and “How Safe are Outlet Strips?” for warnings about poor quality products. It is poor practice to “daisy-chain” several power strips and may actually be a code violation. If you need more outlets than are available on a strip, have additional wall outlets installed.

**Figure 28.1** — Typical division of responsibility for maintenance of electrical power conductors and equipment. The meter is supplied by the utility company.

## What Does UL Listing Mean?

UL is one of several nationally recognized testing laboratories (NRTLs), and probably the most well known. Listing *does not* mean what most consumers expect it to mean! More often than not the listing *does not* relate to the performance of the listed product. The listing simply indicates that a sample of the device meets certain manufacturers' construction criteria. Similar devices from the same or different manufacturers may differ significantly in overall construction and performance even though all are investigated and listed against the same UL product category. There is also a difference between a listed device and a listed component.

Many local laws and regulations, as well as the National Electrical Code, require that equipment and components used in electrical installations be listed by a NRTL. Some jurisdictions (Los Angeles County) require that any electrical equipment sold to consumers be listed.

The consumer must also be aware of the fine distinctions in advertising between a device or component that is advertised as "listed" or "designed to meet" or "meets." The latter two may not actually have been tested, or if tested, may have been tested by the manufacturer, and not an independent body.

It's also important to know that in some cases UL (and other standards organizations) only publish a standardized test procedure, but don't necessarily list or test the devices. Many standards also define varying levels of compliance, so knowing that your device meets some part of the standard may not be enough to know whether it meets *your* particular needs.

Whether you add new outlets or use power strips, be sure not to overload the circuit. National and local codes set permissible branch capacities according to a rather complex process. Here's a safe rule of thumb: consider adding a new circuit if the total load is more than 80% of the circuit breaker or fuse rating. (This assumes that the fuse or breaker is correct. If you have any doubts, have an electrician check it.)

### 28.1.2. Do-It-Yourself Wiring

Amateurs sometimes "rewire" parts of their homes to accommodate their hobby. Most local codes *do* allow for modification of wiring (by building owners), so long as the electrical codes are met. Before making changes to your wiring, it would be wise to determine what

## Grounding and Bonding for the Radio Amateur

There is so much information about ac safety, lightning protection, and dealing with RF in the station that it can be difficult to understand it all. While this chapter is a helpful summary, it is still just a summary. To help hams setting up a station for the first time or trying to improve and existing station, the ARRL has published *Grounding and Bonding for the Radio Amateur*. Along with its website ([www.arrl.org/grounding-and-bonding-for-the-radio-amateur](http://www.arrl.org/grounding-and-bonding-for-the-radio-amateur)) the book collects information about these important practices into one reference.

rules apply and what agency has the authority to enforce them. This is called the *authority having jurisdiction* (AHJ) and it varies from location to location. Also see the following section on the National Electrical Code.

Generally, the building owner must obtain an electrical permit before beginning changes or additions to permanent wiring. Some jobs may require drawings of planned work. Often the permit fee pays for an inspector to review the work. Considering the risk of injury or fire if critical mistakes are left uncorrected, a permit and inspection are well worth the effort. *Don't take chances* — seek assistance from the building officials or an experienced electrician if you have *any* questions or doubts about proper wiring techniques.

*Ordinary 120-V circuits are the most common source of fatal electrical accidents.* Line voltage wiring must use an approved cable, be properly installed in conduit and junction boxes, within a chassis with a cover or lid, or other means described in the electrical code. Remember that high-current, low-voltage power sources, such as car batteries and high-current power supplies, can be just as dangerous as high-voltage sources, from melting metal, sparks and short circuits.

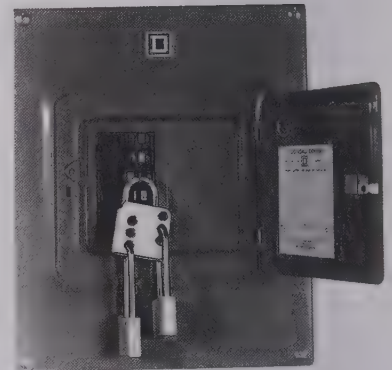

*Never work on electrical wiring with the conductors energized!* Switch off the circuit breaker or remove the fuse and take positive steps to ensure that others do not restore the power while you are working, such as using a circuit-breaker lockout. (Figure 28.2 illustrates one way to ensure that power will be off until you want it turned on.) Check the circuit with an ac voltmeter to be sure that it is "dead" *each time you begin work*.

Before restoring power, check the wiring with an ohmmeter: From the installed outlet, there should be good continuity between the neutral conductor (white wire, "silver" screw) and the grounding conductor (green

## How Safe Are Outlet Strips?

The switch in outlet strips is generally *not* rated for repetitive *load break* duty. Early failure and fire hazard may result from using these devices to switch heavy loads on and off. Misapplications are common (another bit of bad technique that has evolved from the use of personal computers), and manufacturers are all too willing to accommodate the market with marginal products. A lockable disconnect switch or circuit breaker is a better and safer station master switch.

Older power strips not complying with current standards can also be a safety hazard. MOVs in these older strips that are subjected to repeated transients can fail and cause a fire hazard, especially in outlet strips with plastic enclosures. Power strips made after 2009 that comply with UL standards are safe to use.

**Figure 28.2** — If the switch box feeding power to your shack is equipped with a lock-out hole, use it. With a lock through the hole on the box, the power cannot be accidentally turned back on. [Photo courtesy of American ED-CO]

or bare wire, green screw). An ohmmeter should indicate a closed circuit between the conductors. (In the power line, high voltage world, line workers apply a shorting jumper before starting work so if the power does get reapplied, the safety jumper takes the hit.)

With all other loads removed from the circuit (by turning off or unplugging them), an ohmmeter should indicate an *open* circuit between the hot wire and either of the other two conductors. There should be no continuity between the hot conductor (black wire, "brass" screw) and the grounding conductor or the neutral conductor.

Commercially available plug-in testers are a convenient way to test regular three-wire receptacles, but can't distinguish between the neutral and ground being reversed.

It is wise to have an up-to-date reference guide to wiring practices. These guides may be available from home improvement stores and electrical supply houses. As of early 2017, one widely available book is the *Black & Decker Complete Guide to Wiring, 6th edition*. The book is inexpensive and includes many step-by-step instructions for basic and intermediate wiring projects.

### 28.1.3 National Electrical Code (NEC)

Fortunately, much has been learned about how to harness electrical energy safely. This collective experience has been codified into the *National Electrical Code*, or *NEC*, simply known as "the code." The code details safety requirements for many kinds of electrical installations. Compliance with the NEC provides an installation that is *essentially* free from hazard, but not necessarily efficient, convenient or adequate for good service (paraphrased from NEC Article 90-1a and b). While the NEC is national in nature and sees wide application, it is not universal.

Local building authorities set the codes for their area of jurisdiction. They often incorporate the NEC in some form, while considering local issues. For example, Washington State specifically exempts telephone, telegraph, radio and television wires and equipment from conformance to electrical codes, rules and regulations. However, some local jurisdictions (city, county and so on) do impose a higher level of installation criteria, including some of the requirements exempted by the state.

Code interpretation is a complex subject, and untrained individuals should steer clear of the NEC itself. The NEC is not written to be understood by do-it-yourselfers, and one typically has to look in several places to find *all* the requirements. (For instance, Articles 810, 250, and 100 all contain things applicable to typical Amateur Radio installations.) The *NEC Handbook* is a version of the code with additional drawings and discussion. It explains the requirements of the code and how to satisfy those requirements. Written for electricians, even the *NEC Handbook* may be difficult for the non-electrician to understand completely. You may wish to contact local sources of information about code compliance and acceptable practices such as local building officials or inspectors, electrical engineers, and practicing electricians. The NEC and the *NEC Handbook* are available from local libraries.

The internet has a lot of information about electrical safety, the electrical code, and wir-

## About the National Electrical Code

*Exactly how does the National Electrical Code become a requirement? How is it enforced?*

Cities and other political subdivisions have the responsibility to act for the public safety and welfare. To address safety and fire hazards in buildings, regulations are adopted by local laws and ordinances usually including some form of permit and accompanying inspections. Because the technology for the development of general construction, mechanical and electrical codes is beyond most city building departments, model codes are incorporated by reference. There are several general building code models used in the US: Uniform, BOCA and Southern Building Codes are those most commonly adopted. For electrical issues, the National Electrical Code is in effect in virtually every community. City building officials will serve as "the authority having jurisdiction" (AHJ) and interpret the provisions of the Code as they apply it to specific cases.

Building codes differ from planning or zoning regulations: Building codes are directed only at safety, fire and health issues. Zoning regulations often are aimed at preservation of property values and aesthetics.

The NEC is part of a series of reference codes published by the National Fire Protection Association, a non-profit organization. Published codes are regularly kept up-to-date and are developed by a series of technical committees whose makeup represents a wide consensus of opinion. The NEC is updated every three years. It's important to know which version of the code your local jurisdiction uses, since it's not unusual to have the city require compliance to an older version of the code. Fortunately, the NEC is usually backward compatible: that is, if you're compliant to the 2008 code, you're probably also compliant to the 1999 code.

*Do I have to update my electrical wiring as code requirements are updated or changed?*

Generally, no. Codes are typically applied for new construction and for renovating existing structures. Room additions, for example, might not directly trigger upgrades in the existing service panel unless the panel was determined to be inadequate. However, the wiring of the new addition would be expected to meet current codes. Prudent homeowners, however, may want to add safety features for their own value. Many homeowners, for example, have added GFCI protection to bathroom and outdoor convenience outlets.

ing practices, but you need to be careful to make sure the information you are using is current and not out of date. The ARRL Volunteer Consulting Engineer (VCE) program can help you find a professional who understands the amateur radio world, as well as the regulatory environment. There are also a variety of websites with useful information (such as [www.mikeholt.com](http://www.mikeholt.com)), but you need to be aware that advice may be specific to a particular installation or jurisdiction and not applicable for yours. With that understanding, let's look at a few NEC requirements for radio installations.

### Homebrew and "The Code"

In many cases, there are now legal requirements that electrical equipment have been listed by an NRTL, such as Underwriter Laboratories. This raises an issue for hams and homebrew gear, since it's unlikely you would take your latest project down to a test lab and pay them to evaluate it for safety.

For equipment that is not permanently installed, there's not much of an issue with homebrew, as far as the code goes, because the code doesn't deal with what's inside the equipment. For a lot of low voltage equipment, the code rules are fairly easy to meet, as well, as long as the equipment is supplied by a listed power source of the appropriate type.

The problem arises with permanent installations, where the scope of the code and local regulations is ever increasing. Such things as solar panel installations, standby generators, personal computers and home LANs all have received increased attention in local codes.

### 28.1.4 Station Power

Amateur Radio stations generally require a 120-V ac power source, which is then converted to the proper ac or dc levels required for the station equipment. In residential systems voltages from 110 V through 125 V are treated equivalently, as are those from 220 V through 250 V. Amateurs setting up a station in a light industrial or office environment may encounter 208 V line voltage. Most power supplies operate over these ranges, but it's a good idea to measure the voltage range at your station. (The measured voltage usually varies by hour, day, season and location.) Power supply application and use are covered in the **Power Sources** chapter.

Modern solid state rigs often operate from dc power, provided by a suitable dc power supply, perhaps including battery backups. Sometimes, the dc power supply is part of the rig (as in a 50-V power supply for a solid-state linear). Other times, your shack might have a 12-V (13.8 V) bus that supplies many devices. Just because it's low voltage doesn't mean that there aren't aspects of the system that raise safety concerns. A 15-A, 12-V power

## International Power Standards

The power grid of the United States and Canada uses a frequency of 60 Hz and the voltage at ac power outlets is 120 V. This is also the case in other North American countries. If you travel, though, you'll encounter 220 V and 50 Hz with quite an array of plugs and sockets and color codes. If you are planning on taking amateur radio equipment with you on a vacation or DXpedition, you'll need to be prepared with the proper adapters and/or transformers to operate your equipment.

A table of international voltage and frequencies is provided with the downloadable supplemental content, along with a figure showing the most common plug and socket configurations.

switched outlets, you can control multiple low-voltage controlled switched outlets from a common source. Or you can build or buy a portable power distribution box similar to those used on construction sites or stage sets; they are basically a portable subpanel with individual circuit breakers (or GFCIs, discussed later) for each receptacle, and fed by a suitable cord or extension cord. No matter what scheme you use, however, it's important that it be labeled so that someone else will know what to do to turn off the power.

### AC LINE POWER

If your station is located in a room with electrical outlets, you're in luck. If your station is located in the basement, an attic or other area without a convenient 120-V source, you may need to have a new line run to your operating position.

Stations with high-power amplifiers should have a 240-V ac power source in addition to the 120-V supply. Some amplifiers may be powered from 120 V, but they require current levels that may exceed the limits of standard house wiring. To avoid overloading the circuit and to reduce household light dimming or blinking when the amplifier is in use, and for the best possible voltage regulation in the equipment, it is advisable to install a separate 240 or 120-V line with an appropriate current rating if you use an amplifier.

The usual circuits feeding household outlets are rated at 15 or 20 A. This may or may not be enough current to power your station. To determine how much current your station requires, check the VA (volt-amp) ratings for each piece of gear. (See the **Electrical Fundamentals** chapter for a discussion of VA.) Usually, the manufacturer will specify the required current at 120 V; if the power consumption is rated in watts, divide that rating by 120 V to get amperes. Modern switching power supplies draw more current as the line voltage drops, so if your line voltage is markedly lower than 120 V, you need to take

that into account.

Note that the code requires you to use the "nameplate" current, even if you've measured the actual current, and it's less. If the total current required is near 80% of the circuit's rating (12 A on a 15-A circuit or 16 A on a 20-A circuit), you need to install another circuit. Keep in mind that other rooms may be powered from the same branch of the electrical system, so the power consumption of any equipment connected to other outlets on the branch must be taken into account. If you would like to measure just how much power your equipment consumes, the inexpensive Kill-A-Watt meters by P3 International ([www.p3international.com](http://www.p3international.com)) measure volts, amps, VA and power factor.

If you decide to install a separate 120-V line or a 240-V line, consult the local requirements as discussed earlier. In some areas, a licensed electrician must perform this work. Others may require a special building permit. Even if you are allowed to do the work yourself, it might need inspection by a licensed electrician. Go through the system and get the necessary permits and inspections! Faulty wiring can destroy your possessions and take away your loved ones. Many fire insurance policies are void if there is unapproved wiring in the structure.

If you decide to do the job yourself, work closely with local building officials. Most home-improvement centers sell books to guide do-it-yourself wiring projects. If you have any doubts about doing the work yourself, get a licensed electrician to do the installation.

### THREE-WIRE 120-V POWER CORDS

Most metal-cased electrical tools and appliances are equipped with three-conductor power cords. Two of the conductors carry power to the device, while the third conductor is connected to the case, enclosure, or frame. **Figure 28.3** shows two commonly

supply can start a fire as easily as a 15-A, 120-V branch circuit.

### 28.1.5 Connecting and Disconnecting Power

Something that is sometimes overlooked is that you need to have a way to safely disconnect all power to everything in the shack. This includes not only the ac power, but also battery banks, solar panels, and uninterruptible power supplies (UPS). Most hams won't have the luxury of a dedicated room with a dedicated power feed and the "big red switch" on the wall, so you'll have several switches and cords that would need to be disconnected.

The realities of today's shacks, with computers, multiple wall transformers ("wall-warts"), network interfaces and the radio equipment itself makes this tricky to do. One convenient means is a switched outlet strip, as used for computer equipment, if you have a limited number of devices. If you need more

used connectors. (See the **Component Data and References** chapter for a more comprehensive drawing of ac plugs and receptacles.)

When both plug and receptacle are properly wired, the three-contact polarized plug bonds the equipment to the system ground. If an internal short from line to case occurs, the “ground” pin carries the fault current and hopefully has a low enough impedance to trip the branch circuit breaker or blow the fuse in the device. A second reason for grounding the case is to reduce the possibility of shock for a user simultaneously connected to ground and the device. In modern practice, however, shock prevention is often done with GFCI circuit breakers as described below. These devices trip at a much lower level and are more reliable. Most commercially manufactured test equipment and ac-operated amateur equipment is supplied with three-wire cords.

It’s a good idea to check for continuity from case to ground pin, particularly on used equipment, where the ground connection might have been broken or modified by the previous owner. If there is no continuity, have the equipment repaired before use.

Use such equipment only with properly installed three-wire outlets. If your house does not have such outlets, either consult a local electrician to learn about safe alternatives or have a professional review information you might obtain from online or other sources.

Equipment with plastic cases is considered “double insulated” and fed with a two-wire cord. Such equipment is safe because both conductors are insulated from the user by two layers. Nonetheless, there is still a hazard if, say, a double insulated drill were used to drill an improperly grounded case of a transmitter that was still plugged in. Remember, all insulation is prey to age, damage and wear that may erode its initial protection.

## TRANSFER SWITCHES AND GENERATORS

More hams are adding standby generators and using alternate power sources such as solar panels or wind turbines, not as standalone systems like at Field Day, but interconnected with their home electrical system. These present some potential safety problems, such as preventing the local generator from “back-feeding” the utility’s system during a power failure, and the fact that a solar panel puts out power whenever there is light falling on it.

For generators, the recommended approach is to use a *transfer switch*, which is a multipole switch that connects a selection of the house’s circuits to the generator, rather than the utility power. The NEC and local regulations should be consulted for transfer switch selection and connection. The required wiring practices for permanently installed (stationary) generators are different from those for portable generators. Some issues that need to

be considered are whether the neutral should be switched (many transfer switches do not switch the neutral, only the hot wire), and how the generator chassis is bonded to the building’s grounding/bonding system. Most proper transfer switches are of the ON-OFF-ON configuration, with a mechanical interlock that prevents directly switching from one source to the other in a single operation.

The most dangerous thing to do with a generator is to use a so-called “suicide cord” with a male plug at each end: one end plugged into the generator’s output receptacle and the other plugged into a convenient receptacle in the home. This is frequently illegal and at any rate should be avoided because of the inherent danger of having exposed, live contacts and the ease of overloading the circuit being fed.

Back-feeding your home’s power panel should *never* be done unless the main breakers are in the OFF position or preferably removed. If your home’s circuit-breaker panel does not have main breakers that can disconnect the external power line, *do not* use this

technique to connect your generator to the home’s wiring. Your generator is likely to be damaged when power is restored, and back-feeding also endangers power utility workers. Connect appliances to the generator directly with extension cords.

## 28.1.6 Ground-Fault and Arc-Fault Circuit Interrupters

GFCIs are devices that can be used with common 120 V household circuits to reduce the chance of electrocution when the path of current flow leaves the branch circuit (say, through a person’s body to another branch or ground). An AFCI is similar in that it monitors current to watch for a fault condition. Instead of current imbalances, the AFCI detects patterns of current that indicate an arc — one of the leading causes of home fires. The AFCI is not supposed to trip because of “normal” arcs that occur when a switch is opened or a plug is removed.

The NEC requires GFCI outlets in all wet or

**Figure 28.4** — Simplified diagram of a 120-V ac ground fault circuit interrupter (GFCI). When a stray current flows from the load (or outlet) side to ground, the current through the toroid becomes unbalanced allowing detection, amplification and relay actuation to immediately cut off power to the load (and to the stray path!) GFCI units require a manual reset after tripping. GFCIs are required in wet locations (near kitchen sinks, in garages, in outdoor circuits and for construction work.) They are available as portable units or combined with over-current circuit breakers for installation in entrance panels.

potentially wet locations, such as bathrooms, kitchens, and any outdoor outlet with ground-level access, garages and unfinished basements. AFCI protection is required for all circuits that supply bedrooms. Any area with bare concrete floors or concrete masonry walls should be GFCI equipped. GFCIs are available as portable units, duplex outlets and as individual circuit breakers. Some early units may have been sensitive to RF radiation but this problem appears to have been solved. Ham radio shacks in potentially wet areas (basements, out buildings) should be GFCI equipped. **Figure 28.4** is a simplified diagram of a GFCI.

