# Handbook

FOR RADIO COMMUNICATIONS

**ARRL**  
the national association for  
amateur radio

ACB

# *Inherent Passion and Inspiration*

## *Hybrid SDRs (Narrow Band SDR & Direct Sampling SDR)*

2kHz RMDR 123dB+  
2kHz BDR 150dB+  
2kHz 3rd IMDR 110dB+

## *Ultra Low-Noise Local Oscillator System; 400MHz HRDDS (High Resolution Direct Digital Synthesizer)*

2kHz Phase Noise  $-150\text{dBc/Hz}$

## *VC-TUNE (Variable Capacitor Tune) signal peaking Maximum Attenuation $-70\text{dB}$*

## *3DSS (3-Dimensional Spectrum Stream) visual display view up to last 25 seconds of band conditions in real time*

## *TX Signal Purity*

TX Phase Noise  $-150\text{dBc/Hz}$  (TX 14MHz 2kHz separation)

### *In Homage to the Founder of Yaesu – Sako Hasegawa JA1MP*

## **FTDX 101MP** 200W

HF/50MHz TRANSCEIVER

- External Power Supply with 3.94" (100mm) Front Speaker, FPS-101 included
- VC-Tune unit x 2 (MAIN and SUB bands) included
- 300Hz Crystal roofing filter (MAIN band) included
- 600Hz Crystal roofing filter (MAIN and SUB bands) included
- 3kHz Crystal roofing filter (MAIN and SUB bands) included

### *The Ultimate*

## **FTDX 101D** 100W

HF/50MHz TRANSCEIVER

- VC-Tune unit (MAIN band) included
- 600Hz Crystal roofing filter (MAIN and SUB bands) included
- 3kHz Crystal roofing filter (MAIN and SUB bands) included

**YAESU**  
The radio

YAESU USA  
6125 Phyllis Drive, Cypress,  
CA 90630 (714) 827-7600

For the latest Yaesu news, visit us on the Internet: <http://www.yaesu.com>

Specifications subject to change without notice. Some accessories and/or options may be standard in certain areas. Frequency coverage may differ in some countries. Check with your local Yaesu Dealer for specific details.

NINETY-EIGHTH EDITION

#### Editor

H. Ward Silver, NØAX

#### Contributing Editors

Steven R. Ford, WB8IMY

Mark J. Wilson, K1RO

#### Editorial Assistant

Maty Weinberg, KB1EIB

#### Technical Consultants

Bob Allison, WB1GCM

Edward F. Hare, Jr., W1RFI

Zachary H.J. Lau, W1VT

#### Cover Design

Lori Pedrick

#### Production

Jodi Morin, KA1JPA

Michelle Bloom, WB1ENT

David F. Pingree, N1NAS

#### Additional Contributors to the 2021 Edition

Jim Andrews, KH6HTV

Malcolm Bell

Jim Brown, K9YC

Joe Eisenberg, KØNEB

Lou Ernst, WA2GKH

Steve Franke, K9AN

Gary Johnson, NA6O

Matt Kastigar, WØMJ

Ed Krome, K9EK

Mark Kupferschmid, AC9PR

Rick Lindquist, WW1ME

Carl Luetzelschwab, K9LA

Doc Murphy, KØGRM

Tom O'Hara, W6ORG

Wayne Overbeck, N6NB

Tom Rauch, W8JI

Hans Summers, GØUPL

Joe Taylor, K1JT

Jim Tonne, W4ENE

Paul Wade, W1GHZ

# Contents

A more detailed Table of Contents is included at the beginning of each chapter.

## **INTRODUCTION**

### **1 What is Amateur (Ham) Radio?**

- 1.1 Do-It-Yourself Wireless
- 1.2 Joining the Ham Radio Community
- 1.3 Your Ham Radio Station
- 1.4 Getting on the Air
- 1.5 Your Ham Radio “Lifestyle”
- 1.6 Public Service
- 1.7 Ham Radio in the Classroom
- 1.8 Resources
- 1.9 Glossary

## **FUNDAMENTAL THEORY**

### **2 Electrical Fundamentals**

- 2.1 Introduction to Electricity
- 2.2 Resistance and Conductance
- 2.3 Basic Circuit Principles
- 2.4 Power and Energy
- 2.5 Circuit Control Components
- 2.6 Capacitance and Capacitors
- 2.7 Inductance and Inductors
- 2.8 Semiconductor Devices
- 2.9 References and Bibliography

### **3 Radio Fundamentals**

- 3.1 AC Waveforms
- 3.2 Measuring AC Voltage, Current and Power
- 3.3 Effective Radiated Power
- 3.4 AC in Capacitors and Inductors
- 3.5 Working with Reactance
- 3.6 Impedance
- 3.7 Quality Factor (Q) of Components
- 3.8 Resonant Circuits
- 3.9 Analog Signal Processing
- 3.10 Electromagnetic Waves
- 3.11 References and Bibliography

### **4 Circuits and Components**

- 4.1 Practical Resistors
- 4.2 Practical Capacitors
- 4.3 Practical Inductors
- 4.4 Transformers
- 4.5 Practical Semiconductors
- 4.6 Amplifiers
- 4.7 Operational Amplifiers
- 4.8 Miscellaneous Analog ICs
- 4.9 Analog-Digital Interfacing
- 4.10 Analog Device and Circuits Glossary
- 4.11 Heat Management
- 4.12 References and Bibliography

## **PRACTICAL DESIGN AND PRINCIPLES**

### **5 RF Techniques**

- 5.1 Introduction
- 5.2 Lumped-Element versus Distributed Characteristics
- 5.3 Effects of Parasitic (Stray) Characteristics
- 5.4 Semiconductor Circuits at RF
- 5.5 Ferrite Materials
- 5.6 Impedance Matching Networks
- 5.7 RF Transformers
- 5.8 Noise
- 5.9 Two-Port Networks
- 5.10 RF Design Techniques Glossary
- 5.11 References and Bibliography

### **6 Computer-Aided Circuit Design**

- 6.1 Circuit Simulation Overview
- 6.2 Simulation Basics
- 6.3 Limitations of Simulation at RF
- 6.4 Electromagnetic Analysis of RF Circuits
- 6.5 References and Bibliography

- 7 Power Sources**
  - 7.1 Power Processing
  - 7.2 AC-AC Power Conversion
  - 7.3 Power Transformers
  - 7.4 AC-DC Power Conversion
  - 7.5 Voltage Multipliers
  - 7.6 Current Multipliers
  - 7.7 Rectifier Types
  - 7.8 Power Filtering
  - 7.9 Power Supply Regulation
  - 7.10 "Crowbar" Protective Circuits
  - 7.11 DC-DC Switchmode Power Conversion
  - 7.12 High-Voltage Techniques
  - 7.13 Batteries
  - 7.14 Glossary of Power Source Terms
  - 7.15 References and Bibliography
  - 7.16 Power Supply Projects
- 8 DSP and SDR Fundamentals**
  - 8.1 Introduction to DSP
  - 8.2 Introduction to SDR
  - 8.3 Analog-Digital Conversion
  - 8.4 Data Converters for SDR and DSP
  - 8.5 Digital Signal Processors
  - 8.6 Digital (Discrete-time) Signals
  - 8.7 The Fourier Transform
  - 8.8 Glossary of DSP and SDR Terms
  - 8.9 References and Bibliography
- 9 Oscillators and Synthesizers**
  - 9.1 How Oscillators Work
  - 9.2 LC Variable Frequency Oscillator (VFO) Circuits
  - 9.3 Building an Oscillator
  - 9.4 Crystal Oscillators
  - 9.5 Oscillators at UHF and Above
  - 9.6 Frequency Synthesizers
  - 9.7 Phase Noise
  - 9.8 Glossary of Oscillator and Synthesizer Terms
  - 9.9 References and Bibliography
- 10 Analog and Digital Filtering**
  - 10.1 Introduction
  - 10.2 Filter Basics
  - 10.3 Passive LC Filters
  - 10.4 Active Audio Filters
  - 10.5 Digital Filters
  - 10.6 Quartz Crystal Filters
  - 10.7 SAW Filters
  - 10.8 Transmission Line VHF/UHF/Microwave Filters
  - 10.9 Helical Resonators
  - 10.11 Filter Projects
  - 10.12 Glossary of Filter Terms
  - 10.13 References and Bibliography
- 11 Modulation**
  - 11.1 Introduction
  - 11.2 Amplitude Modulation (AM)
  - 11.3 Angle Modulation
  - 11.4 FSK and PSK
  - 11.5 Quadrature Modulation
  - 11.6 Analytic Signals and Modulation
  - 11.7 Image Modulation
  - 11.8 Spread Spectrum Modulation
  - 11.9 Pulse Modulation
  - 11.10 Modulation Bandwidth and Impairments
  - 11.11 Glossary of Modulation Terms
  - 11.12 References and Bibliography
- 12 Receiving**
  - 12.1 Characterizing Receivers
  - 12.2 Heterodyne Receivers
  - 12.3 SDR Receivers
  - 12.4 Mixing and Mixers
  - 12.5 Demodulation and Detection
  - 12.6 Automatic Gain Control (AGC)
  - 12.7 Noise Management
  - 12.8 References and Bibliography
- 13 Transmitting**
  - 13.1 Characterizing Transmitters
  - 13.2 Transmitter Architecture
  - 13.3 Modulators
  - 13.4 Transmitting CW
  - 13.5 Transmitting AM and SSB
  - 13.6 Transmitting Angle Modulation
  - 13.7 Effects of Transmitted Noise
  - 13.8 Microphones and Speech Processing
  - 13.9 Voice Operation
  - 13.10 Transmitter Power Stages
  - 13.11 References and Bibliography
- 14 Transceiver Design Topics**
  - 14.1 Signal Chains in SDR Transceivers
  - 14.2 User Interfaces
  - 14.3 Configuration and Control Interfaces
  - 14.4 SDR Design Tools
  - 14.5 Transverters
- 15 Digital Protocols and Modes**
  - 15.1 Digital "Modes"
  - 15.2 Unstructured Digital Modes
  - 15.3 Fuzzy Modes
  - 15.4 Structured Digital Modes
  - 15.5 Networking Modes
  - 15.6 Digital Mode Table
  - 15.7 Glossary of Digital Protocol and Mode Terms
  - 15.8 References and Bibliography

## **16 Amateur Radio Data Platforms**

- 16.1 Platform Overview
- 16.2 Sensors
- 16.3 Navigation Data and Telemetry
- 16.4 Payloads
- 16.5 High Altitude Balloon Platforms
- 16.6 Unmanned Aerial Vehicles (UAVs)
- 16.7 Rockets
- 16.8 Robotics
- 16.9 Fixed Stations
- 16.10 References and Bibliography

## **17 RF Power Amplifiers**

- 17.1 High Power, Who Needs It?
- 17.2 Types of Power Amplifiers
- 17.3 Vacuum Tube Basics
- 17.4 Tank Circuits
- 17.5 Transmitting Tube Ratings
- 17.6 Sources of Operating Voltages
- 17.7 Tube Amplifier Cooling
- 17.8 Vacuum Tube Amplifier Stabilization
- 17.9 MOSFET Design for RF Amplifiers
- 17.10 Solid-State RF Amplifiers
- 17.11 References and Bibliography

## **18 Repeaters**

- 18.1 A Brief History
- 18.2 Repeater Overview
- 18.3 FM Voice Repeaters
- 18.4 D-STAR Repeater Systems
- 18.5 Digital Mobile Radio (DMR)
- 18.6 System Fusion
- 18.7 Other Digital Voice Repeater Technologies
- 18.8 Glossary of FM and Repeater Terminology
- 18.9 References and Bibliography

## **ANTENNA SYSTEMS AND RADIO PROPAGATION**

### **19 Propagation of Radio Signals**

- 19.1 Fundamentals of Radio Waves
- 19.2 Sky-Wave Propagation and the Sun
- 19.3 MUF Predictions
- 19.4 Propagation in the Troposphere
- 19.5 VHF/UHF Mobile Propagation
- 19.6 Propagation for Space Communications
- 19.7 Noise and Propagation
- 19.8 Propagation Below the AM Broadcast Band
- 19.9 Glossary of Radio Propagation Terms
- 19.10 References and Bibliography

## **20 Transmission Lines**

- 20.1 Transmission Line Basics
- 20.2 Choosing a Transmission Line
- 20.3 The Transmission Line as Impedance Transformer
- 20.4 Matching Impedances in the Antenna System
- 20.5 Baluns and Transmission-Line Transformers
- 20.6 PC Transmission Lines
- 20.7 Waveguides
- 20.8 Glossary of Transmission Line Terms
- 20.9 References and Bibliography

## **21 Antennas**

- 21.1 Antenna Basics
- 21.2 Dipoles and the Half-Wave Antenna
- 21.3 Vertical (Ground-Plane) Antennas
- 21.4 T and Inverted-L Antennas
- 21.5 Slopers and Vertical Dipoles
- 21.6 Yagi Antennas
- 21.7 Quad and Loop Antennas
- 21.8 HF Mobile Antennas
- 21.9 VHF/UHF Mobile Antennas
- 21.10 VHF/UHF Antennas
- 21.11 VHF/UHF Beams
- 21.12 Radio Direction Finding Antennas
- 21.13 Rotators
- 21.14 Glossary
- 21.15 References and Bibliography

## **STATION CONSTRUCTION, MAINTENANCE, AND MANAGEMENT**

### **22 Component Data and References**

- 22.1 Component Data
- 22.2 Resistors
- 22.3 Capacitors
- 22.4 Inductors
- 22.5 Transformers
- 22.6 Semiconductors
- 22.7 Tubes, Wire, Materials, Attenuators, Miscellaneous
- 22.8 Computer Connectors
- 22.9 AC and Power Connectors
- 22.10 RF Connectors and Transmission Lines
- 22.11 Reference Tables and Abbreviations

### **23 Construction Techniques**

- 23.1 Electronic Shop Safety
- 23.2 Tools and Their Use
- 23.3 Soldering Tools and Techniques
- 23.4 Surface Mount Technology (SMT)
- 23.5 Constructing Electronic Circuits
- 23.6 CAD for PCB Design
- 23.7 Microwave Construction
- 23.8 Mechanical Fabrication

- 24 Assembling a Station**
  - 24.1 Fixed Stations
  - 24.2 Mobile Installations
  - 24.3 Portable Installations
  - 24.4 Remote Stations
  
- 25 Test Equipment and Measurements**
  - 25.1 Introduction
  - 25.2 DC Measurements
  - 25.3 AC Measurements
  - 25.4 RF Measurements
  - 25.5 Receiver Measurements
  - 25.6 Transmitter Measurements
  - 25.7 Antenna System Measurements
  - 25.8 Miscellaneous Measurements
  - 25.9 Construction Projects
  - 25.10 References and Further Reading
  - 25.11 Glossary of Test Equipment and Measurement Terms
  
- 26 Troubleshooting and Maintenance**
  - 26.1 Test Equipment
  - 26.2 Components
  - 26.3 Getting Started
  - 26.4 Inside the Equipment
  - 26.5 Testing at the Circuit Level
  - 26.6 After the Repairs
  - 26.7 Professional Repairs
  - 26.8 Typical Symptoms and Faults
  - 26.9 Radio Troubleshooting Hints
  - 26.10 Antenna Systems
  - 26.11 Repair and Restoration of Vintage Equipment
  - 26.12 References and Bibliography

- 27 RF Interference**
  - 27.1 Managing Radio Frequency Interference
  - 27.2 FCC Rules and Regulations
  - 27.3 Elements of RFI
  - 27.4 Identifying the Type of RFI Source
  - 27.5 Locating Sources of RFI
  - 27.6 Power-Line Noise
  - 27.7 Elements of RFI Control
  - 27.8 Troubleshooting RFI
  - 27.9 Automotive RFI
  - 27.10 RFI Projects
  - 27.11 Glossary of RFI Terms
  - 27.12 References and Bibliography
  
- 28 Safe Practices**
  - 28.1 Electrical Safety
  - 28.2 Antenna and Tower Safety
  - 28.3 RF Safety

# Preface

Welcome to the 98th edition of the *ARRL Handbook for Radio Communications*. Like Amateur Radio itself, the *ARRL Handbook* is continually being updated and renewed by the community of knowledgeable amateurs who realize the value of a resource like the *Handbook*.

What's new in the 98th edition? Here are some highlights:

- ◆ A new transverters section by Paul Wade, W1GHZ, and Wayne Overbeck, N6NB
- ◆ Updates on the progress of Solar Cycle 24-25 by Carl Leutzelschwab, K9LA,
- ◆ New feed line chokes for receiving and transmitting applications by Jim Brown, K9YC
- ◆ Updated information on soldering tools and techniques by Joe Eisenberg, KØNEB
- ◆ Antenna tuner troubleshooting by Matt Kastigar, WØMJ
- ◆ Update on the function of FT4, FT8, and MSK144 by the *WSJT-X* team and new sections on using FT4 and FT8 by Steve Ford, WB8IMY
- ◆ Updates to the material on analog and digital amateur television by Jim Andrews, KH6HTV, and Tom O'Hara, W6ORG
- ◆ New projects, including a transmitting tube tester, circuits for low-power TR switching, an FET-controlled power switch, a 432-MHz utility Yagi, a loop antenna for 30 and 40 meters, off-center fed dipole hints, RF sniffer construction hints, and an RFI loop antenna,
- ◆ The companion downloadable material includes a new supplemental articles covering a wide variety of topics in this book, as well as the latest versions of CAD software from Jim Tonne, W4ENE.

# ARRL Handbook Downloadable Supplemental Content (print edition only)

A wealth of additional material for this *Handbook* is available with the downloadable supplemental content. As a purchaser of the print edition, you are entitled to download this material, which was added to your customer account upon purchase of the book.

## Searchable Edition of The Handbook

The downloadable content includes a PDF version of this edition of *The ARRL Handbook*, including text, drawings, tables, illustrations and photographs. Using *Adobe Reader*, you can view, print or search the entire book.

## Supplemental Files for Each Chapter

The downloadable content contains supplemental information for most chapters of this book. This includes articles from *QST*, *QEX* and other sources, material from previous editions of *The ARRL Handbook*, tables and figures in support of the chapter material, and files that contain information to build and test the projects provided in the chapters. The supplemental information is arranged in folders for each chapter.

## Companion Software

The following software is also included with the downloadable supplemental content:

**TubeCalculator**, a Windows application by Bentley Chan and John Stanley, K4ERO, accompanies the tube type RF power amplifier discussion in the **RF Power Amplifiers** chapter.

The following Windows programs by Tonne Software ([www.tonnesoftware.com](http://www.tonnesoftware.com)) are provided by Jim Tonne, W4ENE.

**ClassE** — Designs single-ended Class E RF amplifiers.

**Diplexer** — Designs both high-pass/low-pass and band-pass/band-stop types of diplexer circuits.

**Helical** — Designs and analyzes helical-resonator bandpass filters for the VHF and UHF frequency ranges.

**JJSmith** — A graphics-intensive transmission-line calculator based on the Smith chart.

**Elsie** — The free student edition of *Elsie*, a lumped-element filter design and analysis program.

**MeterBasic** — Designs and prints professional-quality analog meter scales on your printer. The full featured version of *Meter* is available from Tonne Software.

**OptLowpass** — Designs and analyzes very efficient transmitter output low-pass filters.

**PI-EL** — Designs and analyzes pi-L networks for transmitter output.

**Pizza** — A mapping program that generates printable azimuth-equidistant or rectangular maps showing the great-circle path and the sunrise-sunset terminator between your location and selectable locations.

**QuadNet** — Designs and analyzes active quadrature ("90-degree") networks for use in SSB transmitters and receivers.

**SVCfilter** — Standard-value component routine to design low-pass and high-pass filters and delivers exact-values as well as nearest-5% values.

**Tower** — Analyzes vertical antennas. Plots resistance, reactance, and impedance at the base as a function of frequency.

# The Amateur's Code

## **The Radio Amateur is:**

**CONSIDERATE**...never knowingly operates in such a way as to lessen the pleasure of others.

**LOYAL**...offers loyalty, encouragement and support to other amateurs, local clubs, and the American Radio Relay League, through which Amateur Radio in the United States is represented nationally and internationally.

**PROGRESSIVE**...with knowledge abreast of science, a well-built and efficient station and operation above reproach.

**FRIENDLY**...slow and patient operating when requested; friendly advice and counsel to the beginner; kindly assistance, cooperation and consideration for the interests of others. These are the hallmarks of the amateur spirit.

**BALANCED**...radio is an avocation, never interfering with duties owed to family, job, school or community.

**PATRIOTIC**...station and skill always ready for service to country and community.

—*The original Amateur's Code was written by Paul M. Segal, W9EEA, in 1928.*

# Common Schematic Symbols Used in Circuit Diagrams

### Resistors

- Fixed
- Variable
- Tapped
- Thermistor
- Photo

### Capacitors

- Fixed
- Polarized
- Non-Polarized
- Variable
- Split-stator
- Electrolytic
- Feed-through

### Inductors

- Air-core
- Iron-core
- Ferrite-bead
- Adjustable
- Phasing
- Iron-rtc
- Air-rtc

### Tubes

Tube Elements

- Grid
- Anode
- Heater/Or Filament
- Gas Filled
- Cathode
- Cold Cathode
- Deflection Plates

Triode, Pentode, Heated Cath., Twin Triode

### Wiring

- Terminal
- Conductors Joined
- Line-break
- Address or Data Bus
- Shielded Wire or Coaxial Cable
- Multiple Conductor Cable

### Switches

- Toggle
- SPST
- SPDT
- Multi-Point
- Head Open
- Head Closed
- Limit Switch
- Momentary
- Normally Open
- Normally Closed
- Thermal

### Lamps

- Incandescent
- Neon (ac)
- 7-seg

### Grounds

- Chassis
- Earth
- A-analog
- D-digital

### Integrated Circuits (U#)

- General Amplifier
- Op Amp
- Other

### Relays

- Sps1
- Sps2
- Dps2
- Thermal

### Diodes

- LED (DS#)
- Variable Capacitor
- Thyristor (SCR)
- Diode/Rectifier
- Zener
- Schottky
- Tunnel
- Triac
- Bridge Rectifier (U#)

### Transformers

- Air Core
- with Ferrite Core
- with Link
- Adjustable Inductance
- Adjustable Coupling
- Adjustable Core

### Miscellaneous

- Fuse
- Antenna
- Hand Key
- 3-pin Ceramic Resonator
- Water
- Quartz Crystal
- Assembly Or Module (other than IC)
- Mot
- Motor

### Transistors

- NPN
- PNP
- N-channel
- P-channel
- Bipolar
- Junction FET

# WHAT DO YOU WANT TO DO WITH AMATEUR RADIO?

ARRL is the national association for amateur radio in the US. We provide opportunities to discover radio, develop skills, and serve your local community.

## Membership in ARRL can help you:

### Discover New Interests

Whether you're interested in radiosport, new technologies, project building, emergency preparedness, or public service, ARRL has resources to help you learn, get active, and get on the air.

Your membership provides digital access to all four ARRL publications, with offerings for beginners as well as advanced hams. They include *QST*, the membership journal of ARRL; *On the Air*, an introduction to the world of amateur radio; *QEX*, covering topics related to radio communications experimentation; and *National Contest Journal (NCJ)*, covering radio contesting.

### Build & Share Your Knowledge

With online learning courses, members-only web content, and leadership opportunities, you can grow your skills and interest in amateur radio through the many ARRL programs available to members.

### Shape the Future

Your membership dollars help to preserve and protect access to frequencies allocated to the Amateur Radio Service.

---

Anyone who is active in amateur radio or who wishes to get more involved to pursue technological interests, public service, or personal enjoyment will benefit from ARRL Membership.

**Benefits** To get you involved and keep you up to date with all that amateur radio has to offer!

#### INFORMATION

As a member, you will gain access to all four digital magazines, several special interest e-newsletters, & personalized answers to your technical and operating questions.

#### LEARNING

From licensing exam prep, to live training forums; to online training courses for new hams, emergency communicators, and more.

#### PROGRAMS & SERVICES

License renewal, member recognition programs, contesting opportunities, advocacy efforts, and an active local club system.

**Two Easy Ways to Join or Renew**

**ONLINE** at [arrl.org/join](http://arrl.org/join)

**CALL** toll free at 1-888-277-5289

## About ARRL

We're the American Radio Relay League, Inc. — better known as ARRL. We're the largest membership association for the amateur radio hobby and service in the US. For over 100 years, we have been the primary source of information about amateur radio, offering a variety of benefits and services to our members, as well as the larger amateur radio community. We publish books on amateur radio, as well as four magazines covering a variety of radio communication interests. In addition, we provide technical advice and assistance to amateur radio enthusiasts, support several education programs, and sponsor a variety of operating events.

One of the primary benefits we offer to the ham radio community is in representing the interests of amateur radio operators before federal regulatory bodies advocating for meaningful access to the radio spectrum. ARRL also serves as the international secretariat of the International Amateur Radio Union, which performs a similar role internationally, advocating for amateur radio interests before the International Telecommunication Union and the World Administrative Radio Conferences.

Today, we proudly serve nearly 160,000 members, both in the US and internationally, through our national headquarters and flagship amateur radio station, W1AW, in Newington, Connecticut. Every year we welcome thousands of new licensees to our membership, and we hope you will join us. Let us be a part of your amateur radio journey. Visit [www.arrl.org/join](http://www.arrl.org/join) for more information.

# US Amateur Radio Bands

US AMATEUR POWER LIMITS

FCC 97.313 An amateur station must use the minimum transmitter power necessary to carry out the desired communications.  
 (b) No station may transmit with a transmitter power exceeding 1.5 kW PEP.

Amateurs wishing to operate on either 2,200 or 630 meters must first register with the Utilities Technology Council online at <https://utc.org/plc-database-amateur-notification-process/>. You need only register once for each band.

## 2,200 Meters (135 kHz)

## 630 Meters (472 kHz)

5 W EIRP maximum, except in Alaska within 496 miles of Russia where the power limit is 1 W EIRP.

## 160 Meters (1.8 MHz)

Avoid interference to radiolocation operations from 1,900 to 2,000 MHz

## 80 Meters (3.5 MHz)

3,500 3,600 3,700 4,000 MHz

## 60 Meters (5.3 MHz)

CW, 5332 5348 5358.5 5373 5405 kHz

General, Advanced, and Amateur Extra licensees may operate on these five channels on a secondary basis with a maximum effective radiated power (ERP) of 100 W PEP relative to a half-wave dipole. Permitted operating modes include upper sideband voice (USB), CW, RTTY, PSK31 and other digital modes such as PACTOR III. Only one signal at a time is permitted on any channel.

## 40 Meters (7 MHz)

See Sections 97.305(c), 97.307(f)(11) and 97.301(e). These exemptions do not apply to stations in the continental US.

## 30 Meters (10.1 MHz)

Avoid interference to fixed services outside the US.

## 20 Meters (14 MHz)

## 17 Meters (18 MHz)

## 15 Meters (21 MHz)

## 12 Meters (24 MHz)

## 10 Meters (28 MHz)

## 6 Meters (50 MHz)

## 2 Meters (144 MHz)

## 1.25 Meters (222 MHz)

\* Geographical and power restrictions may apply to all bands above 420 MHz. See FCC Part 97.303 for information about your area.

## 70 cm (420 MHz)\*

## 33 cm (902 MHz)\*

## 23 cm (1240 MHz)\*

All licensees except Novices are authorized all modes on the following frequencies:

2300-2310 MHz	10.0-10.5 GHz †	122.25-123.0 GHz
2390-2450 MHz	24.0-24.25 GHz	134-141 GHz
3300-3500 MHz	47.0-47.2 GHz	241-250 GHz
5650-5925 MHz	76.0-81.0 GHz	All above 275 GHz

† No pulse emissions

### Note:

CW operation is permitted throughout all amateur bands.

MCW is authorized above 50.1 MHz, except for 144.0-144.1 and 219-220 MHz. Test transmissions are authorized above 51 MHz, except for 219-220 MHz

- = RTTY and data
- = phone and image
- = CW only
- = SSB phone
- = USB phone, CW, RTTY, and data.
- = Fixed digital message forwarding systems only

- E = Amateur Extra
- A = Advanced
- G = General
- T = Technician
- N = Novice

See ARRL Web at [www.arrl.org](http://www.arrl.org) for detailed band plans.

# What is Amateur (Ham) Radio?

Amateur radio enthusiasts — “hams” — often have been at the forefront of the sweeping blaze of progress over the past century in wireless and electronics, leading to technology that has broadened our horizons and touched virtually all of our lives. In the days before the telephone and household electricity were commonplace and the internet not yet conceived, hams pioneered personal communication. Amateur radio was the first wireless social medium.

From sophisticated smartphones, tablets, devices worn on your wrist, and diminutive laptop PCs that go anywhere, wireless technology is changing so rapidly that it can be difficult to keep current. People-to-people communication is the goal, whether by voice, text, or image. But amateur radio remains vital and active today. In this chapter, Rick Lindquist, WW1ME, provides an overview of amateur radio activities and licensing requirements.

## 1.1 Do-It-Yourself Wireless

Amateur radio, better known as “ham radio,” is many things to many people — more than 750,000 of them in the US alone. Ham radio hobbyists have at their fingertips the ability to directly contact diverse and fascinating people they may never meet who live in distant places they’ll never visit. They do this without any external infrastructure, such as a cell network or the internet, sometimes using simple, inexpensive — often homemade — equipment and antennas. Since the early days of wireless, these experimenters, who had to learn by trial and error, because little information was available at the time, have developed and refined the means to contact one another directly, independent of wired networks. They do it because it’s fun and offers a sense of accomplishment — “*I made this happen!*”

As a radio amateur, you can meet new friends, win awards, experiment with and learn about radio science and technology, challenge yourself in on-the-air competitions (“radiosport”), contribute to your community, travel, promote international goodwill, and continue a more than century-old wireless communication tradition. Your station is yours and yours alone, and it’s independent of any other communication network — no contract to sign, no bill to pay.

Let’s take a closer look.

### THE SECOND CENTURY OF HAM RADIO

We may think of “wireless” as a relatively modern term that applies to a wide variety of electronic devices, but it’s been around since the late 19th century. At some point along the way, “radio” (and later “television”) took over as the preferred term. Being able to communicate from one place to another without connecting wires was a goal of late 19th and early 20th century experimenters. Equipment and methods for early wireless were rudimentary — a simple “crystal” radio to listen, and a “spark gap” transmitter (it *actually* threw sparks) to send Morse code, coupled with what was then called an “aerial” — we’d call it an antenna today. Little to no ready-made equipment was available, and parts for these early radio do-it-yourselfers were expensive and hard to obtain. On a good night, their transmissions might even span 50 miles. In the early 20th century, when few households had telephones and calling long-distance was pricey, ham radio was, in more contemporary terms, “really cool technology.”

In 1914, just two years after the federal government required hams to hold licenses, inventor and industrialist Hiram Percy Maxim, 1AW, and radio enthusiast Clarence Tuska, 1WD, established the American Radio Relay League (ARRL) to bring US radio hobbyists under one tent to serve their common interests. These two founding fathers of ham radio and their peers would be awestruck to see how the world of amateur radio and wireless technology has expanded and evolved in the intervening years.

While Maxim and Tuska were not the first hams, the organization they founded, now known

Figure 1.4 — Electrical engineering student Matthew Stevens, NJ4Y, of Auburndale, Florida, operates during ARRL's National Parks on the Air event from Gulf Islands National Seashore. [Matthew Stevens, NJ4Y, photo]

Figure 1.5 — Jet Jurgensmeyer, KEØUWZ (left), is in the cast of the Fox TV comedy *Last Man Standing*, in which he plays the grandson of Tim Allen's character Mike Baxter. With him is ARRL Communications Content Producer Michelle Patnode, W3MVP.

as ARRL — the National Association for Amateur Radio, has championed and sustained these radio pioneers and their successors. Now more than 100 years down the road — light years in terms of radio science and technology — amateur radio continues to adapt to the times. While many traditions continue, today's ham radio is *not* the ham radio of yesteryear.

## THE ORIGINAL SOCIAL MEDIUM

In this age of multiple sophisticated communication platforms, it's not uncommon for people to ask, "Ham radio? Do they still do that?" Yes, "they" do. But, given the proliferation of communication alternatives, the larger question may be, *Why?*

Ham radio is a hands-on technological and social medium — *personal* communication with no bills, minutes, or data plans. It's personal communication that's "off the grid," a wireless service you can rely on when other services become unavailable.

It doesn't cost a lot to get into amateur radio, and participation is open and accessible to everyone. Hams are mothers, fathers, and children of all ages, ethnic backgrounds, physical abilities, and walks of life who belong to a unique worldwide community of licensed radio hobbyists. Some are even well-known celebrities. All find joy and excitement by experiencing radio communication and electronics on a very personal level across a spectrum of activities.

In the United States, the Federal Communications Commission (FCC) grants licenses in the Amateur Radio Service. With an emphasis on "service," the FCC early on laid down five essential principles underlying amateur radio's fundamental purpose (see sidebar "Ham Radio's Rules of the Airwaves"). These recognize ham radio's value to the public as a "voluntary non-commercial communication service, particularly with respect to providing emergency communications." The service also exists to continue and expand amateur radio's "proven ability" to advance the state of the radio art, as well as both technical and communication skills. Further, the FCC says, the Amateur Radio Service should help to expand the "existing reservoir of trained operators, technicians, and electronics experts," and continue and extend the radio amateur's "unique ability to enhance international goodwill."

## HAMS ARE EVERYWHERE

The driver of that car sporting an odd-looking antenna may be a radio amateur equipped to enjoy his or her hobby while on the road — called mobile operation. Your

## Hams on the Front Lines

Over the years, the military and the electronics industry have often drawn on the ingenuity of radio amateurs to improve designs or solve problems. Hams provided the keystone for the development of modern military communication equipment, for example. In the 1950s, the Air Force needed to convert its long-range communication from Morse code to voice, and jet bombers had no room for skilled radio operators. At the time, hams already were experimenting with and discovering the advantages of single sideband (SSB) voice equipment. With SSB, hams were greatly extending the distances they could transmit.

Air Force Generals Curtis LeMay and Francis "Butch" Griswold, both radio amateurs, hatched an experiment that used ham radio equipment at the Strategic Air Command headquarters. Using an SSB station in an aircraft flying around the world, LeMay and Griswold were able to stay in touch with Offutt Air Force Base in Nebraska from anywhere. The easy modification of this ham radio equipment to meet military requirements saved the government millions of dollars in research costs.

More recent technological experimentation has focused on such techniques as software defined radio (SDR). This approach enables electronic circuit designers to employ *software* to replace more costly — and bulkier — hardware components. It's no surprise that radio amateurs have been among those investigators doing the ground-level research and experimentation to bring this technology from the laboratory to the marketplace. Transceivers built on the SDR model represent the future of equipment design.

Affirming the relationship between amateur radio and cutting-edge technology, the late Howard Schmidt, W7HAS, was White House Cybersecurity Coordinator from 2009 to 2012. An ARRL member, Schmidt, who died in 2017, was one of the world's leading authorities on computer security, with decades of experience in government, business and law enforcement. Schmidt credits ham radio with helping to launch his career. "Building ... computers to support my ham radio hobby gave me the technical skills that I needed to ... start doing computer crime investigations and work on the early stages of computer forensics, in turn enabling me to start working on cybersecurity issues," he once said. Hams are often found in industry and the military as technology presses ahead.

## Ham Radio's Rules of the Airwaves

International and national radio regulations govern the operational and technical standards of all radio stations. The International Telecommunication Union (ITU) governs telecommunication on the international level and broadly defines radio services through the international *Radio Regulations*. In the US, the Federal Communication Commission (FCC) is the agency that administers and oversees the operation of nongovernmental and nonmilitary stations — including amateur radio. Title 47 of the *US Code of Federal Regulations* governs telecommunication, and Part 97 of the Code spells out the Amateur Radio Service rules.

Experimentation has always been the backbone of amateur radio, and the Amateur Service rules provide a framework within which hams enjoy wide latitude to experiment in accordance with the "basis and purpose" of the service. The rules should be viewed as vehicles to promote healthy activity and growth, rather than as constraints leading to stagnation. The FCC's rules governing amateur radio recognize five aspects, paraphrased below, in the Basis and Purpose of the Amateur Service.

- Amateur radio's value to the public, particularly with respect to providing emergency communication support
- Amateur radio's proven ability to contribute to the advancement of the radio art
- Encouraging and improving the Amateur Service through rules that help advance communication and technical skills
- Maintaining and expanding the Amateur Service as a source of trained operators, technicians and electronics experts
- Continuing and extending the radio amateur's unique ability to enhance international goodwill

The Amateur Radio Service rules, Part 97, are in six sections: General Provisions, Station Operation Standards, Special Operations, Technical Standards, Providing Emergency Communication and Qualifying Examination Systems. Part 97 is available in its entirety on the ARRL and FCC websites (see the Resources section at the end of this chapter for further information).

neighbor on the next block with the wires strung between trees or, perhaps, a tower supporting what looks like a very large television antenna, probably is one too.

Modern technology continues to make ham radio more accessible to all, including those living on tight budgets or facing physical challenges. People lacking mobility may find the world of amateur radio a rewarding place to find lasting friendships — on the next block, in the next state, or around the world.

When the coronavirus pandemic forced many of us indoors starting in early 2020, hams remained able to keep in contact with their friends and fellow club members via radio. It became a wonderful way to share experiences while staying at home.

Hams are ambassadors, contacting and making friends with other enthusiasts in other countries and sometimes visiting far-flung locations to get on the air and meet the people who live there. Amateur radio recognizes no international or political boundaries, and it brings the world together in friendship.

## 1.1.1 Making It Happen

A major feature of amateur radio's more than 100-year heritage has been the ham's ability to make do with what's at hand to get on the air. It is in the pursuit of such hands-on, do-it-yourself activities that this *Handbook* can be a guide, especially given a plentiful and growing supply of electronic components today and ever more complex and creative circuit designs.

Amateur radio has always been about what its participants bring *to it* and what they make *of it*. Hams communicate with one another using equipment they've bought or built, or a combination of the two, over a wide range of the radio frequency spectrum. The methods hams use to keep in touch with each other range from the venerable Morse code — no longer a licensing requirement, by the way — to voice, modern digital (computer-based) modes, and even television.

The hybridization of amateur radio, computer technology, and the internet has become a fact of life, as hams continue to invent creative and innovative ways to exploit technology. Most hams these days consider a computer and internet access as essential station components. Today it's possible for a ham to control a transmitting and receiving station via the internet using nothing more

Figure 1.6 — Brian Milesosky, N5ZGT, logs contacts during the 2017 NM5FD Field Day operation, while his son, Landon, and Daughter, Audrey, look on. [Rick Naething, AE5JI, Photo.]

than a laptop or smartphone — even if that station is thousands of miles distant. The wonder of software defined radio (SDR) techniques has even made it possible to create *virtual* radio communication gear that largely consists of computer programming code instead of parts and wires. SDRs require minimal physical components; sophisticated computer software does the heavy lifting!

## 1.1.2 Your Ham Radio Comfort Zone

Amateur radio offers such a wide range of activities that everyone can find a comfortable niche. As one of the few truly *international* hobbies, ham radio makes it possible to communicate with other similarly licensed radio aficionados all over the world. On-the-air competition called contesting or “radiosport” — just to pick one activity many hams enjoy — harnesses those competitive instincts and helps participants to improve their skills and stations. Further, and perhaps more important, amateur radio serves the public by supporting communication in disasters and emergencies, while also serving as a platform for sometimes cutting-edge scientific experimentation. Many of those who got into ham radio as youngsters — such as Nobel Laureate Joe Taylor, K1JT — credit that involvement with their later success in technology careers.

Ham radio's horizon extends into space. The International Space Station boasts more than one ham radio station, and most ISS crew members are amateur radio licensees. Thanks to the Amateur Radio on the International Space Station (ARISS) program, suitably equipped hams can talk directly with NASA astronauts in space, even by using simple, portable equipment. Hams also contact each other through Earth-orbiting satellites designed and built by the nonprofit Radio Amateur Satellite Corporation

(AMSAT) and by educational entities here in the US and abroad. Some radio amateurs even bounce radio signals off the moon and back to other hams on Earth.

Hams talk with one another from vehicles, while hiking or biking in the mountains, from remote camp sites, or while boating. Some hams enjoy sharing photos over the air too, using one of the television modes available to radio amateurs. Through these activities and others, hams establish lifelong friendships, learn a lot and, perhaps most important, have a *lot* of fun. Along the way, radio amateurs often contrib-

ute a genius that propels technological innovation.

Most likely you're already a ham, have experimented with radio and electronics, are part of the Maker movement, or are thinking about getting your ham license. This *Handbook* is an invaluable resource that reveals and explains the “mysteries” governing electronics in general and in radio — or wireless — communication in particular, especially as it pertains to amateur radio.

## 1.1.3 What's in it for Me?

As a community of communities, amateur radio can be whatever *you* want it to be. Whether you are looking for relaxation, excitement, enjoyment or a way to stretch your mental (and physical) horizons, amateur radio can provide it — even if time and money are tight. However it happens, communication between individuals is at the core of nearly all ham radio activities. In its most basic form, ham radio is two people greeting each other over the air, perhaps using inexpensive handheld transceivers (a combination transmitter-receiver) or even homemade gear. In “Hamspeak,” a two-way, on-the-air communication is known as a “QSO” — an old radiotelegraph, or Morse code, abbreviation often pronounced “CUE-so.”

Ham radio can also be a group activity. Hams with common interests often gather on the airwaves to share their thoughts and even pictures. These get-togethers are called “nets” or “roundtables,” depending on their formality. When hams meet on the air for an extended on-the-air conversation, they sometimes call it “ragchewing,” another term with a long history.

Nets form when like-minded hams gather on the air on a regular schedule. Nets often provide an on-the-air venue to find other hams with similar interests both inside and outside

of amateur radio. Topics may be as diverse as vintage radio, chess, gardening, rock climbing, railroads, computer programming,

teaching, or an interest in certain types of radio equipment. Faith-based groups and scattered friends and families may also orga-

nize nets. You can find your special interest in *The ARRL Net Directory* on the ARRL website ([www.arrl.org/arrl-net-directory](http://www.arrl.org/arrl-net-directory)).

## 1.2 Joining the Ham Radio Community

Prospective hams once found Morse code a roadblock to getting a license. Today it's no longer necessary to demonstrate Morse code proficiency to become an amateur radio licensee, even though Morse code still enjoys considerable popularity as an on-the-air mode in amateur radio. You still must hold a license granted by the Federal Communications Commission (FCC) to operate an amateur radio station in the United States, in any of its territories and possessions, or from any vessel or aircraft registered in the US. Age or citizenship are no bar to obtaining a US amateur radio license, and the cost is minimal, sometimes free. Young people not yet in their teens regularly pass ham radio exams!

The FCC offers three classes — or levels — of amateur radio license. From the easiest to the most difficult, they are Technician, General, and Amateur Extra. Applicants must pass a multiple-choice written examination for *each* license class as they move up the licensing ladder. Official question pools for all ham radio license classes are publically available. The more you advance, the more challenging the test and the more generous the operating privileges. To reach the top — Amateur Extra class — you must pass the examinations for all three license classes.

### 1.2.1 Moving Through the Ranks

Most people start out in amateur radio by getting a Technician class license or “ticket,” as a ham license is sometimes called. Obtaining a Technician license requires passing a 35-question multiple-choice exam. The test covers FCC rules and regulations governing the airwaves, courteous operating procedures and techniques, and some basic electronics. The privileges earned give Technicians plenty of room to explore and activities to try. For some, the Technician license is the only one they'll ever want or need.

Technicians enjoy a wide, but somewhat limited, range of voice and digital radio operating privileges. These include access to some “high frequency” (HF or shortwave) frequency “bands” or segments of the radio spectrum. Depending upon license class, hams have access to up to 10 distinct HF bands in the range from 1.8 to 29.7 MHz, where most direct international communication happens. (Frequency and wavelength terms are explained in the **Electrical**

**Fundamentals** chapter.) Technicians also have all amateur privileges in the VHF-UHF and microwave spectrum, which allow operation on widely available FM voice repeaters. A repeater greatly extends the communication range of low-power, handheld radios or mobile stations too far apart to communicate with each other directly. The “Tech ticket” is a great introduction to the fun and excitement of ham radio and to the ways of the hobby.

By upgrading to General class, a Technician licensee earns additional operating privileges, such as access to all amateur radio HF bands. Upgrading to General entails passing another 35-question multiple-choice exam. In addition to Technician privileges, Generals enjoy worldwide communication using voice, digital, image, and television techniques.

Reaching the pinnacle of the amateur radio license structure — Amateur Extra class — means passing a more demanding 50-question examination. Amateur Extra licensees enjoy privileges on all frequency bands and communication modes available to hams. The exam may be challenging, but many hams consider it well worth the effort!

### 1.2.2 Study Aids

You can prepare for the exam on your own, with a group of friends or by taking a class sponsored by a ham radio club in your area. The ARRL offers materials and lesson plans for hams wishing to teach amateur radio licensing classes. Anyone can set up license-study classes. Many amateur radio clubs hold periodic classes, usually for the Technician license. The ARRL supports Registered Amateur Radio Instructors, but registration is not necessary to conduct a class. The ARRL website, [www.arrl.org](http://www.arrl.org), offers information on classes, clubs, and volunteer examiners (VEs) in your area (more on VEs below).

Help is available at every step. The ARRL publishes study materials for all license classes. Visit the ARRL website or contact the ARRL's New Ham Desk for more information on how to get started. The Resources section at the end of this chapter includes an address and telephone number. The ARRL can help you find ham radio clubs in your area as well as ARRL-registered instructors and local Volunteer Examiner teams. Additional information on the ARRL web-

Figure 1.7 — Parachute Mobile! “Jumper 1,” Mark Meltzer, AF6IM, gives new meaning to mobile operation as he enjoys making contacts and enjoying the view, combining his enthusiasm for skydiving and amateur radio. [Captain Jim Wilson, RCAF, photo]

site includes frequencies hams can use, popular operating activities, and how to order the latest ARRL study guide.

For newcomers seeking to obtain a Technician license, *The ARRL Ham Radio License Manual* includes the complete, up-to-date question pool, with the correct answers and clear explanations. The manual assumes no prior electronics background. It delves into the details behind the questions and answers, so you will *understand* the material, rather than simply memorize the correct answers.

If you already have some electronics background or just want brief explanations of the material, you might find *ARRL's Tech Q&A* manual a more appropriate choice. It also includes the entire Technician question pool to help you prepare.

When you are ready to upgrade to a General class license, *The ARRL General Class License Manual* or *ARRL's General Q&A* can help you prepare. In like fashion, *The ARRL Extra Class License Manual* and *ARRL's Extra Q&A* will guide your study efforts for the Amateur Extra Class license. Check the ARRL website for detailed information on these and other license study options.

### 1.2.3 Taking the Test

While the FCC grants US amateur radio licenses, volunteer examiners (VEs) now administer all amateur radio testing. Other countries have adopted similar systems. Ham radio clubs schedule regular exam sessions, so you shouldn't have to wait long or travel far once you're ready. Exam sessions often are available on weekends (frequently at ham radio gatherings called "hamfests") or evenings. Most volunteer examiner teams charge a small fee to recover the cost of administering the test and handling the FCC paperwork.

ARRL is a Volunteer Examiner Coordinator (VEC) and supports the largest VE program in the nation. More information about the VE program is available on the ARRL website.

The questions for each 35- or 50-question test come from a large "question pool" that's specific to each license class. All three question pools — Technician, General and Amateur Extra — are available to the public in study guides and on the internet. If you're studying, make sure you're working with the latest version, since question pools are updated on a set schedule. The Resources section at the end of this chapter has more information on where to find the question pools.

### 1.2.4 Your Ham Radio Mentor

The learning doesn't stop after you pass the exam and earn your amateur radio ticket. New hams often learn the ropes from a men-

tor. In ham radio parlance, such an experienced ham willing to help newcomers is called an "Elmer." This individual teaches newcomers about amateur radio operating, often on a one-to-one basis. Your local ham radio club may be able to pair you with an Elmer, who will be there for you as you study, buy your first radio, and set up your station — which many hams call their "radio shack" or "ham shack," a term held over from the days when ham stations often were in small buildings separate from the owner's residence. Elmers also are pleased and proud to help you with your first on-the-air contacts.

Elmers who belong to the international Courage Kenny Handiham Program ([handiham.org](http://handiham.org)) focus on making study materials and ham radio station operation accessible to those with physical disabilities. Local

Handihams assist such prospective radio amateurs in getting licensed, and the Handiham System may even loan basic radio gear to get the new ham on the air.

### 1.2.5 Your Ham Radio Identity

A ham radio operator is known and recognized by a unique call sign (some hams shorten this to simply "call") that the FCC issues when granting your license. Your call sign not only identifies your station on the air, it's an individual ham radio identity, and many hams become better known by their call signs than by their names! Once your license and call sign grant appear online in the FCC's active Amateur Radio Service database, you have permission to operate.

## ARRL — the national association for Amateur Radio®

The American Radio Relay League (ARRL) is the internationally recognized society representing amateur radio in the US. Since its founding in 1914, ARRL has grown and evolved along with amateur radio. ARRL Headquarters and the Maxim Memorial Station W1AW are in Newington, Connecticut, near Hartford. Through its dedicated volunteers and a professional staff, the ARRL promotes the advancement of the Amateur Service in the US and around the world.

ARRL is a nonprofit, educational and scientific organization dedicated to the promotion and protection of the many privileges that ham radio operators enjoy. Of, by and for the radio amateur, ARRL numbers some 150,000 members — the vast majority of active amateurs in North America. Licensees can become Full Members, while unlicensed persons are eligible to become Associate Members with all membership privileges except for voting in ARRL elections. Anyone with a genuine interest in amateur radio belongs in the ARRL.

The ARRL volunteer corps is called the Field Organization. Working at the state and local level, these individuals tackle ARRL's goals to further amateur radio. They organize emergency communication in times of disaster and work with agencies such as American Red Cross and Citizen Corps. Other volunteers keep state and local government officials abreast of the good that hams do at the state and local level.

When you join ARRL, you add your voice to those who are most involved with ham radio. The most prominent membership benefits are its membership journal *QST*, published monthly in print and digital form, and *On the Air*, a bi-monthly magazine aimed at amateur radio newcomers and hams gaining experience. *QST* includes stories you'll want to read, articles on projects to build, announcements of upcoming hamfests, conventions, contests and other on-air activities, reviews of new equipment, reports on the role hams play in emergencies, and much more.

*On the Air* anchors a suite of benefits that will help you to make the most of your amateur radio license. In addition to the magazine are the *On the Air* podcast, *On the Air* blog, and *On the Air* Facebook community.

Members may elect to receive either *QST* or *On the Air*. A couple of bimonthly specialty magazines aimed at particular segments of amateur radio are available to all ARRL members in online digital format, as a member service: *QEX — The Forum for Communications Experimenters* and *NCJ — National Contest Journal*, which caters to those interested in amateur radio contesting — or "radiosport."

Being an ARRL member is far more than a magazine subscription. ARRL represents your interests before the FCC and Congress, sponsors operating events throughout the year, and offers membership services at a personal level. These include:

- low-cost ham radio equipment insurance
- the Volunteer Examiner program
- the Technical Information Service (which answers your questions about amateur radio technical topics)
- the QSL Service (which helps you exchange QSL cards in bulk with hams in other countries to confirm your contacts with them)

For answers to any questions about amateur radio, email, call or write ARRL Headquarters. See the Resources section at the end of this chapter for contact information.

The FCC went “paperless” in 2015 and no longer routinely prints or mails license documents. Licensees can print their own “official copy” from the FCC Universal Licensing System (ULS) site, however.

A call sign also identifies the issuing country. US call signs, for example, begin with W, K, N, or A followed by some combination of letters and one numeral. Each combination is different. One well-known ham radio call sign is W1AW, assigned to the Hiram Percy Maxim Memorial Station at ARRL Headquarters in Newington, Connecticut.

FCC-assigned call signs come in several flavors, with the shortest — and typically most desirable — combinations available only to Amateur Extra Class licensees. The FCC routinely assigns initial call signs to new Technician licensees in the longest format. These call signs start with two letters, a numeral from 0 to 9, and three more letters. The first part of a call sign including the numeral is called a *prefix*. The part following the numeral is called a *suffix* and is unique to a specific licensee. Typical prefixes in Canada are VE and VA, while the common prefix in Mexico is XE.

At one time, the numeral indicated a US station’s geographical region — 1 for New England, 6 for California, and 9 or 0 (zero) for the Midwest, for example. The FCC has made ham radio call signs portable, however

**Figure 1.9** — The ARRL Field Day “Get on the Air” (GOTA) at the Huntsville Amateur Radio Club’s K4BFT setup in Alabama attracted a group of teachers from the nearby US Space and Rocket Center Space Camp. Todd Cline, K7KDT, demonstrates a digital “waterfall” as club members John Boyette, KK5KKT (leaning at left), and Geoff Suiter, KK4IV (at keyboard), operate the station. [William Martin, KK4FDF, photo]

— just like telephone numbers. So, a call sign with “1” following the prefix may belong to a ham located in Florida.

You don’t have to keep the call sign the FCC assigns. The FCC’s *vanity call sign* pro-

gram permits a ham to select a new call sign from among the database of certain unassigned call signs, based on the applicant’s license class, and file an application for it — free of charge!

**Figure 1.8** — This iconic brick building houses W1AW, the station operated by the ARRL in Newington, Connecticut, and known around the world. W1AW memorializes Hiram Percy Maxim, one of the founders of the ARRL. Visitors are welcome and often operate the station. [Rick Lindquist, WW1ME, photo]

**Figure 1.10** — Adeline Hillier, AA7HH, adjusts the polarization angle of a UHF antenna during an experiment to measure the effect of the change.

### 1.3.2 Computers and Ham Radio

Amateur radio and computers have been best friends for years. Radio amateurs discovered decades ago that interconnecting their PCs with their ham stations not only makes operating more convenient but can open the door to additional activities on the ham bands. Most radio amateurs now have a computer in the shack, often one that's dedicated to ham radio tasks. Software is available for many ham radio applications, from record keeping to antenna and circuit design.

Probably the most common use for a computer in the ham shack is logging your contacts — keeping a record of the stations you have communicated with on the air. This is especially true for contesters, where speed and accuracy are paramount. While there's no longer a legal requirement to maintain a detailed logbook of your on-the-air activities, many hams still keep one, even for casual operating, and computer logging can make the task less tedious (see the sidebar “Keeping a Log”).

Many computer logging applications also let you control many or most of your radio's functions, such as frequency or band selection, without having to leave your logging program. It's also possible to control various accessories, such as antenna rotators or selection switches, by computer.

Via your computer's soundcard, you can

Figure 1.13 — Ella Dietzel, KM4QJM, runs a string of single-sideband (SSB) voice contacts at Schofield Middle School Radio Club (N4SMS) in Aiken, South Carolina, while a classmate looks on. [Kent Hufford, KQ4KK, photo.]

enjoy *digital modes* with nothing more than a couple of simple connections, operating software (often free), and an interface. A big surge in digital operation began in 2017 with the development of the FT8 protocol, which is included among a suite of programs called *WSJT-X* ([physics.princeton.edu/pulsar/k1jt/wsjt.html](http://physics.princeton.edu/pulsar/k1jt/wsjt.html)). Nobel Prize winner and active radio amateur Joe Taylor, K1JT — mentioned above — was a primary developer of the *WSJT-X* suite. FT8 has become a mode of choice for operators of modest stations attempting to contact hams in rare locations, although it does not permit much more than an exchange

of signal reports and locations. More appropriate for “keyboard-to-keyboard” conversations are the venerable RTTY (radioteletype) and PSK31. Like FT8, a big advantage of PSK31 is that it lets you communicate over great distances with a very modest ham station, typically using extremely low power levels.

Computers also can alert you to DX activity on the bands, help you practice taking amateur radio license examinations, or improve your Morse code skill. Many ham radio organizations, interest groups, individuals maintain and, of course, equipment retailers maintain websites too.

## 1.4 Getting on the Air

Amateur radio is a *social* activity as well as a technical pursuit. It's a way to make new friends and acquaintances on the air that you may later meet in person. Some ham radio relationships last a lifetime, even though the individuals sometimes never meet face to face. Ham radio has been the glue that keeps high school and college friends in touch through the years.

Amateur radio also can cement relationships between radio amateurs of different nationalities and cultures, leading to greater international goodwill and understanding — something that's especially beneficial in this era of heightened cultural tensions and misperceptions. When you become an amateur radio operator, you become a “world citizen.” In return you can learn about the lives of the radio amateurs you contact in other countries.

“What do hams say to each other?” you might wonder. When they meet for the first time on the air, hams typically exchange pleasantries in the form of signal reports, names, and locations (abbreviated “QTH” by hams). Radio signal reports indicate how well the operators are hearing (or “copying”) each

other over the air. This name/location/signal report format is typical, regardless of radio mode. With these preliminaries out of the way, ham radio conversations often turn to equipment or may extend to other interests.

Although English is arguably the most common language on the ham bands (even

spoken by hams whose first language may be something *other* than English), English speakers sometimes can make a favorable impression on hams in other countries if they can speak a little of the other person's language — even if it's as simple as *danke, gracias, or arigato*.

Figure 1.14 — Sisters Emma Schaefer, KC9YGJ (left), and Cora Schaefer operated at special event station W9ZL, fielded by the Fox Cities Amateur Radio Club during AirVenture in Oshkosh, Wisconsin.

### 1.4.1 Voice Modes

We've mentioned the use of voice (or "phone," short for "radiotelephone") and Morse code (or CW) on the amateur bands. Although more hams are embracing digital modes every day, phone and CW by far remain the most popular amateur radio communication modes. Ham voice modes are amplitude modulation (AM), which includes the narrower-bandwidth single sideband

(SSB), and frequency modulation (FM). For the most part, SSB is heard on HF, while FM is the typical voice mode employed on VHF, UHF, and microwave bands.

The great majority of ham radio HF phone operators use SSB (subdivided further into upper sideband and lower sideband), but a few still enjoy and experiment with heritage "full-carrier AM." Once the primary ham radio voice mode, this type of AM still is

heard on the standard broadcast band (530 to 1710 kHz). Today's AM buffs appreciate its warm, rich audio quality, and the simplicity of circuit design encourages restoring or modifying vintage ham radio gear that use vacuum tubes or even building from scratch. For more information about AM operation, visit [www.arrrl.org/am-phone-operating-and-activities](http://www.arrrl.org/am-phone-operating-and-activities).

### 1.4.2 Morse Code

Morse code was the very first radio transmission mode, although it wasn't long before early experimenters figured out how to transmit the human voice and even music over the airwaves. Morse is also the original digital mode; the message is transmitted by turning a radio signal on and off ("1" and "0" in digital terms) in a prescribed pattern to represent individual letters, numerals, and characters. This pattern is the International Morse Code, sometimes called the "radio code," which varies in many respects from the original Morse-Vail Code (or "American Morse") used by 19th century railroad telegraphers. Leaning on longstanding tradition, hams often refer to Morse transmissions as "CW," after an archaic definition for "continuous wave" which described the type of radio wave involved.