Older equipment with capacitors in the 0.01  $\mu\text{F}$  to 0.1  $\mu\text{F}$  range connected between line inputs and chassis as an EMI filter (or that has been modified with bypass capacitors) will often cause a GFCI to trip, because of the leakage current through the capacitor. The must-trip current is 5 mA, but many GFCIs trip at lower levels. At 60 Hz, a 0.01  $\mu\text{F}$  capacitor has an impedance of about 265 k $\Omega$ , so there could be a leakage current of about 0.5 mA from the 120 V line. If you had several pieces of equipment with such capacitors, the leakage current will trip the GFCI.

Some early GFCI breakers were susceptible to RFI but as the technology has improved, fewer and fewer such reports have been received. While it is possible to add filtering or RF suppression to the breaker wiring, a simpler and less expensive solution is to simply replace the GFCI breaker with a new unit less susceptible to RF. Reports have not yet been received on AFCI products. For more information on RFI and GFCI/AFCI devices, check the ARRL web page [www.arrl.org/gfci-devices](http://www.arrl.org/gfci-devices).

### 28.1.7 Low-Voltage Wiring

Many ham shacks use low-voltage control wiring for rotators or antenna relays. The electrical code isn't consistent in what it calls low voltage, but a guideline is "less than 50 V." Article 725 of the code contains most of the rules for low voltage/low power remote control and signaling, which is what hams are typically doing. These circuits are divided into three classes, with Class 1 being further subdivided, as shown in **Table 28.1**. There used to be code rules defining the classes in terms of power and voltage, but these days, the code is written so that the class of the circuit is defined by the power source, which has to be listed and labeled with the class. That is, if you have something powered by a wall transformer that is listed and labeled as Class 2, the circuit is Class 2.

A typical example of a Class 1 Power Limited circuit that you might find in your home is 12 V low-voltage garden lighting or halogen lightning systems. A lot of amateur

homebrew gear probably is also in this class, although because it's not made with "listed" components, it technically doesn't qualify. The other Class 1 would apply to a circuit using an isolation transformer of some sort.

Class 2 is very common: doorbells, network wiring, thermostats, and so on are almost all Class 2. To be Class 2, the circuit must be powered from a listed power supply that's marked as being Class 2 with a capacity less than 100 VA. For many applications that hams encounter, this will be the familiar "wall wart" power supply. If you have a bunch of equipment that runs from dc power, and you build a dc power distribution panel with regulators to supply them from a storage battery or a big dc power supply, you're most likely not Class 2 anymore, but logically Class 1. Since your homebrew panel isn't likely to be listed, you're really not even Class 1, but something that isn't covered by the code.

A common example of a Class 3 circuit that is greater than 30 V is the 70 V audio distribution systems used in paging systems and the like. Class 3 wiring must be done with appropriately rated cable.

### WIRING PRACTICES

Low voltage cables must be separated from power circuits. Class 2 and 3 cannot be run with Class 1 low voltage cables. They can't share a cable tray or the same conduit. A more subtle point is that the 2005 code added a restriction [Article 725.56(F)] that audio cables (speakers, microphone, etc.) cannot be run in the same conduit with other Class 2 and Class 3 circuits (like network wiring).

Low voltage and remote control wiring should not be neglected from your transient suppression system. This includes putting appropriate protective devices where wiring enters and leaves a building, and consideration of the current paths to minimize loops which can pick up the field from transients (or RF from your antenna).

### 28.1.8 Grounding and Bonding

As hams we are concerned with at least four kinds of connections called "ground," even if they really aren't in the sense of connection to the Earth. These are easily con-

fused because we call each of them "ground."

- 1) Electrical safety ground (equipment ground or earth connection)
- 2) Lightning and transient dissipation ground
- 3) RF voltage and current management ("RF ground")
- 4) Common reference potential (chassis ground or circuit common)

This section of the chapter is primarily concerned with connections for electrical or safety grounding and lightning and transient dissipation. The remaining types are covered elsewhere in chapters on circuit- and antenna-building and in station construction.

Several commercial and military standards can be used as guidebooks for grounding and bonding:

*National Electrical Code (NEC)*—This is the primary standard for residential and commercial electrical work in the United States. NEC Article 250 deals with grounding and bonding. NEC Article 810 deals with antenna installation. (See the previous section on the NEC.)

*MIL-HDBK-419A — Grounding, Bonding, and Shielding for Electronic Equipments and Facilities (Vol 1 and 2)*—This military standard applies to communication facilities and equipment installations at any frequency. It provides many useful drawings and guidelines covering ground connections and how equipment should be bonded together. It is a public-domain document and may be downloaded without charge at [www.uscg.mil/petaluma/TPF/ET\\_SMS/Mil-STDs/MILHDBK419.pdf](http://www.uscg.mil/petaluma/TPF/ET_SMS/Mil-STDs/MILHDBK419.pdf).

*R56 Standards and Guidelines for Communications Sites*—Motorola is a large vendor of communications systems, mostly for VHF/UHF/microwave applications. This standard applies primarily to equipment and facilities used at those frequencies. It is not a public domain document but may be downloaded without charge from numerous sources.

IEEE Std 1100-2005 (also known as the "Emerald Book," see the Reference listing, section 28.1.13) provides detailed information from a theoretical and practical standpoint for grounding and powering electrical equipment, including lightning protection and RF EMI/EMC concerns. It's expensive to buy, but is available through libraries.

## Grounding or Bonding?

You may notice the term "bonding" is replacing "grounding" in many instances. A primary safety concern is for whatever carries fault currents to be mechanically rugged and reasonably conductive. It's also important that the fault-carrying conductor be connected to a ground rod, but that's a different consideration. Bonding is the term to use when contact between pieces of equipment or between conductors is the primary concern. Grounding is the term to use when referring to an earth connection for electrical safety or lightning protection.

## BONDING

The definition of bonding is “to connect equipment together electrically in order to minimize the potential (voltage) difference between them.” A good bonding connection must have very low impedance and approximately equal voltage everywhere along it at the frequency of interest. As amateurs know, electrical length and impedance of any type of conductor — wire, strap, braid, or sheet — varies with frequency. In addition, the amount of current flowing through the conductor can create significant voltage differences along the conductor. Because of these concerns, it is important to consider the purposes of bonding when making a bonding connection.

In general, for amateurs constructing a station, even a temporary one, it is a good practice to make bonding conductors as short as practical and as heavy as is needed to satisfy all bonding requirements. By doing so, the bonding connection will serve its purpose for all three of the primary bonding needs in your station: ac safety, lightning protection, and RF management.

## ELECTRICAL SAFETY GROUND

Power-line ground is required by building codes to ensure the safety of life and property surrounding electrical systems. The NEC requires that all grounds be bonded together; this is a very important safety feature as well as an NEC requirement.

The usual term one sees for the “third prong” or “green-wire ground” is the *elec-*

*trical safety ground* or *equipment ground*. The purpose of the third, non-load current carrying wire is to provide a path to ensure that the overcurrent protection will trip in the event of a line-to-case short circuit in a piece of equipment. This could either be the fuse or circuit breaker back at the main panel, or the fuse inside the equipment itself.

There is a secondary purpose — shock reduction: The electrical safety ground provides a common reference potential for all parts of the ac system. The conductive case of equipment is required to be connected to the bonded grounding system, which is also connected to earth ground at the service entrance, so someone who is connected to “earth” (for example, standing in bare feet on a conductive

floor) that touches the case won’t get shocked.

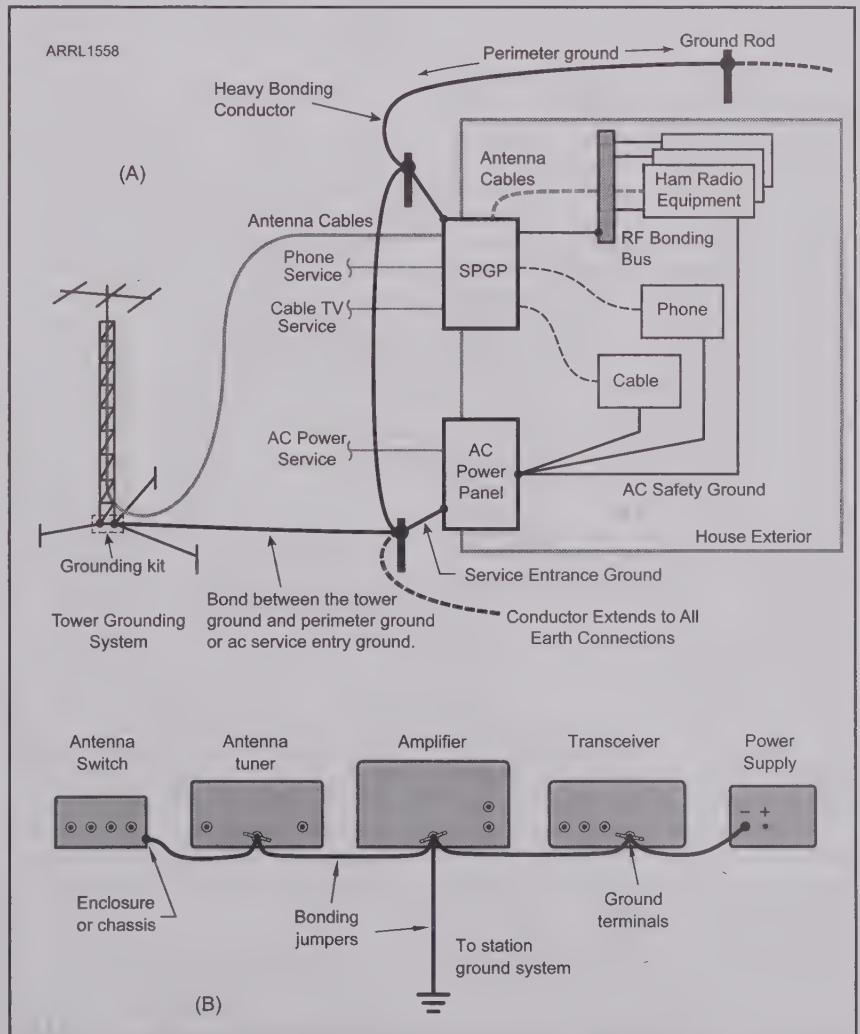

An effective safety ground system is necessary for every amateur station. If you have equipment at the base of the tower, generally, you need to provide a separate bonding conductor to connect the chassis and cases at the tower to the bonding system in the shack. **Figure 28.5A** shows an overall grounding system, emphasizing the requirement to bond all ground connections together, regardless of their purpose.

Equipment-to-equipment bonding can be done directly with wire (#6 to #14 AWG), strap (20 gauge), or through a bonding bus or single-point ground panel (SPGP). The equipment ground or “third-wire” connection in a residence’s branch circuit must be made

## When to Use Strap, Wire, or Braid

The standard for grounding in the communication industry is solid strap or heavy wire. Both can be used indoors or outdoors. Flat-weave, tinned grounding braid can be used if the equipment is subject to vibration or needs to be moved around. Any type of braid should never be used if it will be exposed to moisture or corrosive chemicals. Corrosion on the surface of the small wires used to make up the braid reduces its effectiveness by raising the surface resistance, where the RF currents flow. Poor contact between the individual wires can also result in noise and mixing products. Unless it is mechanically necessary, use solid strap or wire.

It is not recommended to reuse braid removed from coaxial cable. Once removed from its protective jacket, the braid wires immediately begin to loosen and oxidize or corrode. This reduces the braid’s effectiveness at RF quite a bit, making it a poor choice for long-term grounding conductors.

**Figure 28.5** — A grounding system that includes ac safety, lightning protection, and RF management. All ground electrodes must be bonded together and to the residence’s ac service entry ground rod. If a protected ac branch circuit is included, the protector should be mounted on the SPGP (single-point ground panel). Direct equipment-to-equipment bonding (B) can be done with heavy wire or strap or to an RF bonding bus. See the chapter on Assembling a Station for more information on making these connections.

with the same size wire as the hot and neutral conductors. Connections directly to a ground electrode, such as a ground rod, are made with heavy wire (#6 AWG minimum) or 20 gauge strap. Clamps and terminals should be rated or listed for grounding use, particularly for earth connections that are exposed to the weather or buried.

At ac power frequencies of 50 or 60 Hz, the wavelength is miles long so the electrical length of the connection is insignificant. Reactance created by the bonding conductor (about 1 nH per foot for a straight wire) is likewise negligible. The most important characteristics of the bonding connection is resistance and mechanical strength. Unfortunately, an effective bonding conductor at 60 Hz may present very high impedance at RF because of the inductance, or worse yet, wind up being an excellent antenna that picks up the signals radiated by your antenna.

### RF MANAGEMENT AND CHASSIS GROUND

“RF ground” is an obsolete term from days gone by when most operation was at low frequencies and a wire from the chassis or antenna tuner in the shack to a ground rod had low RF impedance. The RF voltage difference between the chassis and “Earth ground” was small. And even if there were small potential differences, the surrounding equipment of those days was relatively insensitive to them.

Today, we have a lot of circuits that are sensitive to interfering signals at millivolt levels, such as audio signals to and from sound cards. As a result, we can no longer ignore the RF voltage differences and shouldn't be using the equipment enclosures or shielding conductors as part of the RF circuit.

Instead, we design our stations to manage the RF picked up on cables, connecting wires, and enclosures so that it does not cause problems. The first step is to create a common reference potential, called the *ground plane* or *reference plane*. Equipment connected to the ground plane is maintained at a common potential. This minimizes RF current that would flow between pieces of equipment. (See the **RF Interference and Assembling a Station** chapters for more information.) The ground plane can be an actual sheet of metal or a low-inductance conductor to which all of the equipment can be connected, often called an *RF bonding bus*. The ground plane is then bonded to the station ground system.

It is sometimes suggested that RF grounds should be isolated from the ac safety and lightning protection ground system — that is not correct! All grounds, including safety, RF, lightning protection and commercial communications, must be bonded together in order to protect life and property. The elec-

trical code requires that antenna grounds be bonded to the rest of the grounding system, although that connection can have an RF choke. Remember that the focus of the electrical code bonding requirement is safety in the event of a short to a power distribution line or other transient.

For decades, amateurs have been advised to bond all equipment cabinets to an RF ground located near the station. Given today's operating frequencies and equipment sensitivity, this practice is inadequate. Even a few meters of wire can have an impedance of hundreds of ohms ( $1 \mu\text{H}/\text{meter} = 88 \Omega/\text{meter}$  at 14 MHz). So a better approach is to connect the chassis together in a well-organized fashion to ensure that the chassis-to-chassis connections minimize RF voltage differences as in Figure 28.5B. An RF bonding bus can be used, as well. (See the **RF Interference and Assembling a Station** chapters for more information.)

### LIGHTNING DISSIPATION GROUND

Lightning dissipation ground is concerned with conducting currents to the surrounding earth. There are distinct similarities between lightning dissipation ground systems and a good ground system for a vertical antenna. Lightning strokes produce electrical energy from a few kHz to more than 10 MHz so the length of the connection is important as well as its resistance. The difference is that an antenna ground plane may handle perhaps a few tens of amps, while the lightning ground needs to handle a peak current of tens of kiloamperes.

A typical lightning stroke is a pulse with a rise time of a few microseconds, a peak current of 20 to 30 kA, and a fall time of 50  $\mu\text{s}$ . The average current is not all that high (a few hundred amps), so the conductor size needed to carry the current without melting is surprisingly small.

However, large conductors (usually specified as #6 AWG minimum by building codes) are used in lightning grounds for other reasons: to reduce inductance, to handle the mechanical forces from the magnetic fields, and for ruggedness to prevent inadvertent breakage. A large diameter wire, or even better, a wide flat strap, has lower inductance. The voltage along a wire is proportional to the change in current and the inductance:

$$|V| = L \frac{\Delta i}{\Delta t}$$

where

$\Delta i/\Delta t$  = rate of change in current, about 20kA/2 $\mu\text{s}$  for lightning, or 10<sup>9</sup> A/s, and L = the inductance.

Consider a connection box on a tower that contains some circuitry terminating a control cable from the shack, appropriately protected

internally with overvoltage protection. If the connection from the box to ground is high inductance, the lightning transient will raise the box potential (relative to the wiring coming from the shack), possibly beyond the point where the transient suppression in the box can handle it. Lowering the inductance of the connection to ground reduces the potential.

The other reason for large conductors on lightning grounds is to withstand the high mechanical forces from the high currents. This is also the reason behind the recommendation that lightning conductors run directly, with minimal bends and large radii for bends that are needed, and certainly no loops. A wire with 20,000 A has a powerful magnetic field surrounding it, and if current is flowing in multiple wires that are close to each other, the forces pushing the wires together or apart can actually break the conductors or deform them permanently.

The force between two conductors carrying 20,000 A, spaced a centimeter apart, is 8000 Newtons/meter of length (over 500 pounds/foot). Such forces can easily break cable strands or rip up brackets and screws. This problem is aggravated if there are loops in the wire, since the interaction of the current and its magnetic field tends to make the loop get larger, to the point where the wire will actually fail from the tension stresses.

### EARTH GROUND

Earth ground usually takes one of several forms, all identified in the NEC and NFPA 780. The preferred earth ground, both as required in the NEC, and verified with years of testing in the field, is a *concrete encasement grounding electrode* (CEGR), also known as a *Ufer ground*, after Herb Ufer, who invented it as a way to provide grounding for military installations in dry areas where ground rods are ineffective. The CEGR can take many forms, but the essential aspect is that a suitable conductor at least 20 feet long is encased in concrete which is buried in the ground. The conductor can be a copper wire (#8 AWG or larger, at least 20 feet long) or the reinforcing bar (rebar) in the concrete, often the foundation footing for the building. The connection of the rebar is either with a stub of the rebar protruding through the concrete's top surface or the copper wire extending through the concrete. There are other variations on the CEGR described in the NEC and in the electrical literature, but they're all functionally the same: a long conductor embedded in a big piece of concrete.

The electrode works because the concrete has a huge contact area with the surrounding soil, providing very low impedance and what's also important, a low current density so that localized heating doesn't occur. Co-

ete, tends to absorb water, so it is also less susceptible to problems with the soil drying at around a traditional ground rod.

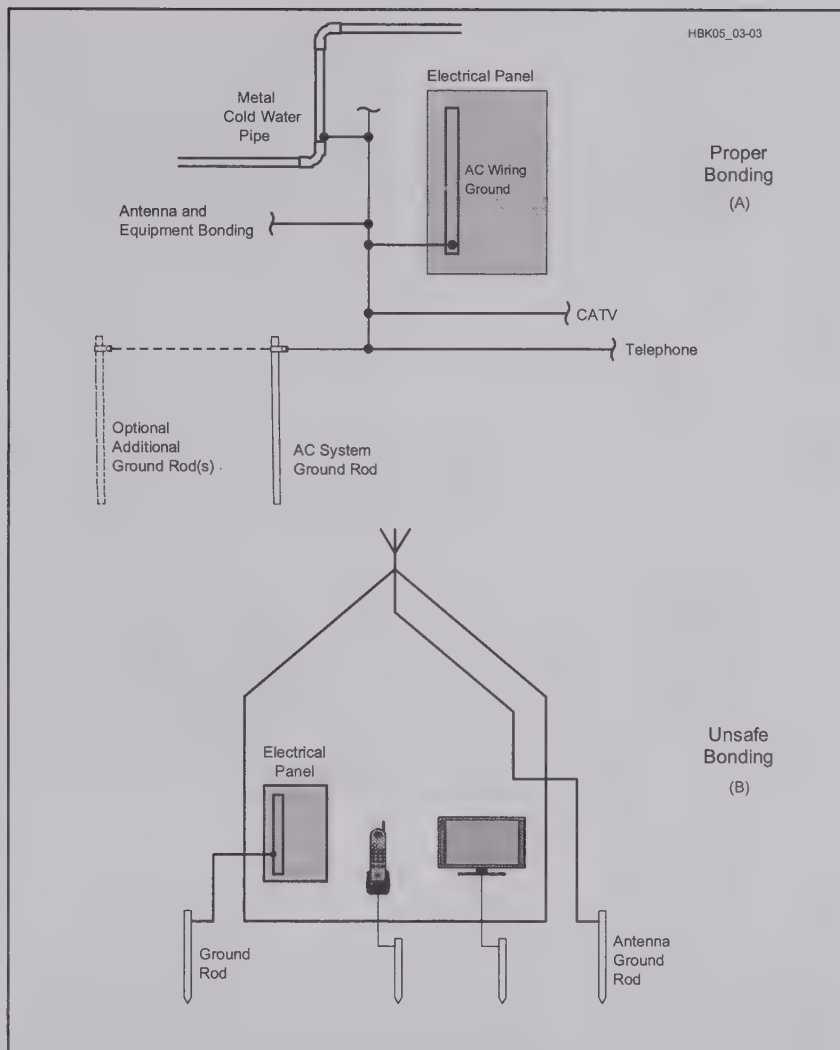

The techniques required for welding rebar and making the necessary connection to the CEGR are somewhat specialized. If you are not familiar with those skills, hire a professional to do the job correctly. Similarly, unless you have documented evidence that the necessary rebar connection or embedded wire is present in a concrete footing or slab, do not attempt to use it as a CEGR.