Federal regulations once required that prospective radio amateurs be proficient in sending and receiving Morse code in order to operate on "worldwide" (i.e., shortwave or HF) ham bands. Although this is no longer the case for any class of amateur radio license in the US, many hams still embrace CW as a favorite mode and use it routinely. One well-known ham says he likes Morse code because it's different from all of the other ways we communicate each day. Hams typically send Morse code signals by manipulating a manual telegraph key, a "semi-automatic" key (called a "bug") or a CW "paddle" and an electronic keyer to form the dots and dashes. Most hams decipher Morse code "by ear," either writing down the letters, numerals and characters as they come through the receiver's headphones or speaker or simply reading it in their heads. Some use one of the available computer-based or stand-alone accessories that can translate CW into plain text without the need to learn the code.

Hams who enjoy CW cite its narrow bandwidth — a CW signal takes up very little of the radio spectrum — simpler equipment, and the ability of a CW signal to "get through" noise and interference with minimal transmitting power. CW is a common low-power (QRP) mode.

### 1.4.3 FM Repeaters

Hams often make their first contacts on local voice repeaters, although in recent years the nearly ubiquitous cell phone has reduced

Figure 1.15 — Then-13-year-old Aidan helped his grandfather, Chuck Schneebeli, K19A, during the 2018 ARRL November Sweepstakes, which attracts thousands of hams to the airwaves each fall.

Figure 1.16 — An amateur radio balloon project by Bill Brown, WB8ELK; Paul Verhage, KD4STH, and Ann Boes, KD0QCA, carries a 4-H Lab Revolution student experiment at 53,000 feet. [Jeff Ducklow, N0NQN, photo]

the popularity of — and even the need for — repeaters for everyday ham communication. Repeaters still have a definite role in supporting communication during disasters and emergencies, however. Repeaters can greatly extend the useful range of a typical handheld FM transceiver much in the same way a cell tower retransmits your voice or text messages, and they carry the vast majority of VHF/UHF traffic, making local and even regional mobile communication possible for many hams. Located on hilltops, tall buildings, or other high structures, repeaters strengthen signals and retransmit them. This provides communication over much greater distances than would be possible when operating point to point or “direct.” The wider coverage can be especially important if the repeater is ever pressed into service during an emergency.

Typically, hams use repeaters for brief contacts, although socializing and “ragchewing” are routine on some “machines,” as repeaters are often called. All repeater users give priority to emergency communications. Most repeaters are maintained by clubs or groups of hams. If you use a particular repeater frequently, you should join and support the repeater organization. Some hams set up their own repeaters as a service to the community.

The best way to learn the customs of a particular repeater is to listen for a while before transmitting. Most repeaters are *open*, meaning that any amateur may use the repeater, although repeaters typically require users to transmit an access tone (which you can select on any modern FM transceiver). A few repeaters are *closed*, meaning that usage is restricted to members of the club or group that owns and operates the repeater. Some repeaters still have “autopatch” capability that allows amateurs to make telephone calls through the repeater. The *ARRL Repeater Directory* shows repeater locations, frequencies, capabilities, and whether the repeater is open or closed.

### 1.4.4 Digital Modes

Digital modes are used to exchange information between computers as individual characters — either in complete files or one character at a time in “keyboard-to-keyboard” contacts. Amateurs use modes originally invented for commercial or military applications and also invent their own! Innovation in digital communications is one of amateur radio’s most important and active contributions.

Two popular digital modes today are FT8, one of several modes in the *WSJT-X* software package ([physics.princeton.edu/pulsar/k1jt/wsjsx.html](http://physics.princeton.edu/pulsar/k1jt/wsjsx.html)), and either PACTOR or WINMOR, which are used to exchange email and other types of information as part of the

Winlink system ([winlink.org](http://winlink.org)). Both FT8 and WINMOR use your PC with its sound card interfaced to a transceiver. The later versions of PACTOR that are most widely used require a special modem between the PC and radio. These modes are described in the **Digital Protocols and Modes** chapter. You’ll also find many helpful articles about using them in the *ARRL Operating Manual* and on the ARRL website.

The free package of *WSJT-X* software includes a number of specialized digital modes developed by a team led by Joe Taylor, K1JT, that are optimized for different applications: JT65 for EME, MSK144 for meteor scatter, FT8 for HF operation (a similar FT4 protocol is customized for radio contesting), WSPR for very low-power beacons, and more. FT8, released in 2017, quickly became extremely popular due to its ability to exchange data with signals many times weaker than the noise. FT8 is a great mode for hams in noisy neighborhoods or who can’t put up big antennas.

Hams interested in public service, especially emergency communications, make use of the Winlink system ([www.winlink.org](http://www.winlink.org)) to maintain contact while camping, boating, or just traveling. Along with PACTOR or WINMOR, which actually transfer data over the air, an email “client” program such as *Winlink Express* is required to manage the information. Many public service teams include Winlink as part of their training and operation programs. The system acts as a worldwide gateway between amateur radio and the internet although the restrictions on commercial content must be strictly followed.

Two other keyboard-to-keyboard modes used by hams to “talk by typing” include radioteletype or RTTY and PSK31. Often pronounced “ritty,” radioteletype was originally developed for point-to-point communications. Hams replaced the original bulky and noisy electromechanical teleprinters with PCs, sound cards, and software such as *fldigi* which is free and supports many different modes (see [www.w1hkj.com](http://www.w1hkj.com)). RTTY’s distinctive two-tone FSK (frequency-shift keying) signals are common on the HF bands.

Somewhat lower in frequency than the RTTY signals, you’ll hear single tones with a buzzing modulation. This is PSK31 which stands for “Phase-shift Keying, 31 baud.” While 31 baud may not sound very fast, it is an average typing speed and perfect for hams to chat back and forth. PSK31 is very effective at low power levels and is one of the many modes in the *fldigi* package.

Another amateur innovation is the *Automatic Packet Reporting System* or APRS which combines position information (such as from GPS) with text messages and packet radio. This worldwide system ([www.aprs.org](http://www.aprs.org)) uses continuously monitoring “gateway”

receivers to listen for the low-power APRS signals, relaying the information to internet servers where the information is viewed. Hams use APRS in their vehicles, while biking or boating, for weather reporting, and even to track high-altitude balloons during experiments.

FT8, PACTOR/WINMOR, RTTY, PSK31, and APRS are just a small fraction of the many different digital modes used in amateur radio. New variations and innovations are being released all the time as experimenters try a new modulation or encoding scheme. This is a great example of the Amateur Service fulfilling its Basis and Purpose by “contribut(ing) to the advancement of the radio art.”

### 1.4.5 Image Communication

Users of current technology often enjoy sharing photos or even talking face-to-face. While not as sophisticated, several ham radio communication modes allow the exchange of still or moving images over the air, and without any data charges. Advances in technology have brought the price of image transmission equipment within range of the average ham’s budget. This has caused a surge of interest in image communication.

Amateur TV (ATV) is full-motion video over the air, sometimes called “fast-scan TV.” An even more advanced form of this is digital amateur radio TV (DATV), which is used to transmit images and voice to Earth via the ham radio stations on the International Space Station (ISS). Amateur radio communication takes on an exciting, new dimension when you can actually *see* the person you’re communicating with. In addition, DATV has proved to be very useful in emergency and disaster communication situations and can transmit a high-definition image. Amateur

Figure 1.17 — European Space Agency Astronaut Tim Peake, KG5BVI/GB1SS, was the first International Space Station crew member to take advantage of the recently commissioned Ham TV digital amateur radio television (DATV) system on the space station while answering questions from students in England during a scheduled contact. [Sian Cleaver photo]

groups in some areas have set up ATV repeaters, allowing lower-power stations to communicate over a fairly wide area. Since this is a wide-bandwidth mode, operation is limited to the UHF bands (70 centimeters and higher).

DATV folds nicely into an amateur radio technological initiative called high-speed multimedia (HSMM), which supports networks such as Broadband-Hamnet and AREDN. The ham bands above 50 MHz can support computer-to-computer communica-

tion at speeds high enough to sustain multimedia applications — voice, data and image. One approach adapts IEEE 802 technologies, particularly 802.11b, operating on specific amateur radio frequencies in the 2400 to 2450 MHz band.

SSTV or “slow-scan TV” is an older, narrow-bandwidth image mode that remains popular in amateur radio. Instead of full-motion video, SSTV enthusiasts exchange photographs and other static images.

Individual SSTV pictures take anywhere from 8 seconds to about 2 minutes to send, depending on the transmission method. These days most SSTV operation is done in color, using computers and soundcards in conjunction with software that’s often free. Images are converted into a series of audio tones representing brightness level and colors. Since SSTV is a narrow-band mode, it is popular on HF on the same frequencies used for voice operation.

## 1.5 Your Ham Radio “Lifestyle”

After getting some on-the-air experience, many amateur radio enthusiasts focus on a particular mode or operating style and may identify themselves primarily as contesters, DXers, CW operators, or VHF-UHFers. Other radio amateurs center their operating on such activities as specialized or experimental modes, operating in the microwave bands, mobile ham radio, very low-power operating (known as “QRP”) and amateur radio direction finding (ARDF).

### 1.5.1 Ham Radio Contesting — Radiosport

Ham radio contesting, often called “radio-sport,” continues to grow in worldwide popularity. Hardly a weekend goes by when there isn’t a ham radio contest of some sort. These on-the-air competitions range from regional operating events with a few hundred participants to national and worldwide competitions with thousands of stations on the air at the same time, attempting to communicate with one another for points — and bragging rights.

Objectives vary from one event to another, but ham radio contests typically involve trying to contact — or “work” — as many other contest participants on the air as possible within a specified period. In each contact, participants exchange certain information, often a signal report and a location, as the contest’s rules dictate. A lot of contest scoring schemes place a premium on two-way contacts with stations in certain geographical locations (countries, states, or zones). Top scorers in the various entry categories usually get certificates, but a few events offer sponsored plaques and trophies. Competition can be fierce among individual contesters and contest clubs.

Contests embrace nearly every available amateur radio mode and

operating preference — voice, Morse code, and digital modes. Some members of the contesting community are earnest competitors who constantly tweak their stations and skills to better their scores. Others take a more casual approach. All have lots of fun.

In the ARRL International DX Contest, for example, participants try to contact as many DX (foreign) stations as possible over the course of a weekend. Experienced hams with sophisticated stations easily contact 1,000 or more stations in more than 100 different countries in a single weekend, but even operators with more modest stations can make lots of contacts too.

Other popular contests include state QSO parties, where the goal is to contact stations in as many of the sponsoring state’s counties. ARRL November Sweepstakes (SS) is a high-energy US-and-Canadian contest that attracts thousands of operators each fall. One weekend is dedicated to CW, another to voice. VHF, UHF, and microwave contests focus on making contacts using our highest-frequency bands. Digital-mode contests have

gained in popularity in recent years, thanks to computer soundcards, radios that offer digital-mode capabilities, and software that is often free. There are contests dedicated to FT# modes, too.

You can find information on contests each month in ARRL’s monthly membership journal *QST*; the contest calendar on the ARRL website also provides up-to-date information on upcoming operating events. ARRL’s bimonthly *National Contest Journal (NCJ)* focuses on topics of particular interest to contesting novices and veterans alike. For timely contest news and information, check out *The ARRL Contest Update* e-newsletter at [www.arrl.org/contest-update-issues](http://www.arrl.org/contest-update-issues), available to ARRL members every other week via email and on the ARRL website.

### ARRL FIELD DAY

An emergency communication training exercise with some elements of a contest, ARRL Field Day (FD) prompts thousands of participants outdoors the field on the fourth full weekend of June. Portable gear in tow,

hams take to the hills, forests, campsites, parking lots and even emergency operations centers or vans to take part. Tracing its origins to the 1930s, Field Day started out as a way to publicly demonstrate ham radio’s ability to operate “in the field” and “off the grid.” Today it’s arguably the most popular operating event on the calendar. The goal is not only to make lots of contacts but to operate successfully under the sorts of conditions that could prevail in the aftermath of a disaster or emergency.

Most stations are set up outdoors and use emergency power sources, such as generators, solar panels, wind turbines, and batteries. Creativity reigns when it comes to power sources! Over the years, Field Day’s contest-like

Figure 1.18 — Sean Kutzko, KX9X, uses a handheld antenna to make contacts through an amateur radio satellite.

Figure 1.19 — Polish radio amateurs Pawel Piotrowski, SP7AH (left), and Mariusz Karcz, SQ7FPD, operate from the SNØHQ Polish Amateur Radio Union headquarters station during the IARU HF World Championship. [Henryk Kotowski, MØJHF, photo]

ture has led to plenty of good-natured competition among clubs and groups. Field Day operations range from simple to elaborate. If a natural disaster were to strike, stations such as these could be set up quickly wherever needed, without having to rely on commercial power.

## 5.2 Chasing DX

People unfamiliar with ham radio often ask, “How far can you talk?” Well, “talking

Figure 1.20 — ARRL Field Day is the largest amateur radio event on the planet, with tens of thousands of hams participating in the 24-hour event each June. These members of the Cheshire County DX Club of Keene, New Hampshire, are enjoying the fun and camaraderie that this popular operating event evokes. [Heather Goodell, photo]

## QSL Cards

Long before the internet and email, hams began the custom of exchanging postcards that became known as QSL cards or simply QSLs. “QSL” is another radiotelegraph, or Morse code, abbreviation that means “I confirm receipt of your transmission.” A QSL card contains information to verify that a two-way contact took place. Exchanging QSL cards can enhance your ham radio enjoyment and even lead to a regular correspondence.

Hams still take great pride in having distinctive QSL cards to exchange following a contact, although today, thanks to the internet, electronic means exist, such as ARRL’s Logbook of The World (see sidebar, “Logbook of The World”) to confirm contacts.

DX stations, especially those in very rare places, are often inundated with QSL cards and requests from US hams. To ease the cost and administrative burden, some DX QSLs travel via QSL bureaus, which ship cards in bulk, then sort and distribute them on the receiving end. The Outgoing QSL Service is available to ARRL members at nominal cost. The incoming QSL bureaus are available to all amateurs. Bureau instructions and addresses are on the ARRL website.

far” is what chasing “DX” is all about. DX stations are those in distant places around the world. Chasing DX is a time-honored ham radio tradition. Hams who focus on contacting stations in far-flung and rare locations are called “DXers.” Ham radio pioneers a century ago often competed in terms of how far they could talk; spanning the Atlantic via ham radio in the early 1920s was a stupendous accomplishment in its day. DXers often have as a goal attaining DX Century Club (DXCC) membership, earning a place on the vaunted DXCC “Honor Roll” or entering the ARRL DX Challenge.

Working DX does not necessarily require top-tier equipment and a huge antenna system. It’s possible to work DX all over the world with very low power, modest antennas — including wires hung from trees or

mounted on a vehicle — or both.

Some hams specialize in certain ham bands to work DX, such as 160 meters, where DXing can be challenging due to the low operating frequency involved, not to mention atmospheric noise and difficult DX propagation in that region of the ham radio spectrum. Others prefer “the high bands,” such as 20, 15, and 10 meters, where DX typically is more common and, in fact, typically abounds in times of favorable propagation.

## DXPEDITIONS

DXers who have run out of new countries to work sometimes couple a love of ham radio and travel to *become* the DX! “DXpeditions” are journeys by hams to “rare” countries having few or no hams, where participants set up a station (or stations), often making thou-

Figure 1.21 — Johannes Hafkenscheid, PA5X, operated from Mauritania as 5T5PA, while working there for several months.

**Figure 1.22** — Dave Spoelstra, N9KT, an instructor at Indiana's Ivy Tech Community College, and Jim Rinehart, K9RU, have been working to recruit interested students into amateur radio. Their efforts paid off last spring with five new student licensees, seen here at the school's ham station: (L – R) Quinton Ritter, KD9MVK; Augustine Busch, KD9MVN; Jahrael Shabzultvorn, KD9MVJ; Karla Jimenez-Vasquez, KD9MVM, and Austin Owens, KD9MVL.

sands of contacts in the space of a few days. These trips can be true adventures, and operators not only have a great time but can promote international goodwill.

Some DXpeditions are huge productions. In October 2019, a 13-member team of radio amateurs traveled to Pitcairn Island in the South Pacific, logging some 80,000 contacts with other hams around the world from their remote encampment. In early 2020, another team of operators journeyed to the sub-Antarctic South Orkney Islands, braving the elements and logging some 60,000 contacts. Members of the worldwide amateur radio community dig deep into their pockets to fund DXpeditions such as these, which can cost hundreds of thousands of dollars.

Most DXpeditions are smaller affairs in which one or two operators may combine a vacation with some on-air fun — sometimes called “holiday style” operating. Activity often peaks in conjunction with major DX contests. If you don't want to pack your radio and antennas along, fully equipped DX stations sometimes are available to rent in more-frequented locations, such as Hawaii and the Caribbean islands.

### DX SPOTS AND NETS

The beginning DXer can get a good jump on DXCC by frequenting the DX spotting sites on the internet. A DX spotting website is essentially an internet clearing house of reports — or “spots” — posted by other DXers of stations actually heard or worked.

The DX Summit website, [www.dxsummit.fi](http://www.dxsummit.fi), hosted in Finland, is a popular one. Users around the world post spots in real time. Each lists the call sign and frequency of the DX station as well as the call sign of the station that posted the spot. Knowing where the DX station is being heard can tell you if you're likely to hear the DX station at *your* location.

A newer wrinkle in identifying the presence of DX stations is something called the Reverse Beacon Network (RBN). An informal, growing volunteer network, the RBN consists of wideband receivers installed at scattered locations across the US and around

the world that can “skim” the call signs of CW and certain digital-mode signals from a band or bands and display them on a website. DX spotting sites or programs also can import these data to offer a clue as to which stations are on the air at the time. Operators also can use the RBN to see where their own signals are being heard and how well, which can be very useful information when conducting antenna and equipment tests.

DX nets offer another DX gateway. On DX nets, a net control station tracks which DX stations have checked into the net, then allows individual operators on frequency to try working one of the DX stations. This permits weaker stations to be heard instead of being covered up by multiple stations calling in a “pileup.”

### 1.5.3 Operating Awards

Earning awards that reflect amateur radio operating accomplishments is a time-honored tradition. Literally hundreds of operating awards are available to suit your level of activity and sense of accomplishment. Here are a few popular ones.

#### WORKED ALL CONTINENTS

The Worked All Continents (WAC) certificate is a good starting point for newcomers. Sponsored by the International Amateur Radio Union (IARU), earning WAC requires working and confirming contacts with one station on each of six continents (excluding Antarctica).

#### WORKED ALL STATES

Hams who can confirm two-way ham radio contacts with stations in each of the 50 United States can apply for the popular ARRL's Worked All States (WAS) award. Those who enjoy operating different bands and a seek a

### Logbook of The World

Instead of exchanging and collecting QSL cards, more and more radio amateurs are taking advantage of the ARRL's Logbook of The World (LoTW) to confirm contacts for award credit. LoTW is a world repository of individual radio contact records submitted by users.

When both participants in a radio contact submit matching QSO records to LoTW, the result is a virtual QSL that each ham can apply toward ARRL award credit. Uploading contact data costs nothing; users only pay to “redeem” their contact credits for an award, such as ARRL's DXCC, VUCC, WAS, as well as the WPX and WAZ Awards sponsored by CQ Communications.

Once signed up as an LoTW user, you can submit new contact records whenever you wish. Your submissions are matched against those of other Logbook users. Whenever a match occurs, you receive instant credit for the contact.

To minimize the chance of fraudulent submissions, all LoTW QSO records are digitally “signed” by the licensee, who must hold an LoTW certificate. Visit the Logbook of The World website, [www.arrrl.org/logbook-of-the-world](http://www.arrrl.org/logbook-of-the-world), to learn more.

greater challenge may attempt the ARRL's 5-Band WAS (5B WAS) award by confirming contacts with all 50 US states on each of the 80, 40, 20, 15 and 10 meter bands.

A twist on the WAS award is the ARRL's Triple Play Award. Introduced in 2009, it was an instant hit. To earn the Triple Play Award, an amateur must contact other amateurs in each of the 50 US states using voice, Morse code, and a digital mode, such as RTTY, PSK31, or an FTx protocol. All qualifying contacts must be confirmed via the ARRL's Logbook of the World (LoTW — see sidebar, "Logbook of The World"). The Triple Play Award is available to hams worldwide.

## DX CENTURY CLUB

The most prestigious and popular DX award is the DX Century Club (DXCC), sponsored by the ARRL. Earning DXCC is quite a challenge. You must confirm two-way contact with stations in 100 countries (or "entities," as they're known in the DXCC program). Hams with very simple stations have earned DXCC. Operating in various DX contests when stations all over the world are looking for contacts is a good way to combine DXing and contesting and to get a leg up on earning DXCC. There's also a 5-Band DXCC (5BDXCC) for earning DXCC on each of five bands, 80, 40, 20, 15 and 10 meters.

Top-rung DX enthusiasts have been challenging themselves and each other through the ARRL DXCC Challenge. This ongoing activity involves confirming contacts with DXCC entities on all bands from 160 through 6 meters.

## VHF/UHF CENTURY CLUB

Hams who operate on the VHF and UHF bands have a "century club" of their own, the VHF/UHF Century Club (VUCC). Instead of working 100 DXCC entities, participants earn awards for making two-way contacts with a specified number of Maidenhead  $2^\circ \times 1^\circ$  grid locators or "grid squares," as they're more commonly known. Grid squares are designated by a combination of two letters and two numbers and represent a specific area on the globe. For operations on 6 meters, 2 meters, and satellite, operators must contact 100 individual grid squares. More information is on the ARRL website, [www.arrrl.org/awards/vucc](http://www.arrrl.org/awards/vucc).

### 1.5.4 Satellite Communication

Amateur radio established its initial foothold in space in 1961, with the launch of the OSCAR 1 satellite (OSCAR is an acronym for Orbiting Satellite Carrying Amateur Radio). Since then, amateurs have launched dozens of satellites, most of the low-Earth orbit (LEO) variety and a small number in

**Figure 1.23** — Island County Amateur Radio Club members Jon Edwards, AE7TE (right), and Wayne Jeffers, WJ7H, use hand-held antennas and radios to successfully contact NA1SS on the International Space Station from the club's ARRL Field Day site on Washington's Whidbey Island. Hams can use the same sort of basic equipment to operate through amateur radio satellites. [Vince Bond, K7NA, photo]

the high-Earth orbit category. Many, if not most, of these are CubeSats — compact, sophisticated multi-purpose spacecraft often built by university students — that can permit radio amateurs on Earth to communicate with each other. The first *geostationary* satellite to sport an amateur radio transponder launched in late 2018. It remains in the same position roughly above the equator to provide communication around the clock that is not dependent on orbital mechanics. The history of amateur radio satellites and information on which ones are in operation is available on the AMSAT website, [www.amsat.org](http://www.amsat.org). Operating awards are available from AMSAT, ARRL, and other organizations specifically for satellite operation.

Satellite operation is neither complex nor difficult; it's possible to work through some satellites with nothing more than a dual-band (VHF/UHF) handheld radio and perhaps a small portable antenna. More serious satellite work requires some specialized equipment. You may be able to work several amateur radio satellites (OSCARs) with the equipment that's now in your shack!

## AMATEUR RADIO IN SPACE

The Amateur Radio on the International Space Station (ARISS) program, [www.ariss.org](http://www.ariss.org), is the international consortium for ham radio in space. It's a cooperative venture of ARRL, the Radio Amateur Satellite Corporation (AMSAT), and NASA in the US, and other international space agencies and amateur radio organizations around the world.

An all-volunteer program, ARISS seeks to inspire students worldwide to pursue careers in science, technology, engineering, and math (STEM) by making available opportunities to speak — interview, actually — via ham radio with on-orbit ISS crew members. ARISS-International includes representatives of nine countries, including the US, several European nations and Japan, Russia and Canada. ARISS-provided ham gear in three ISS modules makes possible analog voice and digital communication — includ-

ing digital amateur radio television (DATV) between earthbound hams and ISS crew members as well as via the onboard ISS digipeater packet radio mailbox and APRS digipeater.

ARISS arranges and schedules contacts with schools, institutions, and events around the globe in advance. Then, a demonstration station is set up at the school or other location, and students can ask an ISS crew member — most hold ham radio licenses — about their time in space and life aboard the space station. These voice contacts typically take place using VHF FM (2 meter) equipment.

A more-recent role involving the ISS is the deployment of amateur radio satellites into orbit from the space station, after they are transported to the station as cargo.

### 1.5.5 QRP: Low-Power Operating

A very active and enthusiastic segment of the amateur radio community enjoys operating with minimal transmitting power. They call themselves "QRP operators" or "QRPers" after the Morse code abbreviation for "I shall decrease transmitter power." According to the FCC amateur radio rules, "An amateur station must use the minimum transmitter power necessary to carry out the desired communications." The FCC allows most hams to transmit or "run" up to 1,500 W (watts), and many hams run 100 W. QRPers, however, typically use 5 W or less — sometimes *far* less (one ham achieved WAS while running 2 milliwatts — that's two-thousandths of a watt!).

Operating QRP can be challenging. Other stations may need to dig deep for your often weak signal, so patience becomes a real virtue, both for the low-power enthusiast and the station on the other end of the contact. What their stations lack in transmitting power QRPers try to make up for with effective antennas and skillful operating, and they make contacts around the world. This operating style has become so popular that many

amateur radio competitions (“radiosport”) now include entry categories for stations running 5 W or less output power.

One of the best reasons to operate QRP is that low-power equipment typically is lightweight and less expensive. Many QRP operators enjoy designing and building their own “flea-power” transceivers, and various organizations support low-power operating by offering kits, circuits, and advice. Several commercial manufacturers also market QRP equipment and kits. The QRP Amateur Radio Club International ([www.qrparci.org](http://www.qrparci.org)) is perhaps the oldest organization to advance and promote QRP as a ham radio way of life. In addition to sponsoring various operating events throughout the year, QRP ARCI publishes *QRP Quarterly*, a journal that includes articles of interest to both QRP operators and the broader ham radio community.

### 1.5.6 Operating Mobile

Many hams enjoy operating on the fly — usually from a car or truck but sometimes from a boat, a motorcycle, a bicycle and even while on foot (sometimes called “pedestrian mobile” or “manpack radio”). Operating radio gear installed in a motor vehicle is the most common form of “mobile,” and manufacturers today offer a wide range of ham radio gear, including antennas, especially for such work. A mobile station can be as simple as a basic VHF or dual-band VHF/UHF radio and a little antenna attached magnetically to the roof, or as complex as an HF station and a more substantial antenna system. Some mobile stations are very sophisticated, with capabilities that rival those of fixed stations.

While most hams who operate mobile use FM or SSB, a significant number enjoy the challenge of using CW while on the road. It takes a bit of practice, in part because the operator must learn to understand (or “copy”) Morse code without having to write it down — and because a vehicle is not always a very steady platform for sending Morse code.

Hams on bicycle treks or hikes carry along lightweight radio gear. A lot of cyclists or hikers pack a small ham radio transceiver and wire antenna along with their sleeping bag, food, and water.

### 1.5.7 VHF, UHF, and Microwave Operating

Hams use many modes and techniques to extend the range of their line-of-sight VHF, UHF, and microwave signals. Those who explore the potential of VHF/UHF communication often are called “weak-signal” operators to differentiate them from FM operators who communicate locally — although the signals involved often are not really *weak*.

These enthusiasts and experimenters probe

Figure 1.24 — Marc Franco, N2UO, uses this 20-foot diameter parabolic dish for Earth-Moon-Earth communication.

the limits of propagation in the upper reaches of the amateur radio spectrum, often with the goal of discovering just how far they can communicate. They use directional antennas (beams or parabolic dishes) and very sensitive receivers. In some instances, they also employ considerable transmitter output power. As a result of their efforts, distance records are broken almost yearly. On 2 meters, for example, conversations between stations hundreds and even thousands of miles apart are not uncommon even though the stations are far beyond “line of sight” separation. Maximum distances decrease as frequencies increase, but communication regularly can span several hundred miles, even at microwave frequencies.

Weak-signal operators for many years depended on SSB and CW, but computer/sound card-based digital modes are now part of their arsenal. These modes use state-of-the-art digital signal processing (DSP) software for transmitting and receiving very weak signals that can be well below levels that the human ear can detect.

### MOONBOUNCE (EME)

EME (Earth-Moon-Earth) communication, commonly called “moonbounce,” fascinates many amateurs. The concept is simple: Use the moon as a passive reflector of VHF and UHF signals. Considering the total path of some 500,000 miles, EME is the ultimate DX — at least to date. The first two-way amateur EME contacts took place in 1952.

In its earliest days EME was a CW mode activity requiring large antennas and high power. Advances in technology, such as low-noise receivers and digital signal processing

(DSP) tools, have made EME contacts possible for more and more amateurs with modest stations.

### METEOR SCATTER

Years ago hams discovered they could bounce signals off the ionized trails of vaporized matter that follow meteors entering Earth’s atmosphere. Such trails often can reflect VHF radio signals for several seconds, during which stations can exchange extremely brief reports. During meteor showers, the ionized region becomes large enough — and lasts long enough — to sustain short contacts. It’s exciting to hear a signal from hundreds of miles away pop out of the noise just for an instant!

Amateurs experimenting with meteor-scatter propagation use transmitter powers of 100 W or more and beam antennas. Most contacts are made using the MSK144 mode that is part of the *WSJT-X* software. Although most SSB and CW QSOs are made during annual meteor showers, digital mode contacts are possible any day of the year. In recent years, meteor-scatter operators have taken advantage of specially designed digital software to decode signals that may last less than 1 second.

### 1.5.8 Vintage Radio

Many, if not most, veteran radio amateurs have a nostalgic streak, and this extends toward vintage radio gear. Present-day commercial amateur radio equipment has reached a level of complexity that often requires specialized test and troubleshooting equipment to repair or align. Modern component manufacturing technology such as surface-mount devices (SMDs) has become so common-

**Figure 1.25** — Restoring and using vintage amateur radio gear is one interest of Dennis Lazar, W4DNN. Hams often call older, tube-type equipment “boat anchors,” because of its weight, compared to today’s far-lighter solid-state gear. [Dennis Lazar, W4DNN, photo]

place that a modular approach to equipment repair is commonplace; rather than troubleshoot and replace a defective component, many manufacturers now prefer to swap out an entire module.

Yet many amateurs still would rather repair and adjust their own equipment and covet the days when this was simpler and easier. This is but one reason behind the surge in vintage radio collecting and operating. Others enjoy vintage gear for its lower cost and wider availability, the novelty of operating older gear on today’s ham bands, and for its rarity and antique value. Many of these radios are affectionately called “boat anchors” by vintage radio aficionados, since early radio gear tends to be relatively large and heavy.

Some enthusiasts enjoy the challenge of collecting and restoring older radios, some-

**Figure 1.26** — Amateur Radio Direction Finding (ARDF) equipment need not be expensive. Yagis made from measuring tapes and PVC pipe are very popular for direction finding on 2 meters with a handheld transceiver. Here, Dan Slater, AG6HF (left), tests an antenna he built. [Joe Moell, KØOV, photo]

times striving to bring the equipment back to its original factory condition. Other vintage radio enthusiasts may have a parallel interest in conventional AM voice transmission. These activities take vintage radio fans back to an era when it was much more common for amateurs to build their own station equipment.

### 1.5.9 Amateur Radio Direction Finding (ARDF)

Amateur radio direction finding (ARDF) is the art of locating a signal or noise source by tracking it with portable receivers and directional antennas. Direction finding is not only fun, it has a practical side as well. Hams who are proficient at DFing have been instrumental in hunting down signals from illegal jammers and malfunctioning transmitters, tracing sources of interference on the ham bands — intentional or inadvertent — or pin-

ning down the location of a suspected “pirate” (unlicensed ham station) in the area. Because DFing only involves receiving, it does not require a ham ticket.

“Fox hunting” — also called “T-hunting,” “radio-orienteeing” or “bunny hunting” — is ham radio’s answer to hide-and-seek. One player is designated the fox; he or she hides a transmitter, and the other players attempt to find it. Rules vary, but the fox must generally place the transmitter within certain boundaries and transmit at specific intervals.

Fox hunts differ from place to place. American fox hunts often employ teams of fox hunters cruising in vehicles over a wide area. European and other fox hunters restrict their events to smaller areas and conduct fox hunts on foot. Competitions held on the national and international levels attract hundreds of participants and follow the European model.

## 1.6 Public Service

Volunteering to provide communication as a public service is a key facet of the Basis and Purpose of the Amateur Radio Service and has been a traditional responsibility of amateur radio from the start. Today, this most often involves ham radio’s volunteer efforts during disasters and emergencies.

When Hurricane Sandy struck New York City and the Middle Atlantic States in the fall of 2012, the amateur radio community from Maine to the Carolinas responded to requests for assistance, activated local nets and supported the operations of the Hurricane Watch Net and the VoIP Hurricane Net. Hams volunteered around the clock to bridge the gap in the wake of downed utility lines to provide communication for evacuation efforts, as well

as to link hospitals experiencing communications breakdowns, shelters, emergency operations centers and non-government relief agencies, such as The American Red Cross and The Salvation Army, which has its own amateur radio contingent, The Salvation Army Team Emergency Radio Network (SATERN). Radio amateurs also assisted after the storm by helping officials to assess damage. Many hams also are part of SKYWARN, which helps to identify and track severe weather activity via ham radio and coordinates its efforts with the National Weather Service.

Public service can take less dramatic forms: Hams also step forward to provide communication for walkathons, marathons,

bike races, parades and other community events. The Boston and New York City marathons are two major events that welcome amateur radio assistance.

### 1.6.1 Public Service Communication

The ability to provide communication during disasters is a major justification for amateur radio’s existence. Government officials on all levels and the general public have come to recognize that amateur radio works when other communications networks are unavailable. Despite the proliferation of cell phones and other personal communication devices, amateur radio continues to prove its value.

Figure 1.27 — Ham radio volunteers from the Sierra Nevada Amateur Radio Society encouraged youngsters to get on the air during a Kids Day event set up at a local sporting goods retail store. [Aline Dodge, N7JWL, photo]

nce it can operate without an existing man-  
made infrastructure. Ham radio doesn't need  
e mobile telephone network or the internet.  
Battery-powered equipment allows hams  
provide essential communication even  
when electrical power has been knocked out.  
n necessary, hams can make and install anten-  
as on the spot from available materials. In

Figure 1.28 — During the annual  
Simulated Emergency Test in 2018,  
Alan Gontang, KD6QPP, an Assistant  
Emergency Coordinator, operates  
a resource net from the Cupertino,  
California, ARES/RACES communications  
vehicle. [Jim Obserhofer, KN6PE, photo]

the wake of hurricanes, forest fires, earth-  
quakes and other natural disasters that cripple  
or compromise normal communications,  
hams may be called upon to handle thousands  
of messages in and out of the stricken region.  
The work that hams do during crisis situations  
cultivates good relations with neighbors and  
with local governments.

Amateur radio operators have a long tradi-  
tion of operating “off the grid” from back-up  
power sources. Through events such as Field  
Day, hams cultivate the ability to set up com-  
munication posts wherever they are needed.  
Moreover, amateur radio can provide com-  
puter networks (with over-the-air links as  
needed) and other services, such as video,  
that no other service can deploy on the fly,  
and even do it on a wide scale.

### 1.6.2 Public Service Communication Organizations

Should a disaster or emergency arise, vol-  
unteer teams of amateurs may be invited by  
emergency managers to work with first  
responders, the Red Cross, and medical per-  
sonnel to provide or supplement communi-  
cation. Hams sometimes are called upon to fill  
the communication gap among agencies with  
radio systems that are incompatible with one  
another.

#### ARES AND RACES

Ham radio disaster response activities  
typically take place under the umbrella of the  
Amateur Radio Emergency Service (ARES®),  
sponsored by ARRL, and the Radio Amateur

Figure 1.29 — Carol Wilson, KCØMOM (left), and her daughter  
Kristi Lundy, KCØINX, had a great time operating in the 2016  
ARRL November Sweepstakes (phone weekend). [Mike  
Wilson, K2KR, photo]

Civil Emergency Service (RACES), admin-  
istered by the Federal Emergency Management  
Agency (FEMA). RACES works with gov-  
ernment agencies to maintain civil prepared-  
ness and provide communication in times of  
civil emergency. RACES is activated at the  
request of a local, state or federal official. To  
maintain their edge and readiness, hams  
affiliated with emergency communication  
teams assess their systems and themselves  
through regularly scheduled nets and simu-  
lated emergency tests (SETS).

ARES and RACES organizations fre-  
quently work hand-in-hand. Amateurs seri-  
ous about disaster response communication  
typically are active in both groups or may  
carry dual ARES/RACES membership. FCC  
rules make it possible for ARES and RACES  
to use many of the same frequencies, so an  
ARES group also enrolled in RACES can  
work within either organization as circum-  
stances dictate.

#### MILITARY AUXILIARY RADIO SYSTEM (MARS)

Begun in 1925, MARS is authorized by  
the US Department of Defense (DOD) and  
administered by the US Army and Air Force.  
The primary mission of MARS is to provide  
contingency HF radio communication sup-  
port to the DOD and the military. MARS  
relies on volunteers from within the amateur  
radio ranks, who receive specialized training  
in military messaging formats and military  
standard digital messaging protocols, with  
an increasing reliance on the latter. MARS  
also supports US combat commands by pro-  
viding humanitarian assistance and disaster

**Figure 1.30 —** The Wilson High School Amateur Radio Emergency Communications team in Long Beach, California, is made up of young women. Here, team members practice passing and copying message traffic. [Devon Day, KF6KEE, photo]

relief. It also offers contingency communication for Defense Support to Civil Authorities (DSCA) when authorized, and provides “morale and welfare communications” in support of the DOD. MARS members serve as the liaison between the DOD and the larger amateur radio community during times of disaster.

MARS volunteers joined amateur radio organizations to assist with medical and humanitarian relief efforts in the wake of the devastating 2010 earthquake in Haiti. In 2016, MARS partnered with the Hurricane Watch Net to provide updated disaster information to the hospital ship *USS Comfort* deploying to Haiti after Hurricane Matthew struck Haiti.

Amateur radio licensees interested in joining either MARS branch must be at least 18 years old (in some cases, amateurs who are 17 may join with the signature of a parent or legal guardian). Volunteers must have access to an amateur radio HF radio. MARS operations take place on DOD-authorized

frequencies outside of the amateur radio bands and consist of regularly scheduled training nets to practice military message formatting using military standard digital protocols.

### 1.6.3 Public Service and Traffic Nets

ARRL came into existence to coordinate and promote the formation of message-handling nets, so public service and traffic nets are part of a tradition that dates back almost to the dawn of amateur radio. In those early days, transmission and reception range was quite limited, and stations cooperated through nets and individual hams to communicate over distances greater than a few miles. From their origination point, messages (also called “traffic”) leapfrogged from amateur station to amateur station to their destination — thus the word “relay” in American Radio Relay League. It still works that way today, although individual stations

typically have a much greater range.

Some nets and stations are only active in emergencies. These include amateur radio station WX4NHC at the National Hurricane Center, the Hurricane Watch Net, SKYWARN (weather observers), The Salvation Army Team Emergency Radio Network (SATERN), The Waterway Net, and the VoIP (Voice over Internet Protocol) SKYWARN/Hurricane Net.

### THE NATIONAL TRAFFIC SYSTEM (NTS)

The National Traffic System™ (NTS™) exists to pass formal written messages from any point in the US to any other point. Messages, which follow a standard format called a “Radiogram,” are relayed from one ham to another, using a variety of modes, including voice, Morse code, RTTY, or packet. An NTS operator who lives near the recipient typically delivers the message by telephone. This may seem odd and archaic in these days of instant communication, but it prepares traffic handlers to move messages when systems may be down in a disaster or emergency. In those times radiograms communicate information critical to saving lives or property or to inquire about the health or welfare of disaster victims. At such times, the NTS works in concert with the Amateur Radio Emergency Service (ARES) and other emergency and disaster-relief organizations, such as the American Red Cross and The Salvation Army.

The NTS oversees many existing traffic nets, which meet daily. Most nets are local or regional. Handling routine message traffic such as birthday and holiday greetings keeps NTS participants prepared for emergencies.

## 1.7 Ham Radio in the Classroom

Amateur radio is a terrific teaching tool! Many individuals began their path toward careers in electronics and wireless communication thanks to their experiences with amateur radio as youngsters and teenagers.

Amateur radio complements any school curriculum and gives students a chance to make direct and immediate connections with their studies. For example, the math and science used in amateur radio apply equally in the classroom. Even geography takes on a new meaning when students are able to contact other countries around the globe and speak with the people who live in them.

Local volunteers are important to establishing an active amateur radio presence in schools. An HF or satellite station or even a

**Figure 1.31 —** At Eisenhower Middle School in Lawton, Oklahoma, Jada, KF5TAT (left) and Kerson, KF5TAQ sit at the Viking Radio Club station in the classroom of teacher Clifton Harper, KE5YZB. The school received a ham radio equipment grant through the ARRL Foundation. Harper also attended an ARRL Education & Technology Program Teacher’s Institute on Wireless Technology at ARRL Headquarters. [Pamely Harper, KF5JXO, photo]

**Figure 1.32** — During his duty tour in space, European Space Agency Astronaut Alexander Gerst, KF5ONO, spoke with students on Earth via ham radio as part of the Amateur Radio on the International Space Station (ARISS) program [NASA photo]

VHF or UHF handheld transceiver tuned to the local repeater can prove an exciting and educational experience for pupils and volunteers alike.

Thanks to the Amateur Radio on the International Space Station (ARISS) program, amateurs all over the nation have made it possible for students to speak directly with astronauts in space via ham radio.

### 1.7.1 ARRL Amateur Radio Education & Technology Program

Through the ARRL Amateur Radio Education & Technology Program (ETP), amateur radio has become a valuable resource for classroom teachers. The goal of the ETP is “to build a foundation of wireless technology literacy to US teachers and students.” Launched in 2000 the program continues to offer resources to schools, including ham radio equipment, at no cost, thanks to the support of donors in the amateur radio community. The ETP emphasizes the integration of technology, math, science, geography,

writing, speaking, and social responsibility within a global society. Applying amateur radio as part of the class curriculum offers students a new dimension to learning. Each summer the ETP sponsors Teachers Institute on Wireless Technology sessions for educators that enable them to make the most effective use of the ETP in their schools.

Amateur radio emphasizes self-challenge, the value of lifelong learning, and the importance of public service. From a more practical standpoint, future employers will be looking for candidates who are familiar not only with computers but with the sorts of wireless communication concepts used in amateur radio.

**Figure 1.33** — Bil Paul, KD6JUI, gets on the air from his kayak, using a multiband antenna of his own design and construction. [Jeff Brook, photo]

The ETP offers a range of resources to encourage educators. These include publications related to the use of technology in wireless communication; workshops, tips, and ideas for teaching wireless technology in schools, community groups, and clubs, and lesson plans and projects to help provide authentic, hands-on radio and electronics experiences for students.

Schools interested in incorporating amateur radio into their curricula, using it as an enrichment program or as a club activity may apply to become Project schools. See [www.arrrl.org/education-technology-program](http://www.arrrl.org/education-technology-program) for more information on the ARRL Education & Technology Program.

## 1.8 Resources

### ARRL—the National Association for Amateur Radio

225 Main St  
Newington, CT 06111-1494

MR #78446

Golden Valley, MN 55422

612-775-2291 or 866-426-3442

### handiham.org

Provides assistance to persons with disabilities who want to earn a ham radio license or set up a station.

## OMIK Amateur Radio Association

[www.omikradio.org](http://www.omikradio.org)

OMIK, an ARRL affiliated club, is the largest predominately African-American amateur radio organization in the US. It promotes fellowship and amateur radio advancement and offers scholarships and other financial assistance for college-bound youth.

# 1.9 Glossary

**AM (amplitude modulation)** — The oldest voice operating mode still found on the amateur bands. The most common HF voice mode, SSB, is actually a narrower-bandwidth variation of AM.

**Amateur radio** — A radiocommunication service for the purpose of self-training, intercommunication and technical investigation carried out by licensed individuals interested in radio technique solely with a personal aim and without pecuniary interest. (*Pecuniary* means payment of any type, whether money or goods.) Also called “ham radio.”

**Amateur radio operator** — A person holding an FCC license to operate a radio station in the Amateur Radio Service.

**Amateur radio station** — A station licensed by the FCC in the Amateur Radio Service, including necessary equipment.

**Amateur (Radio) Service** — A radiocommunication service for the purpose of self-training, intercommunication and technical investigations carried out by licensed individuals interested in radio technique solely with a personal aim and without pecuniary interest.

### AMSAT (Radio Amateur Satellite

**Corporation)** — An international membership organization that designs, builds and promotes the use of amateur radio satellites, sometimes called “OSCARs.”

**APRS**—Automatic Packet/Position Reporting System, a marriage of an application of the Global Positioning System and amateur radio to relay position and tracking information.

### ARES (Amateur Radio Emergency

**Service)** — An ARRL program for radio

## The ARRL Ham Radio License Manual

[www.arrl.org/ham-radio-license-manual](http://www.arrl.org/ham-radio-license-manual)

Complete introduction to ham radio, including the exam question pool, complete explanations of the subjects on the exams. Tips on buying equipment, setting up a station and more.

### The ARRL's Tech Q&A

[www.arrl.org/shop/](http://www.arrl.org/shop/)

Contains all of the questions in the Technician class question pool, with correct answers highlighted and explained in plain English. Includes many helpful diagrams.

amateurs who participate in emergency communication.

**ARISS** — An acronym for Amateur Radio on the International Space Station. NASA, ARRL, AMSAT, and others cooperate in managing the ARISS program on a national and international level.

**ARRL** — The national association for amateur radio in the US; the US member-society in the **IARU** (International Amateur Radio Union).

**ATV (amateur television)** — An amateur radio operating mode for sharing real-time video. ATV may be analog or digital (DATV).

**Band** — A range of frequencies in the radio spectrum, usually designated by approximate wavelength in meters. For example, 7.0 to 7.3 MHz (megahertz) is the 40-meter amateur band. Hams are authorized to transmit on many different bands.

**Bandwidth** — In general, the width of a transmitted signal in terms of occupied spectrum. FCC definition: “The width of a frequency band outside of which the mean power of the transmitted signal is attenuated at least 26 dB below the mean power of the transmitted signal within the band.”

**Beacon** — An amateur station transmitting communication for the purposes of observation of propagation and reception or other related experimental activities.

**Beam antenna** — A ham radio antenna having directional characteristics to enhance the transmitted signal in one direction at the expense of others. A “rotary beam” can be pointed in any direction.

## General Information and Other Study Material

The ARRL website ([www.arrl.org](http://www.arrl.org)) carries a wealth of information for anyone interested in getting started in amateur radio. For complete information on all options available for study material, check out the “Welcome to the World of Ham Radio” page, [www.arrl.org/what-is-ham-radio](http://www.arrl.org/what-is-ham-radio) and its associated links. You can also use the ARRL website to search for clubs, classes and amateur radio exam sessions near you.

**Broadcasting** — Transmissions intended for reception by the general public, either direct or relayed. Amateur radio licensees are not permitted to engage in broadcasting.

**Call sign** — A series of unique letters and numerals that the FCC assigns to an individual who has earned an amateur radio license.

**Contact** — A two-way communication between amateur radio operators.

**Contest** — A competitive amateur radio operating activity in which hams use their stations to contact the most stations within a designated time period.

**Courage Kenny Handiham Program** — Membership organization for ham radio enthusiasts with various physical disabilities and abilities.

**CW** — A synonym for radiotelegraphy (i.e., Morse code by radio). CW is an abbreviation for “continuous wave,” a term used in the early years of wireless.

**Digital communication** — Computer-based communication modes such as RTTY, PSK31, packet and other radio transmissions that employ an accepted digital code to convey intelligence or data.

**Dipole antenna** — Typically, a wire antenna with a feed line connected to its center and having two legs. Dipoles most often are used on the high-frequency (HF) amateur bands.

**DSP (digital signal processing)** — Technology that allows software to replace electronic circuitry.

**DX** — A ham radio abbreviation that refers to distant stations, typically those in other countries.

**CCC** — DX Century Club, a popular ARRL award earned for contacting amateur radio operators in 100 different countries or “entities.”

**Expedition** — A trip, often by a team of operators, to a location — perhaps an uninhabited island or other geographical or political entity — which has few, if any, amateur radio operators, thus making a contact with the DXpedition rare.

**Hammer** — A traditional term for a person who enjoys helping newcomers get started in ham radio; a mentor.

**Emergency communication** — Amateur radio communication during a disaster or emergency that support or supplants traditional means of telecommunication.

**FCC (Federal Communications**

**Commission)** — The government agency that regulates non-government telecommunications, including amateur radio, in the US.

**Field Day** — A popular, annual amateur radio activity sponsored by ARRL, during which hams set up radio stations, often outdoors, using emergency power sources to simulate an emergency situation.

**Field Organization** — A cadre of ARRL volunteers who perform various services for the amateur radio community at the state and local level.

**FM (frequency modulation)** — A method of transmitting voice and the mode commonly used on ham radio repeaters.

**Fox hunt** — A competitive radio direction-finding activity in which participants track down the one or more hidden transmitters.

**Fast-scan television** — A mode of operation that amateur radio operators can use to exchange live TV images from their stations. Also called *ATV (Amateur Television)*.

**Ham band** — A range of frequencies in the radio spectrum on which ham radio communication is authorized.

**Ham radio** — Another name for amateur radio.

**Ham radio operator** — A radio operator holding a license granted by the FCC to operate on amateur radio frequencies.

**HF (high frequency)** — The radio frequencies from 3 to 30 MHz.

**MM (high-speed multimedia)** — A digital radio communication technique using spread spectrum modes primarily on UHF to simultaneously send and receive video, voice, text, and data.

**IARU (International Amateur Radio Union)** — The international organization made up of national amateur radio organizations or societies such as the ARRL.

**Image** — Facsimile and television signals.

**International Morse code** — A digital code in which alphanumeric characters are represented by a defined set of short and long transmission elements — called “dots and dashes” or “dits and dahs” — that many amateur radio operators use to communicate.

**ITU (International Telecommunication Union)** — An agency of the United Nations that allocates the radio spectrum among the various radio services at the international level.

**MARS** — Military Auxiliary Radio System, a volunteer adjunct communication program that supports the mission of the US Department of Defense. Most MARS operators are amateur radio operators.

**Mode** — A type of ham radio communication, such as frequency modulation (FM voice), slow-scan television (SSTV), SSB (single sideband voice), CW (Morse code), or digital (e.g., PSK-31, FT8, or JT65).

**Morse code** — A communication mode characterized by on/off keying of a radio signal to convey intelligence. Hams use the International Morse Code.

**Net** — An on-the-air meeting of hams at a set time, day and radio frequency, usually for a specific purpose.

**Packet radio** — A computer-to-computer radio communication mode in which information is encapsulated in short groups of data called packets. These packets contain addressing and error-detection information.

**Phone** — Emissions carrying speech or other sound information, such as FM, SSB, or AM.

**Public service** — Activities involving amateur radio that hams perform to benefit their communities.

**QRP** — An abbreviation for low transmitter power.

**QSL bureau** — A system for sending and receiving amateur radio verification or “QSL” cards.

**QSL cards** — Cards that provide written confirmation of a communication between two hams.

**QSO** — A contact between amateurs.

**QST** — The monthly journal of the ARRL. QST means “calling all radio amateurs.”

**RACES (Radio Amateur Civil Emergency Service)** — A radio service that uses amateur stations for civil defense communication during periods of local, regional or national civil emergencies.

**RF (radio frequency)** — Electromagnetic radiation in the form of radio waves.

**Radio (or ham) shack** — Slang term that refers to an amateur station, regardless of where it is actually located.

**Radiotelegraphy** — See **Morse code**.

**Receiver** — A device that converts radio signals into a form that can be heard or viewed.

**Repeater** — A typically unattended amateur station, typically located on a mountaintop, hilltop, or tall building, that automatically and simultaneously receives and retransmits the signals of other stations on a different channel or channels for greater range. Repeaters allow radio amateurs using low-power handheld transceivers to transmit over greater distances.

**RTTY (radioteletype)** — Narrow-band direct-printing radioteletype that uses a digital code.

**Space station** — An amateur station located more than 50 km above Earth’s surface.

**SSB (single sideband)** — A common mode of voice of amateur radio voice transmission.

**SSTV (slow-scan television)** — An operating mode used to exchange still pictures.

**SWL (shortwave listener)** — A person who enjoys listening to shortwave radio broadcasts or amateur radio conversations. (A *BCL* is someone who listens for distant AM stations on the Standard Broadcast Band. Some SWLs also are BCLs.)

**TIS (Technical Information Service)** — A service of the ARRL that helps hams solve technical problems ([www.arrl.org/tis](http://www.arrl.org/tis)).

**Transceiver** — A radio transmitter and receiver integrated into a single package. Most hams use transceivers.

**Transmitter** — A device that produces radio-frequency (RF) signals.

**UHF (ultra-high frequency)** — The radio frequencies from 300 to 3000 MHz.

**VE (Volunteer Examiner)** — An amateur radio operator who is qualified to administer amateur radio licensing examinations.

**VHF (very-high frequency)** — The radio frequencies from 30 to 300 MHz.

**WAS (Worked All States)** — An ARRL award that is earned when an amateur radio operator confirms two-way radio contact with other stations in all 50 US states.

**Wavelength** — A means of designating a frequency band, such as the 80-meter band.

**Work** — To contact another ham.

# Electrical Fundamentals

Collecting material on fundamental concepts from previous editions, this chapter summarizes the basic ideas of electricity and electronics. It covers the physical quantities, elementary circuits, basic components, and the laws that govern their behavior. These are the foundations on which all of electronics is constructed. Glossaries are included for each group of topics, as well.

Since many of the basic ideas are expressed or defined in term of mathematics, a tutorial “Radio Mathematics” and the compact summary “Radio Math Formulas and Notes” have been prepared. They are available in the *Handbook’s* downloadable supplemental material (see the information on how to access that content at the front of this book). The tutorial includes sections on some of the mathematical techniques used in radio and electronics and a list of online math resources.

## Chapter 2 — Downloadable Supplemental Content

- “Radio Mathematics” — information about math used in radio and a list of online resources and tutorials about common mathematics
- “Radio Math Formulas and Notes” — a “cheat sheet” for formulas and useful tables and online math resources
- “Hands-On Radio: Laying Down the Laws” by Ward Silver, NØAX
- “Hands-On Radio: Putting the Laws to Work” by Ward Silver, NØAX
- “Hands-On Radio: Kirchoff’s Laws” by Ward Silver, NØAX
- “Hands-On Radio: Thevenin Equivalents” by Ward Silver, NØAX
- “Scientific and Engineering Notation” by Walter Banzhaf, WB1ANE
- “Understanding a Scientific Calculator” by Walter Banzhaf, WB1ANE

## 2.1 Introduction to Electricity

The *atom* is the primary building block of matter and is made up of a *nucleus*, containing *protons* and *neutrons*, surrounded by *electrons*. Protons have a positive electrical charge, electrons a negative charge, and neutrons have no electrical charge. An *element* (or *chemical element*) is a type of atom that has a specific number of protons, the element’s *atomic number*. Each different element, such as iron, oxygen, silicon, or bromine has a distinct chemical and physical identity determined primarily by the number of protons. A *molecule* is two or more atoms bonded together and acting as a single particle.

Unless modified by chemical, mechanical, or electrical processes, all atoms are electrically neutral because they have the same number of electrons as protons. If an atom loses electrons, it has more protons than electrons and thus has a net positive charge. If an atom gains electrons, it has more electrons than protons and a net negative charge. Atoms or molecules with a positive or negative charge are called *ions*. Electrons not bound to any atom, or *free electrons*, can also be considered as ions because they have a negative charge.

### 2.1.1 Electric Charge, Voltage and Current

Any piece of matter that has a net positive or negative electrical charge is said to be *electrically charged*. An electrical force exists between electrically charged particles, pushing charges of the same type apart (like charges repel each other) and pulling opposite charges together (opposite charges attract). Moving charges in a magnetic field also generates an electrical force. This is the *electromotive force* (or EMF), the source of energy that causes charged particles to move. *Voltage* is the general term for the strength of the electromotive force or the difference in electrical potential between two points. Voltage and EMF are often used interchangeably in radio. A good diagram showing the relationship of EMF and voltage is available at [hyperphysics.phy-astr.gsu.edu/hbase/electric/elevol.html#c2](http://hyperphysics.phy-astr.gsu.edu/hbase/electric/elevol.html#c2).

Under most conditions, the number of positive and negative charges in any volume of space is very close to balanced and so the region has no net charge. When there are extra positive ions in one region and extra negative ions (or electrons) in another region, the resulting EMF attracts the charges toward each other. The direction of the force, from the positive region to the negative region, is called its *polarity*. Because an imbalance of charge between two regions generates an EMF, its voltage is always measured between two points, with positive voltage defined as being in the direction from the positively-charged to the negatively-charged region.

If there is no path by which electric charge can move in response to an EMF (called a *conducting path*), the charges cannot move together and so remain separated. If a conducting path is available, then the electrons or ions will flow along the path, neutralizing the net imbalance of charge. The movement of electrical charge is called *electric current*. Materials through which current flows easily are called *conductors*. Most metals, such as copper or aluminum are good conductors. Materials in which it is difficult for current to flow are *insulators*. *Semiconductors*, such as silicon or germanium, are materials with much poorer conductivity than metals. Semiconductors can be chemically altered to acquire properties that make them useful in solid-state devices such as diodes, transistors and integrated circuits.

Voltage differences can be created in a variety of ways. For example, chemical ions can be physically separated to form a battery. The resulting charge imbalance creates a voltage difference at the battery terminals so that if a conductor is connected to both terminals at once, electrons flow between the terminals and gradually eliminate the charge imbalance, discharg-

ing the battery's stored energy. Mechanical means such as friction (static electricity, lightning) and moving conductors in a magnetic field (generators) can also produce voltages. Devices or systems that produce voltage are called *voltage sources*.

### 2.1.2 Electronic and Conventional Current

Electrons move in the direction of positive voltage — this is called *electronic current*. *Conventional current* takes the other point of view — of positive charges moving in the direction of negative voltage. Conventional current was the original model for electricity and results from an arbitrary decision made by Benjamin Franklin in the 18th century when the nature of electricity and atoms was still unknown. It can be imagined as electrons flowing “backward” and is completely equivalent to electronic current.

Conventional current is used in nearly all electronic literature and is the standard used in this book. The direction of conventional current direction establishes the polarity for most electronics calculations and circuit diagrams. The arrows in the drawing symbols for transistors point in the direction of conventional current, for example.