Ground rods are a traditional approach to making a suitable ground connection and are appropriate as supplemental grounds, say at the base of a tower, or as part of an overall grounding system. The best ground rods to use are those available from an electrical supply house. The code requires that at least 8 feet of the rod be in contact with the soil, so the rod sticks out of the ground, it must be longer than 8 feet (10 feet is standard). The rod doesn't have to be vertical, and can be driven at an angle if there is a rock or hard layer, or even buried laying sideways in a suitable trench, although this is a compromise installation. Suitable rods are generally 10 feet long and made from steel with heavy copper plating. (Stainless steel and galvanized rods are also available and may be required by soil conditions in your area. Check with a local electrician or electrical inspector.) Do not depend on shorter, thinly plated rods sold by some home electronics suppliers, as they can quickly rust and soon become worthless.

If multiple ground rods are installed, many references specify a minimum spacing of the rod's length. If the rods are not spaced by at least half the length of the rod, the effectiveness is compromised. IEEE Std 142 and IEEE Std 1100 (see the Reference listing) and other references have tables to give effective ground resistances for various configurations of multiple rods.

Once the ground rods are installed, they must be connected with either an exothermic weld (such as CadWeld) or with a listed pressure clamp. The exothermic weld is preferred, because it doesn't require annual inspection like a clamp does. Some installers use brazing to attach the wiring to the ground rods. Although this is not permitted for a primary ground, it is acceptable for secondary or redundant grounds. Soft solder (tin-lead, as used in plumbing or electrical work) should never be used for grounding conductors because it gets brittle with temperature cycling and can melt if a current surge (as from a lightning strike) heats the conductor. Soft solder is specifically prohibited in the code.

Building cold water supply systems were used as station grounds in years past, but this is no longer recommended or even permitted

**Figure 28.6 — At A, proper bonding of all grounds to electrical service panel. The installation shown at B is unsafe — the separate grounds are not bonded. This could result in a serious accident or electrical fire.**

in some jurisdictions, because of increased use of plastic plumbing both inside and outside houses and concerns about stray currents causing pipe corrosion. If you do use the cold water line, perhaps because it is an existing grounding electrode, it must be bonded to the electrical system ground, typically at the service entrance panel.

### 28.1.9 Ground Conductors

Building codes and wiring standards are quite specific as to the types of conductors that can be used for bonding the various parts of the system together. Grounding conductors may be made from copper, aluminum, copper-clad steel, bronze or similar corrosion-resistant materials. Note that the sizes

of the conductors required are based largely on mechanical strength considerations (to insure that the wire isn't broken accidentally) rather than electrical resistance. Insulation is not required.

There is a "unified" grounding electrode requirement — it is necessary to bond all grounds to the electric service entrance ground. All utilities, antennas and any separate grounding rods used must be bonded together. Figure 28.6 shows correct (A) and incorrect (B) ways to bond ground rods. Figure 28.7 demonstrates the importance of correctly bonding ground rods. (Note: The NEC requirements do not address effective RF bonding. See the **RF Interference and Assembling a Station** chapters of this book for information about RF practices. Keep in mind that RFI is

## 28.1.10 Antennas

Article 810 of the NEC includes several requirements for wire antennas and feed lines that you should keep in mind when designing your antenna system. The “protective grounding conductor” (main conductor running to the ground rod) must be as large as the antenna lead-in, but not smaller than #10 AWG. The grounding conductor (used to bond equipment chassis together) must be at least #14 AWG.

The single most important thing to consider for safety is to address the potential for contact between the antenna system and power lines. As the code says, “One of the leading causes of electric shock and electrocution, according to statistical reports, is the accidental contact of radio, television, and amateur radio transmitting and receiving antennas and equipment with light or power conductors.” (See Article 810.13, Fine Print Note.) The requirements in the code for wire sizes, bonding requirements, and installation practices are mostly aimed at preventing tragedy, by avoiding the contact in the first place and by mitigating the effects of a contact if it occurs.

Article 820 of the NEC applies to Cable TV installations, which almost always use coaxial cable, and which require wiring practices different from Article 810 (for instance, the coax shield can serve as the grounding conductor). Your inspector may look to Article 820 for guidance on a safe installation of coax, since there are many more satellite TV and cable TV installations than Amateur Radio. Ultimately, it is the inspector’s call as to whether your installation is safe.

Article 830 applies to Network Power and Communication Systems, and as amateurs do things like install 802.11 wireless LAN equipment at the top of their tower, they have to pay attention to the requirements in this Article. The NEC requirements discussed in these sections are not adequate for lightning protection and high-voltage transient events. See the section “Lightning/Transient Protection” later in this chapter for more information.

### ANTENNA CONDUCTORS

Transmitting antennas should use hard-drawn copper wire: #14 AWG for unsupported spans less than 150 feet, and #10 AWG for longer spans. Copper-clad steel, bronze, or other high-strength conductors must be #14 AWG for spans less than 150 feet and #12 AWG for longer spans. Open-wire transmission line conductors must be at least as large as those specified for antennas. Steel antennas made with light-gauge wire are not code-compliant.

### LEAD-INS

There are several NEC requirements for

**Figure 28.7** — These drawings show the importance of properly bonded ground rods. In the system shown in A, the 20-A breaker will not trip. In the system in B, the 20-A circuit breaker trips instantly. There is an equipment internal short to ground — the ground rod is properly bonded back to the power system ground. Of course, the main protection should be in a circuit ground wire in the equipment power cord itself!

## Coax Shields as a Grounding Conductor

The importance of significant current-carrying capability in a grounding conductor is determined by your local circumstances. If lightning is a problem or contact with power-carrying conductors due to wind or ice is a possibility, the ability of the coax shield to carry a lot of current is important and a separate grounding conductor is a good idea. In areas where hazards are reduced, a smaller conductor may suffice. Contact a licensed electrician if you aren’t sure about what is prudent for your area.

not an acceptable reason to violate the NEC.) For additional information on good grounding practices, the *NEC Handbook* and IEEE “Emerald Book” (IEEE STD 1100-2005) are good references. Both are available through libraries. Home wiring guides are also available at home improvement stores.

Additionally, the NEC covers safety inside the station. All grounding conductors inside

the building must be at least 4 inches away from conductors of any lighting or signaling circuit except when they are separated from other conductors by conduit or insulator. Other code requirements include enclosing transmitters in metal cabinets that are bonded to the grounding system. Of course, conductive handles and knobs must be grounded as well.

antenna lead-in conductors (transmission lines are lead-in conductors). For transmitting stations, their size must be equal to or greater than that of the antenna. Lead-ins attached to buildings must be firmly mounted at least 3 inches clear of the surface of the building on nonabsorbent insulators. Lead-in conductors must enter through rigid, noncombustible, nonabsorbent insulating tubes or bushings, through an opening provided for the purpose that provides a clearance of at least two inches; or through a drilled windowpane. All lead-in conductors to transmitting equipment must be arranged so that accidental contact is difficult. As with stealth antennas, installations with feed lines smaller than RG-58 are likely not code compliant depending on how your local inspector interprets the code.

### ANTENNA DISCHARGE UNITS (LIGHTNING ARRESTORS)

All antenna systems are required to have a means of draining static charges from the antenna system. A listed antenna discharge unit (lightning arrester) must be installed on each lead-in conductor that is not protected by a permanently and effectively grounded metallic shield, unless the antenna itself is permanently and effectively grounded, such as for a shunt-fed vertical. Note that the usual transient protectors are *not* listed antenna discharge units. (The code exception for installed lead-ins does *not* apply to coax, but to shields such as thin-wall conduit. Coaxial braid is neither “adequate” nor “effectively grounded” for lightning protection purposes.) An acceptable alternative to lightning arrester installation is a switch (capable of withstanding many kilovolts) that connects the lead-in to ground when the transmitter is not in use. A garden-variety knife switch for household appliances is not adequately rated for this job.

### ANTENNA BONDING (GROUNDING) CONDUCTORS

In general the code requires that the conductors used to bond the antenna system to ground be at least as big as the antenna conductors, but also at least #10 AWG in size. Note that the antenna grounding conductor rules are different from those for the regular electrical safety bonding, or lightning dissipation grounds, or even for CATV or telephone system grounds.

### MOTORIZED CRANK-UP ANTENNA TOWERS

If you are using a motorized crank-up tower, the code has some requirements, particularly if there is a remote control. In general, there has to be a way to positively disconnect power to the motor that is within sight of the motorized device, so that someone working on it can be sure that it won't start moving unexpectedly. From a safety standpoint, as

### 28.1.11 Lightning/Transient Protection

Nearly everyone recognizes the need to protect themselves from lightning. From miles away, the sight and sound of lightning boldly illustrates its destructive potential. Many people don't realize that destructive transients from lightning and other events can reach electronic equipment from many sources, such as outside antennas, power, telephone and cable TV installations. Many hams don't realize that the standard protection scheme of several decades, a ground rod and simple “lightning arrester,” is *not* adequate.

Lightning and transient high-voltage protection follows a familiar communications scenario: identify the unwanted signal, isolate it and dissipate it. The difference here is that the unwanted signal is many megavolts at possibly 200,000 A. What can we do?

Effective lightning protection system design is a complex topic. There are a variety of system tradeoffs which must be made and which determine the type and amount of protection needed. A amateur station in a home is a very different proposition from an air traffic control tower which must be available 24 hours a day, 7 days a week. Hams can easily follow some general guidelines that

will protect their stations against high-voltage events that are induced by nearby lightning strikes or that arrive via utility lines. Let's talk about where to find professionals first, and then consider construction guidelines.

### PROFESSIONAL HELP

Start with your local government. Find out what building codes apply in your area and have someone explain the regulations about antenna installation and safety. For more help, look in your telephone yellow pages for professional engineers, lightning protection suppliers and contractors.

Companies that sell lightning-protection products may offer considerable help to apply their products to specific installations. One such source is PolyPhaser Corporation. Look under “References” later in this chapter for a partial list of PolyPhaser's publications.

### CONSTRUCTION GUIDELINES

#### Bonding Conductors

Copper strip (or *flashing*) comes in a number of sizes. The *minimum* recommended grounding conductor for lightning protection is 1.5 inches wide and 0.051 inch thick or #6 AWG stranded wire. Do not use braided strap outside or in wet areas because the individual strands oxidize over time, greatly reducing the effectiveness of braid as an ac conductor. Bear in mind that copper strap has about the same inductance as a wire of the same length. While strap may be easier to install and provides a lower RF loss (if it's part of a vertical antenna grounding system, for instance), it doesn't provide significant improvement over round wire for power line frequencies (the NEC's concern) or lightning (where inductance dominates the effects).

Use bare copper for buried ground wires. (There are some exceptions; seek an expert's advice if your soil is corrosive.) Exposed runs above ground that are subject to physical damage may require additional protection (a conduit) to meet code requirements. Wire size depends on the application, but never use anything smaller than #6 AWG for bonding conductors. The NEC specifies conductors using wire gauge, and doesn't describe the use of flashing. Local lightning-protection experts or building inspectors can recommend sizes for each application.

#### Tower and Antennas

Because a tower is usually the highest metal object on the property, it is the most likely strike target. Proper tower grounding is essential to lightning protection. The goal is to establish short multiple paths to the Earth so that the strike energy is divided and dissipated.

Connect each tower leg and each fan of metal guy wires to a separate ground rod.

**Figure 28.8** — Schematic of a properly grounded tower. A bonding conductor connects each tower leg to a ground rod and a buried (1 foot deep) bare, tinned copper ring (dashed line), which is also connected to the station ground and then to the ac safety ground. Make the ring diameter large enough that ground rods aligned with the tower legs will be approximately 6 feet apart. Buried radial wires extending beyond the ring are recommended but optional. All connectors should be compatible with the tower and conductor materials to prevent corrosion. See text for conductor sizes and details of lightning and voltage transient protection.

Space the rods at least 6 feet apart. Bond the leg ground rods together with #6 AWG or larger copper bonding conductor (form a ring around the tower base, see **Figure 28.8**). Connect a continuous bonding conductor between the tower ring ground and the entrance panel. Make all connections with fittings approved for grounding applications. *Do not use solder for these connections.* Solder will be destroyed in the heat of a lightning strike.

Because galvanized steel (which has a zinc coating) reacts with copper when combined with moisture, use stainless steel hardware between the galvanized metal and the copper grounding materials. Rohn and other manufacturers now offer ground clamps designed for connecting galvanized tower legs to copper ground conductors.

To prevent strike energy from entering a shack via the feed line, ground the feed line *outside* the home. Ground the coax shield to the tower at the antenna and the base to keep the tower and line at the same potential. Several companies offer grounding blocks that make this job easy.

All grounding media at the home must be bonded together. This includes lightning-protection conductors, electrical service, telephone, antenna system grounds and underground metal pipes. Any ground rods used

for lightning protection or entrance-panel grounding should be spaced at least 6 feet from each other and the electrical service or other utility grounds and then bonded to the ac system ground as required by the NEC.

### A Single-Point Ground Panel (SPGP)

The basic concept with transient protection is to make sure that all the radio and other equipment is tied together and “moves together” in the presence of a transient voltage. It’s not so important that the shack be at “ground” potential, but, rather, that everything is at the *same* potential. For fast rise-time transients such as the individual strokes that make up a lightning strike, even a short wire has enough inductance that the voltage drop along the wire is significant, so whether you are on the ground floor, or the 10th floor of a building, your shack is “far” from Earth potential.

The easiest way to ensure that everything is at the same potential is to tie all the signal ground connections to a common reference. In large facilities, this reference would be provided by a grid of large diameter cables under the floor, or by wide copper bars, or even a solid metal floor. A more practical approach for smaller facilities such as a ham

## Voltage Rise On Wires With Fast Transients

A rule of thumb is that a single wire has an inductance of about 1  $\mu\text{H}$  per meter of length. The voltage across an inductor  $V = L \Delta i / \Delta t$ . ( $\Delta i / \Delta t$  is the change in current per unit of time.) A lightning stroke has a rise time of about 1-2  $\mu\text{s}$ , so the current might go from zero to 10 kA in a microsecond or two, a  $\Delta i / \Delta t$  of over 1 kA/ $\mu\text{s}$  ( $10^9 \text{ A/s}$ ). An inductance as low as 1  $\mu\text{H}$  would create a voltage of 1000 volts from this current transient.

shack is to have a *single-point ground panel* (SPGP). The SPGP may be a separate metal panel or it can be enclosed in an electrical box. See the reference articles by Block for a complete discussion of the SPGP. The articles are available online through the ARRL’s Radio Technology Topics website ([www.arrl.org/radio-technology-topics](http://www.arrl.org/radio-technology-topics)) under Safety and in the ARRL book *Grounding and Bonding for the Radio Amateur*.

The SPGP should be mounted outside the building. The easiest way to do this is to install a large metal enclosure or a metal panel with a bulkhead and grounding block. The panel should be connected to the lightning dissipation ground with a short wide conductor (for minimum impedance), and, like all ground connections, be bonded to the electrical system’s ground. Mount all protective devices, switches, and relay disconnects on the outside facing wall. The enclosure or panel should be installed in a way that if lightning currents cause a component to fail, the molten metal and flaming debris do not start a fire.

Every conductor that enters the structure, including antenna system control lines, telephone, and CATV cables, should have its own surge suppressor on an entrance panel. Suppressors are available from a number of manufacturers, including Industrial Communication Engineers (ICE) and PolyPhaser, as well as the usual electrical equipment suppliers such as Square-D.

We want to control the flow of the energy in a strike and eliminate any possible path for surges to enter the building. Route feed lines, rotator control cables, and so on at least six feet away from other nearby grounded metal objects. Keep incoming, unprotected cables well away from cables on the protected side of any lightning arrestors, as well.

### Lightning Arrestors

Feed line lightning arrestors are available for both coax cable and balanced line. Most of the balanced line arrestors use a simple spark gap arrangement, but a balanced line

impulse suppressor is available from ICE. DC blocking arrestors for coaxial cable have a fixed frequency range. They present high-impedance to lightning (less than 1 MHz) while offering a low impedance to RF. DC continuity arrestors (gas tubes and spark gaps) can be used over a wider frequency range than those that block dc. Where the coax carries supply voltages to remote devices (such as a mast-mounted preamp or remote coax switch), dc-continuous arrestors must be used.

## 8.1.12 Other Hazards in the Station

### UPS AND ALTERNATE ENERGY SOURCES

Many hams have alternate energy sources for their equipment, or an uninterruptible power supply (UPS), so that they can keep operating during a utility power outage. This brings some additional safety concerns, because it means that the “turning off the breaker” approach to make sure that power disconnected might not work.

In commercial installations, fire regulations or electrical codes often require that the emergency power off (EPO) system (the big red button next to the door) also disconnect the batteries of the UPS system, or at least, disable the ac output. This is so that firefighters who may be chopping holes with conductive tools or spraying conductive water don't face the risk of electrocution. (According to NEC, Articles 645-10 and 645-11, UPSs above 750 VA installed within information technology rooms must be provided with a means to disconnect power to all UPS supply and output circuits. This disconnecting means

shall also disconnect the battery from its load. The code further requires that the control for these disconnecting means shall be grouped and identified and shall be readily accessible at the principal exit doors.)

A similar problem exists with solar panel installations. Just because the breaker is turned off doesn't mean that dangerous voltages don't exist on the solar panel. As long as light is falling on them, there is voltage present. With no load, even a relatively dim light falling on part of the panels might present a shock or equipment damage hazard. Modern grid-tie solar systems with no batteries often have the panels wired in series, so several hundred volts is not unusual.

Recent revisions of the NEC have addressed many of the aspects of photovoltaic (PV) installations that present problems with disconnects, bonding, and grounding. Consulting your local authorities is always wise, and there are several organizations such as the Southwest Technology Development Institute at New Mexico State University that have prepared useful information (see the references at the end of this section). In general, PV systems at 12 or 24 V aren't covered by the NEC.

### ENERGIZED CIRCUITS

Working with energized circuits can be very hazardous since, without measuring devices, we can't tell which circuits are live. The first thing we should ask ourselves when faced with troubleshooting, aligning or other “live” procedures is, “Is there a way to reduce the hazard of electrical shock?” Here are some ways of doing just that.

1) If at all possible, troubleshoot with an ohmmeter. With a reliable schematic diagram

and careful consideration of how various circuit conditions may reflect resistance readings, it will often be unnecessary to do live testing.

2) Keep a fair distance from energized circuits. What is considered “good practice” in terms of distance? The NEC specifies minimum working space around electric equipment depending on the voltage level. The principle here is that a person doing live work needs adequate space so they are not forced to be dangerously close to energized equipment.

3) If you need to measure the voltage of a circuit, install the voltmeter with the power safely off, back up, and only then energize the circuit. Remove the power before disconnecting the meter.

4) If you are building equipment that has hinged or easily removable covers that could expose someone to an energized circuit, install interlock switches that safely remove power in the event that the enclosure is opened with the power still on. Interlock switches are generally not used if tools are required to open the enclosure.

5) Never assume that a circuit is at zero potential even if the power is switched off and the power cable disconnected. Capacitors can retain a charge for a considerable period of time and may even partially recharge after being discharged. Bleeder resistors should be installed, but don't assume they have discharged the voltage. Instead, after power is removed and disconnected use a “shorting stick” to ground all exposed conductors and terminals to ensure that voltage is not present. If you will be working with charged capacitors that store more than a few joules of energy, you should consider using a “discharging stick” with a high wattage, low value

## Electrical Shock Hazards and Effects

### What happens when someone receives an electrical shock?

Electrocutions (fatal electric shocks) usually are caused by the heart ceasing to beat in its normal rhythm. This condition, called ventricular fibrillation, causes the heart muscles to quiver and stop working in a coordinated pattern, in turn preventing the heart from pumping blood.

The current flow that results in ventricular fibrillation varies between individuals but may be in the range of 100 mA to 500 mA. At higher current levels the heart may have less tendency to fibrillate but serious damage would be expected. Studies have shown 60-Hz alternating current to be more hazardous than dc currents. Emphasis is placed on application of cardiopulmonary resuscitation (CPR), as this technique can provide mechanical flow of some blood until paramedics can “re-

start” the heart's normal beating pattern. Defibrillators actually apply a carefully controlled waveform to “shock” the heart back into a normal heartbeat. It doesn't always work but it's the best procedure available.

### What are the most important factors associated with severe shocks?

You may have heard that the current that flows through the body is the most important factor, and this is generally true. The path that current takes through the body affects the outcome to a large degree. While simple application of Ohm's Law tells us that the higher the voltage applied with a fixed resistance, the greater the current that will flow. Most electrical shocks involve skin contact. Skin, with its layer of dead cells and often fatty tissues, is a fair insulator. Nonetheless, as voltage

increases the skin will reach a point where it breaks down. Then the lowered resistance of deeper tissues allows a greater current to flow. This is why electrical codes refer to the term “high voltage” as a voltage above 600 V.

### How little voltage can be lethal?

This depends entirely on the resistance of the two contact points in the circuit, the internal resistance of the body, and the path the current travels through the body. Historically, reports of fatal shocks suggest that as little as 24 V *could* be fatal under extremely adverse conditions. To add some perspective, one standard used to prevent serious electrical shock in hospital operating rooms limits leakage flow from electronic instruments to only 50  $\mu$ A due to the use of electrical devices and related conductors inside the patient's body.

resistor in series to ground that limits the discharge current to around 5-10 A. A dead short across a large charged capacitor can damage the capacitor because of internal thermal and magnetic stress. Avoid using screwdrivers, as this brings the holder too close to the circuit and could ruin the screwdriver's blade. For maximum protection against accidentally energizing equipment, install a shorting lead between high-voltage circuits and ground while you are working on the equipment.

6) Shorting a series string of capacitors does not ensure that the capacitors are discharged. Consider two 400  $\mu\text{F}$  capacitors in series, one charged to +300 V and the other to -300 V with the midpoint at ground. The net voltage across the series string is zero, yet each has significant (and lethal) energy stored in it. The proper practice is to discharge each capacitor in turn, putting a shorting jumper on it after discharge, and then moving to the next one.

7) If you must hold a probe to take a measurement, always keep one hand in your pocket. As mentioned in the sidebar on high-voltage hazards, the worst path current could take through your body is from hand to hand since the flow would pass through the chest cavity.

8) Make sure someone is in the room with you and that they know how to remove the power safely. If they grab you with the power still on they will be shocked as well.

9) Test equipment probes and their leads must be in very good condition and rated for the conditions they will encounter.

10) Be wary of the hazards of "floating" (ungrounded) test equipment. A number of options are available to avoid this hazard.

11) Ground-fault circuit interrupters can

offer additional protection for stray currents that flow through the ground on 120-V circuits. Know their limitations. They cannot offer protection for the plate supply voltages in linear amplifiers, for example.

12) Older radio equipment containing ac/dc power supplies have their own hazards. If you are working on these live, use an isolation transformer, as the chassis may be connected directly to the hot or neutral power conductor.

13) Be aware of electrolytic capacitors that might fail if used outside their intended applications.

14) Replace fuses only with those having proper ratings. The rating is not just the current, but also takes into account the speed with which it opens, and whether it is rated for dc or ac. DC fuses are typically rated at lower voltages than those for ac, because the current in ac circuits goes through zero once every half cycle, giving an arc time to quench. Switches and fuses rated for 120 V ac duty are typically not appropriate for high-current dc applications (such as a main battery or solar panel disconnect).

## 28.2 Antenna and Tower Safety

By definition, all of the topics in this book are about radio telecommunications. For those communications, receive and transmit antennas are required and those antennas need to be up in the air to work effectively. While antenna design and construction are covered elsewhere, this section covers many of the topics associated with installing antennas, along with related safety issues.

A substantially more detailed treatment of techniques used to erect towers and antennas is available in these references:

*The ARRL Antenna Book*

*Up the Tower: The Complete Guide to*

*Tower Construction* by Steve Morris, K7LXC  
*Antenna Towers for Radio Amateurs* by Don Daso, K4ZA, published by the ARRL.

### 28.2.1 Legal Considerations

Some antenna support structures fall under local building regulations as well as neighborhood restrictions. Many housing developments have Homeowner's Associations (HOAs) as well as Covenants, Conditions and Restrictions (CC&Rs) that may have a direct bearing on whether a tower or similar structure can be erected at all. This is a broad topic

with many pitfalls. Detailed background on these topics is provided in *Antenna Zoning for the Radio Amateur* by Fred Hopengartner, K1VR, an attorney with extensive experience in towers and zoning. You may also want to contact one of the ARRL Field Organization's Volunteer Counsels.

Even without neighborhood issues, a building permit is likely to be required. With the proliferation of cellular and other commercial wireless devices and their attendant R sites, many local governments now require that the structures meet local building codes. Again, K1VR's book is extremely helpful i

...ing all this out. Building permit applica-  
 ...ns may also require Professional Engineer  
 ...E) calculations and stamp (certification).

 ...onsulting Engineer program may be useful  
 ...th the engineering side of your project.

### 3.2.2 Antenna Mounting Structures

#### TREES AND POLES

The original antenna supports were trees: if  
 you've got them, use them. They're free and  
 unregulated, so it couldn't be easier. Single-  
 trunked varieties such as fir and pine trees are  
 easier to use than the multi-trunked vari-  
 eties. Multi-trunked trees are not impossible  
 to use — they just require a lot more work.  
 For dipoles or other types of wire antennas,  
 you can use the tree to support an end of the  
 antenna; trying to install an inverted V or similar  
 configuration is almost impossible due to all  
 the intervening branches.

Install a screw-eye with a pulley at the  
 desired height, trim away enough limbs to

create a "window" for the antenna through  
 the branches and then attach a rope halyard  
 to the antenna insulator. Here's a useful tip:  
 Make the *halyard* a continuous loop as shown  
 in **Figure 28.9**. Since it's almost always  
 the antenna wire that breaks, a continuous  
 halyard makes it easy to reattach the wire  
 and insulator. With just a single halyard, if  
 the antenna breaks, the tree will have to be  
 climbed to reach the pulley, then reinstall  
 and attach the line. If you're unable to climb  
 the support tree, contact a local tree service.  
 Professional tree climbers are often willing  
 to help out for a small fee.

Another way to get wires into trees is with  
 some sort of launcher. Using a bow-and-  
 arrow is a traditional method of shooting a  
 fishing line over a tree to pull up a bigger line.  
 There are now commercial products available  
 that are easier to use and reach higher in the  
 tree. For example, wrist-rocket slingshots and  
 compressed-air launchers can reach heights  
 of more than 200 feet!

Wooden utility poles offer a tree-related  
 alternative but are not cheap, require special  
 installation with a pole-setting truck, and  
 there is no commercial antenna mounting

hardware available for them. That makes  
 them a poor choice for most installations.

#### TOWERS

The two most important parameters to  
 consider when planning a tower installation  
 are the maximum local *wind speed* and the  
 proposed antenna *wind load*. Check with your  
 local building department to find out what  
 the maximum wind speed is for your area.  
 Another source is a list of maximum wind  
 speeds for all counties in the US from the  
 TIA-222, *Structural Standard for Antenna  
 Supporting Structures and Antennas*. This  
 is an expensive professional publication so  
 it's not for everyone, but the list is posted on  
 the Champion Radio Products website under  
 "Tech Notes." Tower capacities are generally  
 specified in square feet of antenna load and  
 antenna wind load specifications are provided  
 by the antenna manufacturer.

Before beginning, learn and follow  
 K7LXC's Prime Directive of tower construc-  
 tion — "DO what the manufacturer says."  
 (And DON'T do what the manufacturer  
 doesn't say to do.) Professional engineers  
 have analyzed and calculated the proper spec-

Figure 28.9 — Loop and halyard method  
 supporting wire antennas in trees.  
 Should the antenna break, the continuous  
 loop of rope allows antenna repair or  
 replacement without climbing the tree.

ifications and conditions for tower structures and their environment. Taking any shortcuts or making different decisions will result in a less reliable installation.

Towers come in the two varieties shown in **Figure 28.10** — guyed and self-supporting. Guyed towers require a bigger footprint because the guys have to be anchored away from the tower — typically 80% of the tower height. Self-supporting towers need bigger bases to counteract the overturning moment and are more expensive than a guyed tower because there is more steel in them (the cost of a tower is largely determined by the cost of the steel).

The most popular guyed towers are the Rohn 25G and 45G. The 25G is a light-duty tower and the 45G is capable of carrying fairly big loads. The online Rohn catalog (see the References) has most of the information you'll need to plan an installation and is considered a "bible" of information for tower construction.

Self-supporting towers are made by several manufacturers and allow building a tower up to 100 feet or higher with a small footprint. Rohn, Trylon and AN Wireless are popular vendors. Another type of self-supporting tower is the *crank-up*, shown in **Figure 28.11**. Using a system of cables, pulleys and winches, crank-up towers can extend from 20 feet to over 100 feet high. These are moderately complex devices. Because they consist of a variety of moving parts, crank-up towers require more maintenance than guyed or other self-supporting designs. The largest manufacturer of crank-up towers is US Towers.

Another simple and effective way to get an antenna up in the air is with a *roof-mounted tower*, seen in **Figure 28.12**. These are four-legged aluminum structures of heights from four to more than 20 feet. While they are designed to be lag-screwed directly into the roof trusses, it is often preferable to through-bolt them into a long 2x4 or 2x6 that acts a backing plate, straddling three to four roof trusses. In any case, if it is not clear how best to install the tower on the structure, have a roofing professional or engineer provide advice. Working on a roof-mounted tower also requires extra caution because of climbing on a roof while also working on a tower. Many of these lightweight, aluminum towers cannot be climbed, so you must use a ladder to access the antenna. Again, extreme caution is required.

### 28.2.3 Tower Construction and Erection

#### THE BASE

Once all the necessary materials and the required approvals have been gathered, tower installation can begin. Let's assume you and

**Figure 28.12** — The roof-mounted tower holding the AA2OW antenna system. [AA2OW photo]

your friends are going to install it. The first job is to construct the base. A base for a guyed tower can be hand-dug as can the guy anchors. For a self-supporting tower, renting an excavator of some sort will make it much easier to move the several cubic yards of dirt.

In the bottom of hole, be sure to add several inches of gravel or crushed stone that will allow water to drain from the hollow tower legs. If the base section is not going to

sit on the gravel, be sure to provide a drainage path for the legs. Water that builds up in the tower legs from condensation or leakage will rust out the steel from the inside where it is not visible until significant damage has been done, creating a severe safety hazard. Similarly, standing water in the legs may also freeze and split the tubing with the same effect on safety.

Next, some sort of rebar cage will be

**Figure 28.11** — The bottom of N6TV's crank-up tower is shown at left. The motor drive mechanism is on the left and a fishing net on the right catches and coils the feed lines and control cables as the tower is lowered. ## Principles of Working Safely

The following safety tenets founded on three fundamental principles: Do it safely or not at all; There's always time to do it right; and If it's worth doing, do it better.

1. Never load or operate structures or equipment outside the design limits. Be careful with tools, ropes, pulleys, and other equipment that can cause injury or damage if they fail due to overload. Use the right stuff!

2. Always move to a safe, controlled condition and seek assistance when a situation is not understood. This is particularly important when working on towers and antennas. If something doesn't look right or isn't going according to plan, return to a safe state and figure out what to do.

3. Always operate with the safety mechanisms engaged. If a safety mechanism prevents you from doing something, either the task is unsafe or you may not be using the right equipment.

4. Always follow safe work practices and procedures. Make a plan before you start and don't do something you know is unsafe.

5. Act to stop unsafe practices. The team's safety depends on every team member. Do not hesitate to stop work if you see it is unsafe. Don't be afraid to speak up or ask for help! Regroup and do it right.

6. Clarify and understand procedures before proceeding. This is particularly important when working with a crew. Be sure everyone understands the procedure and how to communicate.

7. Involve people with expertise and firsthand knowledge in decisions and planning. Ask for advice and guidance from experienced hams when planning a task with which you are unfamiliar.

needed for the concrete. Guyed towers only require rudimentary rebar while a self-supporting tower will need a bigger, heavier and more elaborate cage. Consult the manufacturer's specifications for the exact materials and dimensions.

Typical tower concrete specs call for 3000 psi (minimum) compressive strength concrete and 28 days for a full cure. A local pre-mix concrete company can deliver it. Pouring the concrete is easiest if the concrete truck can back up to the hole. If that's not possible, a truck- or trailer-mounted line pump can pump it up to 400 feet at minimal expense if using a wheelbarrow is not possible or practical. Packaged concrete from the hardware store mixed manually may also be used. Quikrete Mix #1101 is rated at 2500 psi after seven days and 4000 psi after 28 days.

### TOOLS

Once the base and anchors are finished and the concrete has cured, the tower can be constructed. There are several tools that will make the job easier. If the tower is a guyed tower, it can be erected either with a crane or a *gin-pole*. The gin-pole, shown in **Figure 28.13**, is a pipe that attaches to the leg of the tower and has a pulley at the top for the haul rope. Use the gin-pole to pull up one section at a time (see below).

Another useful tool for rigging and hoisting is the *carabiner*. Shown in **Figure 28.14** (A and B), carabiners are oval steel or aluminum snap-links popularized by rock and mountain climbers. They have spring-loaded

gates and can be used for many tower tasks. For instance, there should be one at the end of the haul rope for easy and quick attachment to rotators, parts and tool buckets — virtually anything that needs to be raised or lowered. It can even act as a “third hand” on the tower.

Along with the carabiner, the *nylon loop sling* in **Figure 28.14C** can be wrapped around large or irregularly shaped objects such as antennas, masts or rotators and attached to ropes with carabiners. For a complex job, a professional will often climb with eight to ten slings and use every one!

A pulley or two will also make the job easier. At a minimum, one is needed for the haul rope at the top of the tower. A *snatch block* is also useful; this is a pulley whose top opens up to “snatch” (attach it to) the rope at any point. **Figure 28.15** shows two snatch-block pulleys used for tower work.

### ROPES

Speaking of ropes, use a decent haul rope. Rope that is one-half inch diameter or larger affords a good grip for lifting and pulling. There are several choices of rope material. The best choice is a synthetic material such as nylon or Dacron. A typical twisted rope is fine for most applications. A synthetic rope with a braid over the twisted core is known as *braid-on-braid* or *kernmantle*. While it's more expensive than twisted ropes, the outer braid provides better abrasion resistance. The least expensive type of rope is polypropylene. It's a stiff rope that doesn't take a knot as well as other types but is reasonably durable and cheap. **Table 28.2** shows the safe working

**Figure 28.13** — A gin-pole consists of a leg clamp fixture, a section of aluminum mast and a pulley. It is used to lift the tower section high enough to be safely lowered into place and attached. (Based on Rohn EF2545.)

load ratings for common types of rope.

When doing tower work, being able to tie knots is required. Of all the knots, the *bowline* is the one to know for tower work. The old “rabbit comes up through the hole, around the tree and back down the hole” is the most familiar method of tying a bowline. Most amateurs are knot-challenged so it's a great advantage to know at least this one.

### INSTALLING TOWER SECTIONS

The easiest way to erect a tower is to use a crane. It's fast and safe but more expensive than doing it in sections by hand. To erect a tower by sections, a gin-pole is needed (see **Figure 28.13**). It consists of two pieces — a clamp or some device to attach it to the tower leg and a pole with a pulley at the top. The pole

is typically longer than the work piece being hoisted, allowing it to be held above the tower top while being attached or manipulated.

With the gin-pole mounted on the tower, the haul rope runs up from the ground, through the gin-pole mast and pulley at the top of the gin-pole, and back down the tower. The haul rope has a knot (preferably a bowline) on the end for attaching things to be hauled up or down. A carabiner hooked into the right side of the knot can be attached to objects quickly so that you don't have to untie and re-tie a bowline with every use.

It's a good idea to pass the haul rope through a snatch-block at the bottom of the tower, changing the direction of the rope from vertical to horizontal. This allows the ground crew an easier view up the tower and keeps them back, away from the tower base, in case the climbers accidentally drop something.

## GUYS

For guyed towers, an important construction parameter is guy wire material and guy *tension*. Do not use rope or any other material not rated for use as guy cable as permanent tower guys. Guyed towers for amateurs typically use either 3/16-inch or 1/4-inch EHS (extra-high strength) steel guy cable. The only other acceptable guy material is Phillystran — a lightweight cable made of Kevlar fibers. Phillystran is available with breaking strength similar to EHS cable. The advantage of Phillystran is that it is non-conducting and does not create unwanted electrical interactions with antennas on the tower. It is an excellent choice for towers supporting multiple Yagi and wire antennas and does not have to be broken up into short lengths with insulators.

EHS wire is very stiff — to cut it, use a hand-grinder with thin cutting blades or a circular saw with a metal-cutting aggregate blade. Wear safety glasses and gloves when cutting since there will be lots of sparks

turning steel being thrown off. Phillystran can be cut with a utility knife or a hot knife or cutting plastic.

If the guys are too loose, the result will be wind-induced shock loading. Guys that are too tight exert extra compressive load on the tower legs, reducing the overall capacity and reliability of the tower. The proper tension of HS or Phillystran guys is 10% of the material's ultimate breaking strength. For 3/16-inch HS the ultimate breaking strength is 4900 pounds and for 1/4-inch it's 6000 pounds so the respective guy tension should be 490 pounds and 600 pounds. The easiest to use, most accurate, and least expensive way to measure guy tension is by using a Loos tension gauge, developed for sailboat rigging. It is available at some marine supply stores or from Champion Radio Products.

Guy wires used to be terminated in a loop with cable clamps but those have been largely replaced by pre-formed Big Grips, shown in Figure 28.16. These simply twist onto the guy wire and are very secure. They grip the guy cable by squeezing the cable as tension is applied. Be sure to use the right type of Big Grips for the thickness and material of the guy cable.

### 28.2.4 Antenna Installation

Once the tower is up, it's time to install the antennas. VHF/UHF whips and wire antennas are pretty straightforward, but installing a HF Yagi is a more challenging situation. With a self-supporting tower, there are no guy wires to contend with — generally, the antenna can just be hauled up the tower face. Sometimes it is simply that easy!

In most cases, short of hiring a crane, the easiest way to get a Yagi up and down a tower is to use the tram method. A single tramline is suspended from the tower to the ground and the load is suspended under the tramline. Another technique is the trolley method in which two lines are suspended from the tower to the ground and the antenna rides on top of the lines like a trolley car on tracks. Problems with the trolley technique include trying to get the lines to have the same tension, balancing the antenna so that it won't fall off of the lines, and the added friction of pulling the antenna up two lines. The tram method has none of these problems. Figure 28.17 illustrates the tram method of raising antennas.

Tram and trolley lines are typically attached to the mast above the top of the tower. In the case of a big load, the lines may exert enough force to bend the mast. If in doubt, back-guy the mast with another line in the opposite direction for added support.

## MASTS

A mast is a pipe that sticks out of the top of the tower and connects the rotator to the

antenna. For small antenna loads and moderate wind speeds, any pipe will work. But as wind speed and wind load increase, more force will be exerted on the mast.

There are two materials used for masts — pipe and tubing. Pipe can be water pipe or conduit (EMT). Pipe is a heavy material with not much strength since its job is just to carry water or wires. Pipe is acceptable as mast material for small loads only. Another problem is that 1.5-in. pipe (pipe is measured by its inside diameter or ID) is only 1.9-in. OD. Since most antenna boom-to-mast hardware is designed for a 2-in. mast, the less-than-perfect fit may lead to slippage.