### 2.1.3 Units of Measurement

Measurement of electrical quantities is made in several standard units. Charge is measured in *coulombs* (C) and represented by  $q$  in equations. One coulomb is equal to  $6.25 \times 10^{18}$  electrons (or protons). Current, the flow of charge, is measured in *amperes* (A)

### Schematic Diagrams

The drawing in Figure 2.1 is a *schematic diagram*. Schematics are used to show the electrical connections in a circuit without requiring a drawing of the actual components or wires, called a *pictorial diagram*. Pictorials are fine for very simple circuits like these, but quickly become too detailed and complex for everyday circuits. Schematics use lines and dots to represent the conducting paths and connections between them. Individual electrical devices and electronic components are represented by *schematic symbols* such as the resistors shown here. A set of the most common schematic symbols is provided in the **Component Data and References** chapter. You will find additional information on reading and drawing schematic diagrams in the ARRL website Technology section at [www.arrl.org/circuit-construction](http://www.arrl.org/circuit-construction).

## When Is E a V and V an E?

Beginners in electronics are often confused about the interchange of V and E to refer to voltage in a circuit. When should each be used? Unfortunately, there is no universal convention but  $E$  or  $e$  is usually used when referring to an electric field or the electromotive force in a circuit.  $E$  is also commonly used in the equation for Ohm's Law:  $I = E/R$ .  $V$  or  $v$  is used when describing the difference in voltage between two points in a circuit or the terminal voltage of a power supply or battery. Capital V is always used when referring to units of volts.

## The Origin of Unit Names

Many units of measure carry names that honor scientists who made important discoveries in or advanced the state of scientific knowledge of electrical and radio phenomena. For example, Georg Ohm (1787-1854) discovered the relationship between current, voltage and resistance that now bears his name as Ohm's Law and as the unit of resistance, the ohm. The following table lists the most common electrical units, what they are used to measure, and the scientists for whom they are named. You can find more information on these and other notable scientists in encyclopedia entries on the units that bear their names.

### Electrical Units and Their Namesakes

Unit	Measures	Physical Quantities	Named for
Ampere (A)	Current	Coulombs per second	Andree Ampere 1775 -1836
Coulomb (C)	Charge		Charles Coulomb 1736-1806
Farad (F)	Capacitance	Coulombs per volt	Michael Faraday 1791-1867
Henry (H)	Inductance	Volts per amp per second	Joseph Henry 1797-1878
Hertz (Hz)	Frequency	Cycles per second	Heinrich Hertz 1857-1894
Ohm ( $\Omega$ )	Resistance	Volts per amp	Georg Simon Ohm 1787-1854
Watt (W)	Power	Joules per second	James Watt 1736-1819
Volt (V)	Voltage	Joules per coulomb	Alessandro Volta 1745-1827

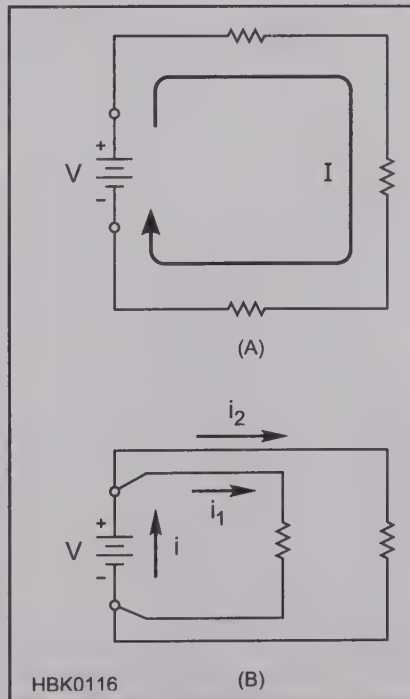

Figure 2.1 — A series circuit (A) has the same current through all components. Parallel circuits (B) apply the same voltage to all components.

and represented by  $i$  or  $I$  in equations. One ampere represents one coulomb of charge flowing past a point (or through a specific area) in one second so  $1 \text{ A} = 1 \text{ C/s}$ . Electromotive force (EMF) is measured in *volts* (V) and represented by  $e$ ,  $E$ ,  $v$ , or  $V$  in equations. One volt is defined as the EMF required for one ampere of current to do one joule (J, a measure of energy) of work and  $1 \text{ V} = 1 \text{ J/C}$ .

### 2.1.4 Series and Parallel Circuits

A *circuit* is any conducting path through which current can flow between two points that have different voltages. An *open circuit* is a circuit in which a desired conducting path is interrupted, such as by a broken wire or a switch. A *short circuit* is a circuit in which a conducting path allows current to flow directly between the two points at different voltages.

The two fundamental types of circuits are shown in Figure 2.1. Part A shows a *series circuit* in which there is only one current path. The current in this circuit flows from the voltage source's positive terminal (the symbol for a battery is shown with its voltage polarity as + and -) in the direction shown by the arrow through three *resistors* (electronic components discussed later in this chapter) and back

to the battery's negative terminal. Current is the same at every point in a series circuit.

Part B shows a *parallel circuit* in which there are multiple paths for the current to take. One terminal of both resistors is connected to the battery's positive terminal. The other terminal of both resistors is connected to the battery's negative terminal. Current flowing out of the battery's positive terminal divides into smaller currents that flow through the individual resistors and then recombine at the battery's negative terminal. All of the components in a parallel circuit experience the same voltage. All circuits are made up of series and parallel combinations of components and sources of voltage and current.

## 2.1.5 Direct and Alternating Current

A circuit is a complete conductive path for current to flow from a source, through a load and back to the source. If the source permits the current to flow in only one direction, the current is *dc* or *direct current*. If the source permits the current to change direction, the current is *ac* or *alternating current*. **Figure 2.2** illustrates the two types of circuits. Circuit A shows the source as a battery, a typical dc source. Circuit B shows a voltage source symbol to indicate ac such as from a generator or household power outlet. In an ac circuit, both the current and the voltage reverse direction. For nearly all ac signals in electronics and radio, the reversal is *periodic*, meaning that the change in direction occurs on a regular basis. The rate of reversal may range from a few times per second to many billion times per second.

Graphs of current or voltage, such as Figure 2.2, begin with a horizontal axis that represents time. The vertical axis represents the amplitude of the current or the voltage, whichever is graphed. Distance above the zero line indicates larger positive amplitude; distance below the zero line means larger negative amplitude. Positive and negative only designate the opposing directions in which current may flow in an alternating current circuit or the opposing *polarities* of an ac voltage.

If the current and voltage never change direction, then we have a dc circuit, even if the level of dc constantly changes. **Figure 2.3A** shows a current that is always positive with respect to 0. It varies periodically in amplitude, however. Whatever the shape of the variations, the current can be called *pulsating dc*. If the current periodically reaches 0, it can be called *intermittent dc*.

We can also look at intermittent and pulsating dc as a combination of an ac and a dc current (Figures 2.3B and 2.3C). Special circuits can separate the two currents into ac and dc *components* for separate analysis or use. There are circuits that combine ac and dc currents and voltages, as well.

## 2.1.6 Glossary — Basic Electricity

**Alternating current (ac)** — A flow of charged particles through a conductor, first in one direction, then in the other direction.

**Ampere** — A measure of flow of charged

particles per unit of time. One ampere (A) represents one coulomb of charge flowing past a point in one second.

**Atom** — The smallest particle of matter that makes up a distinct chemical element. Atoms consist of protons and neutrons in the central region called the nucleus, with electrons surrounding the nucleus.

**Circuit** — Conducting path between two points of different voltage. In a *series circuit*, there is only one current path. In a *parallel circuit*, there are multiple current paths.

**Conductor** — Material in which electrons or ions can move easily.

**Conventional current** — Current defined as the flow of positive charges in the direction of positive to negative voltage. Conventional current flows in the opposite direction of electronic current, the flow of negative charges (electrons) from negative to positive voltage.

**Coulomb** — A unit of measure of a quantity of electrically charged particles. One coulomb (C) is equal to  $6.25 \times 10^{18}$  electrons.

**Current (I)** — The movement of electrical charge, measured in amperes and represented by *i* or *I* in equations.

**Direct current (dc)** — A flow of charged particles through a conductor in one direction only.

**Electronic current** — see **Conventional Current**

**Electromotive force (EMF)** — The source of energy that creates a force between charged particles or regions. Define the force of attraction or repulsion between electrically-charged regions. Also see *voltage*.

**Energy** — Capability of doing work. It is usually measured in electrical terms as the number of watts of power consumed during a specific period of time, such as watt-seconds or kilowatt-hours.

**Insulator** — Material in which it is difficult for electrons or ions to move.

**Ion** — Atom or molecule with a positive or negative electrical charge.

**Joule** — Measure of a quantity of energy. One joule is defined as one newton (a measure of force) acting over a distance of one meter.

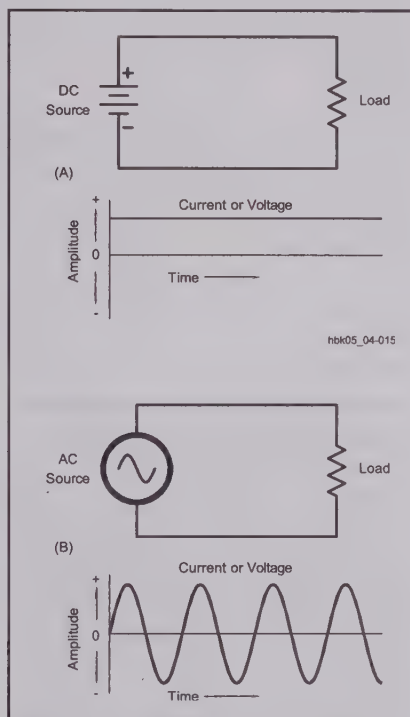

**Polarity** — The direction of EMF or voltage, from positive to negative.

**Potential** — See **voltage**

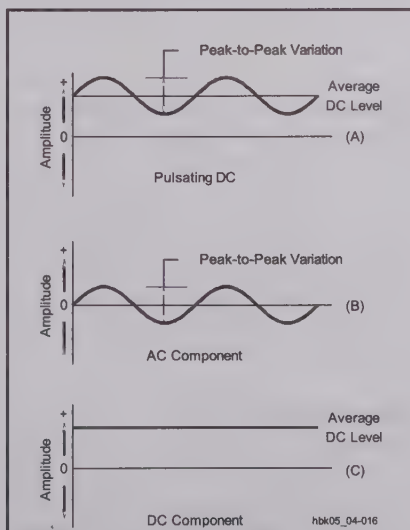

**Power** — Power is the rate at which work is done. One watt of power is equal to one volt of EMF causing a current of one ampere through a resistor.

**Voltage** — The general term for the difference in electrical potential energy between two points. Measured in volts or joules/coulomb.

**Voltage source** — Device or system that creates a voltage difference at its terminals.

**Figure 2.2** — Basic circuits for direct and alternating currents. With each circuit is a graph of the current, constant for the dc circuit, but periodically changing direction in the ac circuit.

**Figure 2.3** — A pulsating dc current (A) and its resolution into an ac component (B) and a dc component (C).

# 2.2 Resistance and Conductance

## 2.2.1 Resistance and Resistors

Any conductor connected to points at different voltages will allow current to pass between the points. No conductor is perfect or lossless, however, at least not at normal temperatures. The moving electrons collide with the atoms making up the conductor and lose some of their energy by causing the atoms to vibrate, which is observed externally as heat. The property of energy loss due to interactions between moving charges and the atoms of the conductor is called *resistance*. The amount of resistance to current is measured in *ohms* ( $\Omega$ ) and is represented by *r* or *R* in equations.

Suppose we have two conductors of the same size and shape, but of different materials. Because all materials have different internal structures, the amount of energy lost by current flowing through the material is also different. The material's ability to impede current flow is its *resistivity*. Numerically, the resistivity of a material is given by the resistance, in ohms, of a cube of the material measuring one centimeter on each edge. The symbol for resistivity is the Greek letter rho,  $\rho$ .

The longer a conductor's physical path, the higher the resistance of that conductor. For direct current and low-frequency alternating currents (up to a few thousand hertz) the conductor's resistance is inversely proportional to the cross-sectional area of the conductor. Given two conductors of the same material and having the same length, but differing in cross-sectional area, the one with the larger area (for example, a thicker wire or sheet) will have the lower resistance.

One of the best conductors is copper, and it is frequently convenient to compare the resistance of a material under consideration with that of a copper conductor of the same size and shape. **Table 2.1** gives the ratio of the resistivity of various conductors to the resistivity of copper.

A package of material exhibiting a certain amount of resistance and made into a single unit or component is called a *resistor*. There are many types of resistors described in the **Circuits and Components** chapter, each suited to different applications and power levels. Next to the transistors built into microprocessors by the billion, resistors are the most common electronic component of all.

## 2.2.2 Conductance

The reciprocal of resistance ( $1/R$ ) is *conductance*. It is usually represented by the symbol *G*. A circuit having high conductance has low resistance, and vice versa. In radio work, the term is used chiefly in connection

**Table 2.1**

**Relative Resistivity of Metals**

Material	Resistivity Compared to Copper
Aluminum (pure)	1.60
Brass	3.7-4.90
Cadmium	4.40
Chromium	8.10
Copper (hard-drawn)	1.03
Copper (annealed)	1.00
Gold	1.40
Iron (pure)	5.68
Lead	12.80
Nickel	5.10
Phosphor bronze	2.8-5.40
Silver	0.94
Steel	7.6-12.70
Tin	6.70
Zinc	3.40

## Ohm's Law Timesaver

This simple diagram presents the mathematical equations relating voltage, current, and resistance. Cover the unknown quantity (E, I, or R) and the remaining symbols are shown as in the equation. For example, covering I shows E over R, as they would be written in the equation  $I = E/R$ .

When the current is small enough to be expressed in milliamperes, calculations are simplified if the resistance is expressed in kilohms rather than in ohms. With voltage in volts, if resistance in kilohms is substituted directly in Ohm's Law, the current will be milliamperes. Expressed as an equation:  $V = mA \times k\Omega$ .

with electron-tube and field-effect transistor characteristics. The units of conductance are siemens (S). A resistance of  $1 \Omega$  has a conductance of 1 S, a resistance of  $1000 \Omega$  has a conductance of 0.001 S, and so on. A unit frequently used in regard to vacuum tubes and the field-effect transistor is the  $\mu S$  or one millionth of a siemens. It is the conductance of a 1-M $\Omega$  resistance. Siemens have replaced the obsolete unit *mho* (abbreviated as an upside-down  $\Omega$  symbol).

## 2.2.3 Ohm's Law

The amount of current that will flow through a conductor when a given voltage is applied will vary with the resistance of the conductor. The lower the resistance, the greater the current for a given EMF. One ohm ( $\Omega$ ) is defined as the amount of resistance that allows one ampere of current to flow between

two points that have a potential difference of one volt. This proportional relationship is known as *Ohm's Law*:

$$R = E / I$$

where

R = resistance in ohms,

E = voltage or EMF in volts and

I = current in amperes.

Rearranging the equation gives the other common forms of Ohm's Law as:

$$E = I \times R$$

and

$$I = E / R$$

All three forms of the equation are used often in electronics and radio. You must remember that the quantities are in volts, ohms and amperes; other units cannot be used in the equations without first being converted. For example, if the current is in milliamperes you must first change it to the equivalent fraction of an ampere before substituting the value into the equations.

The following examples illustrate the use of Ohm's Law in the simple circuit of **Figure 2.4**. If 150 V is applied to a circuit and the current is measured as 2.5 A, what is the resistance of the circuit? In this case R is the unknown, so we will use:

$$R = \frac{E}{I} = \frac{150 \text{ V}}{2.5 \text{ A}} = 60 \Omega$$

No conversion of units was necessary because the voltage and current were given in volts and amperes.

If the current through a 20,000- $\Omega$  resistance is 150 mA, what is the voltage? To find voltage, use  $E = I \times R$ . Convert the current from milliamperes to amperes by dividing by 1000 mA / A (or multiplying by  $10^{-3}$  A / mA) so that 150 mA becomes 0.150 A. (Notice the conversion factor of 1000 does not limit the number of significant figures in the calculated answer.)

**Figure 2.4** — A simple circuit consisting of a battery and a resistor.

$$I = \frac{150 \text{ mA}}{1000 \frac{\text{mA}}{\text{A}}} = 0.150 \text{ A}$$

Then:

$$E = 0.150 \text{ A} \times 20000 \Omega = 3000 \text{ V}$$

In a final example, how much current will flow if 250 V is applied to a 5000-Ω resistor? Since I is unknown,

$$I = \frac{E}{R} = \frac{250 \text{ V}}{5000 \Omega} = 0.05 \text{ A}$$

This value of current is more conveniently stated in mA, and  $0.05 \text{ A} \times 1000 \text{ mA} / \text{A} = 50 \text{ mA}$ .

It is important to note that Ohm's Law applies in any portion of a circuit as well as to the circuit as a whole. No matter how many resistors are connected together or how they are connected together, the relationship between the resistor's value, the voltage across the resistor, and the current through the resistor still follows Ohm's Law.

### 2.2.4 Glossary — Conductance and Resistance

**Conductance (G)** — The reciprocal of

resistance, measured in siemens (S).

**Ohm** — Unit of resistance. One ohm is defined as the resistance that will allow one ampere of current when one volt of EMF is impressed across the resistance.

**Ohm's Law** — The expression that describes resistance (R) as the proportional relationship between voltage (E) and current (I);

$R = E / I$ . Named for Georg Ohm who first described the relationship.

**Resistance (R)** — Opposition to current by conversion into other forms of energy, such as heat, measured in ohms (Ω).

## 2.3 Basic Circuit Principles

Circuits are composed of *nodes* and *branches*. A node is any point in the circuit at which current can divide between conducting paths. For example, in the parallel circuit of Figure 2.5A, the node is represented by the schematic dot. A branch is any unique conducting path between nodes. A series of branches that make a complete current path, such as the series circuit of Figure 2.1A, is called a *loop*.

Very few actual circuits are as simple as those shown in Figure 2.1. However, all circuits, no matter how complex, are constructed of combinations of these series and parallel circuits. We will now use these simple circuits of resistors and batteries to illustrate two fundamental rules for voltage and current, known as *Kirchoff's Laws*.

### 2.3.1 Kirchoff's Current Law

Kirchoff's Current Law (KCL) states, "The sum of all currents flowing into a node and all currents flowing out of a node is equal to zero." KCL is stated mathematically as:

$$(I_{in1} + I_{in2} + \dots) - (I_{out1} + I_{out2} + \dots) = 0$$

The dots indicate that as many currents as necessary may be added.

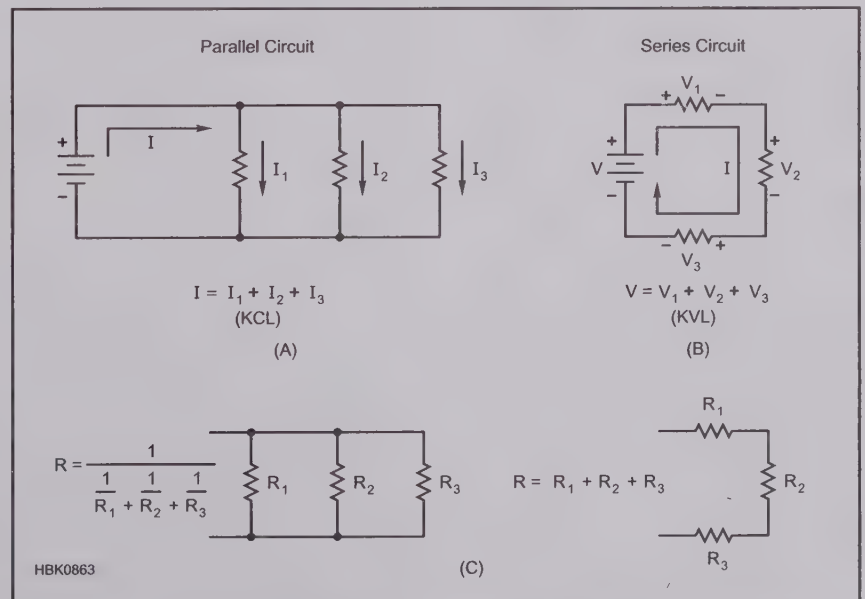

An equivalent way of stating KCL is that the sum of all currents flowing into a node must balance the sum of all currents flowing out of a node:

$$(I_{in1} + I_{in2} + \dots) = (I_{out1} + I_{out2} + \dots)$$

KCL is illustrated by the following example. Suppose three resistors ( $R_1 = 5.0 \text{ k}\Omega$ ,  $R_2 = 20.0 \text{ k}\Omega$ , and  $R_3 = 8.0 \text{ k}\Omega$ ) are connected in parallel as shown in Figure 2.5A. The same voltage, 250 V, is applied to all three resistors. The current through  $R_1$  is  $I_1$ ,  $I_2$  is

the current through  $R_2$ , and  $I_3$  is the current through  $R_3$ .

The current in each can be found from Ohm's Law, as shown below. For convenience, we can use resistance in  $\text{k}\Omega$ , which gives current in milliamperes.

**Figure 2.5** — An example of resistors in parallel (A) and series (B). In series circuits, the current is the same in all components, and voltages are summed. In parallel circuits, voltage across all components is the same and the sum of currents into and out of circuit junctions must be equal. Part C shows how to calculate equivalent values for series and parallel combinations.

$$I_1 = \frac{E}{R_1} = \frac{250 \text{ V}}{5.0 \text{ k}\Omega} = 50.0 \text{ mA}$$

$$I_2 = \frac{E}{R_2} = \frac{250 \text{ V}}{20.0 \text{ k}\Omega} = 12.5 \text{ mA}$$

$$I_3 = \frac{E}{R_3} = \frac{250 \text{ V}}{8.0 \text{ k}\Omega} = 31.2 \text{ mA}$$

Notice that the branch currents are inversely proportional to the resistances. The 20-k $\Omega$  resistor has a value four times larger than the 5-k $\Omega$  resistor, and has a current one-quarter as large. If a resistor has a value twice as large as another, it will have half as much current through it when they are connected in parallel.

Using the balancing form of KCL the current that must be supplied by the battery is:

$$I_{\text{Batt}} = I_1 + I_2 + I_3$$

$$I_{\text{Batt}} = 50.0 \text{ mA} + 12.5 \text{ mA} + 31.2 \text{ mA}$$

$$I_{\text{Batt}} = 93.7 \text{ mA}$$

### 2.3.2 Resistors in Parallel

In a circuit made up of resistances in parallel, the resistors can be represented as a single *equivalent* resistance that has the same value as the parallel combination of resistors. In a parallel circuit, the equivalent resistance is less than that of the lowest resistance value present. This is because the total current is always greater than the current in any individual resistor. The formula for finding the equivalent resistance of resistances in parallel is:

$$R_{\text{EQUIV}} = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \frac{1}{R_4} + \dots}$$

where the dots indicate that any number of parallel resistors can be combined by the same method. The equation is often referred to as the “reciprocal of reciprocals.” Figure 2.5C shows the general rule on a schematic.

In the example of the previous section, the equivalent resistance is:

$$R = \frac{1}{\frac{1}{5 \text{ k}\Omega} + \frac{1}{20 \text{ k}\Omega} + \frac{1}{8 \text{ k}\Omega}} = 2.67 \text{ k}\Omega$$

The notation “//” (two slashes) is frequently used to indicate “in parallel with.” Using that notation, the preceding example would be given as “5.0 k $\Omega$  // 20 k $\Omega$  // 8.0 k $\Omega$ .”

If all the resistors in parallel have the same value, divide the resistor value by the number of resistors,  $N$ , to get the parallel resistance. For example, for five 50- $\Omega$  resistors in parallel, the equivalent resistance is  $R = 50 / N = 50 / 5 = 10 \Omega$ .

For only two resistances in parallel (a very common case) the formula can be reduced to the much simpler (and easier to remember):

$$R_{\text{EQUIV}} = \frac{R_1 \times R_2}{R_1 + R_2}$$

Example: If a 500- $\Omega$  resistor is connected in parallel with a 1200- $\Omega$  resistor, what is the total resistance?

$$R = \frac{R_1 \times R_2}{R_1 + R_2} = \frac{500 \Omega \times 1200 \Omega}{500 \Omega + 1200 \Omega}$$

$$R = \frac{600000 \Omega^2}{1700 \Omega} = 353 \Omega$$

Any number of parallel resistors can be combined two at a time by using this equation until all have been combined into a single equivalent. This is a bit easier than using the general “reciprocal of reciprocals” equation to do the conversion in a single step.

### 2.3.3 Kirchhoff’s Voltage Law

Kirchhoff’s Voltage Law (KVL) states, “The sum of the voltages around a closed current loop is zero.” Where KCL is somewhat intuitive, KVL is not as easy to visualize. In the circuit of Figure 2.5B, KVL requires that the battery’s voltage must be balanced exactly by the voltages that appear across the three resistors in the circuit. If it were not, the “extra” voltage would create an infinite current with no limiting resistance, just as KCL prevents charge from “building up” at a circuit node. KVL is stated mathematically as:

$$E_1 + E_2 + E_3 + \dots = 0$$

where each  $E$  represents a voltage encountered by current as it flows around the circuit loop.

This is best illustrated with an example. Although the current is the same in all three of the resistances in the previous example, the total voltage divides between them, just as current divides between resistors connected in parallel. The voltage appearing across each resistor (the *voltage drop*) can be found from Ohm’s Law. (Voltage across a resistance is often referred to as a “drop” or “I-R drop” because the value of the voltage “drops” by the amount  $E = I \times R$ .)

For the purpose of KVL, it is common to assume that if current flows *into* the more positive terminal of a component the voltage is treated as positive in the KVL equation. If

the current flows *out* of a positive terminal, the voltage is treated as negative in the KVL. Positive voltages represent components that consume or “sink” power, such as resistors. Negative voltages represent components that produce or “source” power, such as batteries. This allows the KVL equation to be written in a balancing form, as well:

$$(E_{\text{source}1} + E_{\text{source}2} + \dots) = (E_{\text{sin}k1} + E_{\text{sin}k2} + \dots)$$

All of the voltages are treated as positive in this form, with the power sources (current flowing *out* of the more positive terminal) on one side and the power sinks (current flowing *into* the more positive terminal) on the other side.

Note that it doesn’t matter what a component terminal’s *absolute* voltage is with respect to ground, only which terminal of the component is more positive than the other. If one side of a resistor is at +1000 V and the other at +998 V, current flowing into the first terminal and out of the second experiences a +2 V voltage drop. Similarly, current supplied by a 9 V battery with its positive terminal at –100 V and its negative terminal at –108.5 V still counts for KVL as an 8.5 V power source. Also note that current can flow *into* a battery’s positive terminal, such as during recharging, making the battery a power sink, just like a resistor.

Here’s an example showing how KVL works: In Figure 2.5B, if the voltage across  $R_1$  is  $E_1$ , that across  $R_2$  is  $E_2$  and that across  $R_3$  is  $E_3$ , then:

$$-250 + I \times R_1 + I \times R_2 + I \times R_3 = 0$$

This equation can be simplified to:

$$-250 + I (R_1 + R_2 + R_3) =$$

$$-250 + I (33000 \Omega) = 0$$

Solving for  $I$  gives  $I = 250 / 33000 = 0.00758 \text{ A} = 7.58 \text{ mA}$ . This allows us to calculate the value of the voltage across each resistor:

$$E_1 = I \times R_1 = 0.00758 \text{ A} \times 5000 \Omega = 37.9 \text{ V}$$

$$E_2 = I \times R_2 = 0.00758 \text{ A} \times 20000 \Omega = 152 \text{ V}$$

$$E_3 = I \times R_3 = 0.00758 \text{ A} \times 8000 \Omega = 60.6 \text{ V}$$

Verifying that the sum of  $E_1$ ,  $E_2$ , and  $E_3$  does indeed equal the battery voltage of 250 V ignoring rounding errors:

$$E_{\text{TOTAL}} = E_1 + E_2 + E_3$$

$$E_{\text{TOTAL}} = 37.9 \text{ V} + 152 \text{ V} + 60.6 \text{ V}$$

$$E_{\text{TOTAL}} = 250 \text{ V}$$

### 2.3.4 Resistors in Series

The previous example illustrated that in a circuit with a number of resistances connected in series, the equivalent resistance of the circuit is the sum of the individual resistances. If these are numbered R1, R2, R3 and so on, then:

$$R_{EQUIV} = R1 + R2 + R3 + R4 \dots$$

Figure 2.5C shows the general rule on a schematic.

Example: Suppose that three resistors are connected to a source of voltage as shown in Figure 2.5B. The voltage is 250 V, R1 is 5.0 kΩ, R2 is 20.0 kΩ and R3 is 8.0 kΩ. The total resistance is then

$$R_{EQUIV} = R1 + R2 + R3$$

$$R_{EQUIV} = 5.0 \text{ k}\Omega + 20.0 \text{ k}\Omega + 8.0 \text{ k}\Omega$$

$$R_{EQUIV} = 33.0 \text{ k}\Omega$$

The current in the circuit is then

$$I = \frac{V}{R} = \frac{250 \text{ V}}{33.0 \text{ k}\Omega} = 7.58 \text{ mA}$$

### 2.3.5 Conductances in Series and Parallel

Since conductance is the reciprocal of resistance,  $G = 1/R$ , the formulas for combining resistors in series and in parallel can be converted to use conductance by substituting  $1/G$  for  $R$ . Conductances in series are thus combined similarly to resistors in parallel:

$$G = \frac{1}{\frac{1}{G1} + \frac{1}{G2} + \frac{1}{G3} + \frac{1}{G4} \dots}$$

and two conductances in series may be combined in a manner similar to two parallel resistors:

$$G_{EQUIV} = \frac{G1 \times G2}{G1 + G2}$$

Conductances in parallel are combined similarly to resistances in series:

$$G_{TOTAL} = G1 + G2 + G3 + G4 \dots$$

This also shows that when faced with a large number of parallel resistances, converting them to conductances may make the math a little easier to deal with.

### 2.3.6 Equivalent Circuits

A circuit may have resistances both in parallel and in series, as shown in Figure 2.6A. In

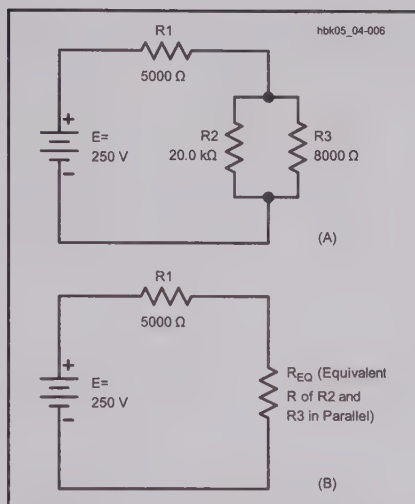

Figure 2.6 — At A, an example of resistors in series-parallel. The equivalent circuit is shown at B.

order to analyze the behavior of such a circuit, *equivalent circuits* are created and combined by using the equations for combining resistors in series and resistors in parallel. Each separate combination of resistors, series or parallel, can be reduced to a single equivalent resistor. The resulting combinations can be reduced still further until only a single resistor remains.

The simplest process begins with combining any two of the resistors into a single equivalent resistance using the formulas for series or parallel resistances. Then combine the resulting equivalent resistance with any single remaining resistor into a new equivalent resistance. Repeat the process of combining the equivalent resistance with a single resistor until all resistances have been combined into a single equivalent resistance. For example, to find the equivalent resistance for the circuit in Figure 2.5A: Combine R2 and R3 to create the equivalent single resistor,  $R_{EQ}$  whose value is equal to R2 and R3 in parallel.

$$R_{EQ} = \frac{R2 \times R3}{R2 + R3} = \frac{20000 \Omega \times 8000 \Omega}{20000 \Omega + 8000 \Omega}$$

$$= \frac{1.60 \times 10^8 \Omega^2}{28000 \Omega} = 5710 \Omega = 5.71 \text{ k}\Omega$$

This resistance in series with R1 then forms a simple series circuit, as shown in Figure 2.5B. These two resistances can then be combined into a single equivalent resistance,  $R_{TOTAL}$ , for the entire circuit:

$$R_{TOTAL} = R1 + R_{EQ} = 5.0 \text{ k}\Omega + 5.71 \text{ k}\Omega$$

$$R_{TOTAL} = 10.71 \text{ k}\Omega$$

Figure 2.7— Voltage sources for dc (A) and ac (B) and current sources (C) are examples of ideal energy sources.

The battery current is then:

$$I = \frac{E}{R} = \frac{250 \text{ V}}{10.71 \text{ k}\Omega} = 23.3 \text{ mA}$$

The voltage drops across R1 and  $R_{EQ}$  are:

$$E1 = I \times R1 = 23.3 \text{ mA} \times 5.0 \text{ k}\Omega = 117 \text{ V}$$

$$E2 = I \times R_{EQ} = 23.3 \text{ mA} \times 5.71 \text{ k}\Omega = 133 \text{ V}$$

These two voltage drops total 250 V, as described by Kirchhoff's Voltage Law.  $E2$  appears across both R2 and R3 so,

$$I2 = \frac{E2}{R2} = \frac{133 \text{ V}}{20.0 \text{ k}\Omega} = 6.65 \text{ mA}$$

$$I3 = \frac{E3}{R3} = \frac{133 \text{ V}}{8.0 \text{ k}\Omega} = 16.6 \text{ mA}$$

where

$I2$  = current through R2 and

$I3$  = current through R3.

The sum of  $I2$  and  $I3$  is equal to 23.3 mA, conforming to Kirchhoff's Current Law.

### 2.3.7 Voltage and Current Sources

In designing circuits and describing the behavior of electronic components, it is often useful to use *ideal sources*. The two most common types of ideal sources are the *voltage source* and the *current source*, symbols for which are shown in Figure 2.7. These sources are considered ideal because no matter what circuit is connected to their terminals, they continue to supply the specified amount of voltage or current. Practical voltage and current sources can approximate the behavior of an ideal source over certain ranges, but are limited in the amount of power they can supply and so under excessive load, their output will drop.

Voltage sources are defined as having zero *internal impedance*, where impedance is a more general form of resistance as described in the sections of this chapter dealing with alternating current. A short circuit across an ideal voltage source would result in the source

providing an infinite amount of current. Practical voltage sources have non-zero internal impedance and this also limits the amount of power they can supply. For example, placing a short circuit across the terminals of a practical voltage source such as a 1.5 V dry-cell battery may produce a current of several amperes, but the battery's internal impedance acts to limit the amount of current produced in accordance with Ohm's Law — as if the resistor in Figure 2.2 were inside of or internal to the battery.

Current sources are defined to have infinite internal impedance. This means that no matter what is connected to the terminals of an ideal current source, it will supply the same amount of current. An open circuit across the terminal of an ideal current source will result in the source generating an infinite voltage at its terminals. Practical current sources will raise their voltage until the internal power supply limits are reached and then reduce output current.

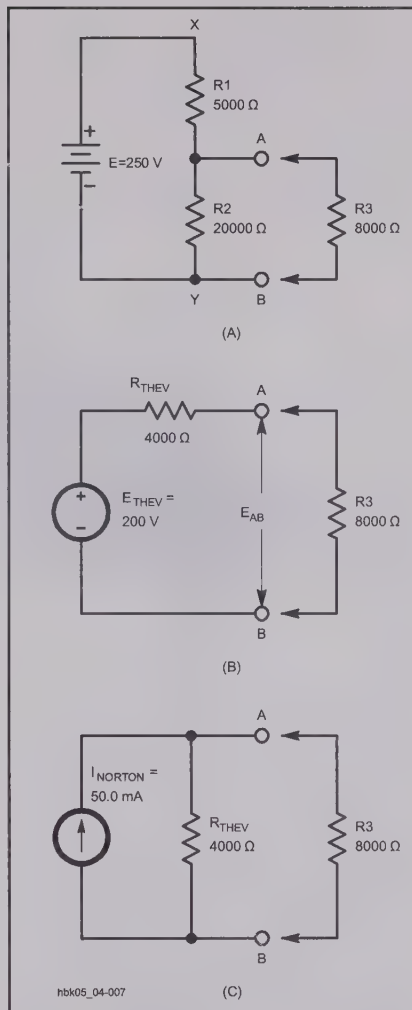

### 2.3.8 Thevenin's Theorem and Thevenin Equivalents

Thevenin's Voltage Theorem (usually just referred to as "Thevenin's Theorem") is a useful tool for simplifying electrical circuits or *networks* (the formal name for circuits) by allowing circuit designers to replace a circuit with a simpler equivalent circuit. Thevenin's Theorem states, "Any two-terminal network made up of resistors and voltage or current sources can be replaced by an equivalent network made up of a single voltage source and a series resistor."

Thevenin's Theorem can be readily applied to the circuit of Figure 2.6A, to find the current through R3. In this example, illustrated in **Figure 2.8**, the circuit is redrawn to show R1 and R2 forming a voltage divider, with R3 as the load (Figure 2.8A). The current drawn by the load (R3) is simply the voltage across R3, divided by its resistance. Unfortunately, the value of R2 affects the voltage across R3, just as the presence of R3 affects the voltage appearing across R2. Some means of separating the two is needed; hence the *Thevenin-equivalent circuit* is constructed, replacing everything connected to terminals A and B with a single voltage source (the *Thevenin-equivalent voltage*,  $E_{THEV}$ ) and series resistor (the *Thevenin-equivalent resistance*,  $R_{TH}$ ).

The first step of creating the Thevenin-equivalent of the circuit is to determine its *open-circuit voltage*, measured when there is no load current drawn from either terminal A or B. Without a load connected between A and B, the total current through the circuit is (from Ohm's Law):

$$I = \frac{E}{R1 + R2}$$

**Figure 2.8 — Equivalent circuits for the circuit shown in Figure 2.6. A shows the circuit to be replaced by an equivalent circuit from the perspective of the resistor (R3 load). B shows the Thevenin-equivalent circuit, with a resistor and a voltage source in series. C shows the Norton-equivalent circuit, with a resistor**

and the voltage between terminals A and B ( $E_{AB}$ ) is:

$$E_{AB} = I \times R2$$

By substituting the equation for current for I, we have an expression for  $E_{AB}$  in which all values are known:

$$E_{AB} = \frac{R2}{R1 + R2} \times E$$

Using the values in our example, this becomes:

$$E_{AB} = \frac{20.0\text{ k}\Omega}{25.0\text{ k}\Omega} \times 250\text{ V} = 200\text{ V}$$

when nothing is connected to terminals A or B.  $E_{THEV}$  is equal to  $E_{AB}$  with no current drawn.

The equivalent resistance between terminals A and B is  $R_{THEV}$ .  $R_{THEV}$  is calculated as the equivalent circuit at terminals A and B with all sources, voltage or current, replaced by their internal impedances. The ideal voltage source, by definition, has zero internal resistance and is replaced by a short circuit. The ideal current source has infinite internal impedance and is replaced by an open circuit.

Assuming the battery to be a close approximation of an ideal source, replace it with a short circuit between points X and Y in the circuit of Figure 2.8A. R1 and R2 are then effectively placed in parallel, as viewed from terminals A and B.  $R_{THEV}$  is then:

$$R_{THEV} = \frac{R1 \times R2}{R1 + R2}$$

$$R_{THEV} = \frac{5000\Omega \times 20000\Omega}{5000\Omega + 20000\Omega}$$

$$R_{THEV} = \frac{1.0 \times 10^8 \Omega^2}{25000\Omega} = 4000\Omega$$

This gives the Thevenin-equivalent circuit as shown in Figure 2.8B. The circuits of Figures 2.8A and 2.8B are completely equivalent from the perspective of R3, so the circuit becomes a simple series circuit.

Once R3 is connected to terminals A and B, there will be current through  $R_{THEV}$ , causing a voltage drop across  $R_{THEV}$  and reducing  $E_{AB}$ . The current through R3 is equal to

$$I3 = \frac{E_{THEV}}{R_{TOTAL}} = \frac{E_{THEV}}{R_{THEV} + R3}$$

Substituting the values from our example:

$$I3 = \frac{200\text{ V}}{4000\Omega + 8000\Omega} = 16.7\text{ mA}$$

This agrees with the value calculated earlier.

The Thevenin-equivalent circuit of an ideal voltage source in series with a resistance is a good model for a real voltage source with non-zero internal resistance. Using this more realistic model, the maximum current that a real voltage source can deliver is seen to be

$$I_{sc} = \frac{E_{THEV}}{R_{THEV}}$$

and the maximum output voltage is  $V_{oc} = E_{THEV}$ .

Sinusoidal voltage or current sources can be modeled in much the same way, keeping in mind that the internal impedance,  $Z_{THEV}$ , for such a source may not be purely resistive, but may have a reactive component that varies with frequency.

### 2.3.9 Norton's Theorem and Norton Equivalents

Norton's Theorem is another method of

creating an equivalent circuit. Norton's Theorem states, "Any two-terminal network made up of resistors and current or voltage sources can be replaced by an equivalent network made up of a single current source and a parallel resistor." Norton's Theorem is to current sources what Thevenin's Theorem is to voltage sources. In fact, the Thevenin-resistance calculated previously is also the Norton-equivalent resistance.

The circuit just analyzed by means of Thevenin's Theorem can be analyzed just as easily by Norton's Theorem. The equivalent Norton circuit is shown in Figure 2.8C. The short circuit current of the equivalent circuit's current source,  $I_{\text{NORTON}}$ , is the current through terminals A and B with the load (R3) replaced by a short circuit. In the case

of the voltage divider shown in Figure 2.8A, the short circuit completely bypasses R2 and the current is:

$$I_{AB} = \frac{E}{R1}$$

Substituting the values from our example, we have:

$$I_{AB} = \frac{E}{R1} = \frac{250 \text{ V}}{5000 \Omega} = 50.0 \text{ mA}$$

The resulting Norton-equivalent circuit consists of a 50.0-mA current source placed in parallel with a 4000- $\Omega$  resistor. When R3 is connected to terminals A and B, one-third of the supply current flows through R3 and the remainder through  $R_{\text{THEV}}$ . This gives a current through R3 of 16.7 mA, again

agreeing with previous conclusions.

A Norton-equivalent circuit can be transformed into a Thevenin-equivalent circuit and vice versa. The equivalent resistor,  $R_{\text{THEV}}$ , is the same in both cases; it is placed in series with the voltage source in the case of a Thevenin-equivalent circuit and in parallel with the current source in the case of a Norton-equivalent circuit. The voltage for the Thevenin-equivalent source is equal to the open-circuit voltage appearing across the resistor in the Norton-equivalent circuit. The current for a Norton-equivalent source is equal to the short circuit current provided by the Thevenin source. A Norton-equivalent circuit is a good model for a real current source that has a less-than infinite internal impedance.

## 2.4 Power and Energy

Regardless of how voltage is generated, energy must be supplied if current is drawn from the voltage source. The energy supplied may be in the form of chemical energy or mechanical energy. This energy is measured in joules (J). One joule is defined from classical physics as the amount of energy or work done when a force of one newton (a measure of force) is applied to an object that is moved one meter in the direction of the force.

Power is another important concept and measures the rate at which energy is generated or used. One watt (W) of power is defined as the generation (or use) of one joule of energy (or work) per second.

One watt is also defined as one volt of EMF causing one ampere of current to flow through a resistance. Thus,

$$P = I \times E$$

where

P = power in watts

I = current in amperes

E = EMF in volts.

(This discussion pertains only to direct current in resistive circuits. See the **Radio Fundamentals** chapter for a discussion about power in ac circuits, including reactive circuits.)

Common fractional and multiple units for power are the milliwatt (mW, one thousandth

of a watt) and the kilowatt (kW, 1000 W).

Example: The plate voltage on a transmitting vacuum tube is 2000 V and the plate current is 350 mA. (The current must be changed to amperes before substitution in the formula, and so is 0.350 A.) Then:

$$P = I \times E = 2000 \text{ V} \times 0.350 \text{ A} = 700 \text{ W}$$

Power may be expressed in *horsepower* (hp) instead of watts, using the following conversion factor:

$$1 \text{ horsepower} = 746 \text{ W}$$

This conversion factor is especially useful if you are working with a system that converts electrical energy into mechanical energy, and vice versa, since mechanical power is often expressed in horsepower in the U.S. In metric countries, mechanical power is usually expressed in watts. All countries use the metric power unit of watts in electrical systems, however. The value 746 W/hp assumes lossless conversion between mechanical and electrical power; practical efficiency is taken up shortly.

### 2.4.1 Energy

When you buy electricity from a power company, you pay for electrical energy, not power. What you pay for is the work that the

electrical energy does for you, not the rate at which that work is done. Like energy, work is equal to power multiplied by time. The common unit for measuring electrical energy is the *watt-hour* (Wh), which means that a power of one watt has been used for one hour. That is:

$$\text{Wh} = P \times t$$

where

Wh = energy in watt-hours

P = power in watts

t = time in hours.

Actually, the watt-hour is a fairly small energy unit, so the power company bills you for *kilowatt-hours* (kWh) of energy used. Another energy unit that is sometimes useful is the *watt-second* (Ws), which is equivalent to joules.

It is important to realize, both for calculation purposes and for efficient use of power resources, a small amount of power used for a long time can eventually result in a power bill that is just as large as if a large amount of power had been used for a very short time.

A common use of energy units in radio is in specifying the energy content of a battery. Battery energy is rated in *ampere-hours* (Ah) or *milliampere-hours* (mAh). While the multiplication of amperes and hours does not result in units of energy, the calculation assumes the result is multiplied by a specified

(and constant) battery voltage. For example, a rechargeable NiMH battery rated to store 2000 mAh of energy is assumed to supply that energy at a terminal voltage of 1.5 V. Thus, after converting 2000 mA to 2 A, the actual energy stored is:

$$\text{Energy} = 1.5 \text{ V} \times 2 \text{ A} \times 1 \text{ hour} = 3 \text{ Wh}$$

Another common energy unit associated with batteries is *energy density*, with units of Ah per unit of volume or weight.

One practical application of energy units is to estimate how long a radio (such as a hand-held unit) will operate from a certain battery. For example, suppose a fully charged battery stores 900 mAh of energy and that the radio draws 30 mA on receive. A simple calculation indicates that the radio will be able receive 900 mAh / 30 mA = 30 hours with this battery, assuming 100% efficiency. You shouldn't expect to get the full 900 mAh out of the battery because the battery's voltage will drop as it is discharged, usually causing the equipment it powers to shut down before the last fraction of charge is used. Any time spent transmitting will also reduce the time the battery will last. The **Power Sources** chapter includes additional information about batteries and their charge/discharge cycles.

### 2.4.2 Generalized Definition of Resistance

Electrical energy is not always turned into heat. The energy used in running a motor, for example, is converted to mechanical motion. The energy supplied to a radio transmitter is largely converted into radio waves. Energy applied to a loudspeaker is changed into sound waves. In each case, the energy is converted to other forms and can be completely accounted for. None of the energy just disappears! These are examples of the Law of Conservation of Energy. When a device converts energy from one form to another, we often say it *dissipates* the energy, or power. (Power is energy divided by time.) Of course the device doesn't really "use up" the energy, or make it disappear, it just converts it to another form. Proper operation of electrical devices often requires that the power be supplied at a specific ratio of voltage to current. These features are characteristics of resistance, so it can be said that any device that "dissipates power" has a definite value of resistance.

This concept of resistance as something that absorbs power at a definite voltage-to-current ratio is very useful; it permits substituting a simple resistance for the load or power-consuming part of the device receiving power, often with considerable simplification of calculations. Of course, every electrical

device has some resistance of its own in the more narrow sense, so a part of the energy supplied to it is converted to heat in that resistance even though the major part of the energy may be converted to another form.

### 2.4.3 Efficiency

In devices such as motors and transmitters, the objective is to convert the supplied energy (or power) into some form other than heat. In such cases, power converted to heat is considered to be a loss because it is not useful power. The efficiency of a device is the useful power output (in its converted form) divided by the power input to the device. In a transmitter, for example, the objective is to convert power from a dc source into ac power at some radio frequency. The ratio of the RF power output to the dc input is the *efficiency* (*Eff* or  $\eta$ ) of the transmitter. That is:

$$\text{Eff} = \frac{P_O}{P_I}$$

where

- Eff = efficiency (as a value or fraction between 0 and 1)
- $P_O$  = power output (W)
- $P_I$  = power input (W).

Example: If the dc input to the transmitter

is 100 W, and the RF power output is 60 W, the efficiency is:

$$\text{Eff} = \frac{P_O}{P_I} = \frac{60 \text{ W}}{100 \text{ W}} = 0.6$$

Efficiency is usually expressed as a percentage — that is, it expresses what percentage of the input power will be available as useful output. To calculate percent efficiency, multiply the value from equation 20 by 100%. The efficiency in the example above is 60%.

Suppose a mobile transmitter has an RF power output of 100 W with 52% efficiency at 13.8 V. The vehicle's alternator system charges the battery at a rate of 5.0 A at that voltage. Assuming an alternator efficiency of 68%, how much horsepower must the engine produce to operate the transmitter and charge the battery? Solution: To charge the battery the alternator must produce 13.8 V  $\times$  5.0 A = 69 W. The transmitter dc input power is 100 W / 0.52 = 190 W. Therefore, the total electrical power required from the alternator is 190 + 69 = 259 W. The engine load then

$$P_I = \frac{P_O}{\text{Eff}} = \frac{259 \text{ W}}{0.68} = 381 \text{ W}$$

We can convert this to horsepower using the conversion factor given earlier to convert between horsepower and watts:

$$\frac{381 \text{ W}}{746 \text{ W / hp}} = 0.51 \text{ horsepower (hp)}$$

## Ohm's Law and Power Circle

During the first semester of my *Electrical Power Technology* program, one of the first challenges issued by our dedicated instructor — Roger Cerie — to his new freshman students was to identify and develop 12 equations or formulas that could be used to determine voltage, current, resistance and power. Ohm's Law is expressed as  $R = E / I$  and it provided three of these equation forms while the basic equation relating power to current and voltage ( $P = I \times E$ ) accounted for another three. With six known equations, it was just a matter of applying mathematical substitution for his students to develop the remaining six. Together, these 12 equations compose the *circle* or *wheel* of voltage (E), current (I), resistance (R) and power (P) shown in **Figure 2.A1**. Just as Roger's previous students had learned at the Worcester Industrial Technical Institute (Worcester, Massachusetts), our Class of '82 now held the basic electrical formulas needed to proceed in our studies or professions. As can be seen in **Figure 2.A1**, we can determine any one of these four electrical quantities by knowing the value of any two others. You may want to keep this page bookmarked for your reference. You'll probably be using many of these formulas as the years go by — this has certainly been my experience. — Dana G. Reed, W1LC

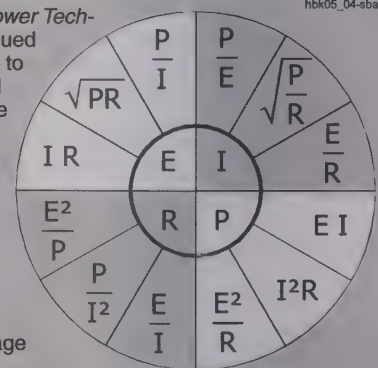

Figure 2.A1 — Electrical formulas

## 4.4 Ohm's Law and Power Formulas

Electrical power in a resistance is turned to heat. The greater the power, the more rapidly the heat is generated. By substituting the Ohm's Law equivalent for E and I, the following formulas are obtained for power:

$$P = E^2 / R$$

and

$$P = I^2 \times R$$

These formulas are useful in power calculations

when the resistance and either the current or voltage (but not both) are known.

Example: How much power will be dissipated by (converted to heat in) a 4000-Ω resistor if the potential applied to it is 200 V?

$$P = \frac{E^2}{R} = \frac{40000 \text{ V}^2}{4000 \text{ } \Omega} = 10.0 \text{ W}$$

As another example, suppose a current of 20 mA flows through a 300-Ω resistor. Then:

$$P = I^2 \times R = 0.020^2 \text{ A}^2 \times 300 \text{ } \Omega$$

$$P = 0.00040 \text{ A}^2 \times 300 \text{ } \Omega$$

$$P = 0.12 \text{ W}$$

Note that the current was changed from milliamperes to amperes before substitution in the formula.

Resistors for radio work are made in many sizes, the smallest being rated to safely operate at power levels of about 1/16 W. The largest resistors commonly used in amateur equipment are rated at about 100 W. Large resistors, such as those used in dummy-load antennas, are often cooled with oil to increase their power-handling capability.

## 2.5 Circuit Control Components

### 2.5.1 Switches

Switches are used to allow or interrupt a current flowing in a particular circuit. Most switches are mechanical devices, although the same effect may be achieved with solid-state devices.

Switches come in many different forms and a wide variety of ratings. The most important ratings are the *voltage-handling* and *current-handling* capabilities. The voltage rating usually includes both the *breakdown voltage rating* and the *interrupt voltage rating*. The breakdown rating is the maximum voltage that the switch can withstand when it is open before the voltage will arc between the switch's terminals. The interrupt voltage rating is the maximum amount of voltage that the switch can interrupt without arcing. Normally, the interrupt voltage rating is the lower value, and therefore the one given for (and printed on) the switch.

Switches typically found in the home are usually rated for 125 V ac and 15 to 20 A. Switches in cars are usually rated for 12 V dc and several amperes. The breakdown voltage rating of a switch primarily depends on the insulating material surrounding the contacts and the separation between the contacts. Plastic or phenolic material normally provides both structural support and insulation. Ceramic material may be used to provide better insulation, particularly in rotary (wafer) switches.

A switch's current rating includes both the *current-carrying capacity* and the *interrupt capability*. The current-carrying capacity of the switch depends on the contact material and size, and on the pressure exerted to keep the contacts closed. It is primarily determined from the allowable contact temperature rise. In larger ac switches and most dc switches, the interrupt capability is usually lower than

the current carrying value.

Most power switches are rated for alternating current use. Because ac current goes through zero twice in each cycle, switches can successfully interrupt much higher alternating currents than direct currents without arcing. A switch that has a 10-A ac current rating may arc and damage the contacts if used to turn off more than an ampere or two of dc.

Switches are normally designated by the number of *poles* (circuits controlled) and *throws* or *positions* (circuit path choices). The simplest switch is the on-off switch, which is a single-pole, single-throw (SPST) switch as shown in **Figure 2.9A**. The off position does not direct the current to another circuit. The

next step would be to change the current path to another path. This would be a single-pole, double-throw (SPDT) switch as shown in **Figure 2.9B**. Adding an off position would give a single-pole, double-throw, center-off (ON-OFF-ON) switch as shown in **Figure 2.9C**.

Several such switches can be "ganged" together or actuated by the same mechanical activator to provide double-pole, triple-pole or even more, separate control paths all activated at once. Switches can be activated in a variety of ways. The most common methods include lever or toggle, push-button and rotary switches. Samples of these are shown in **Figure 2.9D**. Most switches stay in position once set, but some are spring-loaded so they only stay in

**Figure 2.9** — Schematic diagrams of various types of switches. A is an SPST, B is an SPDT, and C is an SPDT switch with a center-off position. The photo (D) shows examples of various styles of switches. The 1/4-inch-ruled graph paper background provides for size comparison.

the desired position while held there. These are called *momentary switches*.

Rotary/wafer switches can provide very complex switching patterns. Several poles (separate circuits) can be included on each wafer. Many wafers may be stacked on the same shaft. Not only may many different circuits be controlled at once, but by wiring different poles/positions on different wafers together, a high degree of circuit switching logic can be developed. Such switches can select different paths as they are turned and can also “short” together successive contacts to connect numbers of components or paths.

Rotary switches can also be designed to either break one contact before making another (*break-before-make*), or to short two contacts together before disconnecting the first one (*make-before-break*) to eliminate arcing or perform certain logic functions. The two types of switches are generally not interchangeable and may cause damage if inappropriately substituted for one another during circuit construction or repair. When buying rotary switches from a surplus or flea-market vendor, check to be sure the type of switch is correct.

*Microswitches* are designed to be actuated by the operation of machine components, opening or closing of a door, or some other mechanical movement. Instead of a handle or button-type actuator that would be used by a human, microswitches have levers or buttons more suitable for being actuated as part of an enclosure or machine.

In choosing a switch for a particular task, consideration should be given to function, voltage and current ratings, ease of use, availability and cost. If a switch is to be operated frequently, a better-quality switch is usually less costly over the long run. If signal noise or contact corrosion is a potential problem (usually in low-current signal applications), it is best to get gold-plated contacts. Gold does not oxidize or corrode, thus providing surer contact, which can be particularly important at very low signal levels. Gold plating will not hold up under high-current-interrupt applications, however.

## 2.5.2 Fuses and Circuit Breakers

Fuses self-destruct to protect circuit wiring or equipment. The fuse *element* that melts or *blows* is a carefully shaped piece of soft metal, usually mounted in a cartridge of some kind. The element is designed to safely carry a given amount of current and to melt at a current value that is a certain percentage above the rated value.

The most important fuse rating is the *nominal current rating* that it will safely carry for an indefinite period without blowing. A fuse’s melting current depends on the type

of material, the shape of the element and the heat dissipation capability of the cartridge and holder, among other factors.

Next most important are the timing characteristics, or how quickly the fuse element blows under a given current overload. Some fuses (*slow-blow*) are designed to carry an overload for a short period of time. They typically are used in motor-starting and power-supply circuits that have a large inrush current when first started. Other fuses are designed to blow very quickly to protect delicate instruments and solid-state circuits.

A fuse also has a voltage rating, both a value in volts and whether it is expected to be used in ac or dc circuits. The voltage rating is the amount of voltage an open fuse can withstand without arcing. While you should never substitute a fuse with a higher current rating than the one it replaces, you may use a fuse with a higher voltage rating.

Figure 2.10A shows typical cartridge-style cylindrical fuses likely to be encountered in ac-powered radio and test equipment. Automotive style fuses, shown in the lower half of Figure 2.10A, have become widely used in low-voltage dc power wiring of amateur stations. These are called “blade” fuses. Rated for vehicle-level voltages, automotive blade fuses should never be used in ac line-powered circuits.

(A)

(B)

Figure 2.10 — These photos show examples of various styles of fuses. Cartridge-type fuses (A, top) can use glass or ceramic construction. The center fuse is a slow-blow type. Automotive blade-type fuses (A, bottom) are common for low-voltage dc use. A typical home circuit breaker for ac wiring is shown at B.

Circuit breakers perform the same function as fuses — they open a circuit and interrupt current flow when an overload occurs. Instead of a melting element, circuit breakers use spring-loaded magnetic mechanisms to open a switch when excessive current is present. Once the overload has been corrected, the circuit-breaker can be reset. Circuit breakers are generally used by amateurs in home ac wiring (a typical ac circuit breaker is shown in Figure 2.10B) and in dc power supplies.

A replacement fuse or circuit breaker should have the same current rating and the same characteristics as the fuse it replaces. Never substitute a fuse with a larger current rating. You may cause permanent damage (maybe even a fire) to wiring or circuit elements by allowing larger currents to flow when there is an internal problem in equipment. (Additional discussion of fuses and circuit breakers is provided in the chapter on **Safety**.)

Fuses blow and circuit breakers open for several reasons. The most obvious reason is that a problem develops in the circuit, causing too much current to flow. In this case, the circuit problem needs to be fixed. A fuse can fail from being cycled on and off near its current rating. The repeated thermal stress causes metal fatigue and eventually the fuse blows. A fuse can also blow because of a momentary power surge, or even by rapidly turning equipment with a large inrush current on and off several times. In these cases it is only necessary to replace the fuse with the same type and value.