For any larger load use carbon-alloy steel tubing rated for high strength. A moderate antenna installation in an 80 MPH wind might exert 40,000 to 50,000 pounds per square inch (psi) on the mast. Pipe has a yield strength of about 35,000 psi, so you can see that pipe is not adequately rated for this type of use. Chrome-moly steel tubing is available with

yield strengths from 40,000 psi up to 115,000 psi but it is expensive. Table 28.3 shows the ratings of several materials used as masts for amateur radio antennas.

Calculating the required mast strength can be done by using a software program such as the Mast, Antenna and Rotator Calculator (MARC) software. (See the References.) The software requires as inputs the local wind speed, antenna wind load, and placement on the mast. The software then calculates the mast bending moment and will recommend a suitable mast material.

### 28.2.5 Weatherproofing Cable and Connectors

The biggest mistake amateurs make with coaxial cable is improper weatherproofing. (Coax selection is covered in the chapter on Transmission Lines.) Figure 28.18 shows how to do it properly. First, use high-quality electrical tape, such as 3M Scotch 33+ or

Figure 28.16 — A PreFormed Line Products Big Grip for guy wires.

Scotch 88 (same as 33+ but 1.5 mil thick). Avoid inexpensive utility tape. Before waterproofing, tighten the connector (use pliers carefully to seat threaded connectors — hand tight isn't good enough).

When you're done making a tape wrap, sever the tape with a knife or tear it vertically — carefully — *do not* stretch the tape until it breaks. This invariably leads to "flagging" where the end of the tape loosens and blows around in the wind. Let the tape relax before applying the next layer.

Begin by applying two wraps of electrical tape around the joint. Next put a layer of butyl rubber vapor wrap over the joint. (3M Butyl Mastic Tape 2212 is one such material. Butyl rubber tape is usually available at the electrical section of hardware and home improvement stores.) Finally, add two more layers of regular tape over the vapor wrap, creating a professional-quality joint that will never leak. Finally, if the coax is vertical, be sure to wrap the final layer so that the tape goes up the cable as shown in Figure 28.8. In that way, the layers will act like roofing shingles, shedding water off the connection. Wrapping it top to bottom will guide water between the layers of tape.

An alternative method suggested by K4Z begins with a wrap of "military grade" Tylon tape — a thread wrapping tape thicker than what you'll find at your local hardware store. (McMaster-Carr #6802K44) Over that, install a layer of Scotch 130C (liner-less rubber sealing tape), using a 50% wrap (half the tape width is overlapped). Cover that with a layer of either Scotch 33+ or Scotch 88. Taken apart, 20-year-old joints have revealed connectors with like new appearance.

### 28.2.6 Climbing Safety

Tower climbing is a potentially dangerous activity, so you'll need to use the proper safety equipment and techniques. OSHA, the Federal Occupational Safety and Health Administration, publishes rules for workplace safety. Although amateurs are not bound by those rules, you'll be much better off by following them. What equipment and techniques you use are up to you. As long as you've got the right safety equipment and follow the basic safety rules you won't have any problems.

(C) The tramming system for getting antennas up and down. Run the antenna part way up the tramline for testing before installation. It just takes a couple of minutes to run an antenna up or down once the tramline is rigged.

## SAFETY AWARENESS AND PREPARATION

One of the most important aspects of safety is having the knowledge and awareness to do a job safely and efficiently. You must have the mental ability to climb and work at altitude while constantly rethinking all connections,

techniques and safety factors. Safely climbing and working on towers is 90% mental. Mental preparedness is something that must be learned. This is an occasion where there is no substitute for experience. The biggest obstacle for anyone is making the mental adjustment. Properly installed towers are inherently safe and accidents are relatively rare.

You should also check your safety equipment every time before you use it. Inspect it for any nicks or cuts to your belt and safety strap. Professional tower workers are required to check their safety equipment every day and you should check yours before each use.

Before climbing any tower, perform a careful inspection of the base and guys. A pair of binoculars allows inspection of the tower and guys above eye level. There should be no visible rust on the base section, especially where it contacts concrete. Look for splits from water freezing in the tower legs. If any of these are apparent, do not climb until further checks and any repairs are done. A small hole ( $\frac{1}{8}$  inch typically) may be drilled in the bottom of a tower leg without compromising strength in order to drain any standing water. Guys should be correctly tensioned and all guy attachments and anchors secure and free of rust.

If the tower is a crank-up model, lower it completely until the lift cable is slack. Tower sections can bind and appear to be lowered completely but slip from a climber's weight, causing serious injury. Before climbing, block all tower sections with a 2x4 or heavier material so no downward motion is possible. Never assume a crank-up tower is fully nested. For tilt-over towers or tower-lowering fixtures, perform a careful inspection of the winch, cable, and fixture before raising or lowering the tower. When the tower is near horizontal, the tension in the cable can be thousands of pounds. Make sure no one is near the tower as it is raised or lowered, and wear protective gear when operating the winch.

## PERSONAL SAFETY EQUIPMENT

One of the most important lessons for tower climbing is that you have four points of attachment and security — two hands and two feet. When climbing, move only one point at a time. That leaves you with three points of contact and a wide margin of safety if you ever need it. This is in addition to having your fall-arrest lanyard (see below) connected at all times.

Another recommended technique is to always do everything the same way every time. That is, always wear your positioning lanyard on the same D-ring and always connect it in the same way. Always look at your belt D-ring while clipping in with your safety strap. This way you'll always confirm that you're securely belted in. Always look!

The most important pieces of safety equipment are the *personal fall arrest system* (PFAS) you wear and the accompanying lanyards that attach to it (Figure 28.19). The PFAS has leg loops and suspenders to help spread the fall forces over more of your body and has the ability to hold you in a natural position with your arms and legs hanging below you where you're able to breathe normally.

Two or more lanyards are used. One is the

(B)

positioning lanyard (Figure 28.20). That is, it holds you in working position and attaches to the D-rings at your waist. They can be adjustable or fixed and are made from different materials such as nylon rope, steel chain, or special synthetic materials. An adjustable positioning lanyard will adjust to almost any situation whereas a fixed-length one is typically either too long or too short. A rope lanyard is the least expensive.

Leather safety equipment was outlawed some years ago by OSHA so don't use it. This includes the old-fashioned safety belt that utility pole linemen used for years but offers no fall arrest capability. If you drop down while wearing a safety belt, your body weight can cause it to rise up from your waist to your ribcage where it will immobilize your diaphragm and suffocate you. On the other hand, you can use a safety belt for positioning when it's worn over an FAH. Just don't depend on it to catch you in case of a fall.

The other lanyard is the fall arrest lanyard shown in Figure 28.21, which attaches to a D-ring between your shoulder blades. The other end attaches to the tower above the working position and catches you in case of a fall. The simplest is a 6 foot rope lanyard which is in

Figure 28.20 —Left-to-right, a collection of locking clips, a belt-type positioning lanyard, a fall-arrest lanyard, and a versatile adjustable lanyard. [Don Daso, K4ZA, photos]

Figure 28.21 — The fall-arrest lanyard is above the climber so that the climber can climb up to it. The fall-arrest and positioning lanyards are then “leapfrogged” so that the climber remains attached to the tower 100 percent of the time. [Steve Morris, K7LXC, photo]

expensive but doesn't offer any shock absorption. There are also shock absorbing varieties that typically have bar-tacked stitches that pull apart under force to decelerate you. *DO NOT* cut corners on buying or using safety equipment; you bet your life on it every time you use it!

OSHA rules and good common sense say you should be attached to the tower 100% of the time. You can do this several ways. One is to attach the fall arrest lanyard above you and climb up to it. Use your positioning lanyard to hold you while you detach it and move it up again. Repeat as necessary. Another option is to use a pair of fall arrest lanyards, attaching one then the other as you climb the tower. This typically means using one with your left hand then the second with your right hand. The attachment point on the tower should be capable of sustaining a 3000-pound load.

Boots should be leather with a steel or fiberglass shank. Diagonal bracing on Rohn 25G is only  $\frac{1}{16}$  inch rod — spending all day standing on that small step will take a toll on your feet. The stiff shank will support your weight and protect your feet; tennis shoes will not. Leather boots are mandatory on towers like Rohn BX that have sharp X-cross braces. Your feet are always on a slant and that is hard on feet.

A hard hat and safety goggles is highly recommended. Just make sure they are ANSI or OSHA approved and that you and your crew wear them. As you'll be looking up and down a lot, a chin strap is essential to keep the hard hat from falling off.

If you do a lot of tower work, your hands will take a beating. Gloves are essential — keep several spare pair for ground crew members who show up without them. Cotton gloves are fine for gardening but not for tower work; they don't provide enough friction for climbing or working with a haul rope. Leather gloves are the only kind to use; either full leather or leather-palmed are fine. The softer the gloves the more useful they'll be. Stiff leather construction gloves are fine for the ground crew but pigskin and other soft leathers are better for the climber because you can thread a nut or do just about any other delicate job with these gloves on.

## 28.3 RF Safety

Amateur Radio is basically a safe activity. In recent years, however, there has been considerable discussion and concern about the possible hazards of electromagnetic fields (EMF), including both RF energy and power frequency (50-60 Hz) EMF. FCC regulations set limits on the maximum permissible exposure (MPE) allowed from the operation of radio transmitters. Following these regulations, along with the

K4ZA recommends what are called “framer's gloves,” which are leather gloves with the thumb and two index finger-tips removed. This provides heavy-duty protection for the palm and backs of the hands, but allows fine finger-tip control for delicate work.

### SAFETY TIPS

1) Don't climb with anything in your hands; attach it to your safety belt if you must climb with it or have your ground crew send it up to you in a bucket.

2) Don't put any hardware in your mouth; it can easily be swallowed.

3) Remove any rings and/or neck chains; they can get hooked on things. Long hair should be secured.

4) Be on the lookout for bees, wasps, hornets, and their nests. If you do run into a stinging insect, use Adolph's Meat Tenderizer on the sting — it contains the enzyme papain which neutralizes the venom. Have a small jar in your tool kit.

5) Don't climb when tired; that's when most accidents occur.

6) Don't try to lift anything by yourself; one person on a tower has very little leverage or strength. Let the ground crew use their strength; save yours for when you really need it.

7) If a procedure doesn't work, assess the situation and re-rig, if necessary, before trying again.

### GROUND CREW SAFETY

The climber on the tower is the boss. Before tower work starts, have a safety meeting with the ground crew. This “tailgate” meeting is important to get everyone on the same page, work-wise, detailing the work to be done and how to do it. This also the time and place to introduce the ground crew to gear or hardware they may be unfamiliar with such as a capstan winch, carabiners, rock climbing gear, special tools, and so on.

Explain what is going to be done and how to do it as well as introducing them to any piece of hardware with which they may not be familiar (for example, carabiners, slings or come-along winches).

As part of the ground crew, there are a few

rules to follow:

1) The climber on the tower is in charge.

2) Don't do anything unless directed by the climber in charge on the tower. This includes handling ropes, tidying up, moving hardware, and so on.

3) If not using radios to communicate, when talking to the climber on the tower, look up and talk directly to him or her in a loud voice. The ambient noise level is higher up on the tower because of traffic, wind and nearby equipment.

4) Communicate with the climber on the tower. Let him or her know when you're ready or if you're standing by or if there is a delay. Advise the climber when lunch is ready!

### 28.3.1 How EMF Affects Mammalian Tissue

All life on Earth has adapted to live in

an environment of weak, natural, low frequency electromagnetic fields, in addition to the Earth's static geomagnetic field. Natural low-frequency EM fields come from two main sources: the sun and thunderstorm activity. During the past 100 years, man-made fields at much higher intensities and with different spectral distributions have altered our EM background. Research-

ers continue to look at the effects of RF exposure over a wide range of frequencies and levels.

Both RF and power frequency fields are classified as *nonionizing radiation* because the frequency is too low for there to be enough photon energy to ionize atoms. *Ionizing radiation*, such as X-rays, gamma rays and some ultraviolet radiation, has enough energy to knock electrons loose from atoms. When this happens, positive and negative *ions* are formed. Still, at sufficiently high power densities, non-ionizing EMF poses certain health hazards.

It has been known since the early days of

radio that RF energy can cause injuries by heating body tissue. Anyone who has ever touched an improperly grounded radio chassis or energized antenna and received an *RF burn* will agree that this type of injury can be quite painful. Excessive RF heating of the male reproductive organs can cause sterility by damaging sperm. Other health problems also can result from RF heating. These heat related health hazards are called *thermal effects*. A microwave oven is an application that puts thermal effects to practical use.

There also have been observations of changes in physiological function in the presence of RF energy levels that are too low to cause

heating. These functions generally return to normal when the field is removed. Although research is ongoing, no harmful health consequences have been linked to these changes.

In addition to the ongoing research, much else has been done to address this issue. For example, FCC regulations set limits on exposure from radio transmitters. The Institute of Electrical and Electronics Engineers, the American National Standards Institute and the National Council for Radiation Protection and Measurement, among others, have recommended voluntary guidelines to limit human exposure to RF energy. The ARRL maintains an RF Safety Committee, consist-

## The ARRL RF Safety Committee

Imagine you wake up one day and the newspaper headlines are screaming that scientists have discovered radio waves cause cancer. How would you react? How would your neighbor react? You may not have to imagine very hard because the news has been inundated with this type of story regularly over the past couple of decades. Clearly our society has not been decimated by epidemics of diseases since the vast increase in cellular telephone use. Some people deal with this discrepancy by ignoring all scientific reports. Others adopt a pessimistic attitude that technology is going to kill us all eventually, while still others treat every such story as "the truth" and militantly try to stop the transmission of RF energy. The reality is that while all scientific study is complex, the study of electromagnetic biological effects is even more so. Few newspaper reporters are capable of understanding the nuances of a scientific study and are even less able to properly report its results to the lay public. As a result many newspaper stories mislead the public into thinking that a scientific study has found something about which they need to be warned.

The ARRL has dealt with this dilemma by creating the RF Safety Committee, a group of experts in the facets of medical, scientific and engineering investigation needed to fully critique and understand the results of studies on electromagnetic biological effects. Experts in Dosimetry, Public Health, Epidemiology, Statistical Methods, General Medicine and specific diseases are well suited to reading and understanding published scientific reports and critiquing their validity.

It is not uncommon to examine how an experiment was performed only to realize that errors were made in the design of the experiment or the interpretation of its results. It takes a group of reviewers with a wide range of expertise to consider the implications of all aspects of the study to recognize the value of the results.

The field of biological effects of electromagnetic energy constitutes a complex combination of scientific disciplines. Many scientific studies in this field do not generate reliable results because they are not based on input from experts in the many fields that affect the interactions between electromagnetic energy and biological organisms. Even well designed scientific studies are subject to misinterpretation when the results are presented to a public that does not understand or appreciate the complex interactions that occur between the physical world and biological organisms and how these affect public health.

Since the 1960s there have been thousands of scientific studies that were intended to discover if electromagnetic energy had an adverse affect on biological tissue. A large number of these studies, designed and performed by biologists, did not accurately expose the subjects to known levels of electromagnetic energy. A field of expertise in RF engineering, called dosimetry, was developed to accurately determine the exact field strengths of both electrical and magnetic fields to

which subjects were exposed. It has been imperative that an expert in electromagnetic dosimetry be involved in study design, though even today this requirement is often ignored. The RF Safety committee contains expertise in dosimetry that often discovers experimental errors in published results due to misstatements of the amount of exposure that subjects experienced.

Epidemiological studies have the potential to recognize disease trends in populations. However, they can also develop misleading results. Epidemiology looks for health trends among people with similar types of exposures as compared to a similar group of people that does not have the same type of exposure. (This type of study has become difficult to perform with cellular telephones because it is hard to find people who do not use them). The great diversity of the population makes it difficult to know that there is not some other exposure that affects the study group. The RF Safety committee contains expertise in epidemiology to make sense of claims based on epidemiological evidence, and the review of the methods and results can reveal a lesser impact of the study than the author or the press had implied.

Some experimental studies correctly demonstrate biological changes due to exposure to electromagnetic fields. A change in a biological tissue that occurs because of the presence of some form of energy may be an interesting finding, but it does not imply that this change will lead to a public health problem. (An obvious example is contraction of the eye pupil in the presence of bright light, a form of electromagnetic energy). The RF Safety Committee contains expertise in Public Health that helps to determine if there may be a correlation between a laboratory finding and any potential concern for the health of people in our society.

The ARRL RF Safety Committee serves as a resource to the ARRL Board of Directors, providing advice that helps them formulate ARRL policy related to RF safety. The RFSC interacts with the ARRL HQ staff to ensure that RF safety is appropriately addressed in ARRL publications and on the ARRL website. The Amateur Radio community corresponds with the RFSC for help with RF safety-related questions and problems. RFSC members monitor and analyze relevant published research. Its members participate in standards coordinating committees and other expert committees related to RF safety. The RFSC is responsible for writing the RF safety text that is included in ARRL publications. The accuracy of RF safety-related issues in articles submitted to *QST* and *QEX* are confirmed by committee members. The RFSC also participates in developing the RF safety questions for FCC amateur question pools and works with the FCC in developing its environmental regulations. Radio amateurs with questions related to RF safety can contact the RFSC via its liaison, Ed Hare, W1RFI, [w1rfi@arri.org](mailto:w1rfi@arri.org). The RFSC maintains a webpage at [www.arri.org/arri-rf-safety-committee](http://www.arri.org/arri-rf-safety-committee).

ing of concerned scientists and medical doctors, who volunteer to serve the radio amateur community to monitor scientific research and to recommend safe practices.

### THERMAL EFFECTS OF RF ENERGY

Body tissues that are subjected to *very high levels* of RF energy may suffer serious heat damage. These effects depend on the frequency of the energy, the power density of the RF field that strikes the body and factors such as the polarization of the wave and the grounding of the body.

At frequencies near the body's natural resonances RF energy is absorbed more efficiently. In adults, the primary resonance frequency is usually about 35 MHz if the person is grounded, and about 70 MHz if insulated from the ground. Various body parts are resonant at different frequencies. Body size thus determines the frequency at which most RF energy is absorbed. As the frequency is moved farther from resonance, RF energy absorption becomes less efficient. *Specific absorption rate (SAR)* is a measure that takes variables such as resonance into account to describe the rate at which RF energy is absorbed in tissue, typically measured in watts per kilogram of tissue (W/kg).

*Maximum permissible exposure (MPE)* limits define the maximum electric and magnetic field strengths, and the plane-wave equivalent power densities associated with these fields, that a person may be exposed to without harmful effect, and are based on whole-body SAR safety levels. The safe exposure limits vary with frequency as the efficiency of absorption changes. The MPE limits Safety factors are included to insure that the MPE field strength will never result in an unsafe SAR.

Thermal effects of RF energy are usually not a major concern for most radio amateurs because the power levels normally used tend to be low and the intermittent nature of most amateur transmissions decreases total exposure. Amateurs spend more time listening than transmitting and many amateur transmissions such as CW and SSB use low-duty-cycle modes. With FM or RTTY, though, the RF is present continuously at its maximum level during each transmission. It is rare for radio amateurs to be subjected to RF fields strong enough to produce thermal effects, unless they are close to an energized antenna or unshielded power amplifier. Specific suggestions for avoiding excessive exposure are offered later in this chapter.

### ATHERMAL EFFECTS OF EMF

Biological effects resulting from exposure to power levels of RF energy that do not generate measurable heat are called *athermal*

*effects*. A number of athermal effects of EMF exposure on biological tissue have been seen in the laboratory. However, to date all athermal effects that have been discovered have had the same features: They are transitory, or go away when the EMF exposure is removed, and they have not been associated with any negative health effects.

### 28.3.2 Researching Biological Effects of EMF Exposure

The statistical basis of scientific research that confuses many non-scientists is the inability of science to state unequivocally that EMF is safe. Effects are studied by scientists using statistical inference where the "null hypothesis" assumes there is no effect and then tries to disprove this assumption by proving an "alternative hypothesis" that there is an effect. The alternative hypothesis can never be entirely disproved because a scientist cannot examine every possible case, so scientists only end up with a *probability* that the alternative hypothesis is *not* true. Thus, to be entirely truthful, a scientist can never say that something was proven; with respect to low-level EMF exposure, no scientist can guarantee that it is absolutely safe. At best, science can only state that there is a very low probability that it is unsafe. While scientists accept this truism, many members of the general public who are suspicious of EMF and its effects on humans see this as a reason to continue to be afraid.

There are two types of scientific study that are used to learn about the effects of EMF exposure on mammalian biology: laboratory and epidemiological.

### LABORATORY STUDY

Scientists conduct laboratory research using animals to learn about biological mechanisms by which EMF may affect mammals. The main advantage of laboratory studies on the biological effects of EMF is that the exposures can be controlled very accurately.

Some major disadvantages of laboratory study also exist. EMF exposure may not affect the species of animals used in the investigations the same way that humans may respond. A common example of this misdirection occurred with eye research. Rabbits had been used for many years to determine that exposure of the eyes to high levels of EMF could cause cataracts. The extrapolation of these results to humans led to the fear that use of radio would harm one's vision. However, the rabbit's eye is on the surface of its skull while the human eye is buried deep within the bony orbit in the skull. Thus, the human eye receives much less exposure from EMF and is less likely to be damaged by the same exposures that had been used in the laboratory experiments on rabbits.

Some biological processes that affect tissue can take many years to occur and laboratory experiments on animals tend to be of shorter duration, in part because the life spans of most animals are much shorter than that of humans. For instance, a typical laboratory rat can be studied at most for two years, during which it progresses from youth to old age with all of the attendant physiological changes that come from normal aging. A disease process that takes multiple exposures over many years to occur is unlikely to be seen in a laboratory study with small animals.

### EPIDEMIOLOGICAL RESEARCH

Epidemiologists look at the health patterns of large groups of people using statistical methods. In contrast to laboratory research, epidemiological research has very poor control of its subjects' exposures to EMF but it has the advantages of being able to analyze the effects of a lifetime of exposure and of being able to average out variations among large populations of subjects. By their basic design, epidemiological studies do not demonstrate cause and effect, nor do they postulate mechanisms of disease. Instead, epidemiologists look for associations between an environmental factor and an observed pattern of illness. Apparent associations are often seen in small preliminary studies that later are shown to have been incorrect. At best, such results are used to motivate more detailed epidemiological studies and laboratory studies that narrow down the search for cause-and-effect.

Some preliminary studies have suggested a weak association between exposure to EMF at home or at work and various malignant conditions including leukemia and brain cancer. A larger number of equally well-designed and performed studies, however, have found no association. Risk ratios as high as 2 have been observed in some studies. This means that the number of observed cases of disease in the test group is up to 2 times the "expected" number in the population. Epidemiologists generally regard a risk ratio of 4 or greater to be indicative of a strong association between the cause and effect under study. For example, men who smoke one pack of cigarettes per day increase their risk for lung cancer tenfold compared to nonsmokers and two packs per day increases the risk to more than 25 times the nonsmokers' risk.

Epidemiological research by itself is rarely conclusive, however. Epidemiology only identifies health patterns in groups — it does not ordinarily determine their cause. There are often confounding factors. Most of us are exposed to many different environmental hazards that may affect our health in various ways. Moreover, not all studies of persons likely to be exposed to high levels of EMF have yielded the same results (see sidebar on preliminary epidemiological studies).

## Preliminary Epidemiology

Just about every week you can pick up the newspaper and see a screaming banner headline such as: "Scientists Discover Link Between Radio Waves and Disease." So why are you still operating your ham radio? You've experienced the inconsistency in epidemiological study of diseases. This is something that every radio amateur should understand in order to know how to interpret the real meaning of the science behind the headlines and to help assuage the fears that these stories elicit in others.

Just knowing that someone who uses a radio gets a disease, such as cancer, doesn't tell us anything about the cause-and-effect of that disease. People came down with cancer, and most other diseases, long before radio existed. What epidemiologists try to identify is a group of people who all have a common exposure to something and all suffer from a particular disease in higher proportion than would be expected if they were not exposed. This technique has been highly effective in helping health officials notice excesses of disease due to things such as poisoning of water supplies by local industry and even massive exposures such as smoking. However, epidemiology rarely proves that an exposure causes a disease; rather it provides the evidence that leads to further study.

While the strength of epidemiology is that it helps scientists notice anomalies in entire populations, its weakness is that it is non-specific. An initial epidemiological study examines only two things: suspected exposures and rates of diseases. These studies are relatively simple and inexpensive to perform and may point to an apparent association that then bears further study. For instance, in one study of the causes of death of Amateur Radio operators, an excess of leukemia was suggested. The percentage of ham radio operators who died of leukemia in that study was higher than expected based on the percentage of the rest of the population that died of leukemia. By itself, this has little meaning and should not be a cause for concern, since the study did not consider anything else about the sample population except that they had ham licenses. Many other questions arise: Were the study subjects exposed to any unusual chemicals? Did any of the study subjects have a family history of leukemia? Did the licensed amateurs even operate radios, what kind and how often? To an epidemiologist, this result might provide enough impetus to raise the funds to gather more specific information about each subject and perform a more complete study that strengthens the apparent associations. However, a slight excess of disease in a preliminary study rarely leads to further study. Commonly, an epidemiologist does not consider a preliminary study to be worth pursuing unless the ratio of excess disease, also called the risk ratio, is 4:1 or greater. Unfortunately, most news reporters are not epidemiologists and do not understand this distinction. Rather, a slight excess of disease in a preliminary study can lead to banner headlines that raise fear in the society, causing unreasonable resistance to things like cell phones and ham radios.

Headlines that blow the results of preliminary epidemiological studies out of proportion are rarely followed by retractions that are as visible if the study is followed up by one that is more complete and shows no association with disease. In the case of the aforementioned epidemiological study of hams' licensing and death records, overblown publicity about the results has led to the urban legend that ham radio operators are likely to come down with leukemia. Not only is this an unfounded conclusion due to the preliminary nature of the original study, but a similar study was recently performed by the National Cancer Institute using a far larger number of subjects and no significant excess of any disease was found. Hams should be able to recognize when sensationalistic headlines are based on inconclusive science and should be prepared to explain to their families, friends and neighbors just how inconclusive such results are.

### 28.3.3 Safe Exposure Levels

How much EMF energy is safe? Scientists and regulators have devoted a great deal of effort to deciding upon safe RF-exposure limits. This is a very complex problem, involving difficult public health and economic considerations. The recommended safe levels have been revised downward several times over the years — and not all scientific bodies agree on this question even today. The latest Institute of Electrical and Electronics Engineers (IEEE) C95.1 standard for recommended radio fre-

quency exposure limits was published in 2006, updating one that had previously been published in 1991 and adopted by the American National Standards Institute (ANSI) in 1992. In the new standard changes were made to better reflect the current research, especially related to the safety of cellular telephones. At some frequencies the new standard determined that higher levels of exposure than previously thought are safe (see sidebar, "Where Do RF Safety Standards Come From?").

The IEEE C95.1 standard recommends frequency-dependent and time-dependent maximum permissible exposure levels. Un-

like earlier versions of the standard, the 1991 and 2006 standards set different RF exposure limits in *controlled environments* (where energy levels can be accurately determined and everyone on the premises is aware of the presence of EM fields) and in *uncontrolled environments* (where energy levels are not known or where people may not be aware of the presence of EM fields). FCC regulations adopted these concepts to include controlled/occupational and uncontrolled/general population exposure limits.

The graph in **Figure 28.22** depicts the 1991 IEEE standard (which is still used as the basis of FCC regulation). It is necessarily a complex graph, because the standards differ not only for controlled and uncontrolled environments but also for electric (E) fields and magnetic (H) fields. Basically, the lowest E-field exposure limits occur at frequencies between 30 and 300 MHz. The lowest H-field exposure levels occur at 100-300 MHz. The ANSI standard sets the maximum E-field limits between 30 and 300 MHz at a power density of 1 mW/cm<sup>2</sup> (61.4 V/m) in controlled environments — but at one-fifth that level (0.2 mW/cm<sup>2</sup> or 27.5 V/m) in uncontrolled environments. The H-field limit drops to 1 mW/cm<sup>2</sup> (0.163 A/m) at 100-300 MHz in controlled environments and 0.2 mW/cm<sup>2</sup> (0.0728 A/m) in uncontrolled environments. Higher power densities are permitted at frequencies below 30 MHz (below 100 MHz for H fields) and above 300 MHz, based on the concept that the body will not be resonant at those frequencies and will therefore absorb less energy.

In general, the ANSI/IEEE standard requires averaging the power level over time periods ranging from 6 to 30 minutes for power-density calculations, depending on the frequency and other variables. The ANSI/IEEE exposure limits for uncontrolled environments are lower than those for controlled environments, but to compensate for that the standard allows exposure levels in those environments to be averaged over much longer time periods (generally 30 minutes). This long averaging time means that an intermittent RF source (such as an Amateur Radio transmitter) will result in a much lower exposure than a continuous-duty station, with all other parameter being equal. Time averaging is based on the concept that the human body can withstand a greater rate of body heating (and thus, a higher level of RF energy) for a short time.

Another national body in the United States, the National Council for Radiation Protection and Measurement (NCRP), also has adopted recommended exposure guidelines. NCRP urges a limit of 0.2 mW/cm<sup>2</sup> for nonoccupational exposure in the 30- 300 MHz range. The NCRP guideline differs from IEEE in

Figure 28.22 — 1991 RF protection guidelines for body exposure of humans. It is known officially as the “IEEE Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz.”

## Where Do RF Safety Standards Come From?

So much of the way we deal with RF Safety is based on “Safety Standards.” The FCC environmental exposure regulations that every ham must follow are largely restatements of the conclusions reached by some of the major safety standards. How are these standards developed and why should we trust them?

The preeminent RF safety standard in the world was developed by the Institute of Electrical and Electronics Engineers (IEEE). The most recent edition is entitled *C95.1 -2005: IEEE Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz*. The IEEE C95.1 Standard has a long history. The first C95.1 RF safety standard was released in 1966, was less than 2 pages long and listed no references. It essentially said that for frequencies between 10 MHz and 100 GHz people should not be exposed to a power density greater than 10 mW/cm<sup>2</sup>. The C95.1 standard was revised in 1974, 1982, 1991 and 2005. The latest (2005) edition of the standard was published in 2006, is 250 pages long and has 1143 references to the scientific literature. Most of the editions of the IEEE C95.1

standard were adopted by the American National Standards Institute (ANSI) a year or two after they were published by IEEE. The 2005 edition was adopted by ANSI in 2006.

The committee at IEEE that developed the latest revision to C95.1 is called International Committee on Electromagnetic Safety Technical Committee 95 Subcommittee 4 and had a large base of participants. The subcommittee was co-chaired by C-K Chou, Ph.D., of Motorola Laboratories, and John D’Andrea, PhD, of the U.S. Naval Health Research Center. The committee had 132 members, 42% of whom were from 23 countries outside the United States. The members of the committee represented academia (27%), government (34%), industry (17%), consultants (20%) and the general public (2%).

Early editions of C95.1 were based on the concept that heat generated in the body should be limited to prevent damage to tissue. Over time the standard evolved to protect against all known adverse biological effects regardless of the amount of heat generated. The 2005 revision was based on

the principles that the standard should protect human health yet still be practical to implement, its conclusions should be based solely on scientific evidence and wherever scientifically defensible it should be harmonized with other international RF safety standards. It based its conclusions on 50 years of scientific study. From over 2500 studies on EMF performed during that time, 1300 were selected for their relevance to the health effects of RF exposure. The science in these studies was evaluated for its quality and methodology and 1143 studies were referenced in producing the latest standard.

Other major standards bodies have published similar standards. The National Council for Radiation Protection and Measurement (NCRP) published its safety standard entitled, *Report No. 86: Biological Effects and Exposure Criteria for Radiofrequency Electromagnetic Fields* in 1986. The International Commission on Non-Ionizing Radiation Protection (ICNIRP) published its safety standard entitled *Guidelines for Limiting Exposure to Time-Varying Electric, Magnetic, and Electromagnetic Fields (Up to 300 GHz)* in 1998.

## FCC RF Exposure Regulations

FCC regulations control the amount of RF exposure that can result from your station's operation (§§97.13, 97.503, 1.1307 (b)(c)(d), 1.1310, 2.1091 and 2.1093). The regulations set limits on the maximum permissible exposure (MPE) allowed from operation of transmitters in all radio services. They also require that certain types of stations be evaluated to determine if they are in compliance with the MPEs specified in the rules. The FCC has also required that questions on RF environmental safety practices be added to Technician and General license examinations.

### THE RULES

#### Maximum Permissible Exposure (MPE)

All radio stations regulated by the FCC must comply with the requirements for MPEs, even QRP stations running only a few watts or less. The MPEs vary with frequency, as shown in **Table A**. MPE limits are specified in maximum electric and magnetic fields for frequencies below 30 MHz, in power density for frequencies above 300 MHz and all three ways for frequencies from 30 to 300 MHz. For compliance purposes, all of these limits must be considered *separately*. If any one is exceeded, the station is not in compliance. In effect, this means that both electric and magnetic field must be determined below 300 MHz but at higher frequencies determining either the electric or magnetic field is normally sufficient.

The regulations control human exposure to RF fields, not the strength of RF fields in any space. There is no limit to how strong a field can be as long as no one is being exposed to it, although FCC regulations require that amateurs use the minimum necessary power at all times (§97.311 [a]).

that it takes into account the effects of modulation on an RF carrier.

The FCC MPE regulations are based on a combination of the 1992 ANSI/IEEE standard and 1986 NCRP recommendations. The MPE limits under the regulations are slightly different than the ANSI/IEEE limits and do not reflect all the assumptions and exclusions of the ANSI/IEEE standard.

### 28.3.4 Cardiac Pacemakers and RF Safety

It is a widely held belief that cardiac pacemakers may be adversely affected in their function by exposure to electromagnetic fields. Amateurs with pacemakers may ask whether their operating might endanger

**Table A**

(From §1.1310) Limits for Maximum Permissible Exposure (MPE)

#### (A) Limits for Occupational/Controlled Exposure

Frequency Range (MHz)	Electric Field Strength (V/m)	Magnetic Field Strength (A/m)	Power Density (mW/cm <sup>2</sup> )	Averaging Time (minutes)
0.3-3.0	614	1.63	(100)*	6
3.0-30	1842/f	4.89/f	(900/f <sup>2</sup> )*	6
30-300	61.4	0.163	1.0	6
300-1500	—	—	f/300	6
1500-100,000	—	—	5	6

f = frequency in MHz

\* = Plane-wave equivalent power density (see Notes 1 and 2).

#### (B) Limits for General Population/Uncontrolled Exposure

Frequency Range (MHz)	Electric Field Strength (V/m)	Magnetic Field Strength (A/m)	Power Density (mW/cm <sup>2</sup> )	Averaging Time (minutes)
0.3-1.34	614	1.63	(100)*	30
1.34-30	824/f	2.19/f	(180/f <sup>2</sup> )*	30
30-300	27.5	0.073	0.2	30
300-1500	—	—	f/1500	30
1500-100,000	—	—	1.0	30

f = frequency in MHz

\* = Plane-wave equivalent power density (see Notes 1 and 2).

Note 1: This means the equivalent far-field strength that would have the E or H-field component calculated or measured. It does not apply well in the near field of an antenna. The equivalent far-field power density can be found in the near or far field regions from the relationships:  $P_d = |E_{total}|^2 / 3770 \text{ mW/cm}^2$  or from  $P_d = |H_{total}|^2 \times 37.7 \text{ mW/cm}^2$ .

Note 2:  $|E_{total}|^2 = |E_x|^2 + |E_y|^2 + |E_z|^2$ , and  $|H_{total}|^2 = |H_x|^2 + |H_y|^2 + |H_z|^2$

### Environments

The FCC has defined two tiers of exposure limits — *occupational/controlled limits* and *general population/uncontrolled limits*. Occupational/controlled limits apply when people are exposed as a condition of their employment and when they are aware of that exposure and can take steps to minimize it, if appropriate. General population/uncontrolled limits apply to exposure of the general public or people who are not normally aware of the exposure or can-

not exercise control over it. The limits for general population/uncontrolled exposure are more stringent than the limits for occupational/controlled exposure. Specific definitions of the exposure categories can be found in Section 1.1310 of the FCC rules.

Although occupational/controlled limits are usually applicable in a workplace environment, the FCC has determined that they generally apply to amateur operators and members of their immediate households. In most cases, occupational/

themselves or visitors to their shacks who have a pacemaker. Because of this, and similar concerns regarding other sources of EM fields, pacemaker manufacturers apply design methods that for the most part shield the pacemaker circuitry from even relatively high EM field strengths.

It is recommended that any amateur who has a pacemaker, or is being considered for one, discuss this matter with his or her physician. The physician will probably put the amateur into contact with the technical representative of the pacemaker manufacturer. These representatives are generally excellent resources, and may have data from laboratory or "in the field" studies with specific model pacemakers.

One study examined the function of a modern (dual chamber) pacemaker in and around

an Amateur Radio station. The pacemaker generator has circuits that receive and process electrical signals produced by the heart, and also generate electrical signals that stimulate (pace) the heart. In one series of experiments, the pacemaker was connected to a heart simulator. The system was placed on top of the cabinet of a 1-kW HF linear amplifier during SSB and CW operation. In another test, the system was placed in close proximity to several 1 to 5-W 2-meter hand-held transceivers. The test pacemaker was connected to the heart simulator in a third test, and then placed on the ground 9 meters below and 5 meters in front of a three-element Yagi HF antenna. No interference with pacemaker function was observed in these experiments.

controlled limits can be applied to your home and property to which you can control physical access. The general population/uncontrolled limits are intended for areas that are accessible by the general public, such as your neighbors' properties.

The MPE levels are based on average exposure. An averaging time of 6 minutes is used for occupational/controlled exposure; an averaging period of 30 minutes is used for general population/uncontrolled exposure.

### Station Evaluations

The FCC requires that certain amateur stations be evaluated for compliance with the MPEs. Although an amateur can have someone else do the evaluation, it is not difficult for hams to evaluate their own stations. The ARRL book *RF Exposure and You* contains extensive information about the regulations and a large chapter of tables that show compliance distances for specific antennas and power levels. Generally, hams will use these tables to evaluate their stations. Some of these tables have been included in the FCC's information — *OET Bulletin 65* and its *Supplement B* (available for downloading at the FCC's RF Safety website). If hams choose, however, they can do more extensive calculations, use a computer to model their antenna and exposure, or make actual measurements.

### Categorical Exemptions

Some types of amateur stations do not need to be evaluated, but these stations must still comply with the MPE limits. The station licensee remains responsible for ensuring that the station meets these requirements.

The FCC has exempted these stations from the evaluation requirement because their output power, operating

mode and frequency are such that they are presumed to be in compliance with the rules.

Stations using power equal to or less than the levels in **Table B** do not have to be evaluated on a routine basis. For the 100-W HF ham station, for example, an evaluation would be required only on 12 and 10 meters.

Hand-held radios and vehicle-mounted mobile radios that operate using a push-to-talk (PTT) button are also categorically exempt from performing the routine evaluation.

Repeater stations that use less than 500 W ERP or those with antennas not mounted on buildings; if the antenna is at least 10 meters off the ground, also do not need to be evaluated.

### Correcting Problems

Most hams are already in compliance with the MPE requirements. Some amateurs, especially those using indoor antennas or high-power, high-duty-cycle modes such as a RTTY bulletin station and specialized stations for moon bounce operations and the like may need to make adjustments to their station or operation to be in compliance.

The FCC permits amateurs considerable flexibility in complying with these regulations. As an example, hams can adjust their operating frequency, mode or power to comply with the MPE limits. They can also adjust their operating habits or control the direction their antenna is pointing.

### More Information

This discussion offers only an overview of this topic; additional information can be found in *RF Exposure and You* and on the ARRL website at [www.arrl.org/rf-exposure](http://www.arrl.org/rf-exposure). The ARRL website has links to the FCC website, with *OET Bulletin 65* and *Supplement B* and links to software that hams can use to evaluate their stations.

Although the possibility of interference cannot be entirely ruled out by these few observations, these tests represent more severe exposure to EM fields than would ordinarily be encountered by an amateur — with an average amount of common sense. Of course prudence dictates that amateurs with pacemakers, who use handheld VHF transceivers, keep the antenna as far as possible from the site of the implanted pacemaker generator. They also should use the lowest transmitter output required for adequate communication. For high power HF transmission, the antenna should be as far as possible from the operating position, and all equipment should be properly grounded.