Panel-mount fuse holders should be wired with the hot lead of an ac power circuit (the black wire of an ac power cord) connected to the end terminal, and the ring terminal is connected to the power switch or circuit inside the chassis. This removes voltage from the fuse as it is removed from the fuse holder. This also locates the line connection at the far end of the fuse holder where it is not easily accessible.

## 2.5.3 Relays and Solenoids

Relays are switches controlled by an electrical signal. *Electromechanical relays* consist of an electromagnetic *coil* and a moving *armature* attracted by the coil’s magnetic field when energized by current flowing in the coil. Movement of the armature pushes the switch contacts together or apart. Many sets of contacts can be connected to the same armature, allowing many circuits to be controlled by a single signal. In this manner, the signal voltage that energizes the coil can control circuits carrying large voltages and/or currents.

Relays have two positions or *states* — *energized* and *de-energized*. Sets of contacts called *normally-closed* (NC) are closed when the relay is de-energized and open when it is energized. *Normally-open* (NO) contact sets

(A)

(B)

(C)

**Figure 2.11** — These photos show examples of various styles and sizes of relays. Photo A shows a large reed relay, and a small reed relay in a package the size of an integrated circuit. The contacts and coil can clearly be seen in the open-frame relay. Photo B shows a reed relay inside a plastic case. The background grid for Photos A and B is  $\frac{1}{4}$  inch to provide a size comparison. Photo C shows three surplus SPDT coaxial relays with type N connectors used for RF switching at VHF and higher frequencies.

are closed when the relay is energized.

Like switches, relay contacts have breakdown voltage, interrupting, and current-carrying ratings. These are not the same as the voltage and current requirements for energizing the relay's coil. Relay contacts (and housings) may be designed for ac, dc or RF signals. The most common control voltages for relays used in amateur equipment are 12 V dc or 120 V ac. Relays with 6, 24, and 28 V dc, and 24 V ac coils are also common. **Figure 2.11** shows some typical relays found in amateur equipment.

A relay's *pull-in voltage* is the minimum voltage at which the coil is guaranteed to cause the armature to move and change the relay's state. *Hold-in voltage* is the minimum voltage at which the relay is guaranteed to hold the armature in the energized position after the relay is activated. A relay's pull-in voltage is higher than its hold-in voltage due to magnetic hysteresis of the coil (see the section

on magnetic materials later in this chapter). *Current-sensing relays* activate when the current through the coil exceeds a specific value, regardless of the voltage applied to the coil. They are used when the control signal is a current rather than a voltage.

*Latching relays* have two coils; each moves the armature to a different position where it remains until the other coil is energized. These relays are often used in portable and low-power equipment so that the contact configuration can be maintained without the need to supply power to the relay continuously.

*Reed relays* have no armature. The contacts are attached to magnetic strips or "reeds" in a glass or plastic tube, surrounded by a coil. The reeds move together or apart when current is applied to the coil, opening or closing contacts. Reed relays can open and close very quickly and are often used in transmit-receive switching circuits.

*Solid-state relays* (SSR) use transistors in-

stead of mechanical contacts and electronic circuits instead of magnetic coils. They are designed as substitutes for electromechanical relays in power and control circuits and are not used in low-level ac or dc circuits.

*Coaxial relays* have an armature and contacts designed to handle RF signals. The signal path in coaxial relays maintains a specific characteristic impedance for use in RF systems. Coaxial connectors are used for the RF circuits. Coaxial relays are typically used to control antenna system configurations or to switch a transceiver between a linear amplifier and an antenna.

A *solenoid* is very similar to a relay, except that instead of the moving armature actuating switch contacts, the solenoid moves a lever or rod to actuate some mechanical device. Solenoids are not commonly used in radio equipment, but may be encountered in related systems or devices.

## 2.6 Capacitance and Capacitors

It is possible to build up and hold an electrical charge in an *electrostatic field*. This phenomenon is called *capacitance*, and the devices that exhibit capacitance are called *capacitors*. (Old articles and texts use the obsolete term *condenser*.) Figure 2.12 shows schematic symbols for capacitors: a fixed capacitor with a single value of capacitance (Figure 2.12A) and variable capacitors adjustable over a range of values (Figure 2.12B). If the capacitor is of a type that is *polarized*, meaning that dc voltages must be applied with a specific polarity, the straight line in the symbol should be connected to the most positive voltage, while the curved line goes to the more negative voltage. For clarity, the positive terminal of a polarized capacitor symbol is usually marked with a + symbol. The symbol for *non-polarized* capacitors may be two straight lines or the + symbol may be omitted. When in doubt, consult the capacitor's specifications or the circuits parts list.

### 2.6.1 Electrostatic Fields and Energy

An *electrostatic field* is created wherever a voltage exists between two points, such as two opposite electric charges or regions that contain different amounts of charge. The field causes electric charges (such as electrons or ions) in the field to feel a force in the direction of the field. If the charges are not free to move, as in an insulator, they store the field's energy as *potential energy*, just as a weight held in place by a surface stores gravitational energy. If the charges are free to move, the field's stored energy is converted to *kinetic energy*

of motion just as if the weight is released to fall in a gravitational field.

The field is represented by *lines of force* that show the direction of the force felt by the electric charge. Each electric charge is surrounded by an electric field. The lines of force of the field begin on the charge and extend away from charge into space. The lines of force can terminate on another charge (such as lines of force between a proton and an electron) or they can extend to infinity.

The strength of the electrostatic field is measured in *volts per meter* (V/m). Stronger fields cause the moving charges to accelerate more strongly (just as stronger gravity causes weights to fall faster) and stores more energy in fixed charges. The stronger the field in V/m, the more force an electric charge in the field will feel. The strength of the electric field diminishes with the square of the distance from its source, the electric charge.

### 2.6.2 The Capacitor

Suppose two flat metal plates are placed close to each other (but not touching) and are connected to a battery through a switch, as illustrated in Figure 2.13A. At the instant the switch is closed, electrons are attracted from the upper plate to the positive terminal of the battery, while the same quantity is repelled from the negative battery terminal and pushed into the lower plate. This imbalance of charge creates a voltage between the plates. Eventually, enough electrons move into one plate and out of the other to make the voltage between the plates the same as the battery voltage. At this point, the voltage between the

plates opposes further movement of electrons and no further current flow occurs.

If the switch is opened after the plates have been charged in this way, the top plate is left with a deficiency of electrons and the bottom plate with an excess. Since there is no current path between the two plates, they remain charged despite the fact that they are no longer connected to the battery which is the source of the voltage. In Figure 2.13B, the separated charges create an electrostatic field between the plates. The electrostatic field contains the energy that was expended by the battery in causing the electrons to flow off of or onto the plates. These two plates create a *capacitor*, a device that has the property of storing electrical energy in an electric field, a property called *capacitance*.

The amount of electric charge that is held on the capacitor plates is proportional to the applied voltage and to the capacitance of the capacitor:

$$Q = CV$$

where

Q = charge in coulombs,

C = capacitance in farads (F), and

V = electrical potential in volts. (The symbol E is also commonly used instead of V in this and the following equation.)

The energy stored in a capacitor is also a function of voltage and capacitance:

$$W = \frac{V^2 C}{2}$$

where W = energy in joules (J) or watt-seconds.

If a wire is simultaneously touched to the two plates (short circuiting them), the voltage between the plates causes the excess electrons on the bottom plate to flow through the wire to the upper plate, restoring electrical neutrality. The plates are then *discharged*.

Figure 2.14 illustrates the voltage and current in the circuit, first, at the moment the switch is closed to charge the capacitor and, second, at the moment the shorting switch is closed to discharge the capacitor. Note that the periods of charge and discharge are very short, but that they are not zero. This finite charging and discharging time can be controlled and that will prove useful in the creation of timing circuits.

During the time the electrons are moving—that is, while the capacitor is being charged or discharged—a current flows in the circuit even though the circuit apparently is broken by the gap between the capacitor plates. The current flows only during the time of charge and discharge, however, and this time is usu-

Figure 2.12 — Schematic symbol for a fixed capacitor is shown at A. The symbols for a variable capacitor are shown at B.

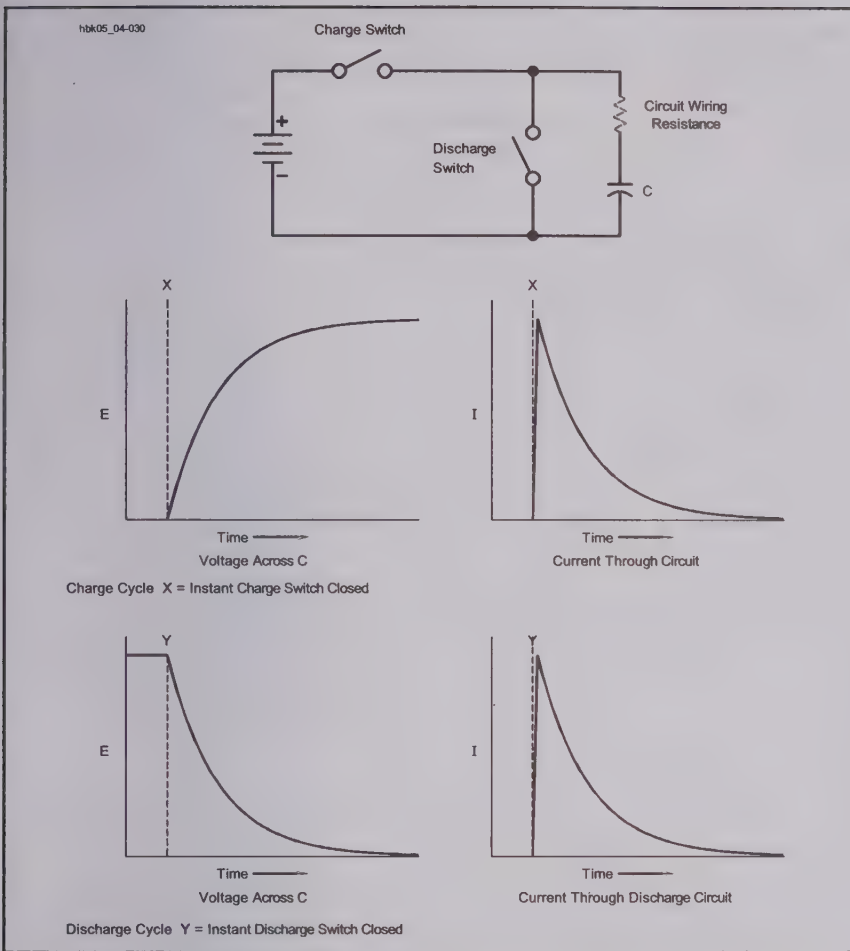

Figure 2.13 — A simple capacitor showing the basic charging arrangement at A, and the retention of the charge due to the electrostatic field at B.

**Figure 2.14** — The flow of current during the charge and discharge of a capacitor. The charging graphs assume that the charge switch is closed and the discharge switch is open. The discharging graphs assume just the opposite.

ally very short. There is no continuous flow of direct current through a capacitor.

Although dc cannot pass through a capacitor, alternating current can. At the same time one plate is charged positively by the positive excursion of the alternating current, the other plate is being charged negatively at the same rate. (Remember that conventional current is shown as the flow of positive charge, equal to and opposite the actual flow of electrons.) The reverse process occurs during the second half of the cycle as the changing polarity of the applied voltage causes the flow of charge to change direction, as well. The continual flow into and out of the capacitor caused by ac voltage appears as an ac current, although with a phase difference between the voltage and current flow as described below.

### UNITS OF CAPACITANCE

The basic unit of capacitance, the ability to store electrical energy in an electrostatic field, is the *farad*. This unit is generally too

large for practical radio circuits, although capacitors of several farads in value are used in place of small batteries or as a power supply filter for automotive electronics. Capacitance encountered in radio and electronic circuits is usually measured in microfarads (abbreviated  $\mu\text{F}$ ), nanofarads (abbreviated nF) or picofarads (pF). The microfarad is one millionth of a farad ( $10^{-6}$  F), the nanofarad is one thousandth of a microfarad ( $10^{-9}$  F) and the picofarad is one millionth of a microfarad ( $10^{-12}$  F). Old articles and texts use the obsolete term micromicrofarad (mmF or  $\mu\mu\text{F}$ ) in place of picofarad.

### CAPACITOR CONSTRUCTION

An idealized capacitor is a pair of parallel metal plates separated by an insulating or *dielectric* layer, ideally a vacuum. The capacitance of a vacuum-dielectric capacitor is given by

$$C = \frac{A \epsilon_r \epsilon_0}{d}$$

where

$C$  = capacitance, in farads

$A$  = area of plates, in  $\text{cm}^2$

$d$  = spacing of the plates in cm

$\epsilon_r$  = dielectric constant of the insulating material

$\epsilon_0$  = permittivity of free space,  $8.85 \times 10^{-14}$  F/cm.

The actual capacitance of such a parallel-plate capacitor is somewhat higher due to *end effect* caused by the electric field that exists just outside the edges of the plates.

The *larger* the plate area and the *smaller* the spacing between the plates, the *greater* the amount of energy that can be stored for a given voltage, and the *greater* the capacitance. The more general name for the capacitor's plates is *electrodes*. However, amateur literature generally refers to a capacitor's electrodes as plates and that is the convention in this text.

The amount of capacitance also depends on the material used as insulating material between the plates; capacitance is smallest with air or a vacuum as the insulator. Substituting other insulating materials for air may greatly increase the capacitance.

The ratio of the capacitance with a material other than a vacuum or air between the plates to the capacitance of the same capacitor with air insulation is called the *dielectric constant* ( $\epsilon_r$  or  $K$ ), of that particular insulating material. The dielectric constants of a number of materials commonly used as dielectrics in capacitors are given in **Table 2.2**. For example, if polystyrene is substituted for air in a capacitor, the capacitance will be 2.6 times greater.

In practice, capacitors often have more than two plates, with alternating plates being connected in parallel to form two sets, as shown in **Figure 2.15**. This practice makes it possible to obtain a fairly large capacitance in a small space, since several plates of smaller individual area can be stacked to form the equivalent of a single large plate of the same total area. Also, all plates except the two on the ends of the stack are exposed to plates of the other group on both sides, and so are twice as effective in increasing the capacitance.

The formula for calculating capacitance from these physical properties is:

$$C = \frac{0.2248 K A (n-1)}{d}$$

where

$C$  = capacitance in pF,

$K$  = dielectric constant of material between plates,

$A$  = area of one side of one plate in square inches,

$d$  = separation of plate surfaces in inches, and

$n$  = number of plates.

**Figure 2.15 — A multiple-plate capacitor. Alternate plates are connected to each other, increasing the total area available for storing charge.**

If the area (A) is in square centimeters and the separation (d) is in centimeters, then the formula for capacitance becomes

$$C = \frac{0.0885 K A (n - 1)}{d}$$

If the plates in one group do not have the same area as the plates in the other, use the area of the smaller plates.

Example: What is the capacitance of two copper plates, each 1.50 square inches in area, separated by a distance of 0.00500 inch, if the dielectric is air?

$$C = \frac{0.2248 K A (n - 1)}{d}$$

$$C = \frac{0.2248 \times 1 \times 1.50 (2 - 1)}{0.00500}$$

$$C = 67.4 \text{ pF}$$

What is the capacitance if the dielectric is mineral oil? (See Table 2.2 for the appropriate dielectric constant.)

$$C = \frac{0.2248 \times 2.23 \times 1.50 (2 - 1)}{0.00500}$$

$$C = 150.3 \text{ pF}$$

### 2.6.3 Capacitors in Series and Parallel

When a number of capacitors are connected in parallel, as in the right side of Figure 2.16, the total capacitance of the group is equal to the sum of the individual capacitances:

$$C_{\text{total}} = C_1 + C_2 + C_3 + C_4 \dots + C_n$$

When two or more capacitors are connected in series, as in the left side of Figure 2.16, the total capacitance is less than that of the smallest capacitor in the group. The rule

**Table 2.2**

**Relative Dielectric Constants of Common Capacitor Dielectric Materials**

Material	Dielectric Constant (k)	(O)rganic or (I)norganic
Vacuum	1 (by definition)	
Air	1.0006	
Ruby mica	6.5 - 8.7	
Glass (flint)	10	
Barium titanate (class I)	5 - 450	
Barium titanate (class II)	200 - 12000	
Kraft paper	≈ 2.6	O

**Figure 2.16 — Capacitors in series and parallel.**

for finding the capacitance of a number of series-connected capacitors is the same as that for finding the resistance of a number of parallel-connected resistors.

$$C_{\text{total}} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \dots + \frac{1}{C_n}}$$

For only two capacitors in series, the formula becomes:

$$C_{\text{total}} = \frac{C_1 \times C_2}{C_1 + C_2}$$

The same units must be used throughout; that is, all capacitances must be expressed in  $\mu\text{F}$ ,  $\text{nF}$  or  $\text{pF}$ , etc. Different units cannot be combined in the same equation.

Capacitors are often connected in parallel to obtain a larger total capacitance than is available in one unit. The voltage rating of capacitors connected in parallel is the lowest voltage rating of any of the capacitors.

When capacitors are connected in series, the applied voltage is divided between them according to Kirchhoff's Voltage Law. The situation is much the same as when resis-

**Figure 2.17 — An example of capacitors connected in series. The text shows how to find the voltage drops, E1 through E3.**

tors are in series and there is a voltage drop across each. The voltage that appears across each series-connected capacitor is inversely proportional to its capacitance, as compared with the capacitance of the whole group. (This assumes ideal capacitors.)

Example: Three capacitors having capacitances of 1, 2 and 4  $\mu\text{F}$ , respectively, are connected in series as in Figure 2.17. The voltage across the entire series is 2000 V. What is the total capacitance? (Since this is a calcula-

on using theoretical values to illustrate a technique, we will not follow the rules of significant figures for the calculations.)

$$C_{\text{total}} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3}}$$

$$\frac{1}{1 \mu\text{F}} + \frac{1}{2 \mu\text{F}} + \frac{1}{4 \mu\text{F}}$$

$$\frac{1}{4 \mu\text{F}} = \frac{4 \mu\text{F}}{4 \mu\text{F}} = 0.5714 \mu\text{F}$$

The voltage across each capacitor is proportional to the total capacitance divided by the capacitance of the capacitor in question. The voltage across C1 is:

$$V_1 = \frac{0.5714 \mu\text{F}}{1 \mu\text{F}} \times 2000 \text{ V} = 1143 \text{ V}$$

Similarly, the voltages across C2 and C3 are:

$$V_2 = \frac{0.5714 \mu\text{F}}{2 \mu\text{F}} \times 2000 \text{ V} = 571 \text{ V}$$

and

$$V_3 = \frac{0.5714 \mu\text{F}}{4 \mu\text{F}} \times 2000 \text{ V} = 286 \text{ V}$$

The sum of these three voltages equals 2000 V, the applied voltage.

Capacitors may be connected in series to enable the group to withstand a larger voltage than any individual capacitor is rated to withstand. The trade-off is a decrease in the total capacitance. As shown by the previous example, the applied voltage does not divide equally between the capacitors except when all the capacitances are precisely the same. Use care to ensure that the voltage rating of any capacitor in the group is not exceeded. If you use capacitors in series to withstand a higher voltage, you should also connect an "equalizing resistor" across each capacitor as described in the **Power Sources** chapter.

## 2.6.4 RC Time Constant

Connecting a dc voltage source directly to the terminals of a capacitor charges the capacitor to the full source voltage almost instantaneously. Any resistance added to the circuit (as R in **Figure 2.18A**) limits the current, lengthening the time required for the voltage between the capacitor plates to build up to the source-voltage value. During this charging period, the current flowing from the source into the capacitor gradually decreases from its initial value. The increasing voltage stored in the capacitor's electric field offers increasing opposition to the steady source voltage.

**Figure 2.18 — An RC circuit. The series resistance delays the process of charging (A) and discharging (B) when the switch, S, is closed.**

**Figure 2.19 — At A, the curve shows how the voltage across a capacitor rises, with time, when charged through a resistor. The curve at B shows the way in which the voltage decreases across a capacitor when discharging through the same resistance. For practical purposes, a capacitor may be considered charged or discharged after five RC periods.**

While it is being charged, the voltage between the capacitor terminals is an exponential function of time, and is given by:

$$V(t) = E \left( 1 - e^{-\frac{t}{RC}} \right)$$

where

- $V(t)$  = capacitor voltage at time  $t$ ,
- $E$  = power source potential in volts,
- $t$  = time in seconds after initiation of charging current,
- $e$  = natural logarithmic base = 2.718,
- $R$  = circuit resistance in ohms, and
- $C$  = capacitance in farads.

(References that explain exponential equations,  $e$ , and other mathematical topics are found in the "Radio Mathematics" article in this book's downloadable supplemental information.)

By letting  $t = RC$ , the above equation becomes:

$$V(RC) = E (1 - e^{-1}) \cong 0.632 E$$

The product of  $R$  in ohms times  $C$  in farads is called the *time constant* (also called the *RC time constant*) of the circuit and is the time in seconds required to charge the capacitor to 63.2% of the applied voltage. (The lower-case Greek letter tau,  $\tau$ , is often used to represent the time constant in electronics circuits.) After two time constants ( $t = 2\tau$ ) the capacitor charges another 63.2% of the difference between the capacitor voltage at one time constant and the applied voltage, for a total charge of 86.5%. After three time constants the capacitor reaches 95% of the applied voltage, and so on, as illustrated in the curve of **Figure 2.19A**. After five time constants, a capacitor is considered fully charged, having reached 99.24% of the applied voltage. Theoretically, the charging process is never really finished, but eventually the charging current drops to an immeasurably small value and the voltage is effectively constant.

If a charged capacitor is discharged through a resistor, as in **Figure 2.18B**, the same time constant applies to the decay of the capacitor voltage. A direct short circuit applied between the capacitor terminals would discharge the capacitor almost instantly. The resistor,  $R$ , limits the current, so a capacitor discharging through a resistance exhibits the same time-constant characteristics (calculated in the same way as above) as a charging capacitor. The voltage, as a function of time while the capacitor is being discharged, is given by:

$$V(t) = E \left( e^{-\frac{t}{RC}} \right)$$

where  $t$  = time in seconds after initiation of discharge and  $E$  is the fully-charged capacitor voltage prior to beginning discharge.

Again, by letting  $t = RC$ , the time constant of a discharging capacitor represents a decrease in the voltage across the capacitor of about 63.2%. After five time-constants, the capacitor is considered fully discharged, since the voltage has dropped to less than 1% of the full-charge voltage. **Figure 2.19B** is a graph of the discharging capacitor voltage in terms of time constants.

Time constant calculations have many uses in radio work. The following examples are all derived from practical-circuit applications.

**Example 1:** A 100- $\mu\text{F}$  capacitor in a high-voltage power supply is shunted by a 100-k $\Omega$

## RC Timesaver

When calculating time constants, it is handy to remember that if R is in units of MΩ and C is in units of μF, the result of R × C will be in seconds. Expressed as an equation: MΩ × μF = seconds

resistor. What is the minimum time before the capacitor may be considered fully discharged? Since full discharge is approximately five RC periods,

$$t = 5 \times RC = 5 \times 100 \times 10^3 \Omega \times 100 \times 10^{-6} \text{ F} = 50000 \times 10^{-3} = 50 \text{ s}$$

**Caution:** Although waiting almost a minute for the capacitor to discharge seems safe in this high-voltage circuit, *never* rely solely on capacitor-discharging resistors (often called *bleeder resistors*). Be certain the power source is removed and the capacitors are totally discharged before touching any circuit components. (See the **Power Sources** chapter for more information on bleeder resistors.)

**Example 2:** Smooth CW keying without clicks requires both the rising and falling edges of the waveform to take approximately 5 ms (0.005 s). If an RC delay circuit in a keyed voltage line is used to set the rise and fall time, what values of R and C should be

used? Since full charge and discharge require 5 RC periods,

$$RC = \frac{t}{5} = \frac{0.005 \text{ s}}{5} = 0.001 \text{ s}$$

Any combination of resistor and capacitor whose values, when multiplied together, equal 0.001 would do the job. A typical capacitor might be 0.05 μF. In that case, the necessary resistor would be:

$$R = \frac{0.001 \text{ s}}{0.05 \times 10^{-6} \text{ F}} = 0.02 \times 10^6 \Omega = 20000 \Omega = 20 \text{ k}\Omega$$

In practice, a builder would use the calculated value as a starting point. The final value would be selected by monitoring the waveform on an oscilloscope.

**Example 3:** The popular 555 timer IC activates its output pin with the trigger input reaches 0.667 of the supply voltage. What value of capacitor and resistor would be required for a 4.5-second timing period?

First we will solve the charging equation for the time constant, RC. The threshold voltage is 0.667 times the supply voltage, so we use this value for V(t).

$$V(t) = E \left( 1 - e^{-\frac{t}{RC}} \right)$$

$$0.667 E = E \left( 1 - e^{-\frac{t}{RC}} \right)$$

$$e^{-\frac{t}{RC}} = 1 - 0.667$$

$$\ln \left( e^{-\frac{t}{RC}} \right) = \ln (0.333)$$

$$-\frac{t}{RC} = -1.10$$

We want to find a capacitor and resistor combination that will produce a 4.5 s timing period, so we substitute that value for t.

$$RC = \frac{4.5 \text{ s}}{1.10} = 4.1 \text{ s}$$

If we select a value of 10 μF, we can solve for R.

$$R = \frac{4.1 \text{ s}}{10 \times 10^{-6} \text{ F}} = 0.41 \times 10^6 \Omega = 410 \text{ k}\Omega$$

A 1% tolerance resistor and capacitor will give good results. You could also use a variable resistor and an accurate method of measuring timing time to set the circuit to a 4.5 s period.

## 2.7 Inductance and Inductors

A second way to store electrical energy is in a *magnetic field*. This phenomenon is called *inductance*, and the devices that exhibit inductance are called *inductors*. Inductance is derived from some basic underlying magnetic properties.

### 2.7.1 Magnetic Fields and Magnetic Energy Storage

As an electric field surrounds an electric charge, magnetic fields surround *magnets*. You are probably familiar with metallic bar, disc, or horseshoe-shaped magnets. **Figure 2.20** shows a bar magnet, but particles of matter as small as an atom can also be magnets.

**Figure 2.20** also shows the magnet surrounded by lines of force called *magnetic flux*, representing a *magnetic field*. (More accurately, a *magnetostatic field*, since the field is not changing.) Similar to those of an electric field, magnetic lines of force (or *flux lines*) show the direction in which a magnet

**Figure 2.20** — The magnetic field and poles of a permanent magnet. The magnetic field direction is from the north to the south pole.

would feel a force in the field.

There is no “magnetic charge” comparable to positive and negative electric charges. All magnets and magnetic fields have a polarity, represented as *poles*, and every magnet — from atoms to bar magnets — possesses

both a *north* and *south pole*. The size of the source of the magnetism makes no difference. The north pole of a magnet is defined as the one attracted to the Earth’s north magnetic pole. (Confusingly, this definition means that Earth’s North Magnetic Pole is magnetically a south pole!) Like conventional current, the direction of magnetic lines of force was assigned arbitrarily by early scientists as pointing *from* the magnet’s north pole *to* the south pole.

An electric field is *open* — that is, its lines of force have one end on an electric charge and can extend to infinity. A magnetic field is *closed* because all magnetic lines of force form a loop passing through a magnet’s north and south poles.

Magnetic fields exist around two types of materials; *permanent magnets* and *electromagnets*. Permanent magnets consist of *ferromagnetic* and *ferrimagnetic* materials whose atoms are or can be aligned so as to produce a magnetic field. Ferro- or ferrimagnetic

materials are strongly attracted to magnets. They can be *magnetized*, meaning to be made magnetic, by the application of a magnetic field. Lodestone, magnetite, and ferrites are examples of ferrimagnetic materials. Iron, nickel, cobalt, Alnico alloys and other materials are ferromagnetic. Magnetic materials with high *retentivity* form permanent magnets because they retain their magnetic properties for long periods. Other materials, such as soft iron, yield temporary magnets that lose their

## The Right-Hand Rule

How do you remember which way the magnetic field around a current is pointing? Luckily, there is a simple method, called the *right-hand rule*. Make your right hand into a fist, then extend your thumb, as in the figure below. If your thumb is pointing in the direction of conventional current flow, then your fingers curl in the same direction as the magnetic field. (If you are dealing with electronic current, use your left hand, instead!)

Figure 2.A2 — Use the right-hand rule to determine magnetic field direction from the direction of current flow.

magnetic properties rapidly.

*Paramagnetic* substances are very weakly attracted to a magnet and include materials such as platinum, aluminum, and oxygen. *Diamagnetic* substances, such as copper, carbon, and water, are weakly repelled by a magnet.

The second type of magnet is an electrical conductor with a current flowing through it. As shown in **Figure 2.21**, moving electrons are surrounded by a closed magnetic field, illustrated as the circular lines of force around the wire lying in planes perpendicular to the current's motion. The magnetic needle of a compass placed near a wire carrying direct current will be deflected as its poles respond to the forces created by the magnetic field around the wire.

If the wire is coiled into a *solenoid* as shown in **Figure 2.22**, the magnetic field greatly intensifies. This occurs as the magnetic fields from each successive turn in the coil add together because the current in each turn is flowing in the same direction.

Note that the resulting *electromagnet* has magnetic properties identical in principle to those of a permanent magnet, including poles and lines of force or flux. The strength of the magnetic field depends on several factors: the number and shape of turns of the coil, the magnetic properties of the materials surrounding the coil (both inside and out), the length of the coil and the amplitude of the current.

Magnetic fields and electric current have a special two-way connection: voltage causing an electrical current (moving charges) in a conductor will produce a magnetic field and a moving magnetic field will create an electrical field (voltage) that produces current in a conductor. This is the principle behind motors and generators, converting mechanical energy into electrical energy and vice-versa. **Table 2.3** shows the similarities: magnetic quantities and circuits have analogues in electrical quantities and circuits. This illustrates the deep relationship between electricity and magnetism, two sides of the same coin.

## MAGNETIC FLUX

Magnetic flux is measured in the SI unit (International System of Units) of the weber, which is a volt-second ( $Wb = V\cdot s$ ). In the *centimeter-gram-second (cgs)* metric system

Figure 2.21 — The magnetic field around a conductor carrying an electrical current. If the thumb of your right hand points in the direction of the conventional current (plus to minus), your fingers curl in the direction of the magnetic field around the wire.

Figure 2.22 — Cross section of an inductor showing its flux lines and overall magnetic field.

Table 2.3  
Magnetic Quantities

Value	Symbol	MKS	cgs
Magnetic Flux	lines	Weber, $Wb = V\cdot s$	Maxwell, $Mx = 10^{-8} Wb$
Magnetic Flux Density	B	Tesla, $T = Wb/m^2$	Gauss, $G = Mx/cm^2$ $T = 10,000 G$
Magnetomotive Force	[T]	Amp-turn = A	Gilbert, $Gb = 0.79577 A$
Magnetic Field Strength	H	A / meter	Oersted, $Oe = Gb/cm = 79.58 A/m$

## Magnetic Circuit Analogies

Electric Circuit	Magnetic Circuit
Voltage drop V	HI magnetovoltage drop
Voltage source V	nI magnetomotive force
Current I	psi = BA magnetic flux

Note — Magnetic circuit analogies as described by Shen and Kong, Applied Electromagnetism

units, magnetic flux is measured in maxwells (1 Mx = 10<sup>-8</sup> Wb). The volt-second is used because of the relationship described in the previous paragraph: 1 volt of electromotive force will be created in a loop of wire in which magnetic flux through the loop changes at the rate of 1 weber per second. The relationship between current and magnetic fields is one of motion and change.

Magnetic field intensity, known as *flux density*, decreases with the square of the distance from the source, either a magnet or current. Flux density (*B*) is represented in gauss (G), where one gauss is equivalent to one line of force (1 Mx) per square centimeter of area measured perpendicularly to the direction of the field ( $G = Mx / cm^2$ ). The Earth's magnetic field at the surface is approximately one gauss. The gauss is a cgs unit. In SI units, flux density is represented by the tesla (T), which is one weber per square meter ( $T = Wb/m^2$  and  $1T = 10,000 G$ ).

### Magnetomotive Force and Field Strength

The magnetizing or *magnetomotive force* ( $\mathfrak{F}$ ) that produces a flux or total magnetic field is measured in gilberts (Gb). Magnetomotive force is analogous to electromotive force in that it produces the magnetic field. The SI unit of magnetomotive force is the ampere-turn, abbreviated A, just like the ampere. (1 Gb = 0.79577 A)

$$\mathfrak{F} = \frac{10 NI}{4\pi}$$

where

- $\mathfrak{F}$  = magnetomotive strength in gilberts,
- N = number of turns in the coil creating the field,
- I = dc current in amperes in the coil, and
- $\pi = 3.1416$ .

The magnetic field strength (*H*) measured in oersteds (Oe) produced by any particular magnetomotive force (measured in gilberts) is given by:

$$H = \frac{\mathfrak{F}}{\ell} = \frac{10 NI}{4\pi \ell}$$

where

- H = magnetic field strength in oersteds, and
- $\ell$  = mean magnetic path length in centimeters.

The *mean magnetic path length* is the average length of the lines of magnetic flux. If the inductor is wound on a closed core as shown in the next section, *l* is approximately the average of the inner and outer circumferences of the core. The SI unit of magnetic field strength is the ampere-turn per meter. (1 Oe = 79.58 A/m)

## 2.7.2 Magnetic Core Properties

### PERMEABILITY

The nature of the material within the coil of an electromagnet, where the lines of force are most concentrated, has the greatest effect upon the magnetic field established by the coil. All core materials are compared relatively to air. The ratio of flux density produced by a given material compared to the flux density produced by an air core is the *permeability* ( $\mu$ ) of the material. Air and non-magnetic materials have a permeability of one.

Suppose the coil in **Figure 2.23** is wound on an iron core having a cross-sectional area of 2 square inches. When a certain current is sent through the coil, it is found that there are 80,000 lines of force in the core. Since the area is 2 square inches, the magnetic flux density is 40,000 lines per square inch. Now suppose that the iron core is removed and the

same current is maintained in the coil. Also suppose the flux density without the iron core is found to be 50 lines per square inch. The ratio of these flux densities, iron core to air, is 40,000 / 50 or 800. This ratio is the core's permeability.

Permeabilities as high as 10<sup>6</sup> have been attained. The three most common types of materials used in magnetic cores are:

A) stacks of thin steel laminations (for power and audio applications, see the discussion on eddy currents below);

B) various ferrite compounds (for cores shaped as rods, toroids, beads and numerous other forms); and

C) powdered iron (shaped as slugs, toroids and other forms for RF inductors).

The permeability of silicon-steel power-transformer cores approaches 5000 in high-quality units. Powdered-iron cores used in RF tuned circuits range in permeability from 3 to about 35, while ferrites of nickel-zinc and manganese-zinc range from 20 to 15,000. Not all materials have permeabilities higher than air. Brass has a permeability of less than one. A brass core inserted into a coil will decrease the magnetic field compared to an air core.

**Table 2.4** lists some common magnetic materials, their composition and their permeabilities. Core materials are often frequency sensitive, exhibiting excessive losses outside the frequency band of intended use. (Ferrite materials are discussed separately in a later section of the chapter on **RF Techniques**.)

As a measure of the ease with which a magnetic field may be established in a material as compared with air, permeability ( $\mu$ ) corresponds roughly to electrical conductivity. Higher permeability means that it is easier to establish a magnetic field in the material.

**Figure 2.23** — A coil of wire wound around a laminated iron core.

**Table 2.4**

### Properties of Some High-Permeability Materials

Material	Approximate Percent Composition					Maximum Permeability
	Fe	Ni	Co	Mo	Other	
Iron	99.91	—	—	—	—	5000
Purified Iron	99.95	—	—	—	—	180,000
4% silicon-iron	96	—	—	—	4 Si	7000
45 Permalloy	54.7	45	—	—	0.3 Mn	25,000
Hipernik	50	50	—	—	—	70,000
78 Permalloy	21.2	78.5	—	—	0.3 Mn	100,000
4-79 Permalloy	16.7	79	—	—	0.3 Mn	100,000
Supermalloy	15.7	79	—	5	0.3 Mn	800,000
Permendur	49.7	—	50	—	0.3 Mn	5000
2V Permendur	49	—	49	—	2 V	4500
Hiperco	64	—	34	—	2 Cr	10,000
2-81 Permalloy*	17	81	—	2	—	130
Carbonyl iron*	99.9	—	—	—	—	132
Ferroxcube III**	(MnFe <sub>2</sub> O <sub>4</sub> + ZnFe <sub>2</sub> O <sub>4</sub> )			1500	—	—

Note: all materials in sheet form except \* (insulated powder) and \*\* (sintered powder). (Reference: L. Ridenour, ed., *Modern Physics for the Engineer*, p 119.)

Permeability is given as:

$$\mu = \frac{B}{H}$$

where

$B$  is the flux density in gauss, and  
 $H$  is the magnetic field strength in oersteds.

## RELUCTANCE

That a force (the magnetomotive force) is required to produce a given magnetic field strength implies that there is some opposition to be overcome. This opposition to the creation of a magnetic field is called *reluctance*. Reluctance ( $\mathcal{R}$ ) is the reciprocal of permeability and corresponds roughly to resistance in an electrical circuit. Carrying the electrical resistance analogy a bit further, the magnetic equivalent of Ohm's Law relates reluctance, magnetomotive force, and flux density:  $\mathcal{R} = \mathcal{Z} / B$ .

## HYSTERESIS

*Retentivity* in magnetic core materials is caused by atoms retaining their alignment from an applied magnetizing force. Retentivity is desirable if the goal is to create a permanent magnet. In an electronic circuit, however, the changes caused by retentivity cause the properties of the core material to depend on the history of how the magnetizing force was applied.

**Figure 2.24** illustrates the change of flux density ( $B$ ) with a changing magnetizing force ( $H$ ). From starting point A, with no flux in the core, the flux reaches point B at the maximum magnetizing force. As the force decreases, so too does the flux, but it does not reach zero simultaneously with the force at point D. As the force continues in the opposite direction, it brings the flux density to point C. As the force decreases to zero, the flux once more lags behind. This occurs because some of the atoms in core retain their alignment, even after the external magnetizing force is removed. This creates *residual flux* that is present even with no applied magnetizing force. This is the property of *hysteresis*.

In effect, a *coercive force* is necessary to reverse or overcome the residual magnetism retained by the core material. If a circuit carries a large ac current (that is, equal to or larger than saturation), the path shown in Figure 2.24 will be retraced with every cycle and the reversing force each time. The result is a power loss to the magnetic circuit, which appears as heat in the core material. Air cores are immune to hysteresis effects and losses.

## SATURATION

Unlike electrical conductivity, which is independent of other electrical parameters, the permeability of a magnetic material varies

**Figure 2.24** — A typical hysteresis curve for a magnetic core, showing the additional energy needed to overcome residual flux.

**Figure 2.25** — A typical permeability curve for a magnetic core, showing the point where saturation begins.

**Figure 2.26** — Magnetic flux linkage and inductance plotted versus coil current for (A) a typical iron-core inductor. As the flux linkage  $N\phi$  in the coil saturates, the inductance begins to decrease since inductance = flux linkage / current. The curves marked B show the effect of adding an air gap to the core. The current-handling capability has increased, but at the expense of reduced inductance.

with the flux density. At low flux densities (or with an air core), increasing the current through the coil will cause a proportionate increase in flux. This occurs because the current passing through the coil forces the atoms of the iron (or other material) to line up, just like many small compass needles. The magnetic field that results from the atomic alignment is *much* larger than that produced by the current with no core. As more and more atoms align, the magnetic flux density also increases.

At very high flux densities, increasing the current beyond a certain point may cause no appreciable change in the flux because all of the atoms are aligned. At this point, the core is said to be *saturated*. Saturation causes a rapid decrease in permeability, because it decreases the ratio of flux lines to those obtainable with the same current using an air core. **Figure 2.25** displays a typical permeability curve, showing the region of saturation. The saturation point varies with the makeup of different magnetic materials. Air and other nonmagnetic materials do not saturate.

## EFFECTS OF SATURATION

An important concept for using inductors is that as long as the coil current remains below saturation, the inductance of the coil is essentially constant. **Figure 2.26** shows graphs of magnetic flux linkage ( $\psi$ ) and inductance ( $L$ ) vs. current ( $I$ ) for a typical iron-core inductor both saturated and non-saturated. These quantities are related by the equation

$$\psi = N\phi = LI$$

where

$\psi$  = the flux linkage  
 $N$  = number of turns,  
 $\phi$  = flux density in webers  
 $L$  = inductance in henrys, and  
 $I$  = current in amperes.

In the lower graph, a line drawn from any point on the curve to the (0,0) point will show the effective inductance,  $L = N\phi / I$ , at that current. These results are plotted on the upper graph.

Note that below saturation, the inductance is constant because both  $\psi$  and  $I$  are increasing at a steady rate. Once the saturation current is reached, the inductance decreases because  $\psi$  does not increase anymore (except for the tiny additional magnetic field the current itself provides).

One common method of increasing the saturation current level is to cut a small air gap in the core (see **Figure 2.27**). This gap forces the flux lines to travel through air for a short distance, reducing the permeability of the core. Since the saturation flux linkage of the core is unchanged, this method works by requiring a higher current to achieve

**Figure 2.27** — Typical construction of a magnetic-core inductor. The air gap greatly reduces core saturation at the expense of reducing inductance. The insulating laminations between the core layers help to minimize eddy currents, as well.

saturation. The price that is paid is a reduced inductance below saturation. The curves in Figure 2.26B show the result of an air gap added to that inductor.

Manufacturer's data sheets for magnetic cores usually specify the saturation flux density. Saturation flux density ( $\phi$ ) in gauss can be calculated for ac and dc currents from the following equations:

$$\phi_{ac} = \frac{3.49 V}{fNA}$$

$$\phi_{dc} = \frac{NIA_L}{10A}$$

where

- V = RMS ac voltage
- f = frequency, in MHz
- N = number of turns
- A = equivalent area of the magnetic path in square inches (from the data sheet)
- I = dc current, in amperes, and
- $A_L$  = inductance index (also from the data sheet).

### EDDY CURRENT

Since magnetic core material is usually conductive, the changing magnetic field produced by an ac current in an inductor also induces a voltage in the core. This voltage causes a current to flow in the core. This *eddy current* (so-named because it moves in a closed path, similarly to eddy currents in water) serves no useful purpose and results in energy being dissipated as heat from the core's resistance. Eddy currents are a particular problem in in-

ductors with iron cores. Cores made of thin strips of magnetic material, called *laminations*, are used to reduce eddy currents. (See also the section on Practical Inductors in the **Circuits and Components** chapter.)

### 2.7.3 Inductance and Direct Current

In an electrical circuit, any element whose operation is based on the transfer of energy into and out of magnetic fields is called an *inductor* for reasons to be explained shortly. **Figure 2.28** shows schematic-diagram symbols and photographs of a few representative inductors. The photograph shows an air-core inductor, a slug-tuned (variable-core) inductor with a nonmagnetic core and an inductor with a magnetic (iron) core. Inductors are often called *coils* because of their construction.

As explained above, when current flows through any conductor—even a straight wire—a magnetic field is created. The transfer of energy to the magnetic field represents work performed by the source of the voltage. Power is required for doing work, and since power is equal to current multiplied by voltage, there must be a voltage drop across the inductor while energy is being stored in the field. This voltage drop, exclusive of any voltage drop caused by resistance in the conductor, is the result of an opposing voltage created in the conductor while the magnetic field is building up to its final value. Once the field becomes constant, the *induced voltage* or *back-voltage* disappears, because no further energy is being stored. Back voltage is analogous to the opposition to current flow in a capacitor from the increasing capacitor voltage.

The induced voltage opposes the voltage

of the source, preventing the current from rising rapidly when voltage is applied. **Figure 2.29A** illustrates the situation of energizing an inductor or magnetic circuit, showing the relative amplitudes of induced voltage and the delayed rise in current to its full value.

The amplitude of the induced voltage is proportional to the rate at which the current changes (and consequently, the rate at which the magnetic field changes) and to a constant associated with the inductor itself, *inductance* ( $L$ ). (*Self-inductance* is sometimes used, distinguishing it from *mutual inductance*, as described below.) The basic unit of inductance is the *henry* (abbreviated H).

$$V = -L \frac{\Delta I}{\Delta t}$$

where

V is the induced voltage in volts,  
L is the inductance in henries, and  
 $\Delta I/\Delta t$  is the rate of change of the current in amperes per second.

An inductance of 1 H generates an induced voltage of one volt when the inducing current is varying at a rate of one ampere per second. The minus sign (–) indicates that the induced voltage has a polarity opposing the change in current.

The energy stored in the magnetic field of an inductor is given by the formula:

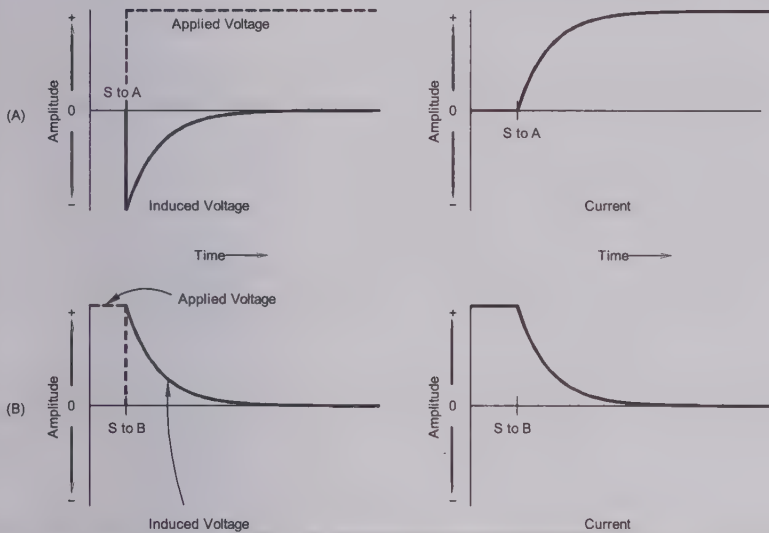

$$W = \frac{I^2 L}{2}$$

where

W = energy in joules,  
I = current in amperes, and  
L = inductance in henrys.

**Figure 2.28** — Photos and schematic symbols for representative inductors. A, an air core inductor and a pie-wound RF choke; B, a variable inductor with a nonmagnetic slug and C, an inductor with a toroidal magnetic core. The 1/4-inch-ruled graph paper background provides a size comparison.

**Figure 2.29** — Inductive circuit showing the generation of induced voltage and the rise of current when voltage is applied to an inductor at A, and the decay of current as the coil shorted at B.

This formula corresponds to the energy-storage formula for capacitors: energy storage is a function of current squared. Inductance is proportional to the amount of energy stored in an inductor's magnetic field for a given amount of current. The magnetic field strength,  $H$ , is proportional to the number of turns in the inductor's winding,  $N$ , (see the equation for magnetic field strength given previously) and for a given amount of current, to the value of  $\mu$  for the core. Thus, inductance is directly proportional to both  $N$  and  $\mu$ .

The polarity of the induced voltage is always such as to oppose any change in the circuit current. (This is why the term "back" is used, as in back-voltage or *back-EMF* for this reason.) This means that when the current in the circuit is increasing, work is being done against the induced voltage by storing energy in the magnetic field. Likewise, if the current in the circuit tends to decrease, the stored energy of the field returns to the circuit, and adds to the energy being supplied by the voltage source. The net effect of storing and releasing energy is that inductors oppose changes in current just as capacitors oppose changes in voltage. This phenomenon tends to keep the current flowing even though the applied voltage may be decreasing or be removed entirely. Figure 2.29B illustrates the decreas-

ing but continuing flow of current caused by the induced voltage after the source voltage is removed from the circuit.

Inductance depends on the physical configuration of the inductor. All conductors, even straight wires, have inductance. Coiling a conductor increases its inductance. In effect, the growing (or shrinking) magnetic field of each turn produces magnetic lines of force that — in their expansion (or contraction) — intercept the other turns of the coil, inducing a voltage in every other turn. (Recall the two-way relationship between a changing magnetic field and the voltage it creates in a conductor.) The mutuality of the effect, called *magnetic flux linkage* ( $\psi$ ), multiplies the ability of the coiled conductor to store magnetic energy.

A coil of many turns will have more inductance than one of few turns, if both coils are otherwise physically similar. Furthermore, if an inductor is placed around a magnetic core, its inductance will increase in proportion to the permeability of that core, if the circuit current is below the point at which the core saturates.

In various aspects of radio work, inductors may take values ranging from a fraction of a nanohenry (nH) through millihenrys (mH) up to about 20 H.

## Rate of Change

The symbol  $\Delta$  represents change in the following variable, so that  $\Delta I$  represents "change in current" and  $\Delta t$  "change in time." A rate of change per unit of time is often expressed in this manner. When the amount of time over which the change is measured becomes very small, the letter  $d$  replaces  $\Delta$  in both the numerator and denominator to indicate infinitesimal changes. This notation is used in the derivation and presentation of the functions that describe the behavior of electric circuits.

**Figure 2.30** — Mutual induction: When S is closed, current flows through coil number 1, setting up a magnetic field that induces a voltage in the turns of coil number 2.

## 2.7.4 Mutual Inductance and Magnetic Coupling

When two inductors are arranged with their axes aligned as shown in **Figure 2.30**, current flowing in through inductor 1 creates a magnetic field that intercepts inductor 2. Consequently, a voltage will be induced in inductor 2 whenever the field strength of inductor 1 is changing. This induced voltage is similar to the voltage of self-induction, but since it appears in the second inductor because of current flowing in the first, it is a mutual effect and results from the *mutual inductance* between the two inductors.

When all the flux set up by one coil intercepts all the turns of the other coil, the mutual inductance has its maximum possible value. If only a small part of the flux set up by one coil intercepts the turns of the other, the mutual inductance is relatively small. Two inductors having mutual inductance are said to be *coupled*.

The ratio of actual mutual inductance to the maximum possible value that could theoretically be obtained with two given inductors is called the *coefficient of coupling* between

the inductors. It is expressed as a percentage or as a value between 0 and 1. Inductors that have nearly the maximum possible mutual inductance (coefficient = 1 or 100%) are said to be closely, or tightly, coupled. If the mutual inductance is relatively small the inductors are said to be loosely coupled. The degree of coupling depends upon the physical spacing between the inductors and how they are placed with respect to each other. Maximum coupling exists when they have a common or parallel axis and are as close together as possible (for example, one wound over the other). The coupling is least when the inductors are far apart or are placed so their axes are at right angles.

The maximum possible coefficient of coupling is closely approached when the two inductors are wound on a closed iron core. The coefficient with air-core inductors may run as high as 0.6 or 0.7 if one inductor is wound over the other, but will be much less if the two inductors are separated. Although unity coupling is suggested by Figure 2.30, such coupling is possible only when the inductors are wound on a closed magnetic core.

Coupling between inductors can be minimized by using separate closed magnetic cores for each. Since an inductor's magnetic field is contained almost entirely in a closed core, two inductors with separate closed cores, such as the toroidal inductor in Figure 2.28C, can be placed close together in almost any relative orientation without coupling.

### UNWANTED COUPLING

The inductance of a short length of straight wire is small, but it may not be negligible. (In free-space, round wire has an inductance on the order of  $1 \mu\text{H}/\text{m}$ , but this is affected by wire diameter and the total circuit's physical configuration.) Appreciable voltage may be induced in even a few inches of wire carrying ac by changing magnetic fields with a frequency on the order of 100 MHz or higher. At much lower frequencies or at dc, the inductance of the same wire might be ignored because the induced voltage would be very small.

There are many phenomena, both natural and man-made, that create sufficiently strong or rapidly-changing magnetic fields to induce voltages in conductors. Many of them create brief but intense pulses of energy called

transients or "spikes." The magnetic fields from these transients intercept wires leading into and out of — and wires wholly within — electronic equipment, inducing unwanted voltages by mutual coupling.

Lightning is a powerful natural source of magnetically-coupled transients. Strong transients can also be generated by sudden changes in current in nearby circuits or wiring. High-speed digital signals and pulses can also induce voltages in adjacent conductors.

### 2.7.5 Inductances in Series and Parallel

When two or more inductors are connected in series (left side of Figure 2.31), the total inductance is equal to the sum of the individual inductances, provided that the inductors are sufficiently separated so that there is no coupling between them (see the preceding section):

$$L_{\text{total}} = L_1 + L_2 + L_3 \dots + L_n$$

If inductors are connected in parallel (right side of Figure 2.31), again assuming no mutual coupling, the total inductance is given by:

$$L_{\text{total}} = \frac{1}{\frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} + \dots + \frac{1}{L_n}}$$

For only two inductors in parallel, the formula becomes:

$$L_{\text{total}} = \frac{L_1 \times L_2}{L_1 + L_2}$$

Thus, the rules for combining inductances in series and parallel are the same as those for resistances, assuming there is no coupling between the inductors. When there is coupling between the inductors, the formulas given above will not yield correct results.

### 2.7.6 RL Time Constant

As with capacitors, the time dependence of inductor current is a significant property. A comparable situation to an RC circuit exists when resistance and inductance are connected in series. In Figure 2.32, first considered the case in which R is zero. Closing S1 sends a current through the circuit. The instantaneous transition from no current to a finite value,

Figure 2.31 — Inductors in series and parallel.

Figure 2.32 — Time constant of an RL circuit being energized.

however small, represents a rapid change in current, and an opposing voltage is induced in L. The value of the opposing voltage is almost equal to the applied voltage, so the resulting initial current is very small.

The opposing voltage is created by change in the inductor current and would cease to exist if the current did not continue to increase. With no resistance in the circuit, the current would increase forever, always growing just fast enough to keep the self-induced opposing voltage just below the applied voltage.

When resistance in the circuit limits the current, the opposing voltage induced in L must only equal the difference between E and the drop across R, because that is the voltage actually applied to L. This difference becomes smaller as the current approaches its final value, limited by Ohm's Law to  $I = E/R$ . Theoretically, the opposing voltage never quite disappears, and so the current never quite reaches the Ohm's Law limit. In practical terms, the difference eventually becomes insignificant, just as described above for capacitors charging to an applied voltage through a resistor.

The inductor current at any time after the switch in Figure 2.32 has been closed, can be found from:

$$I(t) = \frac{E}{R} \left( 1 - e^{-\frac{tR}{L}} \right)$$

where

- I(t) = current in amperes at time t,
- E = power source potential in volts,
- t = time in seconds after application of voltage,
- e = natural logarithmic base = 2.718,
- R = circuit resistance in ohms, and
- L = inductance in henrys.

(References that explain exponential equations,  $e$ , and other mathematical topics are found in the “Radio Mathematics” article in this book’s downloadable supplemental information.) The term  $E/R$  in this equation represents the dc value of  $I$ , or the value of  $I(t)$  when  $t$  becomes very large; this is the *steady-state value* of  $I$ . If  $t = L/R$ , the above equation becomes:

$$V(L/R) = \frac{E}{R}(1 - e^{-1}) \approx 0.632 \frac{E}{R}$$

The time in seconds required for the current to build up to 63.2% of the maximum value is called the *time constant* (also the *RL time constant*), and is equal to  $L/R$ , where  $L$  is in henrys and  $R$  is in ohms. (Time constants are also discussed in the section on RC circuits above.) After each time interval equal to this constant, the current increases by an additional 63.2% closer to the final value of  $E/R$ . This behavior is graphed in Figure 2.32. As is the case with capacitors, after five time constants the current is considered to have reached its maximum value. As with capacitors, we use the lower-case Greek tau ( $\tau$ ) to represent the time constant.

Example: If a circuit has an inductor of 5.0 mH in series with a resistor of 10  $\Omega$ , how long will it take for the current in the circuit to reach full value after power is applied? Since achieving maximum current takes approximately five time constants,

$$t = \frac{5L}{R} = \frac{5 \times 5.0 \times 10^{-3} \text{ H}}{10 \Omega}$$

$$= 2.5 \times 10^{-3} \text{ seconds} = 2.5 \text{ ms}$$

Note that if the inductance is increased to 5.0 H, the required time increases by a factor of 1000 to 2.5 seconds. Since the circuit resistance didn’t change, the final current is the same for both cases in this example. Increasing inductance increases the time required to reach full current.

Zero resistance would prevent the circuit from ever achieving full current. All practical inductors have some resistance in the wire

making up the inductor.

An inductor cannot be discharged in the simple circuit of Figure 2.32 because the magnetic field ceases to exist or “collapses” as soon as the current ceases. Opening S1 does not leave the inductor charged in the way that a capacitor would remain charged. Energy storage in a capacitor depends on the separated charges staying in place. Energy storage in an inductor depends on the charges continuing to move as current.

The energy stored in the inductor’s magnetic field attempts to return instantly to the circuit when S1 is opened. The rapidly changing (collapsing) field in the inductor causes a very large voltage to be induced across the inductor. Because the change in current is now in the opposite direction, the induced voltage also reverses polarity. This induced voltage (called *inductive kick-back*) is usually many times larger than the originally applied voltage, because the induced voltage is proportional to the rate at which the field changes.

The common result of opening the switch in such a circuit is that a spark or arc forms at the switch contacts during the instant the switch opens. When the inductance is large and the current in the circuit is high, large amounts of energy are released in a very short time. It is not at all unusual for the switch contacts to burn or melt under such circumstances.

The spark or arc at the opened switch can be reduced or suppressed by connecting a suitable capacitor and resistor in series across the contacts to absorb the energy non-destructively. Such an RC combination is called a *snubber network*. The current rating for a switch may be significantly reduced if it is used in an inductive circuit.

Transistor switches connected to and controlling inductors, such as relays and solenoids, also require protection from the high kick-back voltages. In most cases, a small power diode connected across the relay coil so that it does not conduct current when the inductor is energized (called a *kick-back diode*) will protect the transistor.

If the excitation is removed without break-

**Figure 2.33 — Time constant of an RL circuit being de-energized. This is a theoretical model only, since a mechanical switch cannot change state instantaneously.**

ing the circuit, as shown in Figure 2.33, the current will decay according to the formula:

$$I(t) = \frac{E}{R} \left( e^{-\frac{tR}{L}} \right)$$

where  $t$  = time in seconds after removal of the source voltage.

After one time constant the current will decay by 63.2% of its steady-state value. (It will decay to 36.8% of the steady-state value.) The graph in Figure 2.33 shows the current-decay waveform to be identical to the voltage-discharge waveform of a capacitor. Be careful about applying the terms *charge* and *discharge* to an inductive circuit, however. These terms refer to energy storage in an electric field. An inductor stores energy in a magnetic field and the usual method of referring to the process is *energize* and *de-energize* (although it is not always followed).