### 28.3.5 Low-Frequency Fields

There has been considerable laboratory research about the biological effects of power line EMF. For example, some separate studies have indicated that even fairly low levels of EMF exposure might alter the human body's circadian rhythms, affect the manner in which T lymphocytes function in the immune system and alter the nature of the electrical and chemical signals communicated through the cell membrane and between cells, among other things. Although these studies are intriguing, they do not demonstrate any effect of these low-level fields on the overall organism.

Much of this research has focused on low-frequency magnetic fields, or on RF fields that are keyed, pulsed or modulated at a low

audio frequency (often below 100 Hz). Several studies suggested that humans and animals could adapt to the presence of a steady RF carrier more readily than to an intermittent, keyed or modulated energy source.

The results of studies in this area, plus speculations concerning the effect of various types of modulation, were and have remained somewhat controversial. None of the research to date has demonstrated that low-level EMF causes adverse health effects.

Given the fact that there is a great deal of ongoing research to examine the health consequences of exposure to EMF, the American Physical Society (a national group of highly respected scientists) issued a statement in May 1995 based on its review of available data pertaining to the possible connections of

cancer to 60-Hz EMF exposure. Their report is exhaustive and should be reviewed by anyone with a serious interest in the field. Among its general conclusions are the following:

1. The scientific literature and the reports of reviews by other panels show no consistent, significant link between cancer and power line fields.

2. No plausible biophysical mechanisms for the systematic initiation or promotion of cancer by these extremely weak 60-Hz fields have been identified.

3. While it is impossible to prove that no deleterious health effects occur from exposure to any environmental factor, it is necessary to demonstrate a consistent, significant, and causal relationship before one can conclude that such effects do occur.

In a report dated October 31, 1996, a committee of the National Research Council of the National Academy of Sciences has concluded that no clear, convincing evidence exists to show that residential exposures to electric and magnetic fields (EMF) are a threat to human health.

A National Cancer Institute epidemiological study of residential exposure to magnetic fields and acute lymphoblastic leukemia in children was published in the *New England Journal of Medicine* in July 1997. The exhaustive, seven-year study concludes that if there is any link at all, it is far too weak to be of concern.

In 1998, the US National Institute on Environmental Health Sciences organized a working group of experts to summarize the research on power-line EMF. The committee used the classification rules of the International Agency for Research on Cancer (IARC) and performed a meta-analysis to combine all past results as if they had been performed in a single study. The NIEHS working group concluded that the research did not show this type of exposure to be a carcinogen but could not rule out the possibility either. Therefore, they defined power-line EMF to be a Class 2b carcinogen under the IARC classification. The definition, as stated by the IARC is: "Group 2B: The agent is possibly carcinogenic to humans. There is limited epidemiological evidence plus limited or inadequate animal evidence." Other IARC Class 2b carcinogens include automobile exhaust, chloroform, coffee, ceramic and glass fibers, gasoline and pickled vegetables.

Readers may want to follow this topic as further studies are reported. Amateurs should be aware that exposure to RF and ELF (60 Hz) electromagnetic fields at all power levels and frequencies has not been fully studied under all circumstances. "Prudent avoidance" of any avoidable EMF is always a good idea. Prudent avoidance doesn't mean that amateurs should be fearful of using their equipment. Most

amateur operations are well within the MPE limits. If any risk does exist, it will almost surely fall well down on the list of causes that may be harmful to your health (on the other end of the list from your automobile). It does mean, however, that hams should be aware of the potential for exposure from their stations, and take whatever reasonable steps they can take to minimize their own exposure and the exposure of those around them.

Although the FCC doesn't regulate 60-Hz fields, some recent concern about EMF has focused on 60 Hz. Amateur Radio equipment can be a significant source of 60 Hz fields, although there are many other sources of this kind of energy in the typical home. Magnetic fields can be measured relatively accurately with inexpensive 60-Hz meters that are made by several manufacturers.

**Table 28.4** shows typical magnetic field intensities of Amateur Radio equipment and various household items.

### 28.3.6 Determining RF Power Density

Unfortunately, determining the power density of the RF fields generated by an amateur station is not as simple as measuring low-frequency magnetic fields. Although sophisticated instruments can be used to measure RF power densities quite accurately, they are costly and require frequent recalibration. Most amateurs don't have access to such equipment, and the inexpensive field-strength meters that we do have are not suitable for measuring RF power density.

**Table 28.5** shows a sampling of measurements made at Amateur Radio stations by the Federal Communications Commission and the Environmental Protection Agency in 1990. As this table indicates, a good antenna well removed from inhabited areas poses no hazard under any of the ANSI/IEEE guidelines. However, the FCC/EPA survey also indicates that amateurs must be careful about using indoor

or attic-mounted antennas, mobile antennas, low directional arrays or any other antenna that is close to inhabited areas, especially when moderate to high power is used.

Ideally, before using any antenna that is in close proximity to an inhabited area, you should measure the RF power density. If that is not feasible, the next best option is make the installation as safe as possible by observing the safety suggestions listed in **Table 28.6**.

It also is possible, of course, to calculate the probable power density near an antenna using simple equations. Such calculations have many pitfalls. For one, most of the situations where the power density would be high enough to be of concern are in the near field. In the near field, ground interactions and other variables produce power densities that cannot be determined by simple arithmetic. In the far field, conditions become easier to predict with simple calculations. (See the February 2013 *QST* article "Q and the Energy Stored Around Antennas" by Kai Siwiak, KE4PT and the **Antennas** chapter of this book for more information about stored energy density near antennas.)

The boundary between the near field and the far field depends on the wavelength of the transmitted signal and the physical size and configuration of the antenna. The boundary between the near field and the far field of an antenna can be as much as several wavelengths from the antenna.

Computer antenna-modeling programs are another approach you can use. *MININEC* or other codes derived from *NEC* (Numerical Electromagnetics Code) are suitable for estimating RF magnetic and electric fields around amateur antenna systems.

These models have limitations. Ground interactions must be considered in estimating near-field power densities, and the "correct ground" must be modeled. Computer modeling is generally not sophisticated enough to predict "hot spots" in the near field — places

where the field intensity may be far higher than would be expected, due to reflections from nearby objects. In addition, “nearby objects” often change or vary with weather or the season, therefore the model so laboriously crafted may not be representative of the actual situation, by the time it is running on the computer.

Intensely elevated but localized fields often can be detected by professional measuring instruments. These “hot spots” are often found near wiring in the shack, and metal objects such as antenna masts or equipment cabinets. But even with the best instrumentation, these measurements also may be misleading in the near field. One need not make precise

measurements or model the exact antenna system, however, to develop some idea of the relative fields around an antenna. Computer modeling using close approximations of the geometry and power input of the antenna will generally suffice. Those who are familiar with *MININEC* can estimate their power densities by computer modeling, and those who have access to professional power-density meters can make useful measurements.

While our primary concern is ordinarily the intensity of the signal radiated by an antenna, we also should remember that there are other potential energy sources to be considered. You also can be exposed to excessive RF fields directly from a power amplifier if it is operated without proper shielding. Transmission lines also may radiate a significant amount of energy under some conditions. Poor microwave waveguide joints or improperly assembled connectors are another source of incidental exposure.

**Table 28.6**  
**RF Awareness Guidelines**

These guidelines were developed by the ARRL RF Safety Committee, based on the FCC/EPA measurements of Table 28.4 and other data.

- Although antennas on towers (well away from people) pose no exposure problem, make certain that the RF radiation is confined to the antennas’ radiating elements themselves. Provide a single, good station ground (earth), and eliminate radiation from transmission lines. Use good coaxial cable or other feed line properly. Avoid serious imbalance in your antenna system and feed line. For high-powered installations, avoid end-fed antennas that come directly into the transmitter area near the operator.
- No person should ever be near any transmitting antenna while it is in use. This is especially true for mobile or ground-mounted vertical antennas. Avoid transmitting with more than 25 W in a VHF mobile installation unless it is possible to first measure the RF fields inside the vehicle. At the 1-kW level, both HF and VHF directional antennas should be at least 35 ft above inhabited areas. Avoid using indoor and attic-mounted antennas if at all possible. If open-wire feeders are used, ensure that it is not possible for people (or animals) to come into accidental contact with the feed line.
- Don’t operate high-power amplifiers with the covers removed, especially at VHF/UHF.
- In the UHF/SHF region, never look into the open end of an activated length of waveguide or microwave feed-horn antenna or point it toward anyone. (If you do, you may be exposing your eyes to more than the maximum permissible exposure level of RF radiation.) Never point a high-gain, narrow-bandwidth antenna (a paraboloid, for instance) toward people. Use caution in aiming an EME (moonbounce) array toward the horizon; EME arrays may deliver an effective radiated power of 250,000 W or more.
- With hand-held transceivers, keep the antenna away from your head and use the lowest power possible to maintain communications. Use a separate microphone and hold the rig as far away from you as possible. This will reduce your exposure to the RF energy.
- Don’t work on antennas that have RF power applied.
- Don’t stand or sit close to a power supply or linear amplifier when the ac power is turned on. Stay at least 24 inches away from power transformers, electrical fans and other sources of high-level 60-Hz magnetic fields.

### 28.3.7 Further RF Exposure Suggestions

Potential exposure situations should be taken seriously. Based on the FCC/EPA measurements and other data, the “RF awareness” guidelines of Table 28.6 were developed by the ARRL RF Safety Committee. A longer version of these guidelines, along with a complete list of references, appeared in a *QST* article by Ivan Shulman, MD, WC2S (“Is Amateur Radio Hazardous to Our Health?” *QST*, Oct 1989, pp 31-34).

In addition, the ARRL has published a book, *RF Exposure and You* that helps hams comply with the FCC’s RF-exposure regulations. The ARRL also maintains an RF-exposure news page on its website. See [www.arrl.org/rf-exposure](http://www.arrl.org/rf-exposure). This site contains reprints of selected *QST* articles on RF exposure and links to the FCC and other useful sites.

### SUMMARY

The ideas presented in this chapter are intended to reinforce the concept that ham radio, like many other activities in modern life, does have certain risks. But by understanding the hazards and how to deal effectively with them, the risk can be minimized. Common-sense measures can go a long way to help us prevent accidents. Traditionally, amateurs are inventors, and experimenting is a major part of our nature. But reckless chance-taking is never wise, especially when our health and well-being is involved. A healthy attitude toward doing things the right way will help us meet our goals and expectations.

## MFJ-929 AutoTuner \$269<sup>95</sup>

Compact 200 Watt *IntelliTuner*™ tunes any unbalanced antenna ultra-fast! 20,000 Virtual Memories, Antenna Switch, Efficient L-network, Matches 6-1600 Ohms from 1.8-30 MHz.

## MFJ-993B AutoTuner \$299<sup>95</sup>

Select 300 Watts (6-1600 Ohms) or 150 Watts (6-3200 Ohms) with the world's only dual power automatic tuner. 1.8-30 MHz, 4:1 current balun, LED lighted cross meter, backlight LCD, more!

## MFJ-998 AutoTuner \$739<sup>95</sup>

Full 1500 Watts SSB/CW. Digital and analog SWR/Wattmeter, 12-1600 Ohms from 1.8-30 MHz, built-in antenna switch, auto amp bypass.

## MFJ-1778 G5RV \$69<sup>95</sup>

Efficient, all band G5RV antenna is only 102' long, has 32.5" ladder line matching section ending in an SO-239 for feedline. Operate 80-10 Meters with tuner. 1500 Watts.

## MFJ-16XX HF Sticks \$21<sup>95</sup>

Rugged, sleek 6-40M mobile *HamTenna*™ antennas, \$21.95 each band. 250 Watts, 7' extended, collapse to about 4 feet for storage. Quickly screws into any 3/8-24 female mount for quick band changing. 60-75M, \$29.95.

## MFJ-1836H Cobweb \$299<sup>95</sup>

Antenna for restricted spaces: 6-bands: 20/17/15/12/10/6 Meters. Flat 9x9x1/2 sq. ft. mounts horizontally on mast. Nearly invisible wire elements, fiberglass spreaders blend in sky. Withstands bad weather.

## MFJ-1786 Hi-Q Loop \$499<sup>95</sup>

10-30 MHz Super Hi-Q loop, remote control. 36" dia. all welded construction, butterfly tuning capacitor. ABS plastic housing. MFJ-1788, \$559.95. 7-22 MHz.

## MFJ-260C Dry Load \$49<sup>95</sup>

300W VHF/HF Dry Dummy Load handles full load for 30 seconds. Derating curve to 5 minutes. SWR below 1.1:1 to 30 MHz. 1.5:1 from 30-650 MHz. MFJ-264, \$89.95. 1.5kW load.

## MFJ-1702C Ant Switch \$49<sup>95</sup>

2-position antenna switch has center ground, auto grounding of unused position, 2.5 kW PEP and works to over 500 MHz. Lightning surge protection. SO-239 Connectors. MFJ-1704, \$109.95. 4 positions.

## MFJ-915 RFI Isolator \$39<sup>95</sup>

Prevents unwanted RF from traveling on your coax shield into your expensive transceiver. Prevents stray RF that causes painful RF "bites" and erratic operation. Heavy duty weather protected PVC is 2Wx5H inches. 1.5 kW. 1.8-30 MHz.

## MFJ-918 4:1 Balun \$39<sup>95</sup>

High-permeability ferrite beads on high-quality RG-303 *Teflon*™ coax. True 1:1 current balun/center insulator. 2" diameter by 6" long. 14 gauge stranded copper wire. Handles 1.5 kW 1.8-30 MHz.

## MFJ-270 Surge Protect \$24<sup>95</sup>

Safeguard your expensive equipment. Shunts to 5000 Amps of peak impulse current harmlessly to ground. SWR less than 1.1:1, less than 0.1 dB loss. Use to 1000 MHz, 400W PEP.

## MFJ-392B Headphones \$39<sup>95</sup>

Perfect for Ham Radio and shortwave listening -- SSB, FM, AM, data and CW. Super lightweight (8 oz.) padded headband and ear cushioned design. Each earphone has own volume control. 3.5mm/1/4" plugs, 9' cord.

## MFJ-4230MV 30A PS \$99<sup>95</sup>

World's most compact 30A switching power supply. V/A meter. 4-16 Volts, adjustable. 5Wx2 1/2 H x6D inches, 3 pounds! Selectable input voltage I20/240 VAC.

## MFJ-4035MV 30A PS \$169<sup>95</sup>

19.2 lb. transformer delivers 35A maximum, 30A continuous. 1-14 VDC out, 110 VAC in. Highly regulated, 1% load regulation. 1 mV Ripple. 5-way binding posts, quick connects.

## MFJ-4245MV 45A PS \$169<sup>95</sup>

Switching power supply. 45A surge/40A continuous. 9-15 VDC out. 85-260 VAC in. Low ripple, highly regulated. 5-way posts, cig lighter, quick connects. 5 lbs., 7 1/2 Wx4 1/4 Hx 9 D".

## MFJ-4275MV 75A PS \$289<sup>95</sup>

Switching power supply. 75A max/70A cont. Great for ALS-500M solid state amp. Adjustable 4-16 VDC. Input 110/220 VAC. Battery charger. 10.5 lbs.

## Antenna Window Feedthrough Panels

Bring your antenna cables into your shack without drilling holes through walls! Place in window sill, close window. Real western cedar 3/4" thick wood naturally resistant to rot, decay and insects, weather edge foam tape included. *Teflon*™ SO-239s for HF/VHF/UHF antennas, ceramic feed-thrus for balanced line/random wire, ground post. Stainless steel in/out plates.

MFJ-4602, \$79<sup>95</sup>

## MFJ-868B Giant Meter \$169<sup>95</sup>

Largest HF+6M SWR/Wattmeter in the world has 6.5" diagonal scale. 20/200/2000W ranges.

## MFJ-1026 Noise Cancel \$219<sup>95</sup>

Wipe out interference! 60 dB null. SSB/CW/AM/FM. BCB to lower VHF, RF sense T/R switch.

## MFJ-4416C BattBoost \$189<sup>95</sup>

Keep mobile rig operational. Boosts low battery voltage. Up to 25 Amps. 7 1/2 Wx4Hx2 1/8".

## MFJ-148BRC Clock \$64<sup>95</sup>

Two atomic 24/12 hour clocks -- single time base. UTC time, 10-minute ID timer. 1.5 inch LCD.

## MFJ-281 Speaker \$15<sup>95</sup>

Get speech fidelity you never knew existed! 3" speaker, 8W, 8 Ohms impedance, 6' cord, 3.5 mm mono.

## MFJ-461 CodeReader \$109<sup>95</sup>

Decodes and displays Morse code on two-line high-contrast LCD. Just hold close to receiver.

## MFJ-557 CodeOsc/Key \$49<sup>95</sup>

Practice sending Morse code. Telegraph key, code oscillator, speaker on heavy non-skid steel base. Volume/tone controls. Use 9V battery.

## MFJ-564 IambicPaddles \$109<sup>95</sup>

Deluxe Iambic paddles. Tension/contact spacing adjustments, steel bearings, precision frame, non-skid feet. Chrome or Black.

## MFJ-108B 24/12 Clock \$27<sup>95</sup>

Read both UTC and local time simultaneously. BIG 5/8 inch digits! Solid brushed aluminum frame. 4 1/2 Wx2Hx1D".

## MFJ-1724B Mobile \$34<sup>95</sup>

World's Best Selling 2Meter 440 MHz magnet mount antenna has 3.5" magnet, 19" stainless steel whip, handles 300 Watts, 15 feet coax.

## MFJ-1728B Mobile \$34<sup>95</sup>

5/8 wave 2M mobile antenna gives maximum possible gain of any single element antenna. 1/4 Wave 6M. 300W, magnet mount, 12' coax, 53" whip.

## MFJ-1729 Mobile \$49<sup>95</sup>

Ham radio's most powerful magnet mount dual band 2M/440 mobile. Get whopping GAIN. 300 Watts, 27.5" stainless steel whip, 12' coax.

# hy-gain® Antennas and Rotators

## HF Verticals

Work amazing DX with these extremely low radiation angle omnidirectional antennas. All self supporting, 1500 Watts PEP SSB, low SWR. Heavy duty, slotted, tapered, swaged, aircraft quality aluminum tubing. Stainless steel hardware. Two year limited warranty.

**AV-680, \$599.95. 9 Bands: (6, 10, 12, 15, 17, 20, 30, 40, 80 Meters). 26 ft., 18.5 lbs.**

Our most popular vertical now has 75/80 Meters! Lets you work exciting DX with a low 17 degree radiation angle! Easily mount on decks, roofs, patios. No ground or radials needed. Extra wide 2:1 SWR bandwidths. Each band tunable. Auto bandswitching, handle 1.5kW, 80 MPH wind survival, low 2.5 sq. ft. wind surface. Aircraft aluminum tubing, stainless steel hardware.

**AV-640, \$499.95.** Like AV-680 less 80M. 251/2', 171/2 lbs.

**AV-620, \$399.95.** Like AV-640 less 40M. 221/2'/101/2 lbs.

**AV-14AVQ, \$229.95. (10, 15, 20, 40 Meters). 18 ft., 9 lbs.** Classic AV-14AVQ uses same trap design as famous hy-gain Thunderbird beams. 3 air dielectric Hi-Q traps with oversize coils give superb stability and 1/4 wave resonance on all bands. Automatic bandswitching.

**AV-12AVQ, \$169.95. (10, 15, 20 Meters). 13 ft., 9 lbs.**

Lowest priced automatic bandswitching tri-band vertical! Uses Thunderbird beam design air dielectric traps for extremely hi-Q performance in limited space.

**AV-18VS, \$149.95. (10, 12, 15, 17, 20, 30, 40, 80M). 18 ft., 4 lbs.**

hy-gain's lowest priced vertical gives you 8 bands. Easily tuned to any band by adjusting base loading coil.

See our website for even more hy-gain vertical antennas!

## HF Beams

hy-gain beams are stronger, lighter, have less wind surface and last years longer. **Why?**

hy-gain uses durable tooled components – massive boom-to-mast bracket, heavy gauge element-to-boom clamps, thick-wall swaged tubing – no failures!