## 2.8 Semiconductor Devices

### 2.8.1 Introduction to Semiconductors

In a conductor, such as a metal, some of the outer, or *valence*, electrons of each atom are free to move about between atoms. These *free electrons* are the constituents of electrical current. In a good conductor, the concentration of these free electrons is very high, on the order of  $10^{22}$  electrons/cm<sup>3</sup>. In an insulator, nearly all the electrons are tightly held by their atoms and the concentration of free electrons is very small — on the order of 10 electrons/cm<sup>3</sup>.

Between the classes of materials considered to be conductors and insulators is a class of elements called *semiconductors*, materials with conductivity much poorer than metals and much better than insulators. (In electronics, “semiconductor” means a device made from semiconductor elements that have been chemically manipulated as described below, leading to interesting properties that create useful applications.)

Semiconductor atoms (silicon, Si, is the most widely used) share their valence electrons in a chemical bond that holds adjacent atoms together, forming a three-dimensional *lattice* that gives the material its physical characteristics. A lattice of pure semiconductor material (one type of atom or molecule) can form a crystal, in which the lattice structure and orientation is preserved throughout the material. *Monocrystalline* or “single-crystal” is the type of material used in electronic semiconductor devices. *Polycrystalline* material is made of up many smaller crystals with their own individual lattice orientations.

Crystals of pure semiconductor material are called *intrinsic* semiconductors. When energy, generally in the form of heat, is added to a semiconductor crystal lattice, some electrons are liberated from their bonds and move freely throughout the lattice. The bond that loses an electron is then unbalanced and the space that the electron came from is referred to as a *hole*. In these materials the number of free electrons is equal to the number of holes.

Electrons from adjacent bonds can leave their positions to fill the holes, thus leaving behind a hole in their old location. As a consequence of the electron moving, two opposite movements can be said to occur: negatively charged electrons move from bond to bond in one direction and positively charged holes move from bond to bond in the opposite direction. Both of these movements represent forms of electrical current, but this is very different from the current in a conductor. While a conductor has free electrons that flow

independently from the bonds of the crystalline lattice, the current in a pure semiconductor is constrained to move from bond to bond.

Impurities can be added to intrinsic semiconductors (by a process called *doping*) to enhance the formation of electrons or holes and thus improve conductivity. These materials are *extrinsic* semiconductors. Since the additional electrons and holes can move, their movement is current and they are called *carriers*. The type of carrier that predominates in the material is called the *majority carrier*. In N-type material the majority carriers are electrons and in P-type material, holes.

There are two types of impurities that can be added: a *donor impurity* with five valence electrons donates free electrons to the crystalline structure; this is called an *N-type impurity*, for the negative charge of the majority carriers. Some examples of donor impurities are antimony (Sb), phosphorus (P) and arsenic (As). N-type extrinsic semiconductors have more electrons and fewer holes than intrinsic semiconductors. *Acceptor impurities* with three valence electrons accept free electrons from the lattice, adding holes to the overall structure. These are called P-type impurities, for the positive charge of the majority carriers; some examples are boron (B), gallium (Ga) and indium (In).

It is important to note that even though N-type and P-type material have different numbers of holes and free electrons than intrinsic material, they are still electrically neutral. When an electron leaves an atom, the positively-charged atom that remains in place in the crystal lattice electrically balances the roaming free electron. Similarly, an atom gaining an electron acquires a negative charge that balances the positively-charged atom it left. At no time does the material acquire a net electrical charge, positive or negative.

*Compound semiconductor* material can be formed by combining equal amounts of N-type and P-type impurity materials. Some examples of this include gallium-arsenide (GaAs), gallium-phosphate (GaP) and indium-phosphide (InP). To make an N-type compound semiconductor, a slightly higher amount of N-type material is used in the mixture. A P-type compound semiconductor has a little more P-type material in the mixture.

Impurities are introduced into intrinsic semiconductors by diffusion, the same physical process that lets you smell cookies baking from several rooms away. (Molecules diffuse through air much faster than through solids.) Rates of diffusion are proportional to temperature, so semiconductors are doped with impurities at high temperature to save time. Once the doped semiconductor material

is cooled, the rate of diffusion of the impurities is so low that they are essentially immobile for many years to come. If an electronic device made from a structure of N- and P-type materials is raised to a high temperature, such as by excessive current, the impurities can again migrate and the internal structure of the device may be destroyed. The maximum operating temperature for semiconductor devices is specified at a level low enough to limit additional impurity diffusion.

The conductivity of an extrinsic semiconductor depends on the charge density (in other words, the concentration of free electrons in N-type, and holes in P-type, semiconductor material). As the energy in the semiconductor increases, the charge density also increases. This is the basis of how all semiconductor devices operate: the major difference is the way in which the energy level is increased. Variations include: The *transistor*, where conductivity is altered by injecting current into the device via a wire; the *thermistor*, where the level of heat in the device is detected by its conductivity, and the *photoconductor*, where light energy that is absorbed by the semiconductor material increases the conductivity.

### 2.8.2 The PN Semiconductor Junction

If a piece of N-type semiconductor material is placed against a piece of P-type semiconductor material, the location at which they join is called a *PN junction*. The junction has characteristics that make it possible to develop diodes and transistors. The action of the junction is best described by a diode operating as a rectifier.

Initially, when the two types of semiconductor material are placed in contact, each type of material will have only its majority carriers: P-type will have only holes and N-type will have only free electrons. The presence of the positive charges (holes) in the P-type material attracts free electrons from the N-type material immediately across the junction. The opposite is true in the N-type material.

These attractions lead to diffusion of some of the majority carriers across the junction, which combine with and neutralize the majority carriers immediately on the other side (a process called *recombination*). As distance from the junction increases, the attraction quickly becomes too small to cause the carriers to move. The region close to the junction is then *depleted* of carriers, and so is named the *depletion region* (also the *space-charge region* or the *transition region*). The

width of the depletion region is very small, on the order of 0.5  $\mu\text{m}$ .

If the N-type material (the *cathode*) is placed at a more negative voltage than the P-type material (the *anode*), current will pass through the junction because electrons are attracted from the lower potential to the higher potential and holes are attracted in the opposite direction. This *forward bias* forces the majority carriers toward the junction where recombination occurs with the opposite type of majority carrier. The source of voltage supplies replacement electrons to the N-type material and removes electrons from the P-type material so that the majority carriers are continually replenished. Thus, the net effect is a *forward current* flowing through the semiconductor, across the PN junction. The *forward resistance* of a diode conducting current is typically very low and varies with the amount of forward current.

When the polarity is reversed, majority-carriers are attracted away from the junction, not toward it. Very little current flows across the PN junction — called *reverse leakage current* — in this case. Allowing only unidirectional current flow is what allows a semiconductor diode to act as rectifier.

### 2.8.3 Junction Semiconductors

Semiconductor devices that operate using the principles of a PN junction are called *junction semiconductors*. These devices can have one or several junctions. The properties of junction semiconductors can be tightly controlled by the characteristics of the materials used and the size and shape of the junctions.

#### SEMICONDUCTOR DIODES

Diodes are commonly made of silicon and occasionally germanium. Although they act similarly, they have slightly different characteristics. The *junction threshold voltage*, or *junction barrier voltage*, is the forward bias voltage ( $V_F$ ) at which current begins to pass through the device. This voltage is different for the two kinds of diodes. In the diode response curve of **Figure 2.34**,  $V_F$  corresponds to the voltage at which the positive portion of the curve begins to rise sharply from the x-axis. Most silicon diodes have a junction threshold voltage of about 0.7 V, while the voltage for germanium diodes is typically 0.3 V. Reverse leakage current is much lower for silicon diodes than for germanium diodes.

The characteristic curve for a semiconductor diode junction is given by the following equation (slightly simplified) called the *Fundamental Diode Equation* because it describes the behavior of all semiconductor PN junctions.

$$I = I_S \left( e^{\frac{V}{\eta V_t}} - 1 \right)$$

where

$I$  = diode current

$V$  = diode voltage

$I_S$  = reverse-bias saturation current

$V_t = kT/q$ , the thermal equivalent of voltage (about 25 mV at room temperature)

$\eta$  = emission coefficient.

The value of  $I_S$  varies with the type of semiconductor material, with the value of  $10^{-12}$  used for silicon.  $\eta$  also varies from 1 to 2 with the type of material and method of fabrication. ( $\eta$  is close to 1 for silicon at normal current values, increasing to 2 at high currents.) This curve is shown in **Figure 2.35B**.

The obvious differences between **Figure**

**Figure 2.34 — Semiconductor diode (PN junction) characteristic curve. (A) Forward-biased (anode voltage higher than cathode) response for Germanium (Ge) and Silicon (Si) devices. Each curve breaks away from the X-axis at its junction threshold voltage. The slope of each curve is its forward resistance. (B) Reverse-biased response. Very small reverse current increases until it reaches the reverse saturation current ( $I_0$ ). The reverse current increases suddenly and drastically when the reverse voltage reaches the reverse breakdown voltage,  $V_{BR}$ .**

2.35A and B are that the semiconductor diode has a finite *turn-on voltage* — it requires a small but nonzero forward bias voltage before it begins conducting. Furthermore, once conducting, the diode voltage continues to increase very slowly with increasing current, unlike a true short circuit. Finally, when the applied voltage is negative, the reverse current is not exactly zero but very small (microamperes). The reverse current flow rapidly reaches a level that varies little with the reverse bias voltage. This is the *reverse-bias saturation current*,  $I_S$ .

For bias (dc) circuit calculations, a useful model for the diode that takes these two effects into account is shown by the artificial I-V curve in **Figure 2.35C**. This model neglects the negligible reverse bias current  $I_S$ .

When converted into an equivalent circuit, the model in **Figure 2.35C** yields the circuit in **Figure 2.35D**. The ideal voltage source  $V_a$  represents the turn-on voltage and  $R_f$  represents the effective resistance caused by the small increase in diode voltage as the diode current increases. The turn-on voltage is material-dependent: approximately 0.3 V for germanium diodes and 0.7 for silicon.  $R_f$  is typically on the order of 10  $\Omega$ , but it can vary according to the specific component.  $R_f$  can often be completely neglected in comparison to the other resistances in the circuit. This very common simplification leaves only a pure *voltage drop* for the diode model.

**Figure 2.35 — Circuit models for rectifying switches (diodes). A: I-V curve of the ideal rectifier. B: I-V curve of a typical semiconductor diode showing the typical small leakage current in the reverse direction. Note the different scales for forward and reverse current. C shows a simplified diode I-V curve for dc-circuit calculations (at a much larger scale than B). D is an equivalent circuit for C.**

## BIPOLAR TRANSISTOR

A bipolar transistor is formed when two PN junctions are placed next to each other. If N-type material is surrounded by P-type material, the result is a PNP transistor. Alternatively, if P-type material is in the middle of two layers of N-type material, the NPN transistor is formed (Figure 2.36).

Physically, we can think of the transistor as two PN junctions back-to-back, such as two diodes connected at their *anodes* (the positive terminal) for an NPN transistor or two diodes connected at their *cathodes* (the negative terminal) for a PNP transistor. The connection point is the base of the transistor. (You can't actually make a transistor this way — this is a representation for illustration only.)

A transistor conducts when the base-emitter junction is forward biased and the base-collector is reverse biased. Under these conditions, the emitter region emits majority carriers into the base region, where they become minority carriers because the materials of the emitter and base regions have opposite polarity. The excess minority carriers in the base are then attracted across the very thin base to the base-collector junction, where they are collected and are once again considered majority carriers before they can flow to the base terminal.

The flow of majority carriers from emitter to collector can be modified by the application

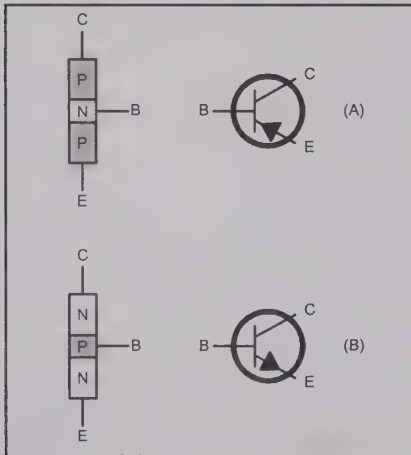

Figure 2.36 — Bipolar transistors. (A) A layer of N-type semiconductor sandwiched between two layers of P-type semiconductor makes a PNP device. The schematic symbol has three leads: collector (C), base (B) and emitter (E), with the arrow pointing in toward the base. (B) A layer of P-type semiconductor sandwiched between two layers of N-type semiconductor makes an NPN device. The schematic symbol has three leads: collector (C), base (B) and emitter (E), with the arrow pointing out away from the base.

of a bias current to the base terminal. If the bias current causes majority carriers to be injected into the base material (electrons flowing into an N-type base or out of a P-type base) the emitter-collector current increases. In this way, a transistor allows a small base current to control a much larger collector current.

As in a semiconductor diode, the forward biased base-emitter junction has a threshold voltage ( $V_{BE}$ ) that must be exceeded before the emitter current increases. As the base-emitter current continues to increase, the point is reached at which further increases in base-emitter current cause no additional change in collector current. This is the condition of *saturation*. Conversely, when base-emitter current is reduced to the point at which collector current ceases to flow, that is the situation of *cutoff*.

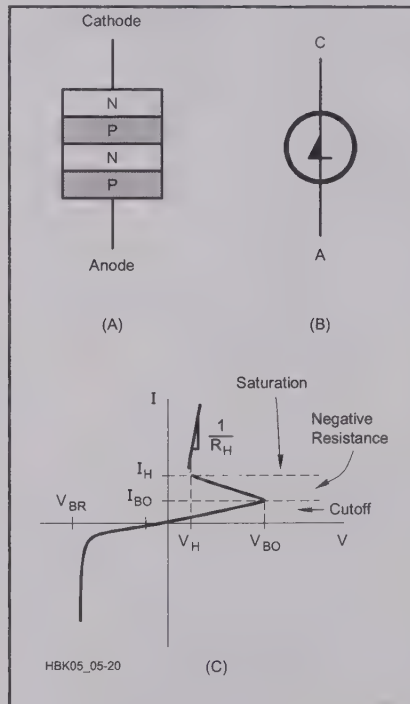

Figure 2.37 — PNP diode. (A) Alternating layers of P-type and N-type semiconductor. (B) Schematic symbol with cathode (C) and anode (A) leads. (C) I-V curve. Reverse-biased response is the same as normal PN junction diodes. Forward biased response acts as a hysteresis switch. Resistance is very high until the bias voltage reaches  $V_{BO}$  (where the center junction breaks over) and exceeds the cutoff current,  $I_{BO}$ . The device exhibits a negative resistance when the current increases as the bias voltage decreases until a voltage of  $V_H$  and saturation current of  $I_H$  is reached. After this, the resistance is very low, with large increases in current for small voltage increases.

## THYRISTORS

Thyristors are semiconductors made with four or more alternating layers of P- and N-type semiconductor material. In a four-layer thyristor, when the anode is at a high potential than the cathode, the first and the third junctions are forward biased and the center junction reverse biased. In this state, there is little current, just as in the reverse-biased diode. The different types of thyristor have different ways in which they turn on, conduct current and in how they turn off or interrupt current flow.

### PNPN Diode

The simplest thyristor is a PNPN (usually pronounced like *pinpin*) diode with three junctions (see Figure 2.37). As the forward bias voltage is increased, the current through the device increases slowly until the *breakover* (or *firing*) voltage,  $V_{BO}$ , is reached and the flow of current abruptly increases. The PNPN diode is often considered to be a switch that is off below  $V_{BO}$  and on above it.

### Bilateral Diode Switch (Diac)

A semiconductor device similar to two

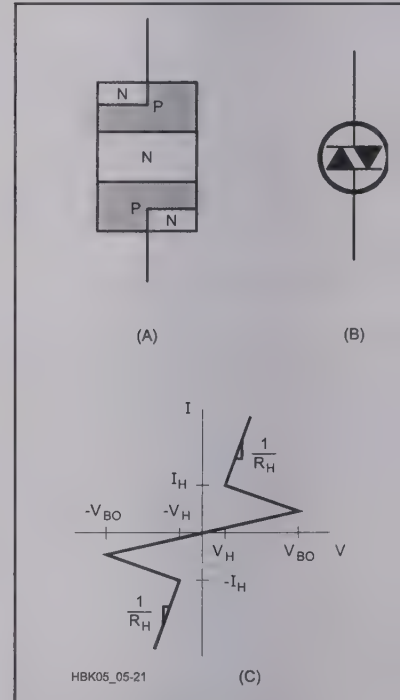

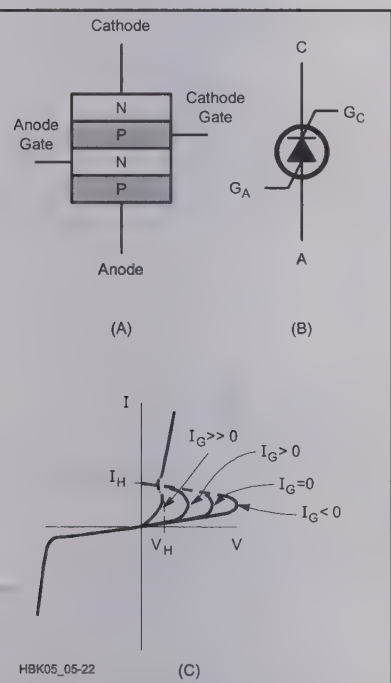

Figure 2.38 — Bilateral diode switch. (A) Alternating layers of P-type and N-type semiconductor. (B) Schematic symbol. (C) I-V curve. The right-hand side of the curve is identical to the PNP diode response in Figure 2.37. The device responds identically for both forward and reverse bias so the left-hand side of the curve is symmetrical with the right-hand side.

PNP diodes facing in opposite directions and attached in parallel is the *bilateral diode switch* or *diac*. This device has the characteristic curve of the PNP diode for both positive and negative bias voltages. Its construction, schematic symbol and characteristic curve are shown in **Figure 2.38**.

### Silicon Controlled Rectifier (SCR)

Another device with four alternate layers of P-type and N-type semiconductor is the *silicon controlled rectifier (SCR)*. (Some sources refer to an SCR as a thyristor, as well.) In addition to the connections to the outer two layers, two other terminals can be brought out from the inner two layers. The connection to the P-type material near the cathode is called the *cathode gate* and the N-type material near the anode is called the *anode gate*. In nearly all commercially available SCRs, only the cathode gate is connected (**Figure 2.39**).

Like the PNP diode switch, the SCR is used to abruptly start conducting when the voltage exceeds a given level. By biasing the gate terminal appropriately, the breakover voltage can be adjusted.

**Figure 2.39** — SCR. (A) Alternating layers of P-type and N-type semiconductor. This is similar to a PNP diode with gate terminals attached to the interior layers. (B) Schematic symbol with anode (A), cathode (C), anode gate ( $G_A$ ) and cathode gate ( $G_C$ ). Many devices are constructed without  $G_A$ . (C) I-V curve with different responses for various gate currents.  $I_G = 0$  has a similar response to the PNP diode.

### Triac

A five-layered semiconductor whose operation is similar to a bidirectional SCR is the *triac* (**Figure 2.40**). This is also similar to a bidirectional diode switch with a bias control gate. The gate terminal of the triac can control both positive and negative breakover voltages and the devices can pass both polarities of voltage.

### Thyristor Applications

The SCR is highly efficient and is used in power control applications. SCRs are available that can handle currents of greater than 100 A and voltage differentials of greater than 1000 V, yet can be switched with gate currents of less than 50 mA. Because of their high current-handling capability, SCRs are used as “crowbars” in power supply circuits, to short the output to ground and blow a fuse when an overvoltage condition exists.

SCRs and triacs are often used to control

**Figure 2.40** — Triac. (A) Alternating layers of P-type and N-type semiconductor. This behaves as two SCR devices facing in opposite directions with the anode of one connected to the cathode of the other and the cathode gates connected together. (B) Schematic symbol.

**Figure 2.41** — Triac operation on sine wave. The dashed line is the original sine wave and the solid line is the portion that conducts through the triac. The relative delay and conduction period times are controlled by the amount or timing of gate current,  $I_G$ . The response of an SCR is the same as this for positive voltages (above the X-axis) and with no conduction for negative voltages.

ac power sources. A sine wave with a given RMS value can be switched on and off at preset points during the cycle to decrease the RMS voltage. When conduction is delayed until after the peak (as **Figure 2.41** shows) the peak-to-peak voltage is reduced. If conduction starts before the peak, the RMS voltage is reduced, but the peak-to-peak value remains the same. This method is used to operate light dimmers and 240 V ac to 120 V ac converters. The sharp switching transients created when these devices turn on are common sources of RF interference. (See the chapter on **RF Interference** for information on dealing with interference from thyristors.)

### 2.8.4 Field-Effect Transistors (FET)

The *field-effect transistor (FET)* controls the current between two points but does so differently than the bipolar transistor. The FET operates by the effects of an electric field on the flow of electrons through a single type of semiconductor material. This is why the FET is sometimes called a *unipolar* transistor. Unlike bipolar semiconductors that can be arranged in many configurations to provide diodes, transistors, photoelectric devices, temperature sensitive devices and so on, the field effect technique is usually only used to make transistors, although FETs are also available as special-purpose diodes, for use as constant current sources.

FET devices are constructed on a *substrate* of doped semiconductor material. The channel is formed within the substrate and has the opposite polarity (a P-channel FET has N-type substrate). Most FETs are constructed with silicon.

Within the FET, current moves in a *channel* as shown in **Figure 2.42**. The channel is made

**Figure 2.42** — JFET devices with terminals labeled: source (S), gate (G) and drain (D). (A) Pictorial of N-type channel embedded in P-type substrate and schematic symbol. (B) P-channel embedded in N-type substrate and schematic symbol.

of either N-type or P-type semiconductor material; an FET is specified as either an N-channel or P-channel device. Current flows from the *source* terminal (where majority carriers are injected) to the *drain* terminal (where majority carriers are removed). A *gate* terminal generates an electric field that controls the current in the channel.

In N-channel devices, the drain potential must be higher than that of the source ( $V_{DS} > 0$ ) for electrons (the majority carriers) to flow in channel. In P-channel devices, the flow of holes requires that  $V_{DS} < 0$ . The polarity of the electric field that controls current in the channel is determined by the majority carriers of the channel, ordinarily positive for P-channel FETs and negative for N-channel FETs.

Variations of FET technology are based on different ways of generating the electric field. In all of these, however, electrons at the gate are used only for their charge in order to create an electric field around the channel. There is a minimal flow of electrons through the gate. This leads to a very high dc input resistance in devices that use FETs for their input circuitry. There may be quite a bit of capacitance between the gate and the other FET terminals, however, causing the input impedance to be quite low at high frequencies.

The current through an FET only has to pass through a single type of semiconductor material. Depending on the type of material and the construction of the FET, drain-source resistance when the FET is conducting ( $r_{DS(ON)}$ ) may be anywhere from a few hundred ohms to much less than an ohm. The output impedance of devices made with FETs is generally quite low. If a gate bias voltage is added to operate the transistor near cutoff, the circuit output impedance may be much higher.

In order to achieve a higher gain-bandwidth product, other materials have been used. Gallium-arsenide (GaAs) has *electron mobility* and *drift velocity* (both are measures of how easily electrons are able to move through the crystal lattice) far higher than the standard doped silicon. Amplifiers designed with GaAsFET devices operate at much higher frequencies and with a lower noise factor at VHF and UHF than those made with silicon FETs (although silicon FETs have improved dramatically in recent years).

### JFET

One of two basic types of FET, the *junction FET (JFET)* gate material is made of the opposite polarity semiconductor to the channel material (for a P-channel FET the gate is made of N-type semiconductor material). The gate-channel junction is similar to a diode's PN junction with the gate material in direct contact with the channel. JFETs are

used with the junction reverse-biased, since any current in the gate is undesirable. The reverse bias of the junction creates an electric field that "pinches" the channel. Since the magnitude of the electric field is proportional to the reverse-bias voltage, the current in the channel is reduced for higher reverse gate bias voltages. When current in the channel is completely halted by the electric field, this is called *pinch-off* and it is analogous to cutoff in a bipolar transistor. The channel in a JFET is at its maximum conductivity when the gate and source voltages are equal ( $V_{GS} = 0$ ).

Because the gate-channel junction in a JFET is similar to a bipolar junction diode, this junction must never be forward biased; otherwise large currents will pass through the gate and into the channel. For an N-channel JFET, the gate must always be at a lower potential than the source ( $V_{GS} < 0$ ). The prohibited condition is for  $V_{GS} > 0$ . For P-channel JFETs these conditions are reversed (in normal operation  $V_{GS} > 0$  and the prohibited condition is for  $V_{GS} < 0$ ).

### MOSFET

Placing an insulating layer between the gate and the channel allows for a wider range of control (gate) voltages and further decreases the gate current (and thus increases the device input resistance). The insulator is typically made of an oxide (such as silicon dioxide,  $SiO_2$ ). This type of device is called a *metal-oxide-semiconductor FET (MOSFET)* or *insulated-gate FET (IGFET)*.

The substrate is often connected to the source internally. The insulated gate is on the opposite side of the channel from the substrate (see **Figure 2.43**). The bias voltage on the gate terminal either attracts or repels the majority carriers of the substrate across its PN-junction with the channel. This narrows (*depletes*) or widens (*enhances*) the channel respectively, as  $V_{GS}$  changes polarity. For example, in the N-channel enhancement-mode MOSFET, positive gate voltages with respect to the substrate and the source ( $V_{GS} > 0$ ) repel holes from the channel into the substrate, thereby widening the channel and

**Figure 2.43** — MOSFET devices with terminals labeled: source (S), gate (G) and drain (D). N-channel devices are pictured. P-channel devices have the arrows reversed in the schematic symbols and the opposite type semiconductor material for each of the layers. (A) N-channel depletion mode device schematic symbol and (B) pictorial of P-type substrate, diffused N-type channel,  $SiO_2$  insulating layer and aluminum gate region and source and drain connections. The substrate is connected to the source internally. A negative gate potential narrows the channel. (C) N-channel enhancement mode device schematic and (D) pictorial of P-type substrate, N-type source and drain wells,  $SiO_2$  insulating layer and aluminum gate region and source and drain connections. Positive gate potential forms a channel between the two N-type wells by repelling the P-carriers away from the channel region in the substrate.

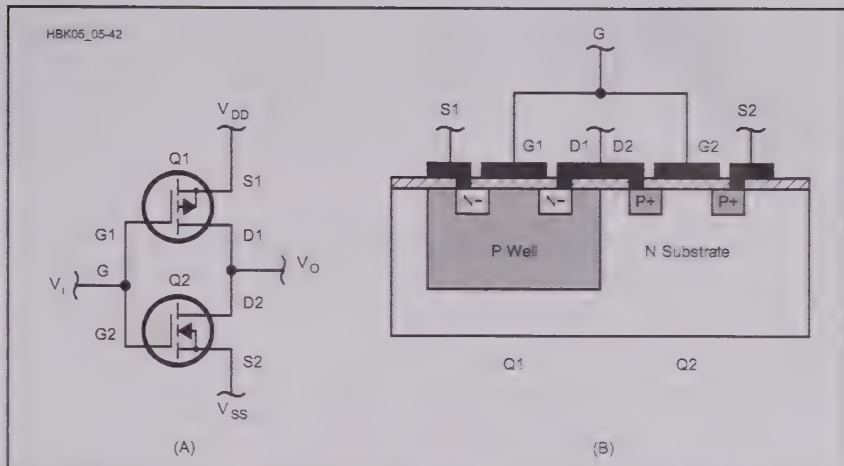

decreasing channel resistance. Conversely,  $V_{GS} < 0$  causes holes to be attracted from the substrate, narrowing the channel and increasing the channel resistance. Once again, the polarities discussed in this example are reversed for P-channel devices. The common abbreviation for an N-channel MOSFET is *NMOS*, and for a P-channel MOSFET, *PMOS*.

Because of the insulating layer next to the gate, input resistance of a MOSFET is usually greater than  $10^{12} \Omega$  (a million megohms). Since MOSFETs can both deplete the channel, like the JFET, and also enhance it, the construction of MOSFET devices differs based on the channel size in the quiescent state,  $V_{GS} = 0$ .

A *depletion mode device* (also called a *normally-on MOSFET*) has a channel in the quiescent state that gets smaller as a reverse bias is applied; this device conducts current with no bias applied (see Figure 2.43A and B). An *enhancement mode device* (also called a *normally-off MOSFET*) is built without a channel and does not conduct current when  $V_{GS} = 0$ ; increasing forward bias forms a temporary channel that conducts current (see Figure 2.43C and D).

## Complementary Metal Oxide Semiconductors (CMOS)

Power dissipation in a circuit can be reduced to very small levels (on the order of a few nanowatts) by using MOSFET devices in complementary pairs (CMOS). Each amplifier is constructed of a series circuit of MOSFET devices, as in Figure 2.44. The gates are tied together for the input signal, as are the drains

**Figure 2.44 — Complementary metal oxide semiconductor (CMOS).** (A) CMOS device is made from a pair of enhancement mode MOS transistors. The upper is a P-channel device, and the lower is an N-channel device. When one transistor is biased on, the other is biased off; therefore, there is minimal current from  $V_{DD}$  to ground. (B) Implementation of a CMOS pair as an integrated circuit.

for the output signal. In saturation and cutoff, only one of the devices conducts. The current drawn by the circuit under no load is equal to the OFF leakage current of either device and the voltage drop across the pair is equal to  $V_{DD}$ , so the steady-state power used by the circuit is always equal to  $V_{DD} \times I_{D(OFF)}$ . Power is only consumed during the switching process, so for ac signals, power consumption is proportional to frequency.

CMOS circuitry could be built with

discrete components, but the number of extra parts and the need for the complementary components to be matched has made that an unusual design technique. The low power consumption and ease of fabrication has made CMOS the most common of all IC technologies. Although CMOS is most commonly used in digital integrated circuitry, its low power consumption has also been put to work by manufacturers of analog ICs, as well as digital ICs.

# Radio Fundamentals

Radio begins with an understanding of alternating current waveforms and how they are measured. This chapter also examines the relationship between ac voltage and current in energy-storing components like capacitors and inductors that defines reactance and impedance. We can then explore quality factor (Q) and the properties of resonant circuits.

Analog system concepts are introduced to explain the concepts and techniques of working with electronic circuits in radio. Finally, we discuss electromagnetic waves that carry information between stations.

As for the previous chapter, additional mathematics resources are available in the article “Radio Mathematics” in this book’s downloadable supplemental information.

## 3.1 AC Waveforms

A *waveform* is the pattern of *amplitudes* reached by voltage or current measured over time, including combinations of ac and dc voltage and current. For example, **Figure 3.1** shows two ac waveforms fairly close in frequency and their combination. **Figure 3.2** shows two ac waveforms dissimilar in both frequency and wavelength, along with the resultant combined waveform.

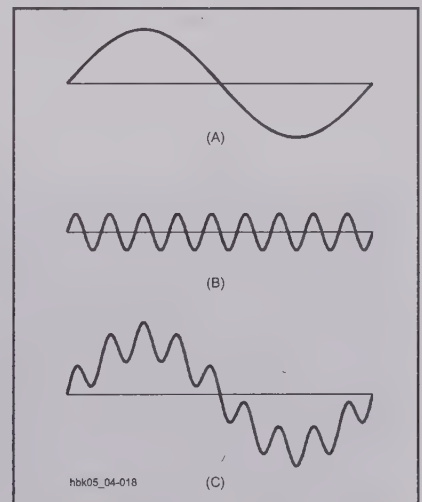

### 3.1.1 Sine Waves and Rotation

Not only is a sine wave the most fundamental ac waveform — energy at a single frequency — it also describes rotation. The cyclical nature of the sine wave is at the heart of much of radio technology, whether analog or digital. A good grasp of the sine wave and the closely related cosine wave are key to understanding the techniques that make up radio. (Sine and cosine functions as well as vectors and phasors are discussed in the “Radio Mathematics” article in this book’s downloadable supplemental information.)

**Figure 3.3** illustrates the relationship. Imagine a rotating wheel with a visible dot at a point anywhere along the circumference (rim) of the wheel. If you spin the wheel at a constant rate and watch the wheel on-edge as in **Figure 3.3A**, the dot will just move up and down. If

**Figure 3.1** — Two ac waveforms of similar frequencies ( $f_1 = 1.5 f_2$ ) with amplitudes added together to form a composite wave. Note the points where the positive peaks of the two waves combine to create high composite peaks at a frequency that is the difference between  $f_1$  and  $f_2$ . The beat note frequency is  $1.5f - f = 0.5f$  and is visible in the drawing.

**Figure 3.2** — Two ac waveforms of widely different frequencies and amplitudes form a composite wave in which one wave appears to ride upon the other.

**Figure 3.3** — This diagram illustrates the relationship between a sine wave and circular rotation. You can see how various points on the circle correspond to values on the sine wave.

**Figure 3.4** — An ac cycle is divided into 360 degrees that are used as a measure of time or phase.

we designate the height at point C as +1 and at point G as -1, then make a table of values as the wheel rotates through 360°, the height values will correspond exactly to the values of the sine function (*sin*). When the wheel is at 0° in position A,  $\sin(0^\circ) = 0$ ; when at 90° in position C,  $\sin(90^\circ) = 1$ , and so forth all the way around.

Now look at the wheel from the side as in Figure 3.3B. Plotting the dot's height around its circular path against degrees on the horizontal axis will then trace out a sine wave as in Figure 3.3C. Each rotation of the wheel corresponds to one *cycle* of the sine wave. The amplitude (A) of the sine wave is equal to the sine of the wheel's *angular position* in degrees ( $\theta$ ):

$$A = \sin(\theta)$$

**Figure 3.4** shows how each cycle of a sine wave is divided into 360° to measure angular position.

### 3.1.2 Frequency, Period, and Harmonics

With a continuously rotating generator, alternating current or voltage will pass through many equal cycles over time. This is a *periodic waveform*, composed of repeated identical cycles. An arbitrary point on any one cycle can be used as a marker of position on a periodic waveform. For this discussion, the positive peak of the waveform will work

as an unambiguous marker. The number of times per second that the current (or voltage) reaches this positive peak in any one second is called the *frequency* of the waveform. In other words, frequency expresses the *rate* at which current (or voltage) cycles occur. The unit of frequency is *cycles per second*, or *hertz*—abbreviated Hz (after Heinrich Hertz, the 19th century physicist who demonstrated the existence of radio waves).

If the sine wave has a constant frequency, every complete cycle takes the same amount of time, the *period*, T, as in **Figure 3.5**. The signal's period is the reciprocal of its frequency:

$$\text{Frequency (f) in Hz} = \frac{1}{\text{Period (T) in seconds}}$$

and

$$\text{Period (T) in seconds} = \frac{1}{\text{Frequency (f) in Hz}}$$

Example: What is the period of 60 Hz ac current?

$$T = \frac{1}{f} = \frac{1}{60 \text{ Hz}} = 0.01666 \text{ s} = 16.6 \text{ ms}$$

To calculate the amplitude, A, of the sine wave at any point in time, t, we need to be able to convert time to the angle,  $\theta$ :

$$\theta = 360 \frac{t}{T}$$

The sine wave equation is now:

$$\begin{aligned} A &= \sin\left(360 \frac{t}{T}\right) = \sin\left(360 \times \frac{1}{T} \times t\right) \\ &= \sin(360 \times f \times t) \end{aligned}$$

### HARMONICS

A *harmonic* is a signal with a frequency that is some integer multiple (2, 3, 4 and so on) of a signal at a *fundamental frequency*. **Figure 3.5** shows a simple example of harmonics. The harmonic at twice the fundamental's frequency is called the *second harmonic*, at three times the fundamental frequency the *third harmonic*, and so forth. There is no "first harmonic." For example, if a complex waveform is made up of sine waves with frequencies of 10, 20, and 30 kHz, 10 kHz is the fundamental and the other two are harmonics. Signals at the frequency of harmonics are said to be *harmonically related* to the fundamental.

### 3.1.3 Phase

Now let's make the connection between angular position and time. Although time is measurable in parts of a second, it is more convenient to treat each cycle as a complete time unit divided into 360°. The conventional starting point for phase in a sinusoidal wave-

## Degrees, Radians, and Angular Frequency

While most electronic and radio mathematics use degrees as a measure of phase, you will occasionally encounter radians. Radians are used because they are more convenient mathematically in certain types of equations and computations. There are  $2\pi$  radians in a circle, just as there are 360°, so one radian =  $360/2\pi \approx 57.3^\circ$ . In this book, unless it is specifically noted otherwise, the convention will be to use degrees in all calculations of phase or angle.

In engineering textbooks and other electronic references, you will often encounter the symbol  $\omega$  used to represent angular frequency. The sine wave equation would then be written:

$$A = \sin(2\omega t) = \sin(\omega t)$$

where  $\omega = 2\pi f$ . The use of angular frequency is more straightforward in many types of engineering calculations. Radians are used for angular position when angular frequency ( $\omega$ ) is being used.

**Figure 3.5** — The frequency of a signal and its period are reciprocals. A higher frequency means a shorter period and vice versa. Harmonics are signals with frequencies that are integer multiples of a fundamental frequency.

form is the *zero point* at which the positive *half cycle* begins as shown in Figure 3.4.

The advantage of treating the ac cycle in this way is that many calculations and measurements can be taken and recorded in a manner that is independent of frequency. The positive peak voltage or current occurs at 90° into the cycle. Relative to the starting point, 90° is the *phase* of the ac at that point. Phase is the position within an ac cycle expressed in degrees or *radians*. Thus, a complete description of an ac voltage or current involves reference to three properties: frequency, amplitude, and phase.

Each degree of phase represents the same amount of time. For example, a sine wave with a frequency of four cycles per second has a period  $T = 0.25$  second and each degree of phase is equivalent to  $T/360 = 0.25 / 360 = 0.00069$  second.

Phase relationships also permit the comparison of two ac voltages or currents at the same frequency. If the zero point of two signals with the frequency occur at the same time, there is zero phase difference between the signals and they are said to be *in phase*.

**Figure 3.6** illustrates two waveforms with a constant phase difference. Since B crosses the zero point in the positive direction after A has already done so, there is a *phase differ-*

*ence* between the two waves. In the example, B *lags* A by 45°, or A *leads* B by 45°. If A and B occur in the same circuit, their composite waveform will also be a sine wave at an intermediate phase angle relative to each. Adding any number of sine waves of the same frequency always results in a sine wave at that frequency. Adding sine waves of different frequencies, as in Figure 3.1, creates a complex waveform with a *beat frequency* that is the difference between the two sine waves.

Figure 3.6 might equally apply to a voltage and a current measured in the same ac circuit. Either A or B might represent the voltage; that is, in some instances voltage will lead the cur-

## Phase versus Polarity

It is important to distinguish between polarity and phase. Polarity is the assigned conventions or directions for positive and negative voltage or current. Phase is a function of time or position in a waveform. It is quite possible for two signals to have opposite polarities, but still be in phase, for example. In a multi-phase ac power system, “phase” refers to one of the distinct voltage waveforms generated by the utility.

**Figure 3.6** — When two waves of the same frequency start their cycles at slightly different times, the time difference or phase difference is measured in degrees. In this drawing, wave B starts 45° (one-eighth cycle) later than wave A, and so lags 45° behind A.

rent and in others voltage will lag the current.

Two important special cases appear in **Figure 3.7**. In Part A, line B lags 90° behind line A. Its cycle begins exactly one quarter cycle later than the A cycle. When one wave is passing through zero, the other just reaches its maximum value. In this example, the two sine waves are said to be *in quadrature*. If waveform B is a sine wave, waveform A is a *cosine wave*, leading waveform B by 90°. Quadrature signals form the basis of I/Q modulation, as is described in the **Modulation** chapter. (I and Q stand for In-Phase and Quadrature.)

In Part B, lines A and B are 180° *out of phase*, sometimes called *anti-phase*. In this

## Vectors and Phasors

In Figure 3.3B, the arrow drawn from the center of the wheel to point A is a *vector* which has both an amplitude (its length) and direction (its angular position). The amplitude of the vector is equal to its length, which we arbitrarily decided would be 1 when constructing the table of sine values. Since the vector is pointing exactly along the horizontal axis, its direction is 0°. Thus, the vector is described as “1 at an angle of 0°” or “1 with a phase of 0°.” In the *phasor notation* commonly used in radio, this is written  $1\angle 0^\circ$ . The rotation of the wheel and the repeated cycles of the sine wave can also be described by a vector that is rotating (spinning around like the hand of a clock) at the frequency of the sine wave. You can find more information about vectors and phasors in the ARRL’s “Radio Mathematics” article in the downloadable supplemental information for this book.

**Figure 3.7** — Two important special cases of phase difference: In the upper drawing, the phase difference between A and B is  $90^\circ$ ; in the lower drawing, the phase difference is  $180^\circ$ .

case, it does not matter which one is considered to lead or lag. Line B is always positive while line A is negative, and vice versa. If the two waveforms are of two voltages or two currents in the same circuit and if they have the same amplitude, they will cancel each other completely.

### 3.1.4 Time and Frequency Domain

To this point in the chapter, our discussions and illustrations have been in the *time domain* in which some characteristic of the signal (usually amplitude) is presented in relation to time. On a graph, this means the horizontal axis represents time. Events to the right take place later; events to the left occur earlier. For pure sinusoids (sine waves), this is enough to describe the signal.

For a complex signal with more than one sine wave, the time domain is insufficient to describe the necessary frequency and time information. The *frequency domain* is better for showing the characteristics of these signals as shown in **Figure 3.8**. A sine signal is shown as a vertical line, with the height of the line showing the signal's amplitude. Note that a sine wave signal occupies a single frequency.

To better understand the relationship between the time and frequency domains, refer to **Figure 3.9**. In **Figure 3.9A**, the three-dimensional coordinates show time (as the line sloping toward the bottom right); frequency (as the line sloping toward the top

**Figure 3.8** — A frequency domain or spectrum graph shows a sine wave as a single vertical line. The horizontal axis represents frequency and the vertical axis represents amplitude. The height of the line representing the sine wave shows its amplitude.

right); and amplitude (as the vertical axis). The two frequencies shown are harmonically related ( $f_1$  and  $2f_1$ ). The time domain is represented in **Figure 3.9B**, in which all frequency components are added together. If the two frequencies were applied to the input of an oscilloscope, we would see the bold line that represents the amplitudes of the signals added together. The frequency domain contains information not found in the time domain, and vice versa.

The display shown in **Figure 3.9C** is typical of a spectrum analyzer's display of a complex waveform. (The spectrum analyzer is described in the **Test Equipment and Measurements** chapter.) In the figure the signal is separated into its individual frequency components, and a measurement made of the amplitude of each signal component. A signal's amplitude can be represented on the vertical scale as its voltage or as its power. You can see that using the frequency domain gives more information about the composition of the signal.

### 3.1.5 Complex Waveforms

A signal composed of more than one sine wave is called a *complex waveform*. A simple example of a complex waveform is the signaling waveform used by telephones when dialing. This waveform is composed of two different sine wave tones, thus the name "dual-tone multi-frequency" or DTMF for that signaling system. Listen carefully next time you dial and you will hear the two tones of different frequencies.

There are certain well-known and common complex waveforms that are made up of a sine wave and its harmonics. These are termed *regular* waveforms because the harmonic relationship of all the sine waves results in a waveform with a single overall frequency

**Figure 3.9** — This diagram shows how a complex waveform may be displayed in either the time domain or frequency domain. Part A is a three-dimensional display of amplitude, time, and frequency. At B, this information is shown in the time domain as on an oscilloscope. At C, the signal's frequency domain information

and period. A waveform that is made of sine waves that are not harmonically related, such as human speech, is an *irregular* waveform. Whether regular or irregular, the sine waves that make up a complex waveform are called its *components*. (Analysis of complex signals in terms of its individual components is addressed in the **DSP and SDR Fundamentals** chapter.)

It is common for complex ac signals to contain a fundamental signal and a series of harmonics. Which harmonics are combined with the fundamental and the relative amplitude of each determine the final shape of the waveform as you will see in the following two sections. The set of all components that make up a signal is called the signal's *spectrum*. (More than one spectrum is *spectra*.)

### SAWTOOTH WAVES

A *sawtooth* waveform, as shown in **Figure 3.10**, has a significantly faster *rise time* (the time it takes for the wave to reach a maximum value) compared to its *fall time* (the time it takes for the wave to reach a minimum value). A sawtooth wave is made up of a sine wave at its fundamental frequency and all of its harmonics. The sawtooth's spectrum is shown in **Figure 3.10**. The *ramp* waveform is similar to the sawtooth but slowly rises (the ramp) then has a fast fall, the opposite of the sawtooth.

Figure 3.10 — The sawtooth waveform is made up of sine waves at the fundamental frequency and all of its harmonics. The amplitude of the harmonics decreases as their frequency increases.

Both the sawtooth and ramp waveforms are useful in timing circuits.

**SQUARE WAVES**

A square wave is one that abruptly changes back and forth between two voltage levels and remains an equal time at each level as in Figure 3.11. (If the wave spends an unequal time at each level, it is known as a *rectangular wave*.) A square wave is made up of sine waves at the fundamental and all the *odd* harmonic frequencies as shown in Figure 3.11.

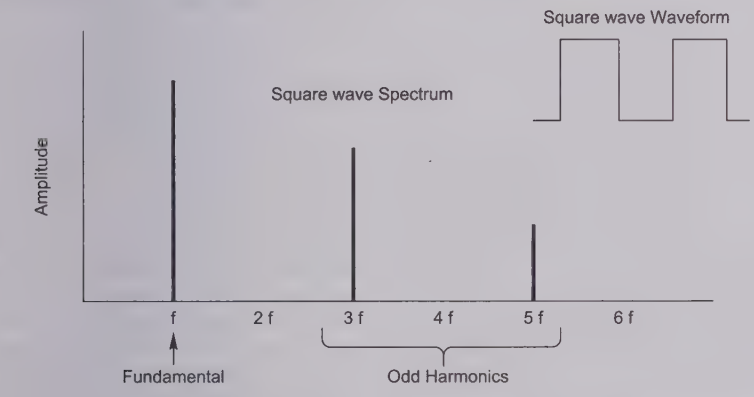

Figure 3.11 — The square wave is made up of sine waves at the fundamental frequency and only the odd harmonics. Amplitude of the harmonics decreases as their frequency increases.

## 3.2 Measuring AC Voltage, Current and Power

Measuring the voltage or current in a dc circuit is straightforward, as Figure 3.12A demonstrates. Since the current flows in only one direction, the voltage and current have constant values until the resistor values are changed.

Figure 3.12B illustrates a perplexing problem encountered when measuring voltages and currents in ac circuits — the current and voltage continuously change direction and value. Which values are meaningful? How are measurements performed? In fact, there are several methods of measuring sine-wave voltage and current in ac circuits with each method providing different information about the waveform. Note that the following sections assume the waveform is a sine wave unless otherwise noted.

### 3.2.1 Instantaneous Values

By far, the most common waveform associ-

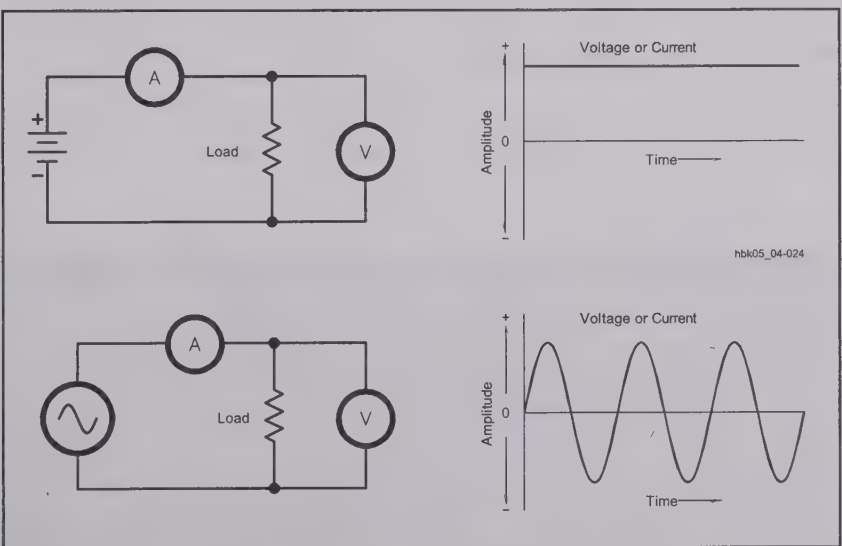

Figure 3.12 — Voltage and current measurements in dc (A) and ac circuits (B).

**Figure 3.13** — Two cycles of a sine wave to illustrate instantaneous, peak, and peak-to-peak ac voltage and current values.

ated with ac of any frequency is the sine wave. Unless otherwise noted, it is safe to assume that measurements of ac voltage or current are of a sinusoidal waveform. **Figure 3.13** shows a sine wave representing a voltage or current of some arbitrary frequency and amplitude. The *instantaneous* voltage (or current) is the value at one instant in time. If a series of instantaneous values are plotted against time, the resulting graph will show the waveform.

In the sine wave of **Figure 3.13**, the instantaneous value of the waveform at any point in time is a function of three factors: the maximum value of voltage (or current) along the curve (point B,  $E_{\max}$ ), the frequency of the wave,  $f$ , and the time elapsed from the preceding positive-going zero crossing,  $t$ , in seconds or fractions of a second. Thus,

$$E_{\text{inst}} = E_{\text{max}} \sin (ft)$$

assuming all sine calculations are done in degrees. (See the sidebar “Degrees, Radians and Angular Frequency.” If the sine calculation is done in radians, substitute  $2\pi ft$  for  $ft$  in the equation.)

If the point’s phase is known — the position along the waveform — the instantaneous volt-

age at that point can be calculated directly as:

$$E_{\text{inst}} = E_{\text{max}} \sin \theta$$

where  $\theta$  is the number of degrees of phase difference from the beginning of the cycle.

Example: What is the instantaneous value of voltage at point D in **Figure 3.13**, if the maximum voltage value is 120 V and point D’s phase is  $60^\circ$ ?

$$E_{\text{inst}} = 120 \text{ V} \times \sin 60^\circ = 120 \times 0.866 = 104 \text{ V}$$

### 3.2.2 Peak and Peak-to-Peak Values

The most important of an ac waveform’s instantaneous values are the maximum or *peak* values reached on each positive and negative half cycle. In **Figure 3.13**, points B and C represent the positive and negative peaks. Peak values (indicated by a “pk” or “p” subscript) are especially important with respect to component ratings, which the voltage or current in a circuit must not exceed without danger.

The *peak power* in an ac circuit is the prod-

uct of the peak voltage and the peak current, or

$$P_{\text{pk}} = E_{\text{pk}} \times I_{\text{pk}}$$

The span from points B to C in **Figure 3.13** represents the largest difference in value of the sine wave. Designated the *peak-to-peak* value (indicated by a “P-P” or “pk-pk” subscript), this span is equal to twice the peak value of the waveform. Thus, peak-to-peak voltage is:

$$E_{\text{p-p}} = 2 E_{\text{pk}}$$

### 3.2.3 RMS Values

The *root mean square* or *RMS* values of voltage and current are the most common values encountered in electronics. Sometimes called *effective* values, the RMS value of an ac voltage or current is the value of a dc voltage or current that would cause a resistor to dissipate the same average amount of power as the ac waveform. This measurement became widely used in the early days of electrification when both ac and dc power utility power were in use. Even today, the values of the ac line voltage available from an electrical power outlet are given as RMS values. Unless otherwise specified, unlabeled ac voltage and current values found in most electronics literature are normally RMS values.

The RMS values of voltage and current get their name from the mathematical method used to derive their value relative to peak voltage and current. This procedure provides the RMS value for any type of periodic waveform, sinusoidal or not. Start by *squaring* the individual values of all the instantaneous values of voltage or current during an entire single cycle of ac. Take the average (*mean*) of these squares (this is done by computing an integral of the waveform) and then find the square *root* of that average.

#### SINE WAVE RMS VALUES

This section applies only when the waveform in question is a sine wave. The simple formulas and conversion factors in this sec-

## Measuring Nonsinusoidal Waveforms

Making measurements of ac waveforms is covered in more detail in the **Test Equipment and Measurements** chapter. However, this is a good point in the discussion to reinforce the dependence of RMS and values on the nature of the waveform being measured.

Analog meters and other types of instrumentation that display RMS values may only be calibrated for sine waves, those being the most common type of ac waveform. Using that instrumentation to accurately measure waveforms other than sine waves — such as speech, intermittent sine waves (such as CW from

a transmitter), square waves, triangle waves or noise — requires the use of *calibration factors* or the measurement may not be valid.

To make calibrated, reliable measurements of the RMS or value of these waveforms requires the use of *true-RMS* instruments. These devices may use a balancing approach to a known dc value or if they are microprocessor-based, may actually perform the full root-mean-square calculation on the waveform. Be sure you know the characteristics of your test instruments if an accurate RMS value is important.

**Figure 3.14** — The relationships between RMS, average, peak, and peak-to-peak values of ac voltage and current for a sine wave. The numeric constants are different for non-sinusoidal waveforms.

are generally *not* true for non-sinusoidal waveforms such as square or triangle waves (see the sidebar “Measuring Non-Sinusoidal Waveforms”). The following formulas are true *only* if the waveform is a sine wave and the circuit is *linear*—that is, raising or lowering the voltage will raise or lower the current proportionally. If those conditions are true, the following conversion factors have been computed and can be used without any additional mathematics.

For a sine wave to produce heat equivalent to a dc waveform the peak ac power required is twice the dc power. Therefore, the average ac power equivalent to a corresponding dc power is half the peak ac power.

$$P_{ave} = \frac{P_{pk}}{2}$$

A sine wave’s RMS voltage and current values needed to arrive at average ac power are related to their peak values by the conversion factors:

$$E_{RMS} = \frac{E_{pk}}{\sqrt{2}} = \frac{E_{pk}}{1.414} = E_{pk} \times 0.707$$

$$I_{RMS} = \frac{I_{pk}}{\sqrt{2}} = \frac{I_{pk}}{1.414} = I_{pk} \times 0.707$$

RMS voltages and currents are what is displayed by most volt and ammeters.

If the RMS voltage is the peak voltage divided by  $\sqrt{2}$ , then the peak voltage must be the RMS voltage multiplied by  $\sqrt{2}$ , or

$$E_{pk} = E_{RMS} \times 1.414$$

$$I_{pk} = I_{RMS} \times 1.414$$

Example: What is the peak voltage and the peak-to-peak voltage at the usual household

ac outlet, if the RMS voltage is 120 V?

$$E_{pk} = 120 \text{ V} \times 1.414 = 170 \text{ V}$$

$$E_{P-P} = 2 \times 170 \text{ V} = 340 \text{ V}$$

In the time domain of a sine wave, the instantaneous values of voltage and current correspond to the RMS values at the 45°, 135°, 225° and 315° points along the cycle shown in **Figure 3.14**. (The sine of 45° is approximately 0.707.) The instantaneous value of voltage or current is greater than the RMS value for half the cycle and less than the RMS value for half the cycle.

Since circuit specifications will most com-

monly list only RMS voltage and current values, these relationships are important in finding the peak voltages or currents that will stress components.

Example: What is the peak voltage across a capacitor if the RMS voltage of a sinusoidal waveform signal across it is 300 V ac?

$$E_{pk} = 300 \text{ V} \times 1.414 = 424 \text{ V}$$

The capacitor must be able to withstand this higher voltage, plus a safety margin. (The capacitor must also be rated for ac use because of the continually reversing polarity and ac current flow.) In power supplies that convert ac to dc and use capacitive input filters, the output voltage will approach the peak value of the ac voltage rather than the RMS value. (See the **Power Sources** chapter for more information on specifying components in this application.)

### 3.2.4 Average Values of AC Waveforms

Certain kinds of circuits respond to the *average* voltage or current (not power) of an ac waveform. Among these circuits are analog electrodynamic meter movements and power supplies that convert ac to dc and use heavily inductive (“choke”) input filters, both of which work with the pulsating dc output of a full-wave rectifier. The average value of each ac half cycle is the *mean* of all the instantaneous values in that half cycle. (The average value of a sine wave or any symmetric ac waveform over an entire cycle is zero!) Related to the peak values of voltage and current, average values for each half-cycle

**Table 3.1**

**Conversion Factors for Sinusoidal AC Voltage or Current**

From	To	Multiply By
Peak	Peak-to-Peak	2
Peak-to-Peak	Peak	0.5
Peak	RMS	$1/\sqrt{2}$ or 0.707
RMS	Peak	$\sqrt{2}$ or 1.414
Peak-to-Peak	RMS	$1/(2 \times \sqrt{2})$ or 0.35355
RMS	Peak-to-Peak	$2 \times \sqrt{2}$ or 2.828
Peak	Average	$2/\pi$ or 0.6366
Average	Peak	$\pi/2$ or 1.5708
RMS	Average	$(2 \times \sqrt{2})/\pi$ or 0.90
Average	RMS	$\pi/(2 \times \sqrt{2})$ or 1.11

Note: These conversion factors apply only to continuous pure sine waves.

## Sine and Square Wave Measurement Definitions

Since square waves are very common waveforms, the following table provides definitions for the two types of waveforms. These are *not* conversion factors between two measurements unless a true-RMS instrument is used.

### AC Measurements for Sine and Square Waves

	<i>Sine Wave</i>	<i>Square Wave</i>
Peak-to-Peak	2 × Peak	2 × Peak
Peak	0.5 × Peak-to-Peak	0.5 × Peak-to-Peak
RMS	0.707 × Peak	Peak
Peak	1.414 × RMS	RMS
Average	0 (full cycle)	0 (full cycle)
	0.637 × Peak (half cycle)	0.5 × Peak (half cycle)

Figure 3.15 — The peak envelope voltage (PEV) for a composite waveform.

of a sine wave are  $2/\pi$  (or 0.6366) times the peak value.

$$E_{\text{ave}} = 0.6366 E_{\text{pk}}$$

$$I_{\text{ave}} = 0.6366 I_{\text{pk}}$$

For convenience, **Table 3.1** summarizes the relationships between all of the common ac values. All of these relationships apply *only* to sine waves in linear circuits.

### 3.2.5 Complex Waveforms and Peak Envelope Values

Complex waveforms, as shown earlier in Figures 3.10 and 3.11, differ from sine waves. For speech signals, the peak voltage may vary significantly from one cycle to the next, for example. Therefore, other amplitude measures are required, especially for accurate measurement of voltage and power with transmitted

speech or data waveforms.

An SSB waveform (either speech or data) contains an RF ac waveform with a frequency many times that of the audio-frequency ac waveform with which it is combined. Therefore, the resultant *composite* waveform appears as an amplitude envelope superimposed upon the RF waveform as illustrated by **Figure 3.15**. For a complex waveform such as this, the *peak envelope voltage* (PEV) is the maximum or peak value of voltage anywhere in the waveform.

Peak envelope voltage is used in the calculation of *peak envelope power* (PEP). The Federal Communications Commission (FCC) sets the maximum power levels for amateur transmitters in terms of peak envelope power. PEP is the *average* power supplied to the antenna transmission line by the transmitter during one RF cycle at the crest of the modulation envelope, taken under normal operating conditions. That is, the average power for the RF cycle during which PEV occurs.

Since calculation of PEP requires the average power of the cycle, and the deviation of the modulated RF waveform from a sine wave is very small, the error incurred by using the conversion factors for sine waves is insignificant. Multiply PEV by 0.707 to obtain an RMS value. Then calculate PEP by using the square of the voltage divided by the load resistance.

$$\text{PEP} = \frac{(\text{PEV} \times 0.707)^2}{R}$$

Figure 3.16 — The FCC defines bandwidth as “the width of a frequency band outside of which the mean (average) power of the transmitted signal is attenuated at least 26 dB below the mean power.” (FCC §97.3(a)(8))

Example: What is the PEP of a transmitter’s output with a PEV of 100 V into a 50-ohm load?

$$\text{PEP} = \frac{(100 \times 0.707)^2}{R} = \frac{(70.7)^2}{50} = 100 \text{ W}$$

### COMPOSITE WAVEFORMS AND BANDWIDTH

*Composite* signals are groups of individual signals that combine to create a complex signal. Composite signals have *components* that generally cover a range of frequencies. The general definition of a signal’s *bandwidth* is the difference in frequency between the two points at which the signal’s amplitude falls to 3 dB below its peak value. For some kinds of very simple and very complex signals this may not be a useful definition.

The FCC has a more specific definition of bandwidth in section §97.3(a)(8): “*Bandwidth*. The width of a frequency band outside of which the mean [average] power of the transmitted signal is attenuated at least 26 dB below the mean power within the band.” **Figure 3.16** illustrates how this measurement is made. This definition is used when evaluating a signal’s occupied bandwidth to determine whether it satisfies FCC rules.

### 3.3 Effective Radiated Power

When evaluating total station performance, accounting for the effects of the entire system is important, including antenna gain. This allows you to evaluate the effects of changes to the station. Transmitting performance is usually computed as *effective radiated power* (ERP). ERP is calculated with respect to a reference antenna system — usually a dipole but occasionally an isotropic antenna — and answers the question, “How much power does any station radiate as compared to that if my antenna was a simple dipole?” Effective isotropic radiated power (EIRP) results when an isotropic antenna is used as the reference. If no antenna reference is specified, assume a dipole reference antenna.

ERP is especially useful in designing and coordinating repeater systems. The effective power radiated from the antenna helps establish the coverage area of the repeater. In addition, the height of the repeater antenna is compared to buildings and mountains in the surrounding area (*height above average terrain*, or HAAT) has a large effect on the repeater coverage. In general, for a given coverage area, with a greater antenna HAAT, less effective radiated power (ERP) is needed. A frequency coordinator may even specify a maximum ERP for a repeater, to help reduce interference between stations using the same frequencies.

ERP calculations begin with the *transmitter power output* (TPO). (This is assumed to be the output of the final power amplification stage if an external power amplifier is used.) Then the *system gain* of the entire antenna system including the antenna, the transmission line, and all transmission line components is applied to TPO to compute the entire station’s output power.

$$\text{System Gain} = \text{Transmission Line Loss} - \text{Transmission Components Loss} + \text{Antenna Gain}$$

There is always some power lost in the feed line and often there are other devices inserted in the line, such as a filter or an impedance-matching network. In the case of a repeater system, there is usually a duplexer so the transmitter and receiver can use the same antenna and perhaps a circulator to reduce the possibility of intermodulation interference. These devices also introduce some loss to the system. The antenna system then usually returns some gain to the system. (See the **Antennas** chapter for information on antenna gain and the **Transmission Lines** chapter for

information on feed line loss.)

$$\text{ERP} = \text{TPO} \times \text{System Gain}$$

Since the system gains and losses are usually expressed in decibels, they can simply be added together, with losses written as negative values. System gain must then be converted back to a linear value from dB to calculate ERP.

$$\text{ERP} = \text{TPO} \times \log^{-1} \left( \frac{\text{System Gain (dB)}}{10} \right)$$

It is also common to work entirely in dBm and dB until the final result for ERP is obtained and then converted back to watts. (dBm represents “decibels with respect to one mW” such that 0 dBm = 1 mW, 30 dBm = 1 W, and so forth.)

$$\text{ERP (in dBm)} = \text{TPO (in dBm)} + \text{System Gain (in dB)}$$

Suppose we have a repeater station that uses a 50 W transmitter and a feed line with 4 dB of loss. There is a duplexer in the line that exhibits 2 dB of loss and a circulator that adds another 1 dB of loss. This repeater uses an antenna that has a gain of 6 dBd. Our total system gain looks like:

$$\text{System gain} = -4 \text{ dB} - 2 \text{ dB} - 1 \text{ dB} + 6 \text{ dBd} = -1 \text{ dB}$$

Note that this is a loss of 1 dB total for the system from TPO to radiated power. The effect on the 50 W of TPO results in:

$$\begin{aligned} \text{ERP} &= 50 \text{ W} \times \log^{-1} \left( \frac{\text{system gain (dB)}}{10} \right) \\ &= 50 \times \log^{-1}(-0.1) = 50 \times 0.79 = 39.7 \text{ W} \end{aligned}$$

This is consistent with the expectation that with a 1 dB system loss we would have somewhat less ERP than transmitter output power.

As another example, suppose we have a transmitter that feeds a 100 W output signal into a feed line that has 1 dB of loss. The feed line connects to an antenna that has a

gain of 6 dBd. What is the effective radiated power from the antenna? To calculate the total system gain (or loss) we add the decibel values given:

$$\text{System gain} = -1 \text{ dB} + 6 \text{ dBd} = 5 \text{ dB}$$

and

$$\begin{aligned} \text{ERP} &= 100 \text{ W} \times \log^{-1} \left( \frac{\text{system gain (dB)}}{10} \right) \\ &= 100 \times \log^{-1}(0.5) = 100 \times 3.16 = 316 \text{ W} \end{aligned}$$

The total system has positive gain, so we should have expected a larger value for ERP than TPO. Keep in mind that the gain antenna concentrates more of the signal in a desired direction, with less signal in undesired directions. So the antenna doesn’t really increase the total available power. If directional antennas are used, ERP will change with direction.

Example: What is the effective radiated power of a repeater station with 150 W transmitter power output, 2 dB feed line loss, 2.2 dB duplexer loss and 7 dBd antenna gain?

$$\text{System gain} = -2 \text{ dB} - 2.2 \text{ dB} + 7 \text{ dBd} = 2.8 \text{ dB}$$

$$\begin{aligned} \text{ERP} &= 150 \text{ W} \times \log^{-1} \left( \frac{\text{system gain (dB)}}{10} \right) \\ &= 150 \times \log^{-1}(0.28) = 150 \times 1.9 = 285 \text{ W} \end{aligned}$$

Example: What is the effective radiated power of a repeater station with 200 W transmitter power output, 4 dB feed line loss, 3.2 dB duplexer loss, 0.8 dB circulator loss and 10 dBd antenna gain?

$$\text{System gain} = -4 - 3.2 - 0.8 + 10 = 2 \text{ dB}$$

$$\begin{aligned} \text{ERP} &= 200 \text{ W} \times \log^{-1} \left( \frac{\text{system gain (dB)}}{10} \right) \\ &= 200 \times \log^{-1}(0.2) = 200 \times 1.58 = 317 \text{ W} \end{aligned}$$

What is the effective isotropic radiated power of a repeater station with 200 W transmitter power output, 2 dB feed line loss, 2.8 dB duplexer loss, 1.2 dB circulator loss and 7 dBi antenna gain?

$$\text{System gain} = -2 - 2.8 - 1.2 + 7 = 1 \text{ dB}$$

$$\begin{aligned} \text{ERP} &= 200 \text{ W} \times \log^{-1} \left( \frac{\text{system gain (dB)}}{10} \right) \\ &= 100 \times \log^{-1}(0.1) = 200 \times 1.26 = 252 \text{ W} \end{aligned}$$

#### The Decibel

The decibel (dB) is discussed in the section on Gain, later in this chapter. It is also covered in the “Radio Mathematics” item in the downloadable supplemental information.

## 3.4 AC in Capacitors and Inductors

Both capacitors and inductors can store electrical or magnetic energy, respectively. When an ac signal is applied to them, the storing and releasing of energy results in a phase shift between the current and voltage waveforms. The phase shift varies with frequency and makes capacitors and inductors behave differently than resistors. They also interact to create frequency-sensitive tuned circuits, filters, impedance-matching circuits, and more.

### 3.4.1 Alternating Current in Capacitance

While a capacitor in a dc circuit will appear as an open circuit except for the brief charge and discharge periods, the same capacitor in an ac circuit will both pass and oppose current. A capacitor in an ac circuit does not handle electrical energy like a resistor, however. Instead of converting the energy to heat and dissipating it, capacitors store electrical energy when the applied voltage is greater than that across the capacitor and return it to the circuit when the opposite is true.

In **Figure 3.17** a sine-wave ac voltage having a maximum value of 100 V is applied to a capacitor. In the period OA, the applied voltage increases from 0 to 38, storing energy in the capacitor; at the end of this period the capacitor is charged to that voltage. In interval AB the voltage increases to 71; that is, by an additional 33 V. During this interval a smaller quantity of charge has been added than in OA, because the voltage rise during interval AB is smaller. Consequently the average current during interval AB is smaller than during OA. In the third interval, BC, the voltage rises from 71 to 92, an increase of 21 V. This is less than the voltage increase during AB, so the quantity of charge added is less; in other words, the average current during interval BC is still smaller. In the fourth interval, CD, the voltage increases only 8 V; the charge added is smaller than in any preceding interval and therefore the current also is smaller.

By dividing the first quarter-cycle into a very large number of such intervals, it can be shown that the current charging the capacitor has the shape of a sine wave, just as the applied voltage does. The current is largest at the beginning of the cycle and becomes zero at the maximum value of the voltage, so there is a phase difference of  $90^\circ$  between the voltage and the current. During the first quarter-cycle the current is flowing in the original (positive) direction through the circuit as indicated by the dashed line in **Figure 3.17**, since the capacitor is being charged.

**Figure 3.17** — Voltage and current phase relationships when an alternating current is applied to a capacitor.

The increasing capacitor voltage indicates that energy is being stored in the capacitor.

In the second quarter-cycle—that is, in the time from D to H—the voltage applied to the capacitor decreases. During this time the capacitor loses charge, returning the stored energy to the circuit. Applying the same reasoning, it is evident that the current is small in interval DE and continues to increase during each succeeding interval. The current is flowing *against* the applied voltage, however, because the capacitor is returning energy to (discharging into) the circuit. The current thus flows in the *negative* direction during this quarter-cycle.

The third and fourth quarter-cycles repeat the events of the first and second, respectively, although the polarity of the applied voltage has reversed, and so the current changes to correspond. In other words, an alternating current flows in the circuit because of the alternate charging and discharging of the capacitance. As shown in **Figure 3.17**, the

current starts its cycle  $90^\circ$  before the voltage, so the current in a capacitor *leads* the applied voltage by  $90^\circ$ . You might find it helpful to remember the word “ICE” as a mnemonic because the current (I) in a capacitor (C) comes before voltage (E). (See the sidebar “ELI the ICE man” in the section on inductors.) We can also turn this statement around, to say the voltage in a capacitor *lags* the current by  $90^\circ$ .

### 3.4.2 Capacitive Reactance and Susceptance

The quantity of electric charge that can be placed on a capacitor is proportional to the applied voltage and the capacitance. If the applied voltage is ac, this amount of charge moves back and forth in the circuit once each cycle. Therefore, the rate of movement of charge (the current) is proportional to voltage, capacitance and frequency. Stated in another way, capacitor current is proportional to capacitance for a given applied voltage and frequency.

When the effects of capacitance and frequency are considered together, they form a quantity called *reactance* that relates voltage and current in a capacitor, similar to the role of resistance in Ohm’s Law. Because the reactance is created by a capacitor, it is called *capacitive reactance*. The units for reactance are ohms, just as in the case of resistance. Although the units of reactance are ohms, there is no power dissipated in reactance. The energy stored in the capacitor during one portion of the cycle is simply returned to the circuit in the next.

### Capacitive Reactance Timesaver

The fundamental units for frequency and capacitance (hertz and farads) are too cumbersome for practical use in radio circuits. If the capacitance is specified in microfarads ( $\mu\text{F}$ ) and the frequency is in megahertz (MHz), however, the reactance is calculated in ohms ( $\Omega$ ).

The formula for calculating the magnitude of the capacitive reactance is:

$$X_C = \frac{1}{2\pi f C}$$

where:

$X_C$  = magnitude of capacitive reactance in ohms,

$f$  = frequency in hertz,

$C$  = capacitance in farads

$\pi = 3.1416$

By convention, capacitive reactance is assigned a negative value whereas inductive reactance (discussed below) is assigned a positive value.

Note: In many references and texts, angular frequency  $\omega = 2\pi f$  is used and the equation would read:

$$X_C = \frac{1}{\omega C}$$

Example: What is the reactance of a capacitor of 470 pF (0.000470  $\mu$ F) at a frequency of 7.15 MHz?

$$X_C = \frac{1}{2\pi f C}$$

$$= \frac{1}{2\pi \times 7.15 \text{ MHz} \times 0.000470 \mu\text{F}}$$

$$= \frac{1 \Omega}{0.0211} = 47.4 \Omega$$

Example: What is the reactance of the same capacitor, 470 pF (0.000470  $\mu$ F), at a frequency of 14.29 MHz?

$$X_C = \frac{1}{2\pi f C}$$

$$= \frac{1}{2\pi \times 14.3 \text{ MHz} \times 0.000470 \mu\text{F}}$$

$$= \frac{1 \Omega}{0.0422} = 23.7 \Omega$$

Current in a capacitor is directly related to the rate of change of the capacitor voltage. The maximum rate of change of voltage in a sine wave increases directly with the frequency, even if its peak voltage remains fixed. Therefore, the maximum current in the capacitor must also increase directly with frequency. Since, if voltage is fixed, an increase in current is equivalent to a decrease in reactance, the reactance of any capacitor decreases proportionally as the frequency increases. **Figure 3.18** illustrates the decrease in reactance of an arbitrary-value capacitor with respect to increasing frequency. The only limitation on the application of the graph is the physical construction of the capacitor, which may favor low-frequency uses or high-frequency applications.

**Figure 3.18** — A graph showing the general relationship of reactance to frequency for a fixed value of capacitance.

### CAPACITIVE SUSCEPTANCE

Just as conductance is sometimes the most useful way of expressing a resistance's ability to conduct current, the same is true for capacitors and ac current. This ability is called *susceptance* (abbreviated *B*). The units of susceptance are siemens (S), the same as that of conductance and admittance.

Susceptance in a capacitor is *capacitive susceptance*, abbreviated *B<sub>C</sub>*. In an ideal capacitor with no resistive losses, susceptance is simply the negative reciprocal of reactance.

$$B_C = -\frac{1}{X_C}$$

where

$X_C$  is the capacitive reactance, and

$B_C$  is the capacitive susceptance.

**Figure 3.19** — Phase relationships between voltage and current when an alternating current is applied to an inductance.

### 3.4.3 Alternating Current in Inductors

For reasons similar to those that cause a phase difference between current and voltage in a capacitor, when an alternating voltage is applied to an ideal inductance with no resistance, the current is 90° out of phase with the applied voltage. In the case of an inductor, however, the current *lags* 90° behind the voltage as shown in **Figure 3.19**, the opposite of the capacitor current-voltage relationship. (Here again, we can also say the voltage across an inductor *leads* the current by 90°.) Interpreting **Figure 3.19** begins with understanding that the cause for current lag in an inductor is the opposing voltage that is induced in the inductor and that the amplitude of the opposing voltage is proportional to the rate at which the inductor current changes.

In time segment OA, when the applied voltage is at its positive maximum, the rate at which the current is changing is also the highest, a 38% change. This means that the opposing voltage is also maximum, allowing the least current to flow. In the segment AB, as a result of the decrease in the applied voltage, current changes by only 33% inducing a smaller opposing voltage. The process continues in time segments BC and CD, the latter producing only an 8% rise in current as the applied and induced opposing voltage approach zero.

In segment DE, the applied voltage changes polarity, causing current to begin to decrease, returning stored energy to the circuit from the inductor's magnetic field. As the current rate of change is now negative (decreasing) the induced opposing voltage also changes polarity. Current flow is still in the original

## ELI the ICE Man

If you have difficulty remembering the phase relationships between voltage and current with inductors and capacitors, you may find it helpful to think of the phrase, "ELI the ICE man." This will remind you that voltage across an inductor leads the current through it, because the E comes before (leads) I, with an L between them, as you read from left to right. (The letter L represents inductance.) Similarly, I comes before (leads) E with a C between them.

direction (positive), but is decreasing as less energy is stored in the inductor.

As the applied voltage continues to increase negatively, the current — although still positive — continues to decrease in value, reaching zero as the applied voltage reaches its negative maximum. The energy once stored in the inductor has now been completely returned to the circuit. The negative half-cycle then continues just as the positive half-cycle.

Similarly to the capacitive circuit discussed earlier, by dividing the cycle into a large number of intervals, it can be shown that the current and voltage are both sine waves, although with a difference in phase.

Compare Figure 3.19 with Figure 3.17. Whereas in a pure capacitive circuit, the current *leads* the voltage by 90°, in a pure inductive circuit, the current *lags* the voltage by 90°. These phenomena are especially important in circuits that combine inductors and capacitors. Remember that the phase difference between voltage and current in both types of circuits is a result of energy being stored and released as voltage across a capacitor and as current in an inductor.

### 3.4.4 Inductive Reactance and Susceptance

The amount of current that can be created in an inductor is proportional to the applied voltage but inversely proportional to the inductance because of the induced opposing voltage. If the applied voltage is ac, the rate of change of the current varies directly with the frequency and this rate of change also determines the amplitude of the induced or reverse voltage. Hence, the opposition to the flow of current increases proportionally to frequency. Stated in another way, inductor current is inversely proportional to inductance for a given applied voltage and frequency.

The combined effect of inductance and frequency is called *inductive reactance*, which — like capacitive reactance — is expressed in ohms. As with capacitive reactance, no power is dissipated in inductive reactance.

The energy stored in the inductor during one portion of the cycle is returned to the circuit in the next portion.

The formula for calculating the magnitude of the inductive reactance is:

$$X_L = 2 \pi f L$$

where

$X_L$  = magnitude of inductive reactance in ohms,

$f$  = frequency in hertz,

$L$  = inductance in henrys, and

$\pi = 3.1416$ .

(If  $\omega = 2 \pi f$ , then  $X_L = \omega L$ .)

Example: What is the reactance of an inductor having an inductance of 8.0 H at a frequency of 120 Hz?

$$X_L = 2 \pi f L$$

$$= 6.2832 \times 120 \text{ Hz} \times 8.0 \text{ H}$$

$$= 6030 \Omega$$

Example: What is the reactance of a 15.0-microhenry inductor at a frequency of 14.0 MHz?

$$X_L = 2 \pi f L$$

$$= 6.2832 \times 14.0 \text{ MHz} \times 15.0 \mu\text{H}$$

$$= 1320 \Omega$$

The resistance of the wire used to make the inductor has no effect on the reactance, but simply acts as a separate resistor connected in series with the inductor.

Example: What is the reactance of the same inductor at a frequency of 7.0 MHz?

$$X_L = 2 \pi f L$$

$$= 6.2832 \times 7.0 \text{ MHz} \times 15.0 \mu\text{H}$$

$$= 660 \Omega$$

The direct relationship between frequency and reactance in inductors, combined with the inverse relationship between reactance and frequency in the case of capacitors, will be of fundamental importance in creating resonant circuits.

### INDUCTIVE SUSCEPTANCE

As a measure of the ability of an inductor to limit the flow of ac in a circuit, inductive reactance is similar to capacitive reactance in having a corresponding susceptance, or ability to pass ac current in a circuit. In an ideal inductor with no resistive losses — that is, no energy lost as heat — susceptance is simply the negative reciprocal of reactance.

$$B_L = -\frac{1}{X_L}$$

## Inductive Reactance Timesaver

Similarly to the calculation of capacitive reactance, if inductance is specified in microhenrys ( $\mu\text{H}$ ) and the frequency is in megahertz (MHz), the reactance is calculated in ohms ( $\Omega$ ). The same is true for the combination of mH and kHz.

where

$X_L$  = the inductive reactance, and  
 $B_L$  = the inductive susceptance.

The unit of susceptance for both inductors and capacitors is the *siemens*, abbreviated S.

### 3.4.5 Glossary — AC Theory and Reactance

**Frequency ( $f$ )** — The rate of change of an ac voltage or current, measured in cycles per second, or hertz (Hz).

**Fundamental** — The lowest frequency in a series of sine waves whose frequencies have an integer relationship.

**Harmonic** — A sine wave whose frequency is an integer multiple of a fundamental frequency.

**Peak (voltage or current)** — The maximum value relative to zero that an ac voltage or current attains during any cycle.

**Peak-to-peak (voltage or current)** — The value of the total swing of an ac voltage or current from its peak negative value to its peak positive value, ordinarily twice the value of the peak voltage or current.

**Period ( $T$ )** — The duration of one ac voltage or current cycle, measured in seconds (s).

**Power ( $P$ )** — The rate of electrical-energy use, measured in watts (W).

**Reactance ( $X$ )** — Opposition to alternating current by storage in an electrical field (by a capacitor) or in a magnetic field (by an inductor), measured in ohms ( $\Omega$ ).

**RMS (voltage or current)** — Literally, "root mean square," the square root of the average of the squares of the instantaneous values for one cycle of a waveform. A dc voltage or current that will produce the same heating effect as the waveform. For a sine wave, the RMS value is equal to 0.707 times the peak value of ac voltage or current.

**Time constant ( $\tau$ )** — The time required for the voltage in an RC circuit or the current in an RL circuit to rise from zero to approximately 63.2% of its maximum value or to fall from its maximum value 63.2% toward zero.

## 3.5 Working with Reactance

### 3.5.1 Ohm's Law for Reactance

Only ac circuits containing capacitance or inductance (or both) have reactance. Despite the fact that the voltage in such circuits is  $90^\circ$  out of phase with the current, circuit reactance does oppose the flow of ac current in a manner that corresponds to resistance. That is, in a capacitor or inductor, reactance is equal to the ratio of ac voltage to ac current and the equations relating voltage, current and reactance take the familiar form of Ohm's Law:

$$E = I X$$

$$I = E / X$$

$$X = E / I$$

where

E = RMS ac voltage in volts,

I = RMS ac current in amperes, and

X = inductive or capacitive reactance in ohms.

Example: What is the voltage across a capacitor of 200 pF at 7.15 MHz, if the current through the capacitor is 50 mA?

Since the reactance of the capacitor is a function of both frequency and capacitance, first calculate the reactance:

$$X_C = \frac{1}{2 \pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 7.15 \times 10^6 \text{ Hz} \times 200 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{8980} = 111 \Omega$$

Next, use:

$$E = I \times X_C = 0.050 \text{ A} \times 111 \Omega = 5.6 \text{ V}$$

Example: What is the current through an 8.0-H inductor at 120 Hz, if 420 V is applied?

$$X_L = 2 \pi f L$$

$$= 2 \times 3.1416 \times 120 \text{ Hz} \times 8.0 \text{ H}$$

$$= 6030 \Omega$$

$$I = E / X_L = 420 / 6030 = 69.6 \text{ mA}$$

Figure 3.20 charts the reactances of ca-

pacitors from 1 pF to 100  $\mu\text{F}$ , and the reactances of inductors from 0.1  $\mu\text{H}$  to 10 H, for frequencies between 100 Hz and 100 MHz. Approximate values of reactance can be read or interpolated from the chart. The formulas will produce more exact values, however. (The chart can also be used to find the frequency at which an inductor and capacitor have equal reactances, creating resonance as described in the section "Reactances At and Near Resonance" below.)

Although both inductive and capacitive reactance oppose the flow of ac current, the two types of reactance differ. With capacitive reactance, the current *leads* the voltage by  $90^\circ$ , whereas with inductive reactance, the current *lags* the voltage by  $90^\circ$ . The convention for charting the two types of reactance appears in Figure 3.21. On this graph, inductive reactance is plotted along the  $+90^\circ$  vertical line, while capacitive reactance is plotted along the  $-90^\circ$  vertical line. This convention of assigning a positive value to inductive reactance and a negative value to capacitive reactance results from the mathematics used for working with impedance as described elsewhere in this chapter.

### 3.5.2 Reactances in Series and Parallel

If a circuit contains two reactances of the same type, whether in series or in parallel, the resulting reactance can be determined by applying the same rules as for resistances in series and in parallel. Series reactance is given by the formula

$$X_{\text{total}} = X_1 + X_2 + X_3 \dots + X_n$$

Example: Two noninteracting inductances are in series. Each has a value of 4.0  $\mu\text{H}$ , and the operating frequency is 3.8 MHz. What is the resulting reactance?

The reactance of each inductor is:

$$X_L = 2 \pi f L$$

$$= 2 \times 3.1416 \times 3.8 \times 10^6 \text{ Hz} \times 4 \times 10^{-6} \text{ H}$$

$$= 96 \Omega$$

$$X_{\text{total}} = X_1 + X_2 = 96 \Omega + 96 \Omega = 192 \Omega$$

We might also calculate the total reactance by first adding the inductances:

$$L_{\text{total}} = L_1 + L_2 = 4.0 \mu\text{H} + 4.0 \mu\text{H} = 8.0 \mu\text{H}$$

$$X_{\text{total}} = 2 \pi f L$$

$$= 2 \times 3.1416 \times 3.8 \times 10^6 \text{ Hz} \times 8.0 \times 10^{-6} \text{ H}$$

$$= 191 \Omega$$

(The fact that the last digit differs by one illustrates the uncertainty of the calculation caused by the limited precision of the measured values in the problem, and differences caused by rounding off the calculated values. This also shows why it is important to follow the rules for significant figures.)

Example: Two noninteracting capacitors are in series. One has a value of 10.0 pF, the other of 20.0 pF. What is the resulting reactance in a circuit operating at 28.0 MHz?

$$X_{C1} = \frac{1}{2 \pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 10.0 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{1760} = 568 \Omega$$

$$X_{C2} = \frac{1}{2 \pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 20.0 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{3520} = 284 \Omega$$

$$X_{\text{total}} = X_{C1} + X_{C2} = 568 \Omega + 284 \Omega = 852 \Omega$$

Alternatively, combining the series capacitors first, the total capacitance is  $6.67 \times 10^{-12}$  F or 6.67 pF. Then:

$$X_{\text{total}} = \frac{1}{2 \pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 6.67 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{1170} = 855 \Omega$$

(Within the uncertainty of the measured values and the rounding of values in the calculations, this is the same result as the 852  $\Omega$ )

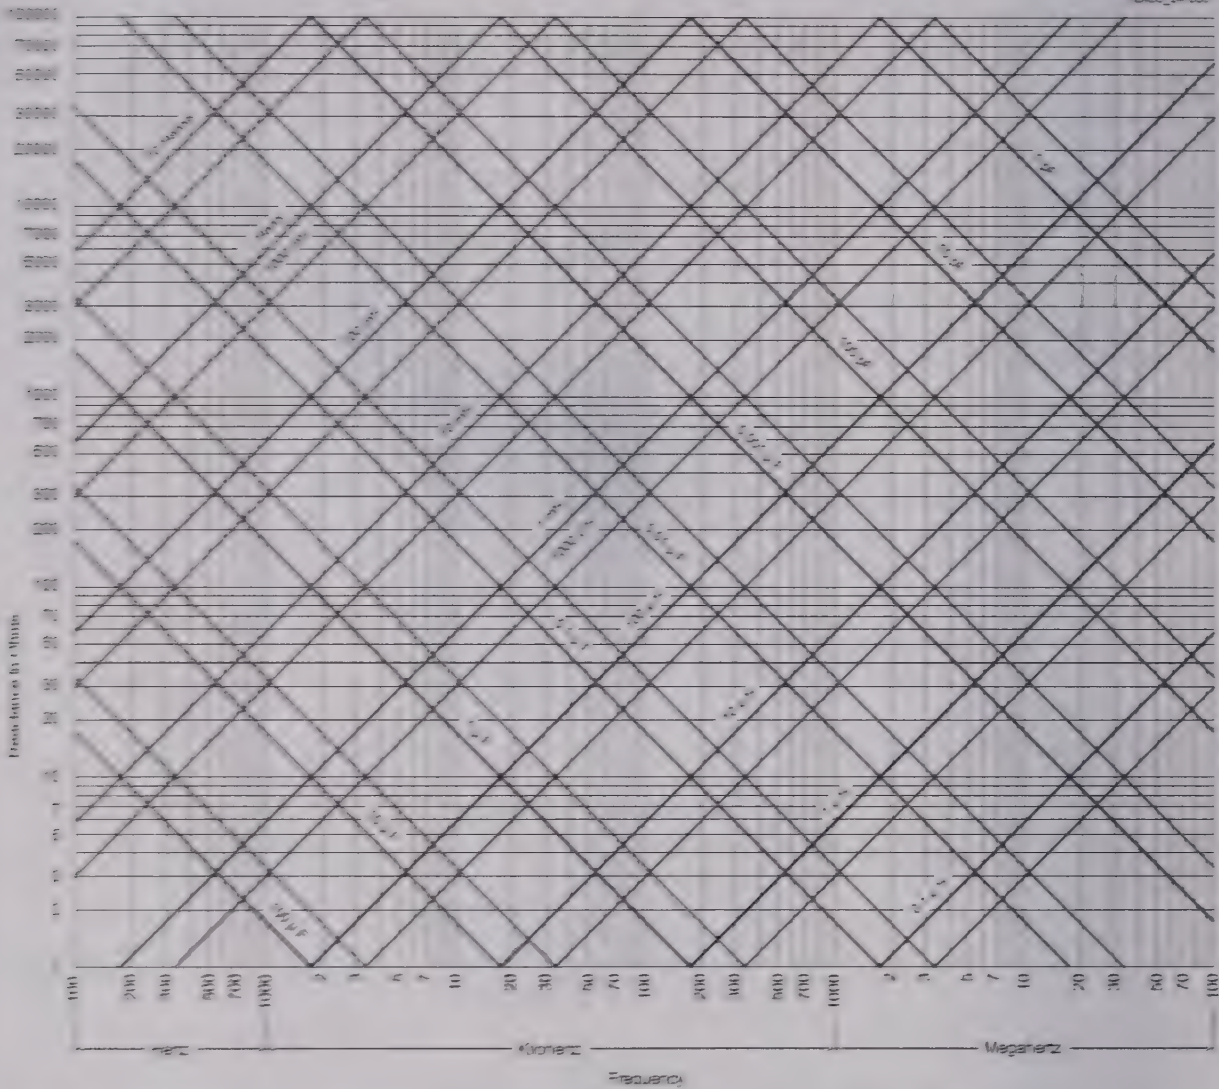

Figure 3.26 — inductive and capacitive reactance vs frequency. Heavy lines represent multiples of 10, intermediate lines multiples of 5. For example, the light line between 10  $\mu$ H and 100  $\mu$ H represents 50  $\mu$ H, the light line between 0.1  $\mu$ F and 1  $\mu$ F represents 0.5  $\mu$ F and so on. Other values can be extrapolated from the chart. For example, the reactance of 10 H at 50 Hz can be found by taking the reactance of 10  $\Omega$  at 500 Hz and dividing by 10 for the 10 times decrease in frequency. (Originally from Terman, *Radio Engineer's Handbook*. See references.)

we combined with the first method.)  
 This example serves to remind us that series capacitance is not calculated in the manner used by other series resistance and inductance, but *series capacitive reactance* does follow the simple additior formula.

For reactances of the same type in parallel, the general formula is:

$$X_{total} = \frac{1}{\frac{1}{X_1} + \frac{1}{X_2} + \frac{1}{X_3} + \dots + \frac{1}{X_n}}$$

or, for exactly two reactances in parallel

$$X_{total} = \frac{X_1 \times X_2}{X_1 + X_2}$$

Example: Place the capacitors in the last example (10.0 pF and 20.0 pF) in parallel in the 28.0 MHz circuit. What is the resultant reactance?

$$X_{total} = \frac{X_1 \times X_2}{X_1 + X_2} = \frac{568 \Omega \times 284 \Omega}{568 \Omega + 284 \Omega} = 189 \Omega$$

Alternatively, two capacitors in parallel can

be combined by adding their capacitances.

$$C_{total} = C_1 + C_2 = 10.0 \text{ pF} + 20.0 \text{ pF} = 30 \text{ pF}$$

$$X_C = \frac{1}{2 \pi f C} = \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 30 \times 10^{-12} \text{ F}} = \frac{10^6 \Omega}{5280} = 189 \Omega$$

**Figure 3.21** — The conventional method of plotting reactances on the vertical axis of a graph, using the upward or “plus” direction for inductive reactance and the downward or “minus” direction for capacitive reactance. The horizontal axis will be used for resistance in later examples.

Example: Place the series inductors above (4.0  $\mu\text{H}$  each) in parallel in a 3.8-MHz circuit. What is the resultant reactance?

$$X_{\text{total}} = \frac{X_{L1} \times X_{L2}}{X_{L1} + X_{L2}}$$

$$= \frac{96 \Omega \times 96 \Omega}{96 \Omega + 96 \Omega} = 48 \Omega$$

Of course, a number (N) of equal reactances (or resistances) in parallel yields a reactance that is the value of one of them divided by N, or:

$$X_{\text{total}} = \frac{X}{N} = \frac{96 \Omega}{2} = 48 \Omega$$

All of these calculations apply only to reactances of the same type; that is, all capacitive or all inductive. Mixing types of reactances requires a different approach.

### UNLIKE REACTANCES IN SERIES

When combining unlike reactances — that is, combinations of inductive and capacitive reactance — in series, it is necessary to take into account that the voltage-to-current phase

relationships differ for the different types of reactance. **Figure 3.22** shows a series circuit with both types of reactance. Since the reactances are in series, the current must be the same in both. The voltage across each circuit element differs in phase, however. The voltage  $E_L$  leads the current by  $90^\circ$ , and the voltage  $E_C$  lags the current by  $90^\circ$ . Therefore,  $E_L$  and  $E_C$  have opposite polarities and cancel each other in whole or in part. The line E in **Figure 3.22** approximates the resulting voltage, which is the difference between  $E_L$  and  $E_C$ .

Since for a constant current the reactance is directly proportional to the voltage, the net reactance is still the sum of the individual reactances. Because inductive reactance is considered to be positive and capacitive reactance negative, the resulting reactance can be either positive (inductive) or negative (capacitive) or even zero (no reactance).

$$X_{\text{total}} = X_L - X_C$$

The convention of using absolute values for the reactances and building the sense of positive and negative into the formula is the preferred method used by hams and will be used in all of the remaining formulas in this chapter. Nevertheless, before using any formulas that include reactance, determine whether this convention is followed before assuming that the absolute values are to be used.

Example: Using **Figure 3.22** as a visual aid, let  $X_C = 20.0 \Omega$  and  $X_L = 80.0 \Omega$ . What is the resulting reactance?

$$X_{\text{total}} = X_L - X_C$$

$$= 80.0 \Omega - 20.0 \Omega = +60.0 \Omega$$

Since the result is a positive value, total reactance is inductive. Had the result been a negative number, the total reactance would have been capacitive.

When reactance types are mixed in a series circuit, the resulting reactance is always smaller than the larger of the two reactances. Likewise, the resulting voltage across the series combination of reactances is always smaller than the larger of the two voltages across individual reactances.

Every series circuit of mixed reactance types with more than two circuit elements can be reduced to this simple circuit by combining all the reactances into one inductive and one capacitive reactance. If the circuit has more than one capacitor or more than one inductor in the overall series string, first use the formulas given earlier to determine the total series inductance alone and the total series capacitance alone (or their respective reactances). Then combine the resulting single capacitive reactance and single inductive reactance as shown in this section.

### UNLIKE REACTANCES IN PARALLEL

The situation of parallel reactances of mixed type appears in **Figure 3.23**. Since the elements are in parallel, the voltage is common to both reactive components. The current through the capacitor,  $I_C$ , leads the voltage by  $90^\circ$ , and the current through the inductor,  $I_L$ , lags the voltage by  $90^\circ$ . In this case, it is the currents that are  $180^\circ$  out of phase and thus cancel each other in whole or in part. The total current is the difference between the individual currents, as indicated by the line I in **Figure 3.23**.

Since reactance is the ratio of voltage to current, the total reactance in the circuit is:

$$X_{\text{total}} = \frac{E}{I_L - I_C}$$

In the drawing,  $I_C$  is larger than  $I_L$ , and the resulting differential current retains the phase of  $I_C$ . Therefore, the overall reactance,  $X_{\text{total}}$ , is capacitive in this case. The total reactance

**Figure 3.22** — A series circuit containing both inductive and capacitive components, together with representative voltage and current relationships.

Figure 3.23 — A parallel circuit containing both inductive and capacitive components, together with representative voltage and current relationships.

of the circuit will be smaller than the larger of the individual reactances, because the total current is smaller than the larger of the two individual currents.

In parallel circuits, reactance and current are inversely proportional to each other for a constant voltage and the equation for two reactances in parallel can be used, carrying the positive and negative signs:

$$X_{\text{total}} = \frac{X_L \times (-X_C)}{X_L - X_C} = \frac{-X_L \times X_C}{X_L - X_C}$$

As with the series formula for mixed reactances, follow the convention of using absolute values for the reactances, since the minus signs in the formula account for capacitive reactance being negative. If the solution yields a negative number, the resulting reactance is capacitive, and if the solution is positive, then the reactance is inductive.

Example: Using Figure 3.23 as a visual aid, place a capacitive reactance of  $10.0 \Omega$  in parallel with an inductive reactance of  $40.0 \Omega$ . What is the resulting reactance?

$$\begin{aligned} X_{\text{total}} &= \frac{-X_L \times X_C}{X_L - X_C} \\ &= \frac{-40.0 \Omega \times 10.0 \Omega}{40.0 \Omega - 10.0 \Omega} \\ &= \frac{-400 \Omega}{30.0 \Omega} = -13.3 \Omega \end{aligned}$$

The reactance is capacitive, as indicated by the negative solution. Moreover, like resistances in parallel, the resultant reactance is always smaller than the larger of the two individual reactances.

As with the case of series reactances, if each leg of a parallel circuit contains more than one reactance, first simplify each leg to a single reactance. If the reactances are of the same type in each leg, the series reactance formulas for reactances of the same type will apply. If the reactances are of different types, then use the formulas shown above for mixed

series reactances to simplify the leg to a single value and type of reactance.

### 3.5.3 Reactances At and Near Resonance

Any series or parallel circuit in which the values of the two unlike reactances are equal is said to be *resonant*. For any given inductance or capacitance, it is theoretically possible to find a value of the opposite reactance type to produce a resonant circuit for any desired frequency.

When a series circuit like the one shown in Figure 3.22 is resonant, the voltages  $E_C$  and  $E_L$  are equal and cancel; their sum is zero. This is a *series-resonant* circuit. Since the reactance of the circuit is proportional to the sum of these voltages, the net reactance also goes to zero. Theoretically, the current, as shown in Figure 3.24, can become infinite. In fact, it is limited only by losses in the components and other resistances that would exist in a real circuit of this type. As the frequency of operation moves slightly off resonance and the reactances no longer cancel completely, the net reactance climbs as shown in the figure. Similarly, away from resonance the current drops to a level determined by the net reactance.

In a *parallel-resonant* circuit of the type in Figure 3.23, the current  $I_L$  and  $I_C$  are equal and cancel to zero. Since the reactance is inversely proportional to the current, as the current approaches zero, the reactance becomes infinite. As with series circuits, component losses and other resistances in the circuit prevent the current from reaching zero. Figure 3.25 shows the theoretical current curve near and at resonance for a purely reactive parallel-resonant circuit. Note that in both Figure 3.24 and Figure 3.25, the departure of current from the resonance value is close to, but not quite, symmetrical above and below the resonant frequency.

Example: What is the reactance of a series L-C circuit consisting of a  $56.04\text{-pF}$  capacitor

Figure 3.24 — The relative generator current with a fixed voltage in a series circuit containing inductive and capacitive reactances as the frequency approaches and departs from resonance.

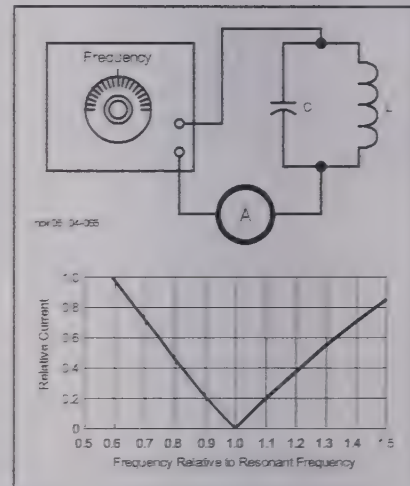

Figure 3.25 — The relative generator current with a fixed voltage in a parallel circuit containing inductive and capacitive reactances as the frequency approaches and departs from resonance. (The circulating current through the parallel inductor and capacitor is a maximum at resonance.)

and an  $8.967\text{-}\mu\text{H}$  inductor at 7.00, 7.10 and 7.20 MHz? Using the formulas from earlier in this chapter, we calculate a table of values:

Frequency (MHz)	$X_L (\Omega)$	$X_C (\Omega)$	$X_{\text{total}} (\Omega)$
7.000	394.4	405.7	-11.3
7.100	400.0	400.0	0
7.200	405.7	394.4	11.3

The exercise shows the manner in which the reactance rises rapidly as the frequency moves above and below resonance. Note that in a

**Figure 3.26** — The transition from capacitive to inductive reactance in a series-resonant circuit as the frequency passes resonance.

**Figure 3.27** — The transition from inductive to capacitive reactance in a parallel-resonant circuit as the frequency passes resonance.

## 3.6 Impedance

When a circuit contains both resistance and reactance, the combined opposition to current is called *impedance*. Symbolized by the letter  $Z$ , impedance is a more general term than either resistance or reactance. Frequently, the term is used even for circuits containing only resistance or reactance. Qualifications such as “resistive impedance” are sometimes added to indicate that a circuit has only resistance, however.

The reactance and resistance comprising

series-resonant circuit, the reactance at frequencies below resonance is capacitive, and above resonance, it is inductive. **Figure 3.26** displays this fact graphically. In a parallel-resonant circuit, where the reactance becomes infinite at resonance, the opposite condition exists: above resonance, the reactance is capacitive and below resonance it is inductive, as shown in **Figure 3.27**. Of course, all graphs and calculations in this section are theoretical and presume a purely reactive circuit. Real circuits are never purely reactive; they contain some resistance that modifies their performance considerably. Real resonant circuits will be discussed later in this chapter.

### 3.5.4 Reactance and Complex Waveforms

All of the formulas and relationships shown in this section apply to alternating current in the form of regular sine waves. Complex wave shapes complicate the reactive situation considerably. A complex or nonsinusoidal wave can be treated as a sine wave of some fundamental frequency and a series of harmonic frequencies whose amplitudes depend on the original wave shape. When such a complex wave — or collection of sine waves — is applied to a reactive circuit, the current through the circuit will not have the same wave shape as the applied voltage. The difference results because the reactance of an inductor and capacitor depend in part on the applied frequency.

For the second-harmonic component of the complex wave, the reactance of the inductor is twice and the reactance of the capacitor is half their respective values at the fundamental frequency. A third-harmonic component produces inductive reactances that are triple and capacitive reactances that are one-third those at the fundamental frequency. Thus, the

an impedance may be connected either in series or in parallel, as shown in **Figure 3.29**. In these circuits, the reactance is shown as a box to indicate that it may be either inductive or capacitive. In the series circuit at A, the current is the same in both elements, with (generally) different voltages appearing across the resistance and reactance. In the parallel circuit at B, the same voltage is applied to both elements, but different currents may flow in the two branches.

**Figure 3.28** — A signal path with a series inductor and a shunt capacitor. The circuit presents different reactances to an ac signal and to its harmonics.

overall circuit reactance is different for each harmonic component.

The frequency sensitivity of a reactive circuit to various components of a complex wave shape creates both difficulties and opportunities. On the one hand, calculating the circuit reactance in the presence of highly variable as well as complex waveforms, such as speech, is difficult at best. On the other hand, the frequency sensitivity of reactive components and circuits lays the foundation for filtering, that is, for separating signals of different frequencies or acting upon them differently. For example, suppose a coil is in the series path of a signal and a capacitor is connected from the signal line to ground, as represented in **Figure 3.28**. The reactance of the coil to the second harmonic of the signal will be twice that at the fundamental frequency and oppose more effectively the flow of harmonic current. Likewise, the reactance of the capacitor to the harmonic will be half that to the fundamental, allowing the harmonic an easier current path away from the signal line toward ground. The result is a low-pass filter that attenuates the harmonic more than the fundamental signal. (See the **Analog and Digital Filtering** chapter for detailed information on filter theory and construction.)

In a resistance, the current is in phase with the applied voltage, while in a reactance it is  $90^\circ$  out of phase with the voltage. Thus, the phase relationship between current and voltage in the circuit as a whole may be anything between zero and  $90^\circ$ , depending on the relative amounts of resistance and reactance.

As shown in **Figure 3.21** in the preceding section, reactance is graphed on the vertical axis to record the phase difference between the voltage and the current.

**Figure 3.30** adds resistance to the graph. Since the voltage is in phase with the current, resistance is recorded on the horizontal axis, using the positive or right side of the scale.

**Figure 3.29** — Series and parallel circuits containing resistance and reactance.

**Figure 3.30** — The conventional method of charting impedances on a graph, using the vertical axis for reactance (the upward or “plus” direction for inductive reactance and the downward or “minus” direction for capacitive reactance), and using the horizontal axis for resistance.

### 3.6.1 Calculating Z from R and X in Series Circuits

Impedance is the complex combination of resistance and reactance. Since there is a 90° phase difference between resistance and reactance (whether inductive or capacitive), simply adding the two values does not correspond to what actually happens in a circuit and will not give the correct result. Therefore, expressions such as “ $Z = R + X$ ” are incorrect because they show resistance and reactance being added directly. The correct expression is “ $Z = R + jX$ ” showing that complex mathematics must be used. In pure mathematics, “ $j$ ” indicates an imaginary number. Because  $i$  represents current in electronics, we use the letter “ $j$ ” for the same mathematical operator, although there is nothing imaginary about what it represents in electronics. (References to explain imaginary numbers, rectangular coordinates, polar coordinates and how to work with them are provided in the “Radio Mathematics” article in this book’s downloadable supplemental information.) With respect to resistance and reactance, the letter  $j$  is normally assigned to those figures on the vertical axis, 90° out of phase with the horizontal axis. The presence of  $j$  means that impedance is a vector and calculating impedance from resistance and reactance involves *vector addition*.

As noted earlier, a vector is a value with both magnitude and direction, such as velocity; “10 meters/second to the north.” Impedance also has a “direction” derived from the phase differences between voltage and current as described below. In vector addition, the result of combining two values with a phase difference is a quantity different from the simple *algebraic addition* of the two values. The result will have a phase difference intermediate between two vectors.

#### RECTANGULAR FORM OF IMPEDANCE

Because this form for impedances,  $Z = R \pm jX$ , can be plotted on a graph using rectangular coordinates, this is the *rectangular form* of impedance. The rectangular coordinate system in which one axis represents real number and the other axis imaginary numbers is called the *complex plane* and impedance with both real (R) and imaginary (X) components is called *complex impedance*. Unless specifically noted otherwise, assume that “impedance” means “complex impedance” and that both R and X may be present.

Consider **Figure 3.31**, a series circuit consisting of an inductive reactance and a resistance. As given, the inductive reactance is 100 Ω and the resistance is 50 Ω. Using *rectangular coordinates*, the impedance becomes

$$Z = R + jX$$

where

- Z = the impedance in ohms,
- R = the resistance in ohms, and
- X = the reactance in ohms.

In the present example,

$$Z = 50 + j100 \Omega$$

This point is located at the tip of the arrow drawn on the graph where the dashed lines cross.

#### POLAR FORM OF IMPEDANCE AND PHASE ANGLE

As the graph in **Figure 3.31** shows, the impedance that results from combining R and X can also be represented by a line completing a right triangle whose sides are the resistance and reactance. The point at the end of the line — the complex impedance — can be described by how far it is from the origin of the graph where the axes cross (the *magnitude* of the impedance indicated by vertical bars around the variable,  $|Z|$ ) and the angle made by the line with the horizontal axis representing 0° (the *phase angle* of the impedance,  $\theta$ ).

**Figure 3.31** — A series circuit consisting of an inductive reactance of 100 Ω and a resistance of 50 Ω. At B, the graph plots the resistance, reactance, and impedance.

This is the *polar form* of impedance and it is written in the form

$$Z = |Z| \angle \theta$$

Occasionally,  $\theta$  may be given in radians. The convention in this handbook is to use degrees unless specifically noted otherwise.

The length of the hypotenuse of the right triangle represents the magnitude of the impedance and can be calculated using the formula for calculating the hypotenuse of a right triangle, in which the square of the hypotenuse equals the sum of the squares of the two sides:

$$|Z| = \sqrt{R^2 + X^2}$$

In this example:

$$|Z| = \sqrt{(50 \Omega)^2 + (100 \Omega)^2}$$

$$= \sqrt{2500 \Omega^2 + 10000 \Omega^2}$$

$$= \sqrt{12500 \Omega^2} = 112 \Omega$$

The magnitude of the impedance that results from combining  $50 \Omega$  of resistance with  $100 \Omega$  of inductive reactance is  $112 \Omega$ . From trigonometry, the tangent of the phase angle is the side opposite the angle ( $X$ ) divided by the side adjacent to the angle ( $R$ ), or

$$\tan \theta = \frac{X}{R}$$

where

$X$  = the reactance, and  
 $R$  = the resistance.

Find the angle by taking the inverse tangent, or arctan:

$$\theta = \arctan \frac{X}{R}$$

Calculators sometimes label the inverse tangent key as “tan<sup>-1</sup>”. Remember to be sure your calculator is set to use the right angular units, either degrees or radians.

In the example shown in Figure 3.31,

$$\theta = \arctan \frac{100 \Omega}{50 \Omega} = \arctan 2.0 = 63.4^\circ$$

Using the information just calculated, the complex impedance in polar form is:

$$Z = 112 \Omega \angle 63.4^\circ$$

This is stated verbally as “112 ohms at an angle of 63 point 4 degrees.”

## POLAR TO RECTANGULAR CONVERSION

The expressions  $R \pm jX$  and  $|Z| \angle \theta$  both provide the same information, but in two different forms. The procedure just given permits conversion from rectangular coordinates into polar coordinates. The reverse procedure is also important. **Figure 3.32** shows an impedance composed of a capacitive reactance and a resistance. Since capacitive reactance appears as a negative value, the impedance will be at a negative phase angle, in this case,  $12.0 \Omega$  at a phase angle of  $-42.0^\circ$  or  $Z = |12.0 \Omega| \angle -42.0^\circ$ .

Remember that the impedance forms a triangle with the values of  $X$  and  $R$  from the rectangular coordinates. The reactance axis forms the side opposite the angle  $\theta$ .

$$\sin \theta = \frac{\text{side opposite}}{\text{hypotenuse}} = \frac{X}{|Z|}$$

Solving this equation for reactance, we have:

$$X = |Z| \times \sin \theta \text{ (ohms)}$$

Likewise, the resistance forms the side adjacent to the angle.

$$\sin \theta = \frac{\text{side opposite}}{\text{hypotenuse}} = \frac{X}{|Z|}$$

Solving for resistance, we have:

$$R = |Z| \times \cos \theta \text{ (ohms)}$$

Then from our example:

$$\begin{aligned} X &= 12.0 \Omega \times \sin(-42^\circ) \\ &= 12.0 \Omega \times -0.669 = -8.03 \Omega \end{aligned}$$

$$\begin{aligned} R &= 12.0 \Omega \times \cos(-42^\circ) \\ &= 12.0 \Omega \times 0.743 = 8.92 \Omega \end{aligned}$$

Since  $X$  is a negative value, it is plotted on the lower vertical axis, as shown in Figure 3.32, indicating capacitive reactance. In rectangular form,  $Z = 8.92 \Omega - j8.03 \Omega$ .

In performing impedance and related calculations with complex circuits, rectangular coordinates are most useful when formulas require the addition or subtraction of values. Polar notation is most useful for multiplying and dividing complex numbers. (See the article “Radio Mathematics” in this book’s downloadable supplemental material for references dealing with the mathematics of complex numbers.)

All of the examples shown so far in this section presume a value of reactance that contributes to the circuit impedance. Reactance is a function of frequency, however, and many impedance calculations may begin with a value of capacitance or inductance and an operating frequency. In terms of these values,  $|Z|$  can be calculated in either of two ways, depending on whether the reactance is inductive or capacitive:

$$|Z| = \sqrt{R^2 + (2\pi fL)^2}$$

$$|Z| = \sqrt{R^2 + \left(\frac{1}{2\pi fC}\right)^2}$$

Example: What is the impedance of a circuit like Figure 3.31 with a resistance of  $100 \Omega$  and a  $7.00\text{-}\mu\text{H}$  inductor operating at a frequency of  $7.00 \text{ MHz}$ ? Using the equation appropriate for inductive reactance,

**Figure 3.32 — A series circuit consisting of a capacitive reactance and a resistance: the impedance is given as  $12.0 \Omega$  at a phase angle  $\theta$  of  $-42$  degrees. At B, the graph plots the resistance, reactance, and impedance.**

$$\begin{aligned}
 |Z| &= \sqrt{R^2 + (2\pi fL)^2} \\
 &= \sqrt{(100\ \Omega)^2 + (2\pi \times 7.0 \times 10^{-6}\ \text{H} \times 7.0 \times 10^6\ \text{Hz})^2} \\
 &= \sqrt{10000\ \Omega^2 + (308\ \Omega)^2} \\
 &= \sqrt{10000\ \Omega^2 + 94900\ \Omega^2} \\
 &= \sqrt{104900\ \Omega^2} = 323.9\ \Omega
 \end{aligned}$$

Since 308  $\Omega$  is the value of inductive reactance of the 7.00- $\mu\text{H}$  coil at 7.00 MHz, the phase angle calculation proceeds as given in the earlier example:

$$\begin{aligned}
 \theta &= \arctan \frac{X}{R} = \arctan \left( \frac{308.0\ \Omega}{100.0\ \Omega} \right) \\
 &= \arctan (3.08) = 72.0^\circ
 \end{aligned}$$

Since the reactance is inductive, the phase angle is positive.

### 3.6.2 Calculating Z from R and X in Parallel Circuits

In a parallel circuit containing reactance and resistance, such as shown in **Figure 3.33**, calculation of the resultant impedance from the values of R and X does not proceed by direct combination as for series circuits. The general formula for parallel circuits is:

$$|Z| = \frac{RX}{\sqrt{R^2 + X^2}}$$

where the formula uses the absolute (unsigned) reactance value. The phase angle for the parallel circuit is given by:

$$\theta = \arctan \left( \frac{R}{X} \right)$$

The sign of  $\theta$  has the same meaning in both series and parallel circuits: if the parallel reactance is capacitive, then  $\theta$  is a negative angle, and if the parallel reactance is inductive, then  $\theta$  is a positive angle.

Example: An inductor with a reactance of 30.0  $\Omega$  is in parallel with a resistor of 40.0  $\Omega$ . What is the resulting impedance and phase angle?

$$\begin{aligned}
 |Z| &= \frac{RX}{\sqrt{R^2 + X^2}} = \frac{30.0\ \Omega \times 40.0\ \Omega}{\sqrt{(30.0\ \Omega)^2 + (40.0\ \Omega)^2}} \\
 &= \frac{1200\ \Omega^2}{\sqrt{900\ \Omega^2 + 1600\ \Omega^2}} = \frac{1200\ \Omega^2}{\sqrt{2500\ \Omega^2}}
 \end{aligned}$$

**Figure 3.33** — A parallel circuit containing an inductive reactance of 30.0  $\Omega$  and a resistor of 40.0  $\Omega$ . No graph is given, since parallel impedances cannot be manipulated graphically in the simple way of series impedances.

$$= \frac{1200\ \Omega^2}{50.0\ \Omega}$$

$$\theta = \arctan \left( \frac{R}{X} \right) = \arctan \left( \frac{40.0\ \Omega}{30.0\ \Omega} \right)$$

$$\theta = \arctan (1.33) = 53.1^\circ$$

In polar form,

$$Z = 24.0 \angle 53.1^\circ\ \Omega$$

Since the parallel reactance is inductive, the resultant angle is positive.

Example: A capacitor with a reactance of 16.0  $\Omega$  is in parallel with a resistor of 12.0  $\Omega$ . What is the resulting impedance and phase angle? (Remember that capacitive reactance is negative when used in calculations.)

$$\begin{aligned}
 |Z| &= \frac{RX}{\sqrt{R^2 + X^2}} = \frac{-16.0\ \Omega \times 12.0\ \Omega}{\sqrt{(12.0\ \Omega)^2 + (-16.0\ \Omega)^2}} \\
 &= \frac{-192\ \Omega^2}{\sqrt{144\ \Omega^2 + 256\ \Omega^2}} = \frac{-192\ \Omega^2}{\sqrt{400\ \Omega^2}}
 \end{aligned}$$

$$= \frac{-192\ \Omega^2}{20.0\ \Omega} = -9.60\ \Omega$$

$$\theta = \arctan \left( \frac{R}{X} \right) = \arctan \left( \frac{12.0\ \Omega}{-16.0\ \Omega} \right)$$

$$\theta = \arctan (-0.750) = -36.9^\circ$$

Because the parallel reactance is capacitive and the reactance negative, the resultant phase angle is negative.

### 3.6.3 Admittance

Impedance also has an inverse: *admittance* (Y), measured in siemens (S). Thus,

$$Y = 1 / Z$$

Since resistance, reactance and impedance are inversely proportional to the current ( $Z = E / I$ ), conductance, susceptance and admittance are directly proportional to current. That is,

$$Y = I / E$$

Admittance can be expressed in rectangular and polar forms, just like impedance,

$$Y = G + jB = |Y| \angle \theta$$

The phase angle for admittance has the opposite sign convention as for impedance: if the susceptance component is inductive, the phase angle is negative, and if the susceptive component is capacitive, the phase angle is positive.

One handy use for admittance is in simplifying parallel circuit impedance calculations. Similar to series combinations, the admittance of a parallel combination of reactance and resistance is the vector addition of susceptance and conductance. In other words, for parallel circuits:

$$|Y| = \sqrt{G^2 + B^2}$$

where

$|Y|$  = magnitude of the admittance in siemens,

G = conductance or 1 / R in siemens, and

B = susceptance or -1 / X in siemens.

Repeating the previous example for an inductor with a reactance of 30.0  $\Omega$  in parallel with a resistor of 40.0  $\Omega$ . Calculate the resulting impedance and phase angle by using admittance.