**TH-11DX, \$1299.95.**

**11-element, 4.0 kW PEP, 10, 12, 15, 17, 20 Meters.**

The choice of top DXers. With 11-elements, excellent gain and 5-bands, the super rugged TH-11DX is the "Big Daddy" of all HF beams! Features low loss log-periodic driven array on all bands with monoband reflectors, BN-4000 high power balun, corrosion resistant wire boom support, hot dipped galvanized and stainless steel parts.

**TH-7DX, \$999.95. 7-Element, 1.5 kW PEP, 10, 15, 20 Meters.**

7-Elements gives you the highest average gain of any hy-gain tribander! Dual driven for broadband operation without compromising gain. SWR less than 2:1 on all bands. Combined monoband and trapped parasitic elements give you an excellent F/B ratio.

**TH-3MK4, \$549.95. 3-Element, 1.5 kW PEP, 10, 15, 20 Meters.**

Gives most gain for your money in full-power, full-size hy-gain tri-bander! Impressive gain and a whopping average front-to-back ratio and still fits on an average size lot. 95 MPH wind survival.

**TH-3JRS, \$419.95. Compact 3-Element, 600 WPEP, 10, 15, 20 Meters.** hy-gain's most popular and lowest-priced tri-bander fits smallest lot, 14.75 ft turning radius, 21 lbs. Excellent gain and front-to-back let you compete with the "big guns"! 80 MPH wind survival.

## hy-gain® Rotators...the First Choice of Hams Around the World!

### HAM-IV – \$709.95

The most popular rotator in the world! For medium communications arrays up to 15 square feet wind load area. New 5-second brake delay! New Test/Calibrate function. New low temperature grease permits normal operation down to -30 degrees F. New alloy ring gear gives extra strength up to 100,000 PSI for maximum reliability. New indicator potentiometer. New ferrite beads reduce RF susceptibility. New Cinch plug plus 8-pin plug at control box. Dual 98 ball bearing race for load bearing strength and electric locking steel wedge brake prevents wind induced antenna movement. North or South center of rotation scale on meter, low voltage control, max mast size of 21/16 inches.

**HAM-VI, \$809.95.** For medium arrays up to 15 sq. ft. wind load. Like HAM-IV but has new DCU-2 Digital Rotator Controller. Just dial in your beam heading or let your computer control your antenna.

**HAM-VII, \$899.95.** Like HAM VI but with DCU-3 digital controller with six programmable memories.

### Tailtwister T-2X – \$869.95

For large medium antenna arrays up to 20 sq. ft. wind load. Choose DCU-2 digital controller (T-2XD2) or analog control box (T-2X) with new 5-second brake delay and new Test/Calibrate function. Low temperature grease, alloy ring gear, indicator potentiometer, ferrite beads on potentiometer wires, new weatherproof AMP connectors plus 8-pin plug at control box, triple bearing race with 138 ball bearings for large load bearing strength, electric locking steel wedge brake, N or S center of rotation scale on meter, low voltage control, 21/16" max. mast.

**T-2XD2, \$979.95.** Tailtwister with DCU-2 digital controller.

**T-2XD3, \$1039.95.** Tailtwister with DCU-3 digital controller with six programmable memories.

**AR-40, \$399.95.** For compact antenna arrays and FM/TV up to 3.0 sq. ft. wind load. Dual 12 ball-bearing race. Fully automatic.

**CD-45II, \$499.95.** For antenna arrays up to 8.5 sq. ft. Bell rotator design gives total weather protection. Dual 58 ball bearing race.

## Digital Rotator Controller with 6 Programmable Beam Headings

DCU-3  
**\$499.95**  
New!

New DCU-3 Digital Controller lets you program 6 beam headings! Gives you fully automatic or manual control of your hy-gain HAM or Tailtwister Rotators.

Push a memory button or dial in your beam heading or let Ham Radio Deluxe (or other program) control your DCU-3. Your antenna automatically rotates precisely and safely to your desired direction.

## hy-gain® VHF/UHF Antennas

**VB-214FM, \$129.95.** 14-element 2-Meter FM beam antenna provides exceptional front-to-back ratio and maximum obtainable gains.

**VB-23FM, \$64.95.** 3-element.

**VB-25FM, \$74.95.** 5-element.

**VB-28FM, \$119.95.** 8-element. Threaded stub for feedpoints. Accepts up to 2 inch mast.

**DB-2345, \$119.95.** Dual band 144 (3-elements) 440 (5-elements) MHz.

**YRC-1, \$369.95.**

Replace your Yaesu rotator controller. More features and a much more robust controller that is far less prone to lightning damage. YRC-1 costs less than repairing your original Yaesu controller!

# AMERITRON...800 Watts... \$1199!

More hams use Ameritron AL-811H amplifiers than any other amplifier in the world!

Only the Ameritron AL-811H gives you four fully neutralized 811A transmitting tubes.

**AL-811H**  
**\$1199**  
Suggested Retail  
4-Tubes, 800 Watts

You get absolute stability and superb performance on higher bands that can't be matched by un-neutralized tubes.

**AL-811**  
**\$1099**  
Suggested Retail  
3-Tubes, 600 Watts

You get a quiet desktop linear that's so compact it'll slide right into your operating position – you'll hardly know it's there... until QRM sets in. And you can conveniently plug it into your nearest

120 VAC outlet – no special wiring needed.

You get all HF band coverage (with license) – including WARC and most MARS bands at 100% rated output. Ameritron's *Adapt-A-Volt™* hi-silicon core power transformer has a special buck-boost winding that lets you compensate for high/low power line voltages.

You also get efficient full size heavy duty tank coils, slug tuned input coils, operate/standby switch, transmit LED, ALC, dual illuminated meters, QSK with optional QSK-5, pressurized cooling that you can hardly hear, full height computer grade filter capacitors and more. 13<sup>3</sup>/<sub>4</sub>W x 8H x 16D inches.

**AL-811, \$1099.** Like AL-811H, but has three 811A tubes and 600 Watts output.

## AMERITRON no tune Solid State Amplifiers

**ALS-500M 500 Watt Mobile Amp**

**ALS-500M**  
**\$999**  
Suggested Retail

500 Watts PEP/400W CW output, 1.5-22 MHz, instant bandswitching, no tuning, no warm-up. SWR, load fault, thermal overload protected. On/Off/Bypass switch. Remote on/off control. DC current meter. Extremely quiet fan. 13.8 VDC. 9W x 3<sup>1</sup>/<sub>2</sub>H x 15D in., 7 lbs. **ALS-500RC, \$64.95**, Remote Head.

**ALS-606S 600 Watt 160-6M Amp**

**ALS-606S**  
**\$2099**  
Suggested Retail

600 Watts PEP/500W CW output, 160-6 Meters with automatic instant bandswitching from your transceiver. Fits on your desktop. 9<sup>3</sup>/<sub>4</sub>W x 7H x 14<sup>1</sup>/<sub>2</sub>D in. and weighs 14.2 lbs., but is only 4 dB below 1500 Watts – less than an S-unit! **ALS-606, \$2299**, like **ALS-606S** but has transformer power supply. **New Lower price!** **ALS-606S, \$1899** with switching power supply. **ALS-600 \$1999** with transformer power supply.

**ALS-1306 1200W 1.5-5.4 MHz Amp**

**ALS-1306**  
**\$3499**  
Suggested Retail

Ameritron's highest power solid state FET amplifier gives you automatic bandswitching! Get 1200W PEP output on all bands, including 6-Meters. No tuning, no warm-up, no tubes to baby and no fuss! Eight rugged MRF-150 power FET's give outstanding reliability. Just 100 Watts drive gives full rated power MHz. Compact 10W x 6<sup>1</sup>/<sub>2</sub>H x 18D in., just 22 lbs. **ALS-1300, \$3099**. Like **ALS-1306** but less automatic bandswitching and 6-M coverage.

**\$4999**  
Eimac® Tube  
Suggested Retail

Ameritron's most powerful amplifier uses the herculean 3CX1500/8877 ceramic tube. 65 watts drive gives you full legal output – it's just loafing with a 2500 Watts power supply.

Toughest – **3CX1200Z7**

**AL-1200**  
**\$4899**  
Suggested Retail

Get ham radio's toughest tube with the Ameritron

**AL-1200** – the Eimac® 3CX1200Z7. It has a 50 Watt control grid dissipation. What makes the Ameritron AL-1200 stand out from other legal limit amplifiers? The answer: a super heavy duty power supply that loads at full legal power – it can deliver the power of more than 2500 Watts PEP two tone output for a half hour.

Classic – **Dual 3-500Gs**

**AL-82**  
**\$3499**  
Suggested Retail

This linear gives you full legal output using a pair of

genuine 3-500Gs. Competing linears using 3-500Gs can't give you 1500 Watts because their lightweight power supplies can't use these tubes to their full potential.

Cushcraft...Keeping You in Touch Around the Globe

MA-6B  
\$759.95

# MA-6B 6-Band Beam

## Small Footprint - Big Signal

### 2-Elements on 20/17/15/12/10/6 Meters!!!

Cushcraft's latest MA-6B gives you 2-elements on six bands! You get solid signal-boosting directivity in a bantam-size and weight.

It mounts on your roof or mast using standard TV hardware. It's perfect for exploring exciting DX without the high cost and heavy lifting of installing a large tower and a full-sized array. Its 7 foot 3-inch boom has less than 9 feet of turning radius. Contest tough - handles 1500 Watts.

The unique MA-6B is a two-element Yagi on 20/17/15/12/10/6 Meters. It delivers solid power-

multiplying gain over a dipole on all bands. You get automatic band switching and a super easy installation in a compact 26-pound package.

When working DX, what really matters are the interfering signals and noise you *don't* hear. That's where the MA-6B's impressive side rejection and front-to-back ratio really shines.

**MA-5B, \$579.95.** Like MA-6B but five bands: 20/17/15/12/10 Meters. 12 and 17 Meters is a single element trapped dipole.

See [cushcraftamateur.com](http://cushcraftamateur.com) for gain figures.

NEW!

## Cushcraft 10, 15 & 20 Meter Tribander Beams

Only the best tri-band antennas become DX classics, which is why the Cushcraft World-Ranger A4S, A3S, and A3WS go to the head of the class. For more than 30 years, these pace-setting performers have taken on the world's most demanding operating conditions and proven themselves every time. The key to success comes from attention to basics. For example, element length and spacing has been carefully refined over time, and high-power traps are still hand-made and individually tuned using laboratory-grade instruments. All this attention to

detail means low SWR, wide bandwidth, optimum directivity, and high efficiency - important performance characteristics you rely on to maintain regular schedules, rack up impressive contest scores, and

grow your collection of rare QSLs!

It goes without saying that the World-Ranger lineup is also famous for its rugged construction. In fact, the majority of these antennas sold years ago are still in service today! Conservative mechanical design, rugged over-sized components, stainless-steel hardware, and aircraft-grade 6063 make all the difference.

The 3-element A3S/A3WS and 4-element A4S are world-famous for powerhouse gain and super performance. **A-3WS, \$549.95**, 12/17 M. **30/40 Meter add-on kits** available.

## Cushcraft R9...80-6 Meters 80 Meters...No Radials...1500W

**R-9 - \$699.95**  
80-6 Meters

**R-8 - \$599.95**  
48-6 Meters

Omni-Directional low angle radiation gives incredible worldwide DX.

**Cushcraft's world famous R8 now has a big brother!**

**Big Brother R9** now includes 75/80 Meters for local ragchewing and worldwide low band DX *without radials!*

Its omni-directional low angle radiation gives you exciting and easy DX on all 9 bands: 75/80, 40, 30, 20, 17, 15, 12, 10 and 6 Meters with low SWR. QSY instantly - no antenna tuner needed.

Use full 1500 Watts SSB/CW when the going gets tough to break through pileups/poor band conditions.

The R9 is super easy to assemble, installs just about anywhere, and its low profile blends inconspicuously into the background in urban and country settings alike.

**Compact Footprint:** Installs in an area about the size of a child's sandbox - no ground radials to bury with all RF-energized surfaces safely out of reach.

**Rugged Construction:** Thick fiberglass insulators, all stainless steel hardware and 6063 aircraft-aluminum tubing is double or triple walled at key stress points to handle anything Mother Nature can dish out.

**31.5** feet tall, 25 lbs. Mounting mast 1.25 to 2 inches. Wind surface area is 4 square feet.

**R8, \$599.95.** Like R9 antenna but less 75/80 Meters.

**R-8TB, \$99.95.** Tilt-base lets you tilt your antenna up/down easily by yourself to work on.

**R-8GK, \$79.95.** Three-point guy kit for high winds.

## Cushcraft Famous Ringos Compact FM Verticals

### Cushcraft Dual-Band Yagis

**One Yagi for Dual-Band FM Radios**

**Dual-band** VHF rigs are the norm these days, so why not complement your FM base station with a dual-band Yagi? Not only will you eliminate a costly feed line, you'll realize extra gain for digital modes like high-speed packet and D-Star! Cushcraft's A270-6S provides three elements per band and the A270-10S provides five for solid point-to-point performance. They're both pre-tuned and assembly is a snap using the fully illustrated manual.

**W1BX's** famous Ringo antenna has been around for a long time and remains unbeaten for solid reliability. The Ringo is broadbanded, lightning protected, extremely rugged, economical, electrically bullet-proof, low-angle, and more - but mainly, it just plain works! To discover why hams and commercial two-way installers around the world still love this antenna, order yours now!

## NOBODY BEATS AN HRO DEAL!

### FTDX101MP | 200W HF/50MHz Transceiver

• Hybrid SDR Configuration • Unparalleled 70 dB Max. Attenuation VC-Tune • New Generation Scope Display 3DSS • ABI (Active Band Indicator) & MPVD (Multi-Purpose VFO Outer Dial) • PC Remote Control Software to Expand the Operating Range • Includes External Power With Matching Front Speaker

### FT-891 | HF+50 MHz All Mode Mobile Transceiver

Rugged Construction in an Ultra Compact Body • Stable 100 Watt Output with Efficient Dual Internal Fans • 32-Bit IF DSP Provides Effective and Optimized QRM Rejection • Large Dot Matrix LCD Display with Quick Spectrum Scope • USB Port Allows Connection to a PC with a Single Cable • CAT Control, PTT/RTTY Control

### FTM-400XD | 2M/440 Mobile

• Color display-green, blue, orange, purple, gray • GPS/APRS • Packet 1200/9600 bd ready • Spectrum scope • Bluetooth • MicroSD slot • 500 memory per band

### FTDX3000 | 100W HF + 6M Transceiver

• 100 Watt HF/6 Meters • Large and wide color LCD display • High Speed Spectrum Scope built-in • 32 bit high speed DSP /Down Conversion 1st IF

### FTM-300DR | C4FM/FM 144/430MHz Dual Band

• 50W Reliable Output Power • Real Dual Band Operation (V+V, U+U, V+U, U+V) • 2-inch High-Res Full Color TFT Display • Band Scope • Built-in Bluetooth • WIRES-X Portable Digital Node/Fixed Node with HRI-200

### FT-991A | HF/VHF/UHF All Mode Transceiver

Real-time Spectrum Scope with Automatic Scope Control • Multi-color waterfall display • State of the art 32-bit Digital Signal Processing System • 3kHz Roofing Filter for enhanced performance • 3.5 Inch Full Color TFT USB Capable • Internal Automatic Antenna Tuner • High Accuracy TCXO

### FT-2980R | Heavy-Duty 80W 2M FM Transceiver

• Massive heatsink guarantees 80 watts of solid RF power • Loud 3 watts of audio output for noisy environments • Large 6 digit backlit LCD display for excellent visibility • 200 memory channels for serious users

### FTDX101D | HF + 6M Transceiver

• Narrow Band SDR • Direct Sampling SDR • Crystal Roofing Filters Phenomenal Multi-Signal Receiving Characteristics • Unparalleled - 70dB Maximum Attenuation VC-Tune • 15 Separate (HAM 10 + GEN 5) Powerful Band Pass Filters • New Generation Scope Displays 3-Dimensional Spectrum Stream

### FTM-7250DR | C4FM/FM 144/430MHz Dual Band

• 50 Watt Mobile • System Fusion-II Compatible • Operates Advanced C4FM Digital & Conventional FM Modes • 3 Watt Powerful & Clear Audio with Front Speaker

### FT-70DR C4FM/FM 144/430MHz Xcvr

• System Fusion Compatible • Large Front Speaker delivers 700 mW of Loud Audio Output • Automatic Mode Select detects C4FM or Fm Analog and Switches Accordingly • Huge 1,105 Channel Memory Capacity • External DC Jack for DC Supply and Battery Charging

### FT-3DR C4FM/FM 144/430 MHz Xcvr

• High Res Full-Color Touch Screen TFT LCD Display • Easy Hands-Free Operation w/Built-In Bluetooth Unit • Built-In High Precision GPS Antenna • 1200/9600bps APRS Data Communications • Simultaneous C4FM/C4FM Standby • Micro SD Card Slot

### FT-65R | 144/430 MHz Transceiver

Compact Commercial Grade Rugged Design • Large Front Speaker Delivers 1W of Powerful Clear Audio • 5 Watts of Reliable RF Power Within a compact Body • 3.5-Hour Rapid Charger Included • Large White LED Flashlight, Alarm and Quick Home Channel Access

### FT-60R | 2M/440 5W HT

• Wide receiver coverage • AM air band receive • 1000 memory channels w/alpha labels • Huge LCD display • Rugged die-cast, water resistant case • NOAA severe weather alert with alert scan

- 1800W PEP
- 160 to 6 meters
- 3 Antenna outputs
- Stepper motor controlled L & C

## TURN YOUR RADIO INTO A LEGAL LIMIT BEAST.

Our Power Genius XL solid state, software defined amplifier is exceptionally clean and delivers full 1.5kW ICAS duty cycle on all bands and modes including RTTY & FT8. The only fully SO2R/Multi-Single capable amplifier on the market, it has 70dB nominal isolation between transceiver inputs, diplexed filters, and ultra-fast high SWR protection. Like our entire transceiver product line-up, the PGXL is Ethernet connected and fully integrated with SmartSDR for remote operation. Making all controls and meters available from anywhere. Just one more way to help you find everywhere. [flexradio.com/PowerGenius-XL](http://flexradio.com/PowerGenius-XL)

## The ARRL Antenna Book for Radio Communications

### Showcasing 80 Years of Antenna Know How

The ARRL Antenna Book is a single resource covering antenna design, practical treatments, and projects. It contains everything you need to understand how radio signals propagate, how antennas work, and how to construct your own antenna system.

- Learn more about those highly popular HF transmitting loops.
- See the all-new chapter on VHF/UHF antennas.
- Try building some new MF, HF, or 6-meter antennas.
- Discover the importance of ground and bonding.
- Find out how to troubleshoot your antenna tuner quickly and easily.
- Get the most out of your antenna analyzer.
- Design a high-performance Band-Optimized Log Periodic Dipole Array.

Plus, download the fully searchable digital edition of the printed book, as well as utility programs and supplemental content including expanded technical papers, in depth construction guides, and referenced articles.

## Our Handbook

### The ARRL Handbook for Radio Communications

is your complete guide to radio experimentation, discovery, and innovation. It is *the Handbook*—written by radio amateurs for everyone with a desire to advance the pursuit of wireless technology.

### Always Updated! New Projects and Content...

- PIN diode RF switching circuits
- A new section on transverters
- An updated discussion of waveguides
- A new section on soldering tools
- Antenna tuner troubleshooting techniques
- An updated discussion of the latest digital modes — FT8, FT4, and MSK144
- New feed line choke designs for receiving and transmitting
- Updated CAD software from Tonnesoft

### Download Included: eBook and Supplemental Content

Download the fully searchable digital edition of the printed book, as well as expanded supplemental content, software, PC board templates, and other support files.

**System Requirements:** *Windows 7, 8, or 10; Windows Vista or Windows XP*, as well as Macintosh systems, using *Adobe Acrobat Reader* software. Acrobat Reader is a free download at [www.adobe.com](http://www.adobe.com). PDF files are *Linux* readable. Other included software is *Windows* compatible only.

## About ARRL

ARRL is the national membership association for amateur radio operators in the US. ARRL has books, software, online content, and other resources for licensing, operating, and lifelong learning.