The inductor's susceptance is  $-1 / 30.0\ \Omega = -0.0333\ \text{S}$  and the resistor's conductance is  $1 / 40.0\ \Omega = 0.0250\ \text{S}$ .

$$\begin{aligned}
 |Y| &= \sqrt{(-0.0333\ \text{S})^2 + (0.0250\ \text{S})^2} \\
 &= \sqrt{0.00173\ \text{S}^2} = 0.0417\ \text{S}
 \end{aligned}$$

The admittance's phase angle in terms of conductance and susceptance is:

$$\theta = \arctan \left( \frac{B}{G} \right)$$

$$\theta = \arctan \left( \frac{-0.0333\ \text{S}}{0.0250\ \text{S}} \right) = \arctan (-1.33) = -53.1^\circ$$

In polar form,

$$Y = 0.0417 \angle -53.1^\circ$$

Converting back to impedance:

$$|Z| = \frac{1}{|Y|} = \frac{1}{0.0417 \text{ S}} = 24.0 \Omega$$

The impedance's phase angle is the negative of the admittance's phase angle, so:

$$\angle Z = -\angle Y = \angle 53.1^\circ$$

and in polar form

$$Z = 24.0 \angle 53.1^\circ \Omega$$

Conversion between resistance, impedance and admittance is very useful in working with complex circuits and in impedance matching of antennas and transmission lines. There are many on-line calculators that can perform these operations and many programmable calculators and suites of mathematical computer software have these functions built-in. Knowing when and how to use them, however, demands some understanding of the fundamental strategies shown here.

### 3.6.4 More than Two Elements in Series or Parallel

When a circuit contains several resistances or several reactances in series, simplify the circuit before attempting to calculate the impedance. Resistances in series add, just as in a purely resistive circuit. Series reactances of the same kind—that is, all capacitive or all inductive—also add, just as in a purely reactive circuit. The goal is to produce a single value of resistance and a single value of reactance that can be used in the impedance calculation.

Figure 3.34 illustrates a more difficult case in which a circuit contains two different reactive elements in series, along with a series resistance. The series combination

Figure 3.34 — A series impedance containing mixed capacitive and inductive reactances can be reduced to a single reactance plus resistance by combining the reactances algebraically.

Figure 3.35 — A parallel impedance containing mixed capacitive and inductive susceptances can be reduced to a single reactance plus resistance using formulas shown earlier in the chapter. By converting reactances to susceptances, as shown in A, you can combine the susceptances algebraically into a single susceptance, as shown in B.

of  $X_C$  and  $X_L$  reduce to a single value using the same rules of combination discussed in the section on purely reactive components. As Figure 3.34B demonstrates, the resultant reactance is the difference between the two series reactances.

For parallel circuits with multiple resistances or multiple reactances of the same type, use the rules of parallel combination to reduce the resistive and reactive components to single elements. Where two or more reactive components of different types appear in the same circuit, they can be combined using formulas shown earlier for pure reactances. As Figure 3.35 suggests, however, they can also be combined as susceptances. Parallel susceptances of different types add, with attention to their differing signs. The resulting single susceptance can then be combined with the conductance to arrive at the overall circuit admittance whose inverse is the final circuit impedance.

### 3.6.5 Equivalent Series and Parallel Circuits

The two circuits shown in Figure 3.29 are equivalent if the same current flows when a given voltage of the same frequency is applied, and if the phase angle between voltage and current is the same in both cases. It is possible, in fact, to transform any given series circuit into an equivalent parallel circuit, and vice versa.

A series RX circuit can be converted into its parallel equivalent by means of the formulas:

$$R_P = \frac{R_S^2 + X_S^2}{R_S}$$

$$X_P = \frac{R_S^2 + X_S^2}{X_S}$$

where the subscripts P and S represent the parallel- and series-equivalent values, respectively. If the parallel values are known, the equivalent series circuit can be found from:

$$R_S = \frac{R_P X_P^2}{R_P^2 + X_P^2}$$

and

$$X_S = \frac{R_P^2 X_P}{R_P^2 + X_P^2}$$

Example: Let the series circuit in Figure 3.29 have a series reactance of  $-50.0 \Omega$  (indicating a capacitive reactance) and a resistance of  $50.0 \Omega$ . What are the values of the equivalent parallel circuit?

$$R_P = \frac{R_S^2 + X_S^2}{R_S} = \frac{(50.0 \Omega)^2 + (-50.0 \Omega)^2}{50.0 \Omega}$$

$$= \frac{2500 \Omega^2 + 2500 \Omega^2}{50.0 \Omega} = \frac{5000 \Omega^2}{50 \Omega} = 100 \Omega$$

$$X_P = \frac{R_S^2 + X_S^2}{X_S} = \frac{(50.0 \Omega)^2 + (-50.0 \Omega)^2}{-50.0 \Omega}$$

$$= \frac{2500 \Omega^2 + 2500 \Omega^2}{-50.0 \Omega} = \frac{5000 \Omega^2}{-50 \Omega} = -100 \Omega$$

A capacitive reactance of  $100 \Omega$  in parallel with a resistance of  $100 \Omega$  is the equivalent circuit to the series circuit.

### 3.6.6 Ohm's Law for Impedance

Ohm's Law applies to circuits containing impedance just as readily as to circuits having resistance or reactance only. The formulas are:

$$E = I Z$$

$$I = E / Z$$

$$Z = E / I$$

where

- E = voltage in volts,
- I = current in amperes, and
- Z = impedance in ohms.

$Z$  must now be understood to be a complex number, consisting of resistive and reactive components. If  $Z$  is complex, then so are  $E$  and  $I$ , with a magnitude and phase angle. The rules of complex mathematics are then applied and the variables are written in boldface type as  $Z$ ,  $E$ , and  $I$ , or an arrow is added above them to indicate that they are complex, such as,

$$\vec{E} = \vec{I} \vec{Z}$$

If only the magnitude of impedance, voltage, and currents are important, however, then the magnitudes of the three variables can be combined in the familiar ways without regard to the phase angle. In this case  $E$  and  $I$  are assumed to be RMS values (or some other steady-state value such as peak, peak-to-peak, or average). **Figure 3.36** shows a simple circuit consisting of a resistance of  $75.0 \Omega$  and a reactance of  $100 \Omega$  in series. From the series-impedance formula previously given, the impedance is

$$\begin{aligned} Z &= \sqrt{R^2 + X_L^2} = \sqrt{(75.0 \Omega)^2 + (100 \Omega)^2} \\ &= \sqrt{5630 \Omega^2 + 10000 \Omega^2} \\ &= \sqrt{15600 \Omega^2} = 125 \Omega \end{aligned}$$

If the applied voltage is 250 V, then

$$I = \frac{E}{Z} = \frac{250 \text{ V}}{125 \Omega} = 2.0 \text{ A}$$

This current flows through both the resistance and reactance, so the voltage drops are:

$$E_R = I R = 2.0 \text{ A} \times 75.0 \Omega = 150 \text{ V}$$

$$E_{X_L} = I X_L = 2.0 \text{ A} \times 100 \Omega = 200 \text{ V}$$

**Figure 3.36** — A series circuit consisting of an inductive reactance of  $100 \Omega$  and a resistance of  $75.0 \Omega$ . Also shown is the applied voltage, voltage drops across the circuit elements, and the current.

## AC Component Summary

Basic Unit	Resistor	Capacitor	Inductor
Units Commonly Used	ohm ( $\Omega$ )	farad (F) microfarads ( $\mu\text{F}$ ) picofarads (pF)	henry (H) millihenrys (mH) microhenrys ( $\mu\text{H}$ )
Time constant	(None)	RC	L/R
Voltage-Current Phase	In phase	Current leads voltage Voltage lags current	Voltage leads current Current lags voltage
Resistance or Reactance	Resistance	$X_C = 1 / 2\pi f C$	$X_L = 2\pi f L$
Change with increasing frequency	No	Reactance decreases	Reactance increases
Q of circuit	Not defined	$X_C / R$	$X_L / R$

Illustrating one problem of working only with RMS values, the simple arithmetical sum of these two drops, 350 V, is greater than the applied voltage because the two voltages are  $90^\circ$  out of phase. When phase is taken into account,

$$\begin{aligned} E &= \sqrt{(150 \text{ V})^2 + (200 \text{ V})^2} \\ &= \sqrt{22500 \text{ V}^2 + 40000 \text{ V}^2} \\ &= \sqrt{62500 \text{ V}^2} = 250 \text{ V} \end{aligned}$$

### 3.6.7 Reactive Power and Power Factor

Although purely reactive circuits, whether simple or complex, show a measurable ac voltage and current, we cannot simply multiply the two together to arrive at power. Power is the rate at which energy is consumed by a circuit, and purely reactive circuits do not consume energy. The charge placed on a capacitor during part of an ac cycle is returned to the circuit during the next part of a cycle. Likewise, the energy stored in the magnetic field of an inductor returns to the circuit later in the ac cycle. A reactive circuit simply cycles and recycles energy into and out of the reactive components. If a purely reactive circuit were possible in reality, it would consume no energy at all.

In reactive circuits, circulation of energy accounts for seemingly odd phenomena. For example, in a series circuit with capacitance and inductance, the voltages across the components may exceed the supply voltage. That condition can exist because, while energy is being stored by the inductor, the capacitor is returning energy to the circuit from its previously charged state, and vice-versa. In a parallel circuit with inductive and capacitive branches, the current circulating through the

components may exceed the current drawn from the source. Again, the phenomenon occurs because the inductor's collapsing magnetic field supplies current to the capacitor, and the discharging capacitor provides current to the inductor.

To distinguish between the non-dissipated energy circulating in a purely reactive circuit and the dissipated or *real power* in a resistive circuit, the unit of *reactive power* is called the *volt-ampere reactive*, or VAR. The term watt is not used and sometimes reactive power is called "wattless" power. VAR has only limited use in radio circuits. Formulas similar to those for resistive power are used to calculate VAR:

$$\text{VAR} = I \times E$$

$$\text{VAR} = I^2 \times X$$

$$\text{VAR} = E^2 / X$$

where  $E$  and  $I$  are RMS values of voltage and current.

Real, or dissipated, power is measured in watts. *Apparent power* is the product of the voltage across and the current through an impedance. To distinguish apparent power from real power, apparent power is measured in *volt-amperes* (VA).

In the circuit of Figure 3.36, an applied voltage of 250 V results in a current of 2.00 A, giving an apparent power of  $250 \text{ V} \times 2.00 \text{ A} = 500 \text{ W}$ . Only the resistance actually consumes power, however. The real power dissipated by the resistance is:

$$E = I^2 R = (2.0 \text{ A})^2 \times 75.0 \Omega = 300 \text{ W}$$

and the reactive power is:

$$\text{VAR} = I^2 \times X_L = (2.0 \text{ A})^2 \times 100 \Omega = 400 \text{ VA}$$

The ratio of real power to the apparent power is called the circuit's *power factor* (PF).

$$PF = \frac{P_{\text{consumed}}}{P_{\text{apparent}}} = \frac{R}{Z}$$

Power factor is frequently expressed as a percentage. The power factor of a purely resistive circuit is 100% or 1, while the power factor of a pure reactance is zero. In the example of Figure 3.36 the power factor would be 300 W / 500 W = 0.600 or 60%.

Apparent power has no direct relationship to the power actually dissipated unless the power factor of the circuit is known.

$$P = \text{Apparent Power} \times \text{Power Factor}$$

An equivalent definition of power factor is:

$$PF = \cos \theta$$

where  $\theta$  is the phase angle of the circuit impedance.

Since the phase angle in the example equals:

$$\theta = \arctan \left( \frac{X}{R} \right) = \arctan \left( \frac{100 \Omega}{75.0 \Omega} \right)$$

$$\theta = \arctan (1.33) = 53.1^\circ$$

and the power factor is:

$$PF = \cos 53.1^\circ = 0.600$$

as the earlier calculation confirms.

Since power factor is always rendered as a positive number, the value must be followed by the words "leading" or "lagging" to identify the phase of the voltage with respect to the current. Specifying the numerical power factor is not always sufficient. For example, many dc-to-ac power inverters can safely operate loads having a large net reactance of one sign but only a small reactance of the opposite sign. Hence, the final calculation of the power factor in this example would be reported as "0.600, leading."

### 3.7 Quality Factor (Q) of Components

Components that store energy, such as capacitors and inductors, may be compared in terms of *quality factor* or *Q factor*, abbreviated *Q*. The concept of *Q* originated in 1914 (then dubbed *K*) and first appeared in print in 1923 when Kenneth S. Johnson used it to represent the ratio of reactance to resistance as a "figure of merit" for inductors in US patent 1,628,983. For a series or parallel representation of a reactive circuit element:

$$Q = \frac{X_S}{R_S} = \frac{R_P}{X_P}$$

where for series-connected reactance and its series loss resistance (such as an inductor)

- Q = quality factor (no units),
- X<sub>S</sub> = series reactance of the component (in ohms), and
- R<sub>S</sub> = the sum of all series resistances associated with the energy losses in the component (in ohms).

For a parallel connected reactance and its parallel loss resistance (such as a capacitor)

- Q = quality factor (no units),
- X<sub>P</sub> = parallel-connected reactance of the component (in ohms), and
- R<sub>P</sub> = the total parallel resistance associated with the energy losses in the component (in ohms).

Several exactly equivalent formulas for Q may be seen in **Table 3.2**. In Table 3.2, equation [a] most naturally represents the Q of an inductor, while equation [b] is useful for a capacitor. Both representations are equivalent to equation [c] which relates the energy storage to energy losses in inductors and capacitors. Note that in a series circuit representation,

**Table 3.2**  
Equivalent Formulas for Expressing Q and Their Uses

[a]	$Q = \frac{\text{Series Reactance}}{\text{Series Resistance}}$	Johnson's historical definition of Q for inductors, used for series circuits
[b]	$Q = \frac{\text{Parallel Resistance}}{\text{Parallel Reactance}}$	Parallel equivalent circuit definition of Q, useful for capacitors.
[c]	$Q = \frac{2\pi \times \text{Stored energy}}{\text{Energy lost in one cycle}}$	Fundamental energy definition, useful with antennas, reactive components, and mechanical systems.
[d]	$Q = \frac{\sqrt{f_U f_L}}{f_U - f_L} = \frac{\text{Frequency}}{\text{Bandwidth}}$	Bandwidth formula for simple resonant circuits. Impedance $Z = R + jX$ , and $f_U$ is the upper frequency where $R = X$ , and $f_L$ is the lower frequency where $R = -X$ , and $f_U - f_L$ represents the -3 dB bandwidth.

the series resistance is proportional to energy loss, and the series reactance is proportional to stored energy. In a parallel circuit, however, the reciprocal of the resistance is proportional to the lost energy and the reciprocal of the reactance is proportional to the stored energy. The Q of a tuned circuit may be found by measuring the upper and lower frequencies where the resistance equals the magnitude of the reactance, and applying equation [d]. The geometrical mean frequency is

$$f = \sqrt{f_U f_L}$$

and may be replaced by the center frequency for high-Q circuits. In circuits having several reactive components, such as the tuned circuits

in Figure 3.42 later in this chapter, the circuit Q is the parallel combination of the individual Q factors. For example:

$$Q = 1 / \left( \frac{1}{Q_C} + \frac{1}{Q_L} \right)$$

where Q<sub>C</sub> is the capacitor Q (sometimes specified by a manufacturer) and the inductor Q is Q<sub>L</sub>.

The Q of capacitors is ordinarily high. Good quality ceramic capacitors and mica capacitors may have Q values of 1200 or more. Microwave capacitors can have poor Q values — 10 or less at 10 GHz and higher frequencies because X<sub>C</sub> will be low. Capacitors are subject to predominantly dielectric losses which are modeled as a parallel loss resistance across

the capacitive reactance. Capacitors also have a series loss resistance associated with the conductor leads and capacitor plates, but this loss is often small enough to ignore.

Inductors are subject to several types of electrical energy losses such as wire resistance (including skin effect) and core losses. All electrical conductors have some resistance through which electrical energy is lost as heat. Wire conductors suffer additional losses because alternating current tends to flow on the conductor surface due to the skin effect discussed in the chapter on **RF Tech-**

**niques**. If the inductor's core is iron, ferrite or brass, the core will introduce additional losses of energy. Note that core losses for inductors are modeled as a resistor in parallel with the inductor (analogous to capacitor dielectric losses). The specific details of these losses are discussed in connection with each type of core material.

The sum of all core losses may be depicted by showing an equivalent series connected resistor with the inductor (see the section on Practical Inductors in the **Circuits and Components** chapter), although there is no

separate component represented by the resistor symbol. As a result of inherent energy losses, inductor Q rarely approaches capacitor Q in a circuit where both components work together. Although many circuits call for the highest Q inductor obtainable, other circuits may call for a specific Q, even a very low one.

Q is also discussed in the following section on Resonant Circuits. For these circuits Q is closely related to circuit bandwidth and selectivity. In addition, the circuit Q depends on whether or not a load is attached.

### 3.8 Resonant Circuits

A circuit containing both an inductor and a capacitor — and therefore, both inductive and capacitive reactance — is often called a *tuned circuit* or a *resonant circuit*. For any such circuit, there is a particular frequency at which the inductive and capacitive reactances are the same, that is,  $X_L = X_C$ . For most purposes, this is the *resonant frequency* of the circuit. At the resonant frequency — or at *resonance*, for short:

$$X_L = 2 \pi f L = X_C = \frac{1}{2 \pi f C}$$

By solving for f, we can find the resonant frequency of any combination of inductor and capacitor from the formula:

$$f = \frac{1}{2 \pi \sqrt{L C}}$$

where

- f = frequency in hertz (Hz),
- L = inductance in henrys (H),
- C = capacitance in farads (F), and
- $\pi = 3.1416$ .

For most high-frequency (HF) radio work, smaller units of inductance and capacitance and larger units of frequency are more convenient. The basic formula becomes:

$$f = \frac{10^3}{2 \pi \sqrt{L C}}$$

where

- f = frequency in megahertz (MHz),
- L = inductance in microhenrys ( $\mu$ H),
- C = capacitance in picofarads (pF), and
- $\pi = 3.1416$ .

Example: What is the resonant frequency of a circuit containing an inductor of 5.0  $\mu$ H and a capacitor of 35 pF?

$$f = \frac{10^3}{2 \pi \sqrt{L C}} = \frac{10^3}{6.2832 \sqrt{5.0 \times 35}}$$

$$= \frac{10^3}{83} = 12 \text{ MHz}$$

To find the matching component (inductor or capacitor) when the frequency and one component is known (capacitor or inductor) for general HF work, use the formula:

$$f^2 = \frac{1}{4 \pi^2 L C}$$

where f, L and C are in basic units. For HF work in terms of MHz,  $\mu$ H and pF, the basic relationship rearranges to these handy formulas:

$$L = \frac{25,330}{f^2 C}$$

$$C = \frac{25,330}{f^2 L}$$

where

- f = frequency in MHz,
- L = inductance in  $\mu$ H, and
- C = capacitance in pF

For most radio work, these formulas will permit calculations of frequency and component values well within the limits of component tolerances.

Example: What value of capacitance is needed to create a resonant circuit at 21.1 MHz, if the inductor is 2.00  $\mu$ H?

$$C = \frac{25,330}{f^2 L} = \frac{25,330}{(21.1^2 \times 2.0)}$$

$$= \frac{25,330}{890} = 28.5 \text{ pF}$$

Figure 3.20 can also be used if an approximate answer is acceptable. From the horizontal axis, find the vertical line closest to the desired resonant frequency. Every pair of diagonals that cross on that vertical line represent a combination of inductance and capacitance that will resonate at that frequency. For example, if the desired frequency is 10 MHz, the pair of diagonals representing 5  $\mu$ H and 50 pF cross quite close to that frequency. Interpolating between the given diagonals will provide more resolution — remember that all three sets of lines are spaced logarithmically.

Resonant circuits have other properties of importance, in addition to the resonant frequency, however. These include impedance, voltage drop across components in series-resonant circuits, circulating current in parallel-resonant circuits, and bandwidth. These properties determine such factors as the selectivity of a tuned circuit and the component ratings for circuits handling significant amounts of power. Although the basic determination of the tuned-circuit resonant frequency ignores any resistance in the circuit, that resistance will play a vital role in the circuit's other characteristics.

#### 3.8.1 Series-Resonant Circuits

Figure 3.37 presents a basic schematic diagram of a *series-resonant circuit*. Although most schematic diagrams of radio circuits would show only the inductor and the capacitor, resistance is always present in such circuits. The most notable resistance is associated with the series resistance losses in the inductor at HF. The dominant losses in the capacitor may be modeled as a parallel resistance (not shown), but these losses are low enough at HF to be ignored. The current meter shown in the circuit is a reminder that it

**Figure 3.37** — A series circuit containing L, C, and R is resonant at the applied frequency when the reactance of C is equal to the reactance of L. The I in the circle is the schematic symbol for an ammeter.

series circuits, the same current flows through all elements.

At resonance, the reactance of the capacitor cancels the reactance of the inductor. The voltage and current are in phase with each other, and the impedance of the circuit is determined solely by the resistance. The actual current through the circuit at resonance, and for frequencies near resonance, is determined by the formula:

$$I = \frac{E}{Z} = \frac{E}{\sqrt{R^2 + \left[ 2\pi fL - \frac{1}{(2\pi fC)} \right]^2}}$$

where all values are in basic units.

At resonance, the reactive factor in the formula is zero (the bracketed expression under the square root symbol). As the frequency is shifted above or below the resonant frequency without altering component values, however, the reactive factor becomes significant, and the value of the current becomes smaller than at resonance. At frequencies far from resonance, the reactive components become dominant, and the resistance no longer significantly affects the current amplitude.

The exact curve created by recording the current as the frequency changes depends on the ratio of reactance to resistance. When the reactance of either the coil or capacitor is of the same order of magnitude as the resistance, the current decreases rather slowly as the frequency is moved in either direction away from resonance. Such a curve is said to be *broad*. Conversely, when the reactance is considerably larger than the resistance, the current decreases rapidly as the frequency moves away from resonance, and the circuit is said to be *sharp*. A sharp circuit will respond a great deal more readily to the resonant frequency than to

**Figure 3.38** — Relative current in series-resonant circuits with various values of series resistance and Q. (An arbitrary maximum value of 1.0 represents current at resonance.) The reactance at resonance for all curves is 1000 Ω. Note that the current is hardly affected by the resistance in the circuit at frequencies more than 10% away from the resonant frequency.

frequencies quite close to resonance; a broad circuit will respond almost equally well to a group or band of frequencies centered around the resonant frequency.

Both types of resonance curves are useful. A sharp circuit gives good selectivity — the ability to respond strongly (in terms of current amplitude) at one desired frequency and to discriminate against others. A broad circuit is used when the apparatus must give about the same response over a band of frequencies, rather than at a single frequency alone.

**Figure 3.38** presents a family of curves, showing the decrease in current as the frequency deviates from resonance. In each case, the inductive and capacitive reactances are assumed to be 1000 Ω. The maximum current, shown as a relative value on the graph, occurs with the lowest resistance, while the lowest peak current occurs with the highest resistance. Equally important, the rate at which the current decreases from its maximum value also changes with the ratio of reactance to resistance. It decreases most rapidly when the ratio is high and most slowly when the ratio is low.

### UNLOADED Q

As noted in equation [a] of Table 3.2 earlier in this chapter, Q is the ratio of series reactance representing  $2\pi$  times the stored energy (equation [c] in Table 3.2) to series resistance

**Figure 3.39** — Relative current in series-resonant circuits having different values of  $Q_U$ . The current at resonance is normalized to the same level for all curves in order to show the rate of change of decrease in current for each value of  $Q_U$ . The half-power points are shown to indicate relative bandwidth of the response for each curve. The bandwidth is indicated for a circuit with a  $Q_U$  of 10.

or consumed energy. Since both terms of the ratio are measured in ohms, Q has no units and is known as the *quality factor* (and less frequently, the *figure of merit* or the *multiplying factor*). The series resistive losses of the coil often dominate the energy consumption in HF series-resonant circuits, so the inductor Q largely determines the resonant-circuit Q. Since this value of Q is independent of any external load to which the circuit might transfer power, it is called the *unloaded Q* or  $Q_U$  of the circuit.

Example: What is the unloaded Q of a series-resonant circuit with a series loss resistance of 5 Ω and inductive and capacitive components having a reactance of 500 Ω each? With a reactance of 50 Ω each?

$$Q_{U1} = \frac{X1}{R} = \frac{500 \Omega}{5 \Omega} = 100$$

$$Q_{U2} = \frac{X2}{R} = \frac{50 \Omega}{5 \Omega} = 10$$

### BANDWIDTH

**Figure 3.39** is an alternative way of drawing the family of curves that relate current to frequency for a series-resonant circuit. By assuming that the peak current of each curve is the same, the rate of change of current for various values of  $Q_U$  and the associated ra-

tions of reactance to resistance are more easily compared. From the curves, it is evident that the lower  $Q_U$  circuits pass current across a greater *bandwidth* of frequencies than the circuits with a higher  $Q_U$ . For the purpose of comparing tuned circuits, bandwidth is often defined as the frequency spread between the two frequencies at which the current amplitude decreases to 0.707 (or  $\sqrt{2}/2$ ) times the maximum value. Since the power consumed by the resistance,  $R$ , is proportional to the square of the current, the power at these points is half the maximum power at resonance, assuming that  $R$  is constant for the calculations. The half-power, or  $-3$  dB, points are marked on Figure 3.39.

For  $Q$  values of 10 or greater, the curves shown in Figure 3.39 are approximately symmetrical. On this assumption, bandwidth (BW) can be easily calculated by inverting equation [d] in Table 3.2, and approximating the geometrical mean  $-3$  dB frequency by  $f$ :

$$BW = \frac{f}{Q_U}$$

where BW and  $f$  are in the same units, that is, in Hz, kHz or MHz.

Example: What is the 3 dB bandwidth of a series-resonant circuit operating at 14 MHz with a  $Q_U$  of 100?

$$BW = \frac{f}{Q_U} = \frac{14 \text{ MHz}}{100} = 0.14 \text{ MHz} = 140 \text{ kHz}$$

The relationship between  $Q_U$ ,  $f$  and BW provides a means of determining the value of circuit  $Q$  when inductor losses may be difficult to measure. By constructing the series-resonant circuit and measuring the current as the frequency varies above and below resonance, the half-power points can be determined. Then:

$$Q_U = \frac{f}{BW}$$

Example: What is the  $Q_U$  of a series-resonant circuit operating at 3.75 MHz, if the  $-3$  dB bandwidth is 375 kHz?

$$Q_U = \frac{f}{BW} = \frac{3.75 \text{ MHz}}{0.375 \text{ MHz}} = 10.0$$

If the loss resistance of the inductor is much greater than of the capacitor (the usual case), BW is approximately  $R/L$ . The  $Q$  of a series resonant circuit can also be stated

$$Q_U = \frac{f_0}{BW} = \frac{1}{R} \sqrt{\frac{L}{C}}$$

The illustrations the relationship between  $Q$  and bandwidth at [hyperphysics.phy-astr.gsu.edu/hbase/electric/serres.html](http://hyperphysics.phy-astr.gsu.edu/hbase/electric/serres.html) are helpful in understanding the concept. Table 3.3 provides some simple formulas for estimating the maximum current and

**Table 3.3**

**The Selectivity of Resonant Circuits**

Approximate percentage of current at resonance <sup>1</sup> or of impedance at resonance <sup>2</sup>	Bandwidth (between half-power or $-3$ dB points on response curve)	Series circuit current phase angle (degrees)
95	$f/3Q$	18.5
90	$f/2Q$	26.5
70.7	$f/Q$	45
44.7	$2f/Q$	63.5
24.2	$4f/Q$	76
12.4	$8f/Q$	83

<sup>1</sup>For a series resonant circuit

<sup>2</sup>For a parallel resonant circuit

phase angle for various bandwidths, if both  $f$  and  $Q_U$  are known.

**VOLTAGE DROP ACROSS COMPONENTS**

The voltage drop across the coil and across the capacitor in a series-resonant circuit are each proportional to the reactance of the component for a given current (since  $E = IX$ ). These voltages may be many times the applied voltage for a high- $Q$  circuit. In fact, at resonance, the voltage drop is:

$$E_X = Q_U E_{AC}$$

where

$E_X$  = the voltage across the reactive component,

$Q_U$  = the circuit unloaded  $Q$ , and

$E_{AC}$  = the applied voltage in Figure 3.37.

(Note that the voltage drop across the inductor is the vector sum of the voltages across the resistance and the reactance; however, for  $Q$  greater than 10, the error created by using this is not ordinarily significant.) Since the calculated value of  $E_X$  is the RMS voltage, the peak voltage will be higher by a factor of 1.414. Antenna couplers and other high- $Q$  circuits handling significant power may experience arcing from high values of  $E_X$ , even though the source voltage to the circuit is well within component ratings.

**CAPACITOR LOSSES**

Although capacitor energy losses tend to be insignificant compared to inductor losses up to about 30 MHz, the losses may affect circuit  $Q$  in the VHF range. Leakage resistance, principally in the solid dielectric that forms the insulating support for the capacitor plates, appears as a resistance in parallel with the capacitor plates. Instead of forming a series resistance, capacitor leakage usually forms a parallel resistance with the capacitive reactance. If the leakage resistance of a capacitor is significant enough to affect the  $Q$  of a series-resonant circuit, the parallel resis-

tance ( $R_P$ ) may be converted to an equivalent series resistance ( $R_S$ ) before adding it to the inductor's resistance.

$$R_S = \frac{X_C^2}{R_P} = \frac{1}{R_P \times (2\pi f C)^2}$$

Example: A 10.0 pF capacitor has a leakage resistance of 10,000  $\Omega$  at 50.0 MHz. What is the equivalent series resistance?

$$R_S = \frac{1}{R_P \times (2\pi f C)^2} = \frac{1}{1.0 \times 10^4 \times (6.283 \times 50.0 \times 10^6 \times 10.0 \times 10^{-12})^2} = \frac{1}{1.0 \times 10^4 \times 9.87 \times 10^{-6}} = \frac{1}{0.0987} = 10.1 \Omega$$

In calculating the impedance, current and bandwidth for a series-resonant circuit in which this capacitor might be used, the series-equivalent resistance of the unit is added to the loss resistance of the coil. Since inductor losses tend to increase with frequency because of skin effect in conductors, and capacitor dielectric losses also tend to increase with frequency, the combined losses in the capacitor and the inductor can seriously reduce circuit  $Q$ .

**3.8.2 Parallel-Resonant Circuits**

Although series-resonant circuits are common, the vast majority of resonant circuits used in radio work are *parallel-resonant circuits*. Figure 3.40 represents a typical HF parallel-resonant circuit. As is the case for series-resonant circuits, the inductor is the chief source of resistive losses (that is, the parallel loss resistance across the capacitor is not shown), and these losses appear in series with the coil. Because current through parallel-resonant circuits is lowest at resonance, and

**Figure 3.40** — A typical parallel-resonant circuit, with the resistance shown in series with the inductive leg of the circuit. Below a  $Q_U$  of 10, resonance definitions may lead to three separate frequencies which converge at higher  $Q_U$  levels. See text.

impedance is highest, they are sometimes called *antiresonant* circuits. (You may encounter the old terms *acceptor* and *rejector* referring to series- and parallel-resonant circuits, respectively.)

Because the conditions in the two legs of the parallel circuit in Figure 3.40 are not the

same — the resistance is shown in only one of the legs — all of the conditions by which series resonance is determined do not occur simultaneously in a parallel-resonant circuit. **Figure 3.41** graphically illustrates the situation by showing the currents through the two components. (Currents are drawn in the manner of complex impedances shown previously to show the phase angle for each current.) When the inductive and capacitive reactances are identical, the condition defined for series resonance is met as shown at point (a). The impedance of the inductive leg is composed of both  $X_L$  and  $R$ , which yields an impedance greater than  $X_C$  and that is not  $180^\circ$  out of phase with  $X_C$ . The resultant current is greater than the minimum possible value and is not in phase with the voltage.

By altering the value of the inductor slightly (and holding the  $Q$  constant), a new frequency can be obtained at which the current reaches its minimum. When parallel circuits are tuned using a current meter as an indicator, this point (b) is ordinarily used as an indication of resonance. The current “dip” indicates a condition of maximum impedance and is sometimes called the *antiresonant* point or *maximum impedance resonance* to distinguish it from the condition at which  $X_C = X_L$ . Maximum impedance is achieved at this point by vec-

tor addition of  $X_C$ ,  $X_L$  and  $R$ , however, and the result is a current somewhat out of phase with the voltage.

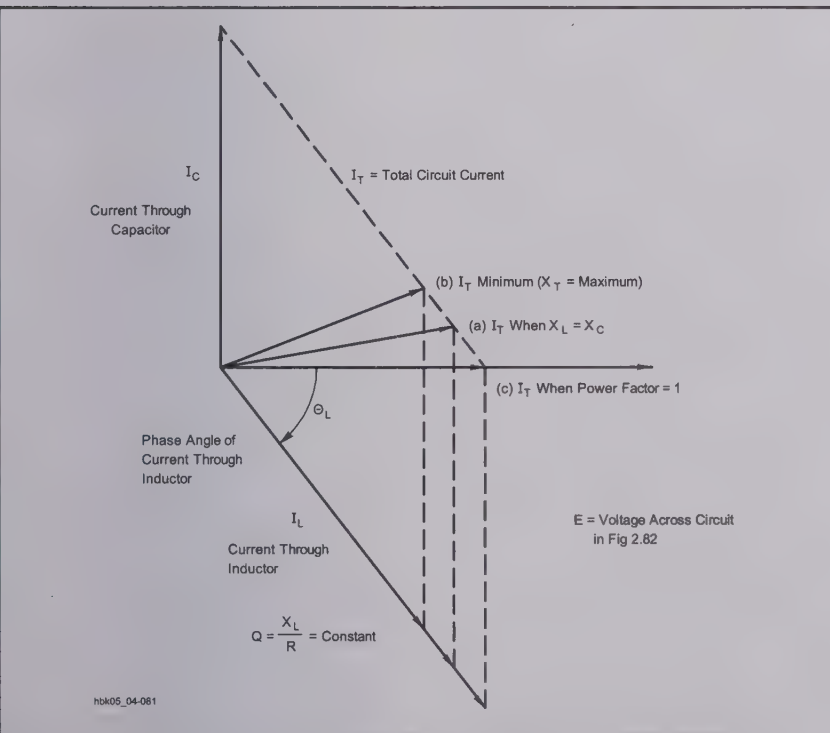

Point (c) in the figure represents the *unity-power-factor* resonant point. Adjusting the inductor value and hence its reactance (while holding  $Q$  constant) produces a new resonant frequency at which the resultant current is in phase with the voltage. The new value of inductive reactance is the value required for a parallel-equivalent inductor and its parallel-equivalent resistor (calculated according to the formulas in the last section) to just cancel the capacitive reactance. The value of the parallel-equivalent inductor is always smaller than the actual inductor in series with the resistor and has a proportionally smaller reactance. (The parallel-equivalent resistor, conversely, will always be larger than the coil-loss resistor shown in series with the inductor.) The result is a resonant frequency slightly different from the one for minimum current and the one for  $X_L = X_C$ .

The points shown in the graph in Figure 3.41 represent only one of many possible situations, and the relative positions of the three resonant points do not hold for all possible cases. Moreover, specific circuit designs can draw some of the resonant points together, for example, compensating for the resistance of the coil by retuning the capacitor. The differences among these resonances are significant for circuit  $Q$  below 10, where the inductor’s series resistance is a significant percentage of the reactance. Above a  $Q$  of 10, the three points converge to within a percent of the frequency and the differences between them can be ignored for practical calculations. Tuning for minimum current will not introduce a sufficiently large phase angle between voltage and current to create circuit difficulties.

### PARALLEL CIRCUITS OF MODERATE TO HIGH $Q$

The resonant frequencies defined above converge in parallel-resonant circuits with  $Q$  higher than about 10. Therefore, a single set of formulas will sufficiently approximate circuit performance for accurate predictions. Indeed, above a  $Q$  of 10, the performance of a parallel circuit appears in many ways to be simply the inverse of the performance of a series-resonant circuit using the same components.

Accurate analysis of a parallel-resonant circuit requires the substitution of a parallel-equivalent resistor for the actual inductor-loss series resistor, as shown in **Figure 3.42**. Sometimes called the *dynamic resistance* of the parallel-resonant circuit, the parallel-equivalent resistor value will increase with circuit  $Q$ , that is, as the series resistance value decreases. To calculate the approxi-

**Figure 3.41** — Resonant conditions for a low- $Q_U$  parallel circuit. Resonance may be defined as (a)  $X_L = X_C$  (b) minimum current flow and maximum impedance or (c) voltage and current in phase with each other. With the circuit of Figure 3.40 and a  $Q_U$  of less than 10, these three definitions may represent three distinct frequencies.

**Figure 3.42** — Series and parallel equivalents when both circuits are resonant. The series resistance,  $R_S$  in A, is replaced by the parallel resistance,  $R_P$  in B, and vice versa.  $R_P = X_L^2 / R_S$ .

mate parallel-equivalent resistance, use the formula:

$$R_P = \frac{X_L^2}{R_S} = \frac{(2\pi f L)^2}{R_S} = Q_U X_L$$

for  $R_S \ll X_C \ll R_P$  and  $X_P \approx X_S$  in the equations for series-parallel conversion in the section on Impedance.

Example: What is the parallel-equivalent resistance for a coil with an inductive reactance of  $350 \Omega$  and a series resistance of  $5.0 \Omega$  at resonance?

$$R_P = \frac{X_L^2}{R_S} = \frac{(350 \Omega)^2}{5.0 \Omega} = \frac{122,500 \Omega^2}{5.0 \Omega} = 24,500 \Omega$$

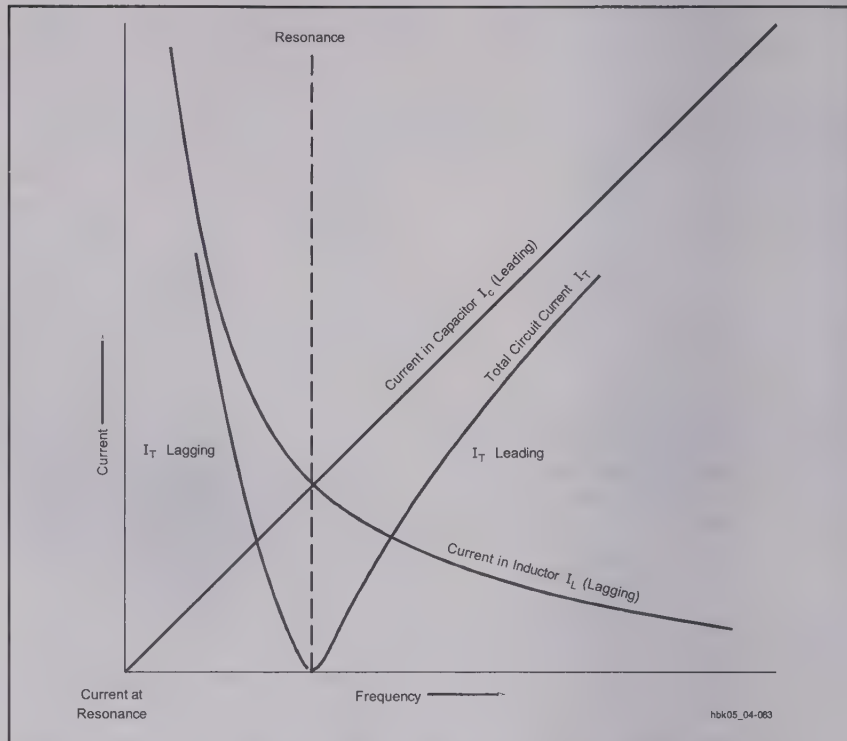

Since the coil  $Q_U$  remains the inductor's reactance divided by its series resistance, the coil  $Q_U$  is 70. Multiplying  $Q_U$  by the reactance also provides the approximate parallel-equivalent resistance of the coil series resistance.

At resonance, where  $X_L = X_C$ ,  $R_P$  defines the impedance of the parallel-resonant circuit. The reactances just equal each other, leaving the voltage and current in phase with each other. In other words, the circuit shows only the parallel resistance. Therefore, the equation for  $R_P$  can be rewritten as:

$$Z = \frac{X_L^2}{R_S} = \frac{(2\pi f L)^2}{R_S} = Q_U X_L$$

In this example, the circuit impedance at resonance is  $24,500 \Omega$ .

At frequencies below resonance the current through the inductor is larger than that through the capacitor, because the reactance of the coil is smaller and that of the capacitor is larger than at resonance. There is only partial cancellation of the two reactive currents, and the total current therefore is larger than

**Figure 3.43** — The currents in a parallel-resonant circuit as the frequency moves through resonance. Below resonance, the current lags the voltage; above resonance the current leads the voltage. The base line represents the current level at resonance, which depends on the impedance of the circuit at that frequency.

the current taken by the resistance alone. At frequencies above resonance the situation is reversed and more current flows through the capacitor than through the inductor, so the total current again increases.

The current at resonance, being determined wholly by  $R_P$ , will be small if  $R_P$  is large, and large if  $R_P$  is small. **Figure 3.43** illustrates the relative current flows through a parallel-tuned circuit as the frequency is moved from below resonance to above resonance. The base line represents the minimum current level for the particular circuit. The actual current at any frequency off resonance is simply the vector sum of the currents through the parallel equivalent resistance and through the reactive components.

To obtain the impedance of a parallel-tuned circuit either at or off the resonant frequency, apply the general formula:

$$Z = \frac{Z_C Z_L}{Z_S}$$

where

$Z$  = overall circuit impedance

$Z_C$  = impedance of the capacitive leg (usually, the reactance of the capacitor),

$Z_L$  = impedance of the inductive leg (the vector sum of the coil's reactance and resistance), and

$Z_S$  = series impedance of the capacitor-inductor combination as derived from the equation for current in a series-resonant circuit.

After using vector calculations to obtain  $Z_L$  and  $Z_S$ , converting all the values to polar form — as described earlier in this chapter — will ease the final calculation. Of course, each impedance may be derived from the resistance and the application of the basic reactance formulas on the values of the inductor and capacitor at the frequency of interest.

Since the current rises away from resonance, the parallel-resonant-circuit impedance must fall. It also becomes complex, resulting in an ever-greater phase difference between the voltage and the current. The rate at which the impedance falls is a function of  $Q_U$ . **Figure 3.44** presents a family of curves showing the impedance drop from resonance for circuit  $Q$  ranging from 10 to 100. The curve family for parallel-circuit impedance is essentially the same as the curve family for series-circuit current.

As with series-resonant circuits, the higher the  $Q$  of a parallel-tuned circuit, the sharper will be the response peak. Likewise, the lower the  $Q$ , the wider the band of frequencies to which the circuit responds. Using the

**Figure 3.44** — Relative impedance of parallel-resonant circuits with different values of  $Q_U$ . The curves are similar to the series-resonant circuit current level curves of Figure 3.38. The effect of  $Q_U$  on impedance is most pronounced within 10% of the resonance frequency.

half-power ( $-3$  dB) points as a comparative measure of circuit performance as in series-resonant circuits,  $BW = f/Q_U$  and  $Q_U = f/BW$ , where the resonant frequency and the bandwidth are in the same units. Also similarly to the series-resonant circuit:

$$Q_U = R \sqrt{\frac{C}{L}}$$

As a handy reminder, **Table 3.4** summarizes the performance of parallel-resonant circuits at high and low  $Q$  and above and below resonant frequency.

It is possible to use either series- or parallel-resonant circuits to do the same work in many circuits, thus giving the designer considerable flexibility. **Figure 3.45** illustrates this general principle by showing a series-resonant circuit in the signal path and a parallel-resonant circuit shunted from the signal path to ground. Assume both circuits are resonant at the same frequency,  $f$ , and have the same  $Q$ . The series-resonant circuit at A has its lowest impedance at  $f$ , permitting the maximum possible current to flow along the signal path. At all other frequencies, the impedance is greater and the current at those frequencies is less. The circuit passes the desired signal and tends to impede signals at undesired frequencies. The parallel circuit at B provides the highest impedance at resonance,  $f$ , making the signal path the lowest impedance path for the signal. At frequencies off resonance, the parallel-resonant circuit presents a lower impedance, thus presenting signals with a path to ground and away from the signal path. In theory, the effects will be the same relative to a signal current on the

**Table 3.4**

**The Performance of Parallel-Resonant Circuits**

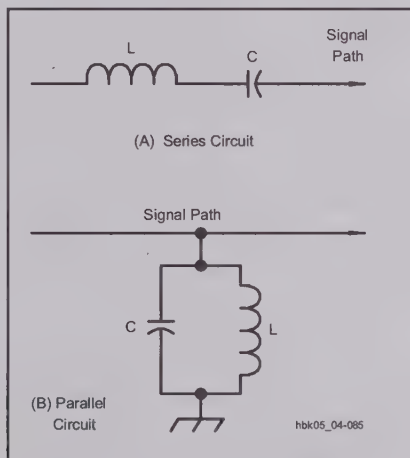

**A. High- and Low-Q Circuits (in relative terms)**

Characteristic	High-Q Circuit	Low-Q Circuit
Selectivity	high	low
Bandwidth	narrow	wide
Impedance	high	low
Total current	low	high
Circulating current	high	low

**B. Off-Resonance Performance for Constant Values of Inductance and Capacitance**

Characteristic	Above Resonance	Below Resonance
Inductive reactance	increases	decreases
Capacitive reactance	decreases	increases
Circuit resistance	unchanged*	unchanged*
Relative impedance	decreases	decreases
Total current	increases	increases
Circulating current	decreases	decreases
Circuit impedance	capacitive	inductive

\*This is true for frequencies near resonance. At distant frequencies, skin effect may alter the resistive losses of the inductor.

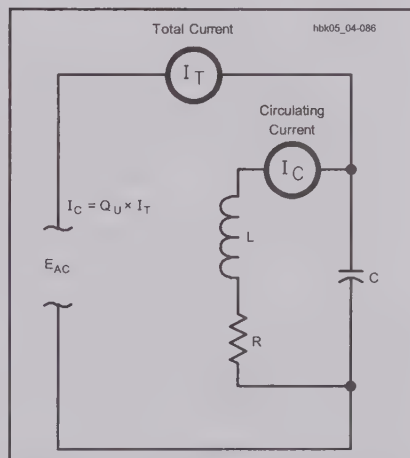

**Figure 3.45** — Series- and parallel-resonant circuits configured to perform the same theoretical task: passing signals in a narrow band of frequencies along the signal path. A real design example would consider many other factors.

signal path. In actual circuit design exercises, of course, many other variables will enter the design picture to make one circuit preferable to the other.

**CIRCULATING CURRENT**

In a parallel-resonant circuit, the source voltage is the same for all the circuit elements. The current in each element, however, is a function of the element's reactance. **Figure 3.46** redraws the parallel-resonant circuit to indicate the total current and the current circulating between the coil and the capacitor. The current drawn from the source may be low, because the overall circuit impedance is

**Figure 3.46** — A parallel-resonant circuit redrawn to illustrate both the total current and the circulating current.

high. The current through the individual elements may be high, however, because there is little resistive loss as the current circulates through the inductor and capacitor. For parallel-resonant circuits with an unloaded  $Q$  of 10 or greater, this *circulating current* is approximately:

$$I_C = Q_U I_T$$

where

- $I_C$  = circulating current in A, mA or  $\mu$ A,
- $Q_U$  = unloaded circuit  $Q$ , and
- $I_T$  = total current in the same units as  $I_C$ .

Example: A parallel-resonant circuit permits an ac or RF total current of 30 mA and has a Q of 100. What is the circulating current through the elements?

$$I_X = Q_U I = 100 \times 30 \text{ mA} = 3000 \text{ mA} = 3 \text{ A}$$

Circulating currents in high-Q parallel-tuned circuits can reach a level that causes component heating and power loss. Therefore, components should be rated for the anticipated circulating currents, and not just the total current.

### LOADED Q

In many resonant-circuit applications, the only power lost is that dissipated in the resistance of the circuit itself. At frequencies below 30 MHz, most of this resistance is in the coil. Within limits, increasing the number of turns in the coil increases the reactance faster than it raises the resistance, so coils for circuits in which the Q must be high are made with relatively large inductances for the frequency.

When the circuit delivers energy to a load (as in the case of the resonant circuits used in transmitters), the energy consumed in the circuit itself is usually negligible compared with that consumed by the load. The equivalent of such a circuit is shown in **Figure 3.47**, where the parallel resistor,  $R_L$ , represents the load to which power is delivered. If the power dissipated in the load is at least 10 times as great as the power lost in the inductor and capacitor, the parallel impedance of the resonant circuit itself will be so high compared with the resistance of the load that for all practical purposes the impedance of the combined circuit is equal to the load impedance. Under these conditions, the load resistance replaces the circuit impedance in calculating Q. The Q of a parallel-resonant circuit loaded by a resistive impedance is:

$$Q_L = \frac{R_L}{X}$$

where

$Q_L$  = circuit loaded Q,

$R_L$  = parallel load resistance in ohms, and

X = reactance in ohms of either the inductor or the capacitor.

Example: A resistive load of 3000  $\Omega$  is connected across a resonant circuit in which the inductive and capacitive reactances are each 250  $\Omega$ . What is the circuit Q?

$$Q_L = \frac{R_L}{X} = \frac{3000 \Omega}{250 \Omega} = 12$$

The effective Q of a circuit loaded by a parallel resistance increases when the reactances are decreased. A circuit loaded with

**Figure 3.47** — A loaded parallel-resonant circuit, showing both the inductor-loss resistance and the load,  $R_L$ . If smaller than the inductor resistance,  $R_L$  will control the loaded Q of the circuit ( $Q_L$ ).

a relatively low resistance (a few thousand ohms) must have low-reactance elements (large capacitance and small inductance) to have reasonably high Q. Many power-handling circuits, such as the output networks of transmitters, are designed by first choosing a loaded Q for the circuit and then determining component values. See the chapter on **RF Power Amplifiers** for more details.

Parallel load resistors are sometimes added to parallel-resonant circuits to lower the circuit Q and increase the circuit bandwidth. By using a high-Q circuit and adding a parallel resistor, designers can tailor the circuit response to their needs. Since the parallel resistor consumes power, such techniques ordinarily apply to receiver and similar low-power circuits, however.

Example: Specifications call for a parallel-resonant circuit with a bandwidth of 400 kHz at 14.0 MHz. The circuit at hand has a  $Q_U$  of 70.0 and its components have reactances of 350  $\Omega$  each. What is the parallel load resistor that will increase the bandwidth to the specified value? The bandwidth of the existing circuit is:

$$BW = \frac{f}{Q_U} = \frac{14.0 \text{ MHz}}{70.0} = 0.200 \text{ MHz}$$

$$= 200 \text{ kHz}$$

The desired bandwidth, 400 kHz, requires a circuit with a Q of:

$$Q = \frac{f}{BW} = \frac{14.0 \text{ MHz}}{0.400 \text{ MHz}} = 35.0$$

Since the desired Q is half the original value, halving the resonant impedance or parallel-resistance value of the circuit is in order. The present impedance of the circuit is:

$$Z = Q_U X_L = 70.0 \times 350 \Omega = 24500 \Omega$$

The desired impedance is:

$$Z = Q_U X_L = 35.0 \times 350 \Omega$$

$$= 12250 \Omega = 12.25 \text{ k}\Omega$$

or half the present impedance.

A parallel resistor of 24,500  $\Omega$ , or the nearest lower value (to guarantee sufficient bandwidth), will produce the required reduction in Q and bandwidth increase. Although this example simplifies the situation encountered in real design cases by ignoring such factors as the shape of the band-pass curve, it illustrates the interaction of the ingredients that determine the performance of parallel-resonant circuits.

### IMPEDANCE TRANSFORMATION

An important application of the parallel-resonant circuit is as an impedance matching device. Circuits and antennas often need to be connected to other circuits or feed lines that do not have the same impedance. To transfer power effectively requires a circuit that will convert or “transform” the impedances so that each connected device or system can operate properly.

**Figure 3.48** shows such a situation where the source,  $E_{AC}$ , operates at a high impedance, but the load,  $R_L$ , operates at a low impedance. The technique of impedance transformation shown in the figure is to connect the parallel-resonant circuit, which has a high impedance, across the source, but connect the load across only a portion of the coil. (This is called *tapping the coil* and the connection point is a *tap*.) The coil acts as an *autotransformer*, described in the following section, with the magnetic field of the coil shared between what are effectively two coils in series, the upper coil having many turns and the lower coil fewer turns. Energy stored in the field induces larger voltages in the many-turn coil than it does in the fewer-turn coil, “stepping down” the

**Figure 3.48** — A parallel-resonant circuit with a tapped inductor to effect an impedance match. Although the impedance presented to  $E_{AC}$  is very high, the impedance at the connection of the load,  $R_L$ , is lower.

input voltage so that energy can be extracted by the load at the required lower voltage-to-current ratio (which is impedance). The correct tap point on the coil usually has to be experimentally determined, but the technique is very effective.

When the load resistance has a very low value (say below  $100\ \Omega$ ) it may be connected in series in the resonant circuit (such as  $R_S$  in Figure 3.42A, for example), in which case the series L-R circuit can be transformed to an equivalent parallel L-R circuit as previously described. If the  $Q$  is at least 10, the equivalent parallel impedance is:

$$Z_R = \frac{X^2}{R_L}$$

## 3.9 Analog Signal Processing

The term *analog signal* refers to voltages, currents and waves that make up ac radio and audio signals, dc measurements, even power. The essential characteristic of an analog signal is that the information or energy it carries is continuously variable. Even small variations of an analog signal affect its value or the information it carries. This stands in contrast to *digital signals* that have values only within well-defined and separate ranges called *states*. To be sure, at the fundamental level all circuits and signals are analog: Digital signals are created by designing circuits that restrict the values of analog signals to those discrete states.

*Analog signal processing* involves various electronic stages to perform functions on analog signals such as amplifying, filtering, modulation and demodulation. A piece of electronic equipment, such as a radio, is constructed by combining a number of these circuits. How these stages interact with each other and how they affect the signal individually and in tandem is the subject of sections later in the chapter.

### 3.9.1 Terminology

A similar terminology is used when describing active electronic devices. The letter  $V$  or  $v$  stands for voltages and  $I$  or  $i$  for currents. Capital letters are often used to denote dc or bias values (bias is discussed later in this chapter). Lower-case often denotes instantaneous or ac values.

Voltages generally have two subscripts indicating the terminals between which the voltage is measured ( $V_{BE}$  is the dc voltage between the base and the emitter of a bipolar transistor). Currents have a single subscript indicating the terminal into which the current flows ( $I_C$  is the dc current into the collector of a bipolar transistor). If the current flows

where

$Z_R$  = resistive parallel impedance at resonance,

$X$  = reactance (in ohms) of either the coil or the capacitor, and

$R_L$  = load resistance inserted in series.

If the  $Q$  is lower than 10, the reactance will have to be adjusted somewhat — for the reasons given in the discussion of low- $Q$  parallel resonant circuits — to obtain a resistive impedance of the desired value.

These same techniques work in either “direction” — with a high-impedance source and low-impedance load or vice versa. Using a

out of the device, it is generally treated as a negative value.

Resistance is designated with the letter  $R$  or  $r$ , and impedance with the letter  $Z$  or  $z$ . For example,  $r_{DS}$  is resistance between drain and source of an FET and  $Z_i$  is input impedance. For some parameters, values differ for dc and ac signals. This is indicated by using capital letters in the subscripts for dc and lower-case subscripts for ac. For example, the common-emitter dc current gain for a bipolar transistor is designated as  $h_{FE}$ , and  $h_{fe}$  is the ac current gain. (See the section on transistor amplifiers in the **Circuits and Components** chapter for a discussion of the common-emitter circuit.) Qualifiers are sometimes added to the subscripts to indicate certain operating modes of the device. SS for saturation, BR for breakdown, ON and OFF are all commonly used.

Power supply voltages have two subscripts that are the same, indicating the terminal to which the voltage is applied.  $V_{DD}$  would represent the power supply voltage applied to the drain of a field-effect transistor.

Since integrated circuits are collections of semiconductor components, the abbreviations for the type of semiconductor used also apply to the integrated circuit. For example,  $V_{CC}$  is a power supply voltage for an integrated circuit made with bipolar transistor technology in which voltage is applied to transistor collectors.

### 3.9.2 Linearity

The premier properties of analog signals are *superposition* and *scaling*. Superposition is the property by which signals are combined, whether in a circuit, in a piece of wire, or even in air, as the sum of the individual signals. This is to say that at any one point in time, the voltage of the combined signal is the sum

parallel-resonant circuit for this application does have some disadvantages. For instance, the common connection between the input and the output provides no dc isolation. Also, the common ground is sometimes troublesome with regard to ground-loop currents. Consequently, a circuit with only mutual magnetic coupling is often preferable. With the advent of ferrites, constructing impedance transformers that are both broadband and permit operation well up into the VHF portion of the spectrum has become relatively easy. The basic principles of broadband impedance transformers appear in the **RF Techniques** chapter.

of the voltages of the original signals at the same time. In a *linear system* any number of signals will add in this way to give a single combined signal. (Mathematically, this is a *linear combination*.) For this reason, analog signals and components are often referred to as *linear signals* or *linear components*. A linear system whose characteristics do not change, such as a resistive voltage divider, is called *time-invariant*. If the system changes with time, it is *time-varying*. The variations may be random, intermittent (such as being adjusted by an operator) or periodic.

One of the more important features of superposition, for the purposes of signal processing, is that signals that have been combined by superposition can be separated back into the original signals. This is what allows multiple signals that have been received by an antenna to be separated back into individual signals by a receiver.

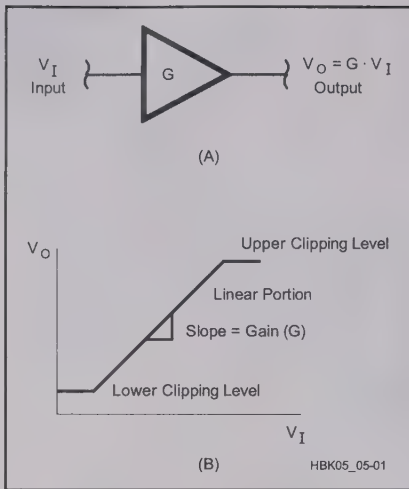

### 3.9.3 Linear Operations

Any operation that modifies a signal and obeys the rules of superposition and scaling is a *linear operation*. The following sections explain the basic linear operations from which linear systems are made.

## AMPLIFICATION AND ATTENUATION

*Amplification* and *attenuation* scale signals to be larger and smaller, respectively. The operation of *scaling* is the same as multiplying the signal at each point in time by a constant value; if the constant is greater than one then the signal is amplified, if less than one then the signal is attenuated.

An *amplifier* is a circuit that increases the amplitude of a signal. Schematically, a generic amplifier is signified by a triangular symbol, its input along the left face and its output at the point on the right (see Figure 3.49).

**Figure 3.49 — Generic amplifier. (A) Symbol.** For the linear amplifier, gain is the constant value,  $G$ , and the output voltage is equal to the input voltage times  $G$ ; (B) Transfer function, input voltage along the x-axis is converted to the output voltage along the y-axis. The linear portion of the response is where the plot is diagonal; its slope is equal to the gain,  $G$ . Above and below this range are the clipping limits, where the response is not linear and the output signal is clipped.

The linear amplifier multiplies every value of a signal by a constant value. Amplifier gain is often expressed as a multiplication factor ( $\times 5$ , for example).

$$\text{Gain} = V_o/V_i$$

where  $V_o$  is the output voltage from an amplifier when an input voltage,  $V_i$ , is applied.

An *attenuator* is a circuit that reduces the amplitude of a signal. Attenuators can be constructed from passive circuits, such as the attenuators built using resistors, described in the chapter on **Test Equipment and Measurements**. Active attenuator circuits include amplifiers whose gain is less than one or circuits with adjustable resistance in the signal path, such as a PIN diode attenuator or amplifier with gain is controlled by an external voltage.

### GAIN AND TRANSCONDUCTANCE

The operation of an amplifier is specified by its *gain*. Gain in this sense is defined as the change ( $\Delta$ ) in the output parameter divided by the corresponding change in the input parameter. If a particular device measures its input and output as currents, the gain is called a *current gain*. If the input and output are voltages, the amplifier is defined by its *voltage gain*. *Power gain* is often used, as well. Gain is technically unit-less, but is often given in V/V. Decibels are often used

## The Decibel

The decibel (dB) is the standard unit for comparing two quantities, such as power or voltage, as a ratio. It is logarithmic so very large and very small ratios are easy to work with. The formula for calculating decibels is:

$$\text{dB} = 10 \log \left( \frac{P_2}{P_1} \right) = 20 \log \left( \frac{V_2}{V_1} \right)$$

For more on working with decibels, read the articles “Radio Mathematics” found in this book’s downloadable supplemental information. Rohde & Schwarz has published Application Note IMA98 “dB or not dB? Everything you ever wanted to know about decibels but were afraid to ask...” at the website listed in the References and Bibliography section of this chapter.

to specify gain, particularly power gain. (Gain is often expressed in decibels (dB) — see the sidebar “The Decibel!”.)

If an amplifier’s input is a voltage and the output is a current, the ratio of the change in output current to the change in input voltage is called *transconductance*,  $g_m$ .

$$g_m = \frac{\Delta I_o}{\Delta V_i}$$

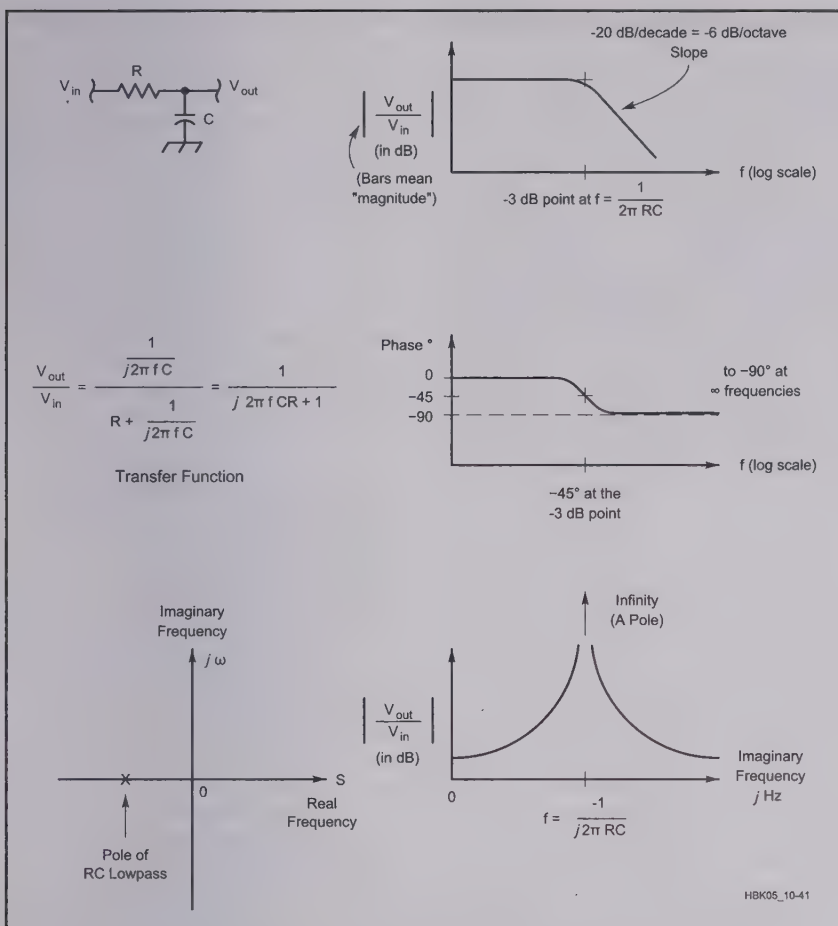

Transconductance has the same units as

conductance and admittance, siemens (S), but is only used to describe the operation of active devices, such as transistors or vacuum tubes.

Ideal linear amplifiers have the same gain for all parts of a signal. Thus, a gain of 10 changes 10 V to 100 V, 1 V to 10 V and  $-1$  V to  $-10$  V. (Gain can also be less than one.) The ability of an amplifier to change a signal’s level is limited by the amplifier’s *dynamic range*, however. An amplifier’s dynamic range is the range of signal levels over which the amplifier

**Figure 3.50 — Bode plot of (A) band-pass filter magnitude response and (B) an RC low-pass filter phase response.**

**Figure 3.51** — The transfer function for a circuit describes both the magnitude and phase response of a circuit. The RC circuit shown at the upper left has a pole at  $f = 2\pi RC$ , the filter's  $-3$  dB or cutoff frequency, at which the phase response is a  $45^\circ$  lagging phase shift. Poles cause an infinite response on the imaginary frequency axis.

produces the required gain without distortion. Dynamic range is limited for small signals by noise, distortion and other nonlinearities.

Dynamic range is limited for large signals because an amplifier can only produce output voltages (and currents) that are within the range of its power supply. (Power-supply voltages are also called the *rails* of a circuit.) As the amplified output approaches one of the rails, the output cannot exceed a given voltage near the rail and the operation of the amplifier becomes nonlinear as described below in the section on Clipping and Rectification.

Another similar limitation on amplifier linearity is called *slew rate*. Applied to an amplifier, this term describes the maximum rate at which a signal can change levels and still be accurately amplified in a particular device. *Input slew rate* is the maximum rate of change to which the amplifier can react linearly. *Output slew rate* refers to the maximum rate at which the amplifier's output current can change. Slew rate is an important

concept, because there is a direct correlation between a signal level's rate of change and the frequency content of that signal. The amplifier's ability to react to or reproduce that rate of change affects its frequency response and dynamic range.

### FREQUENCY RESPONSE AND BODE PLOTS

Another important characteristic of a circuit is its *frequency response*, a description of how it modifies a signal of any frequency. Frequency response can be stated in the form of a mathematical equation called a *transfer function*, but it is more conveniently presented as a graph of gain vs frequency. The ratio of output amplitude to input amplitude is often called the circuit's *magnitude* or *amplitude response*. Plotting the circuit's magnitude response in dB versus frequency on a logarithmic scale, such as in **Figure 3.50A**, is called a *Bode plot* (after Henrik Wade Bode). The combination of decibel

and log-frequency scales is used because the behavior of most circuits depends on ratios of amplitude and frequency and thus appears linear on a graph in which both the vertical and horizontal scales are logarithmic.

Most circuits also affect a signal's phase along with its amplitude. This is called *phase shift*. A plot of phase shift from the circuit's input to its output is called the *phase response*, seen in **Figure 3.50B**. Positive phase greater than  $0^\circ$  indicates that the output signal *leads* the input signal, while *lagging* phase shift has a negative phase. The combination of an amplitude and phase response plot gives a good picture of what effect the circuit has on signals passing through it.

### TRANSFER CHARACTERISTICS

*Transfer characteristics* are the ratio of an output parameter to an input parameter, such as output current divided by input current,  $h_{FE}$ . There are different families of transfer characteristics, designated by letters such as h, s, y or z. Each family compares parameters in specific ways that are useful in certain design or analysis methods. The most common transfer characteristics used in radio are the h-parameter family (used in transistor models) and the s-parameter family (used in RF design, particularly at VHF and above). See the **RF Techniques** chapter for more discussion of transfer characteristics.

### COMPLEX FREQUENCY

We are accustomed to thinking of frequency as a real number — so many cycles per second — but frequency can also be a complex number, s, with both a real part, designated by  $\sigma$ , and an imaginary part, designated by  $j\omega$ . ( $\omega$  is also equal to  $2\pi f$ .) The resulting complex frequency is written as  $s = \sigma + j\omega$ . At the lower left of **Figure 3.51** a pair of real and imaginary axes are used to plot values of s. This is called the *s-plane*. Complex frequency is used in Laplace transforms, a mathematical technique used for circuit and signal analysis. (Thorough treatments of the application of complex frequency can be found in college-level textbooks on circuit and signal analysis.)

When complex frequency is used, a sinusoidal signal is described by  $Ae^{st}$ , where A is the amplitude of the signal and t is time. Because s is complex,  $Ae^{st} = Ae^{(\sigma+j\omega)t} = A(e^{\sigma t})(e^{j\omega t})$ . The two exponential terms describe independent characteristics of the signal. The second term,  $e^{j\omega t}$ , is the sine wave with which we are familiar and that has frequency f, where  $f = \omega/2\pi$ . The first term,  $e^{\sigma t}$ , represents the rate at which the signal increases or decreases. If  $\sigma$  is negative, the exponential term decreases with time and the signal gets smaller and smaller. If  $\sigma$  is positive, the signal gets larger and larger. If  $\sigma = 0$ , the exponential term equals 1, a constant, and the

## Obtaining a Frequency Response

With the computer tools such as spreadsheets, it's easy to do the calculations and make a graph of frequency response. If you don't have a spreadsheet program, then use semi-log graph paper with the linear axis used for dB or phase and the logarithmic axis for frequency. An Excel spreadsheet set up to calculate and display frequency response is available in this book's downloadable supplemental information. You can modify it to meet your specific needs.

Follow these rules whether using a spreadsheet or graph paper:

- Measure input and output in the same units, such as volts, and use the same conventions, such as RMS or peak-to-peak.
  - Measure phase shift from the input to the output. (The **Test Equipment and Measurements** chapter discusses how to make measurements of amplitude and phase.)
  - Use  $10 \log (P_O/P_I)$  for power ratios and  $20 \log (V_O/V_I)$  for voltage or current.
- To make measurements that are roughly equally spaced along the logarithmic frequency axis, follow the "1-2-5 rule." Dividing a range this way, for example 1-2-5-10-20-50-100-200-500 Hz, creates steps in approximately equal ratios that then appear equally spaced on a logarithmic axis.

signal amplitude stays the same.

Complex frequency is very useful in describing a circuit's stability. If the response to an input signal is at a frequency on the right-hand side of the  $s$ -plane for which  $\sigma > 0$ , the system is *unstable* and the output signal will get larger until it is limited by the circuit's power supply or some other mechanism. If the response is on the left-hand side of the  $s$ -plane, the system is *stable* and the response to the input signal will eventually die out. The larger the absolute value of  $\sigma$ , the faster the response changes. If the response is precisely on the  $j\omega$  axis where  $\sigma = 0$ , the response will persist indefinitely.

In Figure 3.51 the equation for the simple RC-circuit's transfer function is shown at the left of the figure. It describes the circuit's behavior at real-world frequencies as well as imaginary frequencies whose values contain  $j$ . Because complex numbers are used for  $f$ , the transfer function describes the circuit's phase response, as well as amplitude. At one such frequency,  $f = -j/2\pi RC$ , the denominator of the transfer function is zero, and the gain is infinite! Infinite gain is a pretty amazing thing to achieve with a passive circuit — but because this can only happen at an imaginary frequency, it does not happen in the real world.

The practical effects of complex frequency can be experienced in a narrow CW crystal or LC filter. The poles of such a filter are just to the left of the  $j\omega$  axis, so the input signal causes the filters to "ring", or output a damped sine wave along with the desired signal. Similarly, the complex frequency of an oscillator's output at power-up must have  $\sigma > 0$  or the oscillation would never start! The output amplitude continues to grow until limiting takes place, reducing gain until  $\sigma = 0$  for a steady output.

## POLES AND ZEROES

Frequencies that cause the transfer function to become infinite are called *poles*. This is shown at the bottom right of Figure 3.51 in the graph of the circuit's amplitude response for imaginary frequencies shown on the horizontal axis. (The pole causes the graph to extend up "as a pole under a tent," thus the name.) Similarly, circuits can have *zeroes* which occur at imaginary frequencies that cause the transfer function to be zero, a less imaginative name, but quite descriptive.

A circuit can also have poles and zeroes at frequencies of zero and infinity. For example, the circuit in Figure 3.51 has a zero at infinity because the capacitor's reactance is zero at infinity and the transfer function is zero, as well. If the resistor and capacitor were exchanged, so that the capacitor was in series with the output, then at zero frequency (dc), the output would be zero because the capacitor's reactance was infinite, creating a zero.

Complex circuits can have multiple poles or multiple zeroes at the same frequency. Poles and zeroes can also occur at frequencies that are combinations of real and imaginary numbers. The poles and zeroes of a circuit form a pattern in the complex plane that corresponds to certain types of circuit behavior. (The relationships between the pole-zero pattern and circuit behavior is beyond the scope of this book, but are covered in textbooks on circuit theory.)

### What is a Pole?

Poles cause a specific change in the circuit's amplitude and phase response for real-world frequencies, even though we can't experience imaginary frequencies directly. A pole is associated with a bend in a magnitude response plot that changes the slope of

the response downward with increasing frequency by 6 dB per octave (20 dB per decade; an octave is a 2:1 frequency ratio, a decade is a 10:1 frequency ratio).

There are four ways to identify the existence and frequency of a pole as shown in Figure 3.51:

1) For a downward bend in the magnitude versus frequency plot, the pole is at the  $-3$  dB frequency for a single pole. If the bend causes a change in slope of more than 6 dB/octave, there must be multiple poles at this frequency.

2) A  $90^\circ$  lagging change on a phase versus frequency plot, where the lag increases with frequency. The pole is at the point of  $45^\circ$  added lag on the S-shaped transition. Multiple poles will add their phase lags, as above.

3) On a circuit diagram, a single pole looks like a simple RC low-pass filter. The pole is at the  $-3$  dB frequency ( $f = 1/2\pi RC$  Hz). Any other circuit with the same response has a pole at the same frequency.

4) In an equation for the transfer function of a circuit, a pole is a theoretical value of frequency that would result in infinite gain. This is clearly impossible, but as the value of frequency will either be absolute zero, or will have an imaginary component, it is impossible to make an actual real-world signal at a pole frequency.

For example, comparing the amplitude responses at top and bottom of Figure 3.51 shows that the frequency of the pole is equal to the circuit's  $-3$  dB cutoff frequency ( $1/2\pi fC$ ) multiplied by  $j$ , which is also the frequency at which the circuit causes a  $-45^\circ$  (lagging) phase shift from input to output.

### What Is a Zero?

A zero is the complement of a pole. In math, it is a frequency at which the transfer function equation of a circuit is zero. This is not impossible in the real world (unlike the pole), so zeroes can be found at real-number frequencies as well as complex-number frequencies.

Each zero is associated with an *upward* bend of 6 dB per octave in a magnitude response. Similarly to a pole, the frequency of the zero is at the  $+3$  dB point. Each zero is associated with a transition on a phase-versus-frequency plot that reduces the lag by  $90^\circ$ . The zero is at the  $45^\circ$  leading phase point. Multiple zeroes add their phase shifts just as poles do.

In a circuit, a zero creates gain that increases with frequency forever above the zero frequency. This requires active circuitry that would inevitably run out of gain at some frequency, which implies one or more poles up there. In real-world circuits, zeroes are usually not found by themselves, making the magnitude response go up, but rather paired with a pole of a different frequency, resulting

in the magnitude response having a slope between two frequencies but flat above and below them.

Real-world circuit zeroes are only found accompanied by a greater or equal number of poles. Consider a classic RC high-pass filter, such as if the resistor and capacitor in Figure 3.51 were exchanged. The response of such a circuit increases at 6 dB per octave from 0 Hz (so there must be a zero at 0 Hz) and then levels off at  $1/2\pi RC$  Hz. This leveling off is due to the presence of a pole adding its 6 dB-per-octave roll-off to cancel the 6 dB-per-octave roll-up of the zero. The transfer function for such a circuit would equal zero at zero frequency and infinity at the imaginary pole frequency.

## FEEDBACK AND OSCILLATION

The *stability* of an amplifier refers to its ability to provide gain to a signal without tending to oscillate. For example, an amplifier just on the verge of oscillating is not generally considered to be “stable.” If the output of an amplifier is fed back to the input, the feedback can affect the amplifier stability. If the amplified output is added to the input, the output of the sum will be larger. This larger output, in turn, is also fed back. As this process continues, the amplifier output will continue to rise until the amplifier cannot go any higher (clamps). Such *positive feedback* increases the amplifier gain, and is called *regeneration*. (The chapter on **Oscillators and Synthesizers** includes a discussion of positive feedback.)

Most practical amplifiers have some intrinsic and unavoidable feedback either as part of the circuit or in the amplifying device(s) itself. To improve the stability of an amplifier, *negative feedback* can be added to counteract any unwanted positive feedback. Negative feedback is often combined with a phase-shift *compensation* network to improve the amplifier stability.

Although negative feedback reduces amplifier or stage gain, the advantages of *stable* gain, freedom from unwanted oscillations and the reduction of distortion are often key design objectives and advantages of using negative feedback.

The design of feedback networks depends on the desired result. For amplifiers, which should not oscillate, the feedback network is customized to give the desired frequency response without loss of stability. For oscillators, the feedback network is designed to create a steady oscillation at the desired frequency.

## SUMMING

In a linear system, nature does most of the work for us when it comes to adding signals; placing two signals together naturally causes

**Figure 3.52 — Summing amplifier.** The output voltage is equal to the sum of the input voltages times the amplifier gain,  $G$ . As long as the resistance values,  $R$ , are equal and the amplifier input impedance is much higher, the actual value of  $R$  does not affect the output signal.

them to add according to the principle of superposition. When processing signals, we would like to control the summing operation so the signals do not distort or combine in a nonlinear way. If two signals come from separate stages and they are connected together directly, the circuitry of the stages may interact, causing distortion of either or both signals.

*Summing amplifiers* generally use a resistor in series with each stage, so the resistors connect to the common input of the following stage. This provides some *isolation* between the output circuits of each stage. **Figure 3.52** illustrates the resistors connecting to a summing amplifier. Ideally, any time we wanted to combine signals (for example, combining an audio signal with a sub-audible tone in a 2 meter FM transmitter prior to modulating the RF signal) we could use a summing amplifier.

## FILTERING

A *filter* is a common linear stage in radio equipment. Filters are characterized by their ability to selectively attenuate certain frequencies in the filter’s *stop band*, while passing or amplifying other frequencies in the *passband*. If the filter’s passband extends to or near dc, it is a *low-pass* filter, and if to infinity (or at least very high frequencies for the circuitry involved), it is a *high-pass* filter. Filters that pass a range of frequencies are *band-pass* filters. *All-pass* filters are designed to affect only the phase of a signal without changing the signal amplitude. The range of frequencies between a band-pass circuit’s low-pass and high-pass regions is its *mid-band*.

Figure 3.50A is the amplitude response for a typical band-pass audio filter. It shows that the input signal is passed to the output with no loss (0 dB) between 200 Hz and 5 kHz. This is the filter’s *mid-band response*. Above and below those frequencies the response of the

filter begins to drop. By 20 Hz and 20 kHz, the amplitude response has been reduced to one-half of (–3 dB) the mid-band response. These points are called the circuit’s *cutoff* or *corner* or *half-power frequencies*. The range between the cutoff frequencies is the filter’s passband. Outside the filter’s passband, the amplitude response drops to 1/200th (–23 dB) of mid-band response at 1 Hz and only 1/1000th (–30 dB) at 500 kHz. The steepness of the change in response with frequency is the filter’s *roll-off* and it is usually specified in dB/octave (an octave is a doubling or halving of frequency) or dB/decade (a decade is a change to 10 times or 1/10th frequency).

Figure 3.50B represents the phase response of a different filter—the simple RC low-pass filter shown at the upper right. As frequency increases, the reactance of the capacitor becomes smaller, causing most of the input signal to appear across the fixed-value resistor instead. At low frequencies, the capacitor has little effect on phase shift. As the signal frequency rises, however, there is more and more phase shift until at the cutoff frequency, there is 45° of lagging phase shift, plotted as a negative number. Phase shift then gradually approaches 90°.

Practical analog (both passive and active) and digital filters are discussed in the chapter **Analog and Digital Filtering**. Filters at RF may also be created by using transmission lines as described in the **Transmission Lines** chapter. All practical amplifiers are in effect either low-pass filters or band-pass filters, because their magnitude response decreases as the frequency increases beyond their ability to amplify signals.

## 3.9.4 Nonlinear Operations

All signal processing doesn’t have to be linear. Any time that we treat various signal levels differently, the operation is called *nonlinear*. This is not to say that all signals must be treated the same for a circuit to be linear. High-frequency signals are attenuated in a low-pass filter while low-frequency signals are not, yet the filter can be linear. The distinction is that the amount of attenuation at different frequencies is always the same, regardless of the amplitude of the signals passing through the filter.

What if we do not want to treat all voltage levels the same way? This is commonly desired in analog signal processing for clipping, rectification, compression, modulation and switching.

## CLIPPING AND RECTIFICATION

Clipping is the process of limiting the range of signal voltages passing through a circuit (in other words, *clipping* those voltages outside

the desired range from the signals). There are a number of reasons why we would like to do this. As shown in Figure 3.49, clipping is the process of limiting the positive and negative peaks of a signal. (Clipping is also called *clamping*.)

Clipping might be used to prevent a large audio signal from causing excessive deviation in an FM transmitter that would interfere with communications on adjacent channels. Clipping circuits are also used to protect sensitive inputs from excessive voltages. Clipping distorts the signal, changing it so that the original signal waveform is lost.

Another kind of clipping results in *rectification*. A *rectifier* circuit clips off all voltages of one polarity (positive or negative) and passes only voltages of the other polarity, thus changing ac to pulsating dc (see the **Power Sources** chapter). Another use of rectification is in a *peak detection* circuit that measures the peak value of a waveform. Only one polarity of the ac voltage needs to be measured and so a rectifier clips the unwanted polarity.

### LIMITING

Another type of clipping occurs when an amplifier is intentionally operated with so much gain that the input signals result in an output that is clipped at the limits of its power supply voltages (or some other designated voltages). The amplifier is said to be driven into *limiting* and an amplifier designed for this behavior is called a *limiter*. Limiters are used in FM receivers to amplify the signal until all amplitude variations in the signal are removed and the only characteristic of the original signal that remains is the frequency.

### LOGARITHMIC AMPLIFICATION

It is sometimes desirable to amplify a signal logarithmically, which means amplifying low levels more than high levels. This type of amplification is often called *signal compression*. Speech compression is sometimes used in audio amplifiers that feed modulators. The voice signal is compressed into a small range of amplitudes, allowing more voice energy to be transmitted without overmodulation (see the **Modulation** and the **Transmitting** chapters).

### 3.9.5 System Design Functions

Many kinds of electronic equipment are developed by combining basic analog signal processing circuits, often treating them as independent functional blocks. This section describes several topics associated with building systems from multiple blocks. Because analog circuits often interface with digital circuits or include digital elements in

a hybrid circuit, some topics associated with digital systems are included. Many similar functions are implemented as part of Digital Signal Processing (DSP) systems and have similar behaviors and concerns. Although not all basic electronic functions are discussed here, the concepts associated with combining them can be applied generally.

Since our main concern is the effect that circuitry has on a signal, we often describe the circuit by its actions rather than by its specific components. A *black box* is a circuit that can be described entirely by the behavior of its interfaces with other blocks and circuitry. When circuits are combined in such a way as to perform sequential operations on a signal, the individual circuits are called *stages*.

The most general way of referring to an analog circuit is as a *network*. Two basic properties of analog networks are of principal concern: the effect that the network has on a signal and the interaction that the network has with the circuitry surrounding it. Interfaces between the network and the rest of the network are called *ports*.

Many analog circuits are analyzed as *two-port networks* with an input and an output port. The signal is fed into the input port, is modified inside the network and then exits from the output port. (See the chapter on **RF Techniques** for more information on two-port networks.)

### TRANSFER FUNCTIONS

The specific way in which the analog circuit modifies the signal can be described mathematically as a transfer function. The mathematical operation that combines a signal with a transfer function is pictured symbolically in **Figure 3.53**. The transfer function,  $h(t)$  or  $h(f)$ , describes the circuit's modification of the input signal in the time domain where all values are functions of time, such as  $a(t)$  or  $b(t)$ , or in the frequency domain where all values are functions of frequency, such as  $a(f)$  or  $b(f)$ . The mathematical operation by which  $h(t)$  operates on  $a(t)$  is called *convolution* and is represented as a dot, as in  $a(t) \cdot h(t) = b(t)$ . In the frequency domain, the transfer function multiplies the input, as in  $a(f) \times h(f) = b(f)$ .

While it is not necessary to understand transfer functions mathematically to work with analog circuits, it is useful to realize that they describe how a signal interacts with other signals in an electronic system. In general, the output signal of an analog system depends not only on the input signal at the same time, but also on past values of the input signal. This is a very important concept and is the basis of such essential functions as analog filtering.

### CASCADING STAGES

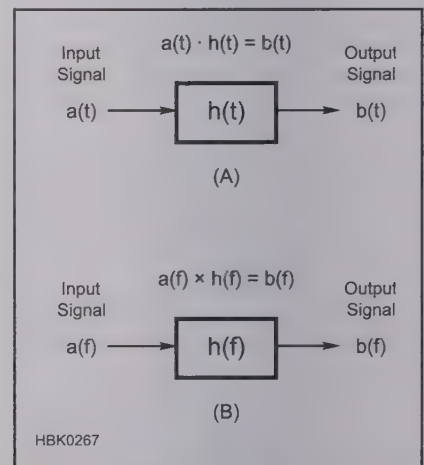

If an analog circuit can be described with

a transfer function, a combination of analog circuits can also be described similarly. This description of the combined circuits depends upon the relationship between the transfer functions of the parts and that of the combined circuits. In many cases this relationship allows us to predict the behavior of large and complex circuits from what we know about the parts of which they are made. This aids in the design and analysis of analog circuits.

When two analog circuits are cascaded (the output signal of one stage becomes the input signal to the next stage) their transfer functions are combined. The mechanism of the combination depends on the interaction between the stages. The ideal case is the functions of the stages are completely independent. In other words, when the action of a stage is unchanged, regardless of the characteristics of any stages connected to its input or output.

Just as the signal entering the first stage is modified by the action of the first transfer function, the ideal cascading of analog circuits results in changes produced only by the individual transfer functions. For any number of stages that are cascaded, the combination of their transfer functions results in a new transfer function. The signal that enters the circuit is changed by the composite transfer function to produce the signal that exits in the cascaded circuits.

While each stage in a series may use feedback within itself, feedback around more than one stage may create a function — and resultant performance — different from any of the included stages. Examples include

**Figure 3.53** — Linear function blocks and transfer functions. The transfer function can be expressed in the time domain (A) or in the frequency domain (B). The transfer function describes how the input signal  $a(t)$  or  $a(f)$  is transformed into the output signal  $b(t)$  or  $b(f)$ .

oscillation or negative feedback.

## AMPLIFIER FREQUENCY RESPONSE

At higher frequencies a typical amplifier acts as a low-pass filter, decreasing amplification with increasing frequency. Signals within a range of frequencies are amplified consistently but outside that range the amplification changes. At high gains many amplifiers work properly only over a small range of frequencies. The combination of gain and frequency response is often expressed as a *gain-bandwidth product*. For many amplifiers, gain times bandwidth is approximately constant. As gain increases, bandwidth decreases, and vice versa.

Performance at lower frequencies depends on whether the amplifier is *dc- or ac-coupled*. Coupling refers to the transfer of signals between circuits. A dc-coupled amplifier amplifies signals at all frequencies down to dc. An ac-coupled amplifier acts as a high-pass filter, decreasing amplification as the frequency decreases toward dc. Ac-coupled circuits usually use capacitors to allow ac signals to flow between stages while blocking the dc bias voltages of the circuit.

## INTERSTAGE LOADING AND IMPEDANCE MATCHING

Every two-port network can be further defined by its input and output impedance. The input impedance is the opposition to current, as a function of frequency, seen when looking into the input port of the network. Likewise, the output impedance is similarly defined when looking back into a network through its output port.

If the transfer function of a stage changes when it is cascaded with another stage, we say that the second stage has *loaded* the first stage. This often occurs when an appreciable amount of current passes from one stage to the next. Interstage loading is related to the relative output impedance of a stage and the input impedance of the stage that is cascaded after it.

In some applications, the goal is to transfer a maximum amount of power from the output of the stage to a load connected to the output. In this case, the output impedance of the stage is *matched* or transformed to that of the load (or vice versa). This allows the stage to operate at its optimum voltage and current levels. In an RF amplifier, the impedance at the input of the transmission line feeding an antenna is transformed by means of a matching network to produce the resistance the amplifier needs in order to efficiently produce RF power.

In contrast, it is the goal of most analog signal processing circuitry to modify a signal rather than to deliver large amounts of power. Thus, an impedance-matched condition may

not be required. Instead, current between stages can be minimized by using mismatched impedances. Ideally, if the output impedance of a network is very low and the input impedance of the following stage is very high, very little current will pass between the stages, and interstage loading will be negligible.

## NOISE

Generally we are only interested in specific man-made signals. Nature allows many signals to combine, however, so the desired signal becomes combined with many other unwanted signals, both man-made and naturally occurring. The broadest definition of noise is any signal that is not the one in which we are interested. One of the goals of signal processing is to separate desired signals from noise. (See the **RF Techniques** chapter for a more complete discussion on noise, including calculation and use of noise factor and noise figure.)

One form of noise that occurs naturally and must be dealt with in low-level processing circuits is called *thermal noise*, or *Johnson noise*. Thermal noise is produced by random motion of free electrons in conductors and semiconductors. This motion increases as temperature increases, hence the name. This kind of noise is present at all frequencies and is proportional to temperature. Naturally occurring noise can be reduced either by decreasing the circuit's bandwidth or by reducing the temperature in the system. Thermal noise voltage and current vary with the circuit impedance and follow Ohm's Law. Low-noise-amplifier-design techniques are based on these relationships.

Analog signal processing stages are characterized in part by the noise they add to a signal. A distinction is made between enhancing existing noise (such as amplifying it) and adding new noise. The noise added by analog signal processing is commonly quantified by the *noise factor*,  $f$ . Noise factor is the ratio of the total output noise power (thermal noise plus noise added by the stage) to the amplifier input noise power when the termination is at the standard temperature of 290 K (17 °C). When the noise factor is expressed in dB, we often call it *noise figure*,  $NF$ .

In a system of many cascaded signal processing stages, such as a communications receiver, each stage contributes to the total noise of the system. The noise factor of the first stage dominates the noise factor of the entire system because noise added at the first stage is then multiplied by each following stage. Noise added by later stages is not multiplied to the same degree and so is a smaller contribution to the overall noise at the output. Designers try to optimize system noise factor by using a first stage with a minimum

possible noise factor and maximum possible gain. (Caution: A circuit that overloads is often as useless as one that generates too much noise.)

## BUFFERING

It is often necessary to isolate the stages of an analog circuit. This isolation reduces the loading, coupling and feedback between stages. It is often necessary to connect circuits that operate at different impedance levels between stages. An intervening stage, a type of amplifier called a *buffer*, is often used for this purpose. If signal level is sufficient, an attenuation can also serve as a buffer at the expense of some signal loss.

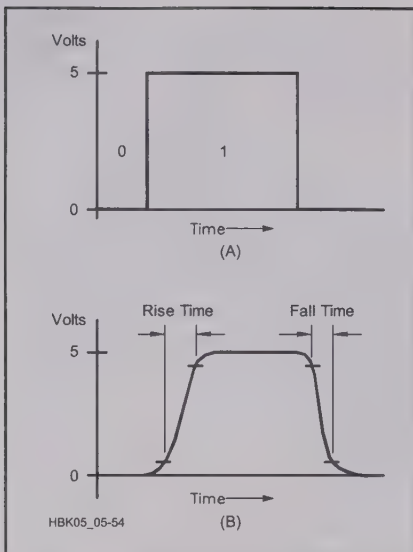

Buffers can have high values of amplification but this is unusual. A buffer used for impedance transformation generally has a low or unity gain. In some circuits, notably power amplifiers, the desired goal is to deliver a maximum amount of power to the output device (such as a speaker or an antenna). Matching the amplifier output impedance to the output-device impedance provides maximum power transfer. A buffer amplifier may be just the circuit for this type of application. Such amplifier circuits must be carefully designed to avoid distortion. Combinations of buffer stages can also be effective at isolating the stages from each other and making impedance transformations, as well.

## TRANSITION TIME

The transition between the binary 0 and binary 1 states of a digital signal or circuit does not occur instantly. There is a *transition time* between states. This transition time is a result of the time it takes to charge or discharge the stray capacitance in wires and other components because voltage cannot change instantaneously across a capacitor. Stray inductance in the wires also has an effect because the current through an inductor can't change instantaneously. The rate at which the digital circuit's output transistors can change state may also be a factor.

Distributed inductances and capacitances in wires or PC-board traces may cause rise and fall times to increase as the pulse moves away from the source. Ringing and reflections may occur due to transmission line effects as discussed in the **Transmission Lines** chapter.

The transition from a 0 to a 1 state is called the *rise time*, and is usually specified as the time for the pulse to rise from 10% of its final value to 90% of its final value. Similarly, the transition from a 1 to a 0 state is called the *fall time*, with a similar 10% to 90% definition. Note that these times need not be the same. **Figure 3.54A** shows an ideal signal, or *pulse*, with zero-time switching. **Figure 3.54B** shows

**Figure 3.54 — (A) An ideal digital pulse and (B) a typical actual pulse, showing the gradual transition between states.**

a typical pulse, as it changes between states in a smooth curve.

The faster the rise or fall time, the wider the bandwidth of signals associated with the transition. These signals can be radiated, causing noise and interfering signals in

**Figure 3.55 — Propagation delay in a digital circuit.**

receivers or sensitive circuits. The general rule of thumb for the bandwidth of digital signals is:

$$\begin{aligned}
 \text{BW}(\text{GHz}) &= \frac{0.35}{\text{RT}(\text{ns})} \text{ and } \text{RT}(\text{ns}) \\
 &= \frac{0.35}{\text{BW}(\text{GHz})}
 \end{aligned}$$

Rise and fall times for digital integrated circuits vary with the logic family used and the location in a circuit. Typical values of transition time are in the range of microseconds (4000-series CMOS with high-impedance loads) to sub-nanosecond range (modern TTL-derivatives and CMOS).

## PROPAGATION DELAY

Rise and fall times only describe a relationship within a pulse. For a circuit, a pulse input into the circuit must propagate through the circuit; in other words it must pass through each component in the circuit until eventually it arrives at the circuit output. The time delay between providing an input to a circuit and seeing a response at the output is the *propagation delay* and is illustrated by **Figure 3.55**.

For modern switching logic, typical propagation delay values are in the 1 to 15 nanosecond range. (It is useful to remember that the propagation delay along a wire or printed-circuit-board trace is about 1.0 to 1.5 ns per inch.) Propagation delay is the result of cumulative transition times as well as transistor switching delays, reactive element charging times and the time for signals to travel through wires. In complex circuits, different propagation delays through different paths can cause problems when pulses must arrive somewhere at exactly the same time.

The effect of these delays on digital devices can be seen by looking at the speed of the digital pulses. Most digital devices and all PCs use *clock pulses*. If two pulses are supposed to arrive at a logic circuit at the same time, or very close to the same time, the path length for the two signals cannot be any different than two to three inches. This can be a very significant design problem for high-speed logic designs.

## 3.10 Electromagnetic Waves

*Audio* or *sonic* energy is the energy imparted by the mechanical movement of a medium, which can be air, metal, water or even the human body. Sound that humans can hear normally requires the movement of air between 20 Hz and 20 kHz, although the human ear loses its ability to detect the extremes of this range as we age. Some animals, such as elephants, can detect air vibrations well below 20 Hz, while others, such as dogs and cats, can detect air vibrations well above 20 kHz.

Electrical circuits do not directly produce air vibrations. Sound production requires a *transducer*, a device to transform one form of energy into another form of energy; in this case electrical energy into sonic energy. The speaker and the microphone are the most common audio transducers. There are numerous ultrasonic transducers for various applications.

Radio frequency energy exists at frequencies for which it is practical to generate and

detect waves that exist independently of the movement of electrical charge, such as a radio signal. Like sonic energy, a transducer — an antenna — is required to convert the electrical energy in a circuit to electromagnetic waves. In a physical circuit, such as a wire, electromagnetic energy exists as both electromagnetic waves and the physical movement of electrical charge.

Electromagnetic waves have been generated and detected in many forms with frequen-

cies from below 1 Hz to above  $10^{12}$  GHz, including at the higher frequencies infrared, visible, and ultraviolet light, and a number of energy forms of greatest interest to physicists and astronomers. **Table 3.5** provides a brief glimpse at the total spectrum of electromagnetic energy. The *radio spectrum* is generally considered to begin around 3 kHz and end at infrared light.

Within the part of the electromagnetic energy spectrum of most interest to radio amateurs, frequencies have been classified into groups and given names. Table 3.5 provides a reference list of these classifications. To a significant degree, the frequencies within each group exhibit similar properties, both in circuits and as RF waves. For example, HF or high frequency waves, with frequencies from 3 to 30 MHz, all exhibit ionospheric refraction that permits regular long-range radio communications. This property also applies occasionally both to MF (medium frequency) and to VHF (very high frequency) waves, as well.

Despite the close relationship between electromagnetic energy and waves, it remains important to distinguish the two. To a circuit producing or amplifying a 15-kHz alternating current, the ultimate transformation and use of the electrical energy may make no difference to the circuit's operation. By choosing the right transducer, one can produce either a sonic wave or an electromagnetic wave — or both. Such is a common problem of video monitors and switching power supplies; forces created by the ac currents cause electronic parts both to vibrate audibly *and* to radiate electromagnetic energy.

### 3.10.1 Electric and Magnetic Fields

Electrical and magnetic energy are invisible — you can't detect them with any of your senses. All you can do is observe their effects such as when a resistor gets hot, a motor spins, or an electromagnet picks up iron or steel. The energy exists as a *field* — a region of space in which energy is stored and through which electrical and magnetic forces act. (For serious inquiries as to the nature of fields, see [en.wikipedia.org/wiki/Electric\\_field](http://en.wikipedia.org/wiki/Electric_field) and [en.wikipedia.org/wiki/Magnetic\\_field](http://en.wikipedia.org/wiki/Magnetic_field).)

You are already quite familiar with fields in the form of gravity. You are being pulled down toward the Earth as you read this because you are in the Earth's *gravitational field*. Because your body has mass it interacts with the gravitational field in such a way that the Earth attracts you. (You have your own gravitational field, too, but many orders of magnitude smaller than that of the Earth.) Think of a bathroom scale as a “gravitational

**Table 3.5**

#### Key Regions of the Electromagnetic Energy Spectrum

Region Name	Frequency Range	
Radio frequencies*	$3.0 \times 10^3$ Hz	to $3.0 \times 10^{11}$ Hz
Infrared	$3.0 \times 10^{11}$ Hz	to $4.3 \times 10^{14}$ Hz
Visible light	$4.3 \times 10^{14}$ Hz	to $7.5 \times 10^{14}$ Hz
Ultraviolet	$7.5 \times 10^{14}$ Hz	to $6.0 \times 10^{16}$ Hz
X-rays	$6.0 \times 10^{16}$ Hz	to $3.0 \times 10^{19}$ Hz
Gamma rays	$3.0 \times 10^{19}$ Hz	to $5.0 \times 10^{20}$ Hz
Cosmic rays	$5.0 \times 10^{20}$ Hz	to $8.0 \times 10^{21}$ Hz

Range Name	Abbreviation	Frequency Range
Very Low Frequency	VLF	3 kHz - 30 kHz
Low Frequency	LF	30 kHz - 300 kHz
Medium Frequency	MF	300 kHz - 3 MHz
High Frequency	HF	3 MHz - 30 MHz
Very High Frequency	VHF	30 MHz - 300 MHz
Ultra High Frequency	UHF	300 MHz - 3 GHz
Super High Frequency	SHF	3 GHz - 30 GHz
Extremely High Frequency	EHF	30 GHz - 300 GHz

\*Note: The range of radio frequencies can also be written as 3 kHz to 300 GHz

voltmeter” that instead of reading “volts,” reads “pounds.” The heavier something is, the stronger the Earth is attracting it. Weight is the same as force. (Metric scales provide readings in kilograms, a unit of mass. To do so, the scales assume a standard strength for gravity in order to convert weight [a force] to an equivalent mass in kilograms.)

This field makes you do work, such as when you climb stairs. Work has a precise definition when it comes to fields: *Work* equals force times distance moved in the direction of the field's force. For example, let's say you pick up a mass — a stone that weighs 1 pound — and lift it to a shelf 10 feet above where it previously lay. How much work did you do? You moved a weight of 1 pound a distance of 10 feet against the attraction of the field, so you have done 10 foot-pounds of work. (It doesn't count if you move the stone sideways instead of vertically.)

What did that work accomplish? You stored gravitational energy in the stone equal to the amount of work that you performed. This stored energy is called *potential energy*, whether gravitational, electrical or magnetic. You could store the same amount of gravitational energy by lifting a 10-pound stone 1 foot or by lifting a stone that weighs 1/10th of a pound 100 feet. If you drop the stone (or it falls off the shelf), the same amount of potential energy is converted back to *kinetic energy* as the stone moves toward the Earth in the gravitational field.

In electronics we are interested in two types of fields: *electric fields* and *magnetic fields*. Electric fields can be detected as voltage differences between two points. The electric field's analog to gravitational mass is electric charge. Every electric charge has its own electric field, just as every mass has its own

gravitational field. The more charged a body is, the “heavier” it is in terms of an electric field. Just as a body with mass feels a force to move in a gravitational field, so does an electric charge in an electric field. Electrical energy is stored by moving electrical charges apart so that there is a voltage between them. If the field does not change with time, it is called an *electrostatic field*.

Magnetic energy is detected by its effects on moving electrical charges or current. Magnetic energy is stored through the motion of electric charge (current) creating a magnetic field. Magnetic fields that don't change with time, such as from a stationary permanent magnet, are called *magnetostatic fields*.

The potential energy is released by allowing the charges to move in the field. For example, electric energy is released when a current flows from a charged-up capacitor. Magnetic energy stored by current flowing in an inductor is released when the current is allowed to change, such as a relay's armature does when the coil is de-energized.

### 3.10.2 Electromagnetic Fields and Waves

An *electromagnetic field* is created when the potential energy stored in an electric field or magnetic field changes. The changing electric and magnetic fields create *electromagnetic waves* (what we call *radio waves*) that propagate through space carrying both electric and magnetic energy. The electric and magnetic fields in the wave vary with time in a sinusoidal pattern. The potential energy is shared between the electric and magnetic fields making up the electromagnetic field.

The *field strength* of an electromagnetic wave can be measured either by the elec-

tric field (volts/meter) or the magnetic field (amps/meter). Usually the wave's field strength is stated only in volts/meter since that is easier to measure than the magnetic field. If we multiply the electric and magnetic field strengths, we have power per unit area:

$$\frac{E}{m} \times \frac{H}{m} = \frac{\text{watts}}{m^2}$$

### MAXWELL'S EQUATIONS

The basic theory of electromagnetic fields was established by James Maxwell in 1860-1864. The behavior of the fields are described by the four equations known today as Maxwell's equations. (This form of the equations was actually produced by Oliver Heaviside in his work prior to 1890.) The existence of the electromagnetic waves predicted by Maxwell in 1864 was demonstrated by Heinrich Hertz in 1886. For more information about the experiment, see the References and Bibliography listing at the end of this chapter for G.S. Smith's article analyzing Hertz's experiments.

A discussion of Maxwell's equations and their application to electromagnetic simulation is presented in the **Computer-Aided Circuit Design** chapter. A more complete treatment is provided by Bob Zavrel, W7SX, in his book *Antenna Physics: An Introduction* (see the References and Bibliography section of this chapter). A summary treatment of the equations in a pair of Hand-On Radio columns by Ward Silver, NØAX, is included in the downloadable supplemental information. These include an explanation of the vector calculus concepts of gradient, divergence, and curl, as well as illustrating how waves are created by moving electric charge.

### 3.10.3 Electromagnetic Wave Propagation

All electromagnetic energy has one thing in common: it travels, or *propagates*, at the speed of light, abbreviated *c*. This speed is approximately 300,000,000 (or  $3 \times 10^8$ ) meters per second in a vacuum, termed *free space*.

In general, the speed at which electromagnetic waves travel or *propagate* depends on the permittivity and permeability of the medium through which they travel.

$$c = \frac{1}{\sqrt{\epsilon_0 \mu_0}}$$

The speed of light is highest in the vacuum of free space and only slightly lower in air. In materials such as glass or plastic, however, velocity can be quite a bit lower. For example, in polyethylene (commonly used as a center insulator in coaxial cable), the *velocity of propagation* is about two-thirds (67%) of that in free space.

Electromagnetic waves have a wavelength uniquely associated with each possible frequency. (See **Figure 3.56**) The *wavelength* ( $\lambda$ ) is the speed of propagation, *c*, divided by the frequency (*f*) in hertz.

$$f \text{ (Hz)} = \frac{3.0 \times 10^8 \left( \frac{m}{s} \right)}{\lambda \text{ (m)}}$$

and

$$\lambda \text{ (m)} = \frac{3.0 \times 10^8 \left( \frac{m}{s} \right)}{f \text{ (Hz)}}$$

Example: What is the frequency of an RF wave with wavelength of 80 meters?

$$f \text{ (Hz)} = \frac{3.0 \times 10^8 \left( \frac{m}{s} \right)}{\lambda \text{ (m)}}$$

$$= \frac{3.0 \times 10^8 \left( \frac{m}{s} \right)}{80.0 \text{ m}}$$

$$= 3.75 \times 10^6 \text{ Hz}$$

This is 3.750 MHz or 3750 kHz, a frequency in the middle of the ham band known as "80 meters."

A similar equation is used to calculate the wavelength of a sound wave in air, substituting the speed of sound instead of the speed of light in the numerator. The speed of propagation of the mechanical movement of air that we call sound varies considerably with air temperature and altitude. The speed of sound

at sea level is about 331 m/s at 0 °C and 344 m/s at 20 °C.

To calculate the frequency of an electromagnetic wave directly in kilohertz, change the speed constant to 300,000 ( $3 \times 10^5$ ) km/s.

$$f \text{ (kHz)} = \frac{3.0 \times 10^5 \left( \frac{km}{s} \right)}{\lambda \text{ (m)}}$$

and

$$\lambda \text{ (m)} = \frac{3.0 \times 10^5 \left( \frac{km}{s} \right)}{f \text{ (kHz)}}$$

For frequencies in megahertz, change the speed constant to 300 ( $3 \times 10^2$ ) Mm/s.

$$f \text{ (MHz)} = \frac{300 \left( \frac{Mm}{s} \right)}{\lambda \text{ (m)}}$$

and

$$\lambda \text{ (m)} = \frac{300 \left( \frac{Mm}{s} \right)}{f \text{ (MHz)}}$$

Stated as it is usually remembered and used, "wavelength in meters equals 300 divided by frequency in megahertz." Assuming the proper units for the speed of light constant simplify the equation.

$$\lambda \text{ (in m)} = \frac{300}{f \text{ (in MHz)}}$$

$$\text{and } f \text{ (in MHz)} = \frac{300}{\lambda \text{ (in m)}}$$

Example: What is the wavelength of an RF wave whose frequency is 4.0 MHz?

**Figure 3.56** — As a radio wave travels, it oscillates at the frequency of the signal. The distance covered by the wave during the time it takes for one complete cycle is its wavelength.

$$\lambda(\text{m}) = \frac{300}{f(\text{MHz})} = \frac{300}{4.0} = 75 \text{ m}$$

At higher frequencies, circuit elements with lengths that are a significant fraction of a wavelength can act like transducers. This property can be useful, but it can also cause problems for circuit operations. Therefore, wavelength calculations are of some importance in designing ac circuits for those frequencies.

### 3.10.4 Electromagnetic Wave Structure

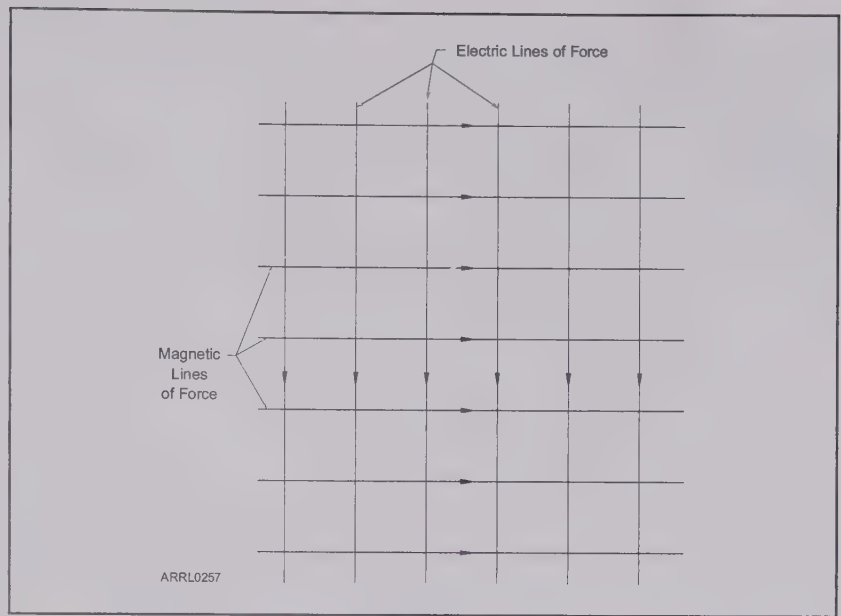

The waves move through space independently of any component or conductor. The electric and magnetic fields of the wave are oriented at right angles to each other as shown by **Figure 3.57**. The direction of the right angle between the electric and magnetic fields determines the direction the wave travels, as illustrated by **Figure 3.50**. The term “lines of force” in the figure means the direction in which a force would be felt by an electron (from the electric field) or by a magnet (from the magnetic field).

An important note about electromagnetic waves: The electric and magnetic fields making up the wave are not just perpendicular electric and magnetic fields that simply happen to be in the same place at the same time! The fields are *coupled*; that is they are both aspects of the same entity — the electromagnetic wave. The fields cannot be separated although the energy in the wave can be detected as either electric or magnetic force. The electromagnetic wave is created as a single entity by the motion of electrons, such as in a transmitting antenna.

#### WAVEFRONTS

To an observer staying in one place, such as a fixed station’s receiving antenna, the electric and magnetic fields of the wave appear to oscillate as the wave passes. That is, the fields create forces on electrons in the antenna that increase and decrease in the sine wave pattern. Some of the energy in the propagating wave is transferred to the electrons as the forces from the changing fields cause them to move. This creates a sine wave current in the antenna with a frequency determined by the rate at which the field strength changes in the passing wave.

If the observer is moving along with the wave at the same speed, however, the strength of the fields will not change. To that observer, the electric and magnetic field strengths are fixed, as in a photograph. This is a *wavefront* of the electromagnetic wave — a flat surface or plane moving through space on which the electric and magnetic fields have a constant value as illustrated in **Figure 3.57**.

**Figure 3.57** — Representation of electric and magnetic lines of force in an electromagnetic wavefront. Arrows indicate the instantaneous directions of the fields for a wavefront in a wave traveling toward you, out of the page. Reversing the direction of either of the fields would also reverse the direction of the wave.

**Figure 3.58** — Representation of the magnetic and electric field strengths of a vertically polarized electromagnetic wave. In the diagram, the electric field is oriented vertically and the magnetic field horizontally.

Just as an ac voltage is made up of an infinite sequence of instantaneous voltages, each slightly larger or smaller than the next, an infinite number of wavefronts make up an electromagnetic wave, one behind another like a deck of cards. The direction of the wave is the direction in which the wavefronts move. The fields on each successive wavefront have a slightly different strength, so as they pass a fixed location the detected field strength changes as well. The result is that the fixed

observer “sees” fields with strengths varying as a sine wave.

**Figure 3.58** is a drawing of what would happen if we could suddenly freeze all of the wavefronts in the wave and take measurements of the electric and magnetic field strengths in each. In this example, the electric field is oriented vertically and the magnetic field horizontally. (Each of the vertical lines in the electric field can be thought of as representing an individual wavefront.)

**Figure 3.59** illustrates the right-angle relationship of the  $E$  and  $H$  fields, and the direction of their motion.

All of the wavefronts are moving in the direction indicated — the whole set of them moves together at the same speed. As the wave — the set of wavefronts — moves past the receive antenna, the varying field strengths of the different wavefronts are perceived as a continuously changing wave. What we call a “wave” is really this entire group of wavefronts moving through space.

### POLARIZATION

The orientation of the pair of fields in an electromagnetic wave can have any orientation with respect to the surface of the Earth, but the electric and magnetic fields will always be at right angles to each other. The orientation of the wave’s electric field determines the *polarization* of the wave. If the electric field’s lines of force are parallel to the surface of the Earth (meaning those of the magnetic field are perpendicular to the Earth), the wave is *horizontally polarized*. Conversely, if the magnetic field’s lines of force are parallel to the surface of the Earth (and those of the electric field are perpendicular to the Earth), the wave is *vertically polarized*. Knowing the polarization of the wave allows the receiving antenna to be oriented so that the passing wave will exert the maximum force on the electrons in the antenna, maximizing received signal strength.

For the most part, the wave’s polarization is determined by the type of transmitting antenna and its orientation. For example, a Yagi antenna with its elements parallel to the Earth’s surface transmits a horizontally polarized wave. On the other hand, an amateur mobile whip antenna, mounted vertically on an automobile, radiates a vertically polarized wave. If a vertically polarized antenna is used to receive a horizontally polarized radio wave (or vice versa), received signal strength can be reduced by more than 20 dB as compared to using an antenna with the same polarization as the wave. This is called *cross-polarization*.

It is also possible to generate electromagnetic waves in which the orientation of succes-

**Figure 3.59** — The right-hand rule shows how to determine direction of propagation of an electromagnetic wave. Point your thumb in the positive direction for the  $E$  field, your index finger in the positive direction for  $H$ , and your middle finger will point in the direction the wave is traveling.

sive wavefronts rotates around the direction of travel — both the electric and magnetic fields. This is called *circular polarization*. Imagine the wave of Figure 3.51 being twisted so at one point the direction of the electric field is horizontal and a bit further along the wave it is vertical. As the twisted, circularly polarized wave passes the receiving antenna, the polarization of its fields will appear to rotate. The rate at which the polarization changes and the direction of the rotation — *right-handed* or *left-handed* — is determined by the construction of the transmitting antenna. Note that the electric and magnetic fields rotate together so the right-angle between them remains fixed. Polarization that does not rotate is called *linear polarization* or *plane polarization*. Horizontal and vertical polarization are examples of linear polarization.

To best receive a circularly polarized wave, the structure of the receiving antenna should match that of the transmitting antenna. It is particularly helpful to use circular polarization in satellite communication, where polar-

ization tends to shift with the orientation of the satellite and the path of its signal through the atmosphere. Circular polarization is usable with linearly polarized antennas at one end of the signal’s path. There will be some small loss in this case, however.

### IMPEDANCE OF FREE SPACE

Maxwell’s equations provide the relationships (direction and ratio) between the magnetic and electric fields associated with an electromagnetic wave. Far from an antenna or other distorting surfaces, the wave is treated as a *plane* wave in which the wavefronts are infinite, flat planes. In a plane wave, the ratio of the two fields’ amplitudes remains constant and the two fields are always at right angles. (There are exceptions but they are not discussed here.)

Since the ratio of the two fields is constant in free space, that gives rise to the idea of an intrinsic impedance. If the impedance is zero or infinite, the magnetic and electric fields would have to be infinite or zero and there could be no electromagnetic radiation.

The impedance can be derived from the permittivity ( $\epsilon_0$ ) and permeability ( $\mu_0$ ) of free space:

$$\epsilon_0 = \frac{F(\text{farads})}{\text{meter}} \quad \text{and} \quad \mu_0 = \frac{H(\text{henries})}{\text{meter}}$$

Taking the ratio of the two, noting that farads have units of joules/volt<sup>2</sup> and henries have units of joules/ampere<sup>2</sup>:

$$\sqrt{\frac{\mu_0}{\epsilon_0}} = \sqrt{\frac{H}{F}} = \sqrt{\frac{J/I^2}{J/V^2}} = \sqrt{\frac{V^2}{I^2}} = \frac{V}{I} \approx 377\Omega$$

It is interesting to remember that the speed of light is:

$$c = \frac{1}{\sqrt{\epsilon_0 \mu_0}}$$

This links the fundamental electrical and magnetic constants to both velocity of electromagnetic waves and an impedance describing how energy is distributed between the electric and magnetic fields.

# Circuits and Components

This chapter begins by covering the various aspects of dealing with real components — resistors, capacitors, inductors, and transformers. All of these have special features and behaviors you must take into account, especially at RF. We then cover common semi-conductors you'll encounter in radio and their important characteristics.

The discussion then proceeds to building block circuits, beginning with various types of amplifiers constructed with bipolar and field-effect transistors. Building-block circuits including op amps and miscellaneous analog ICs are also covered. Finally, a section on Heat Management discusses how to deal with heat in electronic devices.

## 4.1 Practical Resistors

### 4.1.1 Resistance of Wires

The problem of determining the resistance of a round wire of given diameter and length — or the converse, finding a suitable size and length of wire to provide a desired amount of resistance — can easily be solved with the help of the copper wire table given in the chapter on **Component Data and References**. This table gives the resistance, in ohms per 1000 ft, of each standard wire size. For example, suppose you need a resistance of 3.5 Ω, and some #28 AWG wire is on hand. The wire table shows that #28 AWG wire has a resistance of 63.31 Ω / 1000 ft. Since the desired resistance is 3.5 Ω, the required length of wire is:

$$\begin{aligned} \text{Length} &= \frac{R_{\text{DESIRED}}}{\frac{R_{\text{WIRE}}}{1000 \text{ ft}}} = \frac{3.5 \Omega}{\frac{63.31 \Omega}{1000 \text{ ft}}} \\ &= \frac{3.5 \Omega \times 1000 \text{ ft}}{63.31 \Omega} = 53.6 \text{ ft} \end{aligned}$$

As another example, suppose that the resistance of wire in a radio's power cable must not exceed 0.05 Ω and that the length of wire required for making the connections totals 14 ft. Then:

$$\begin{aligned} \frac{R_{\text{WIRE}}}{1000 \text{ ft}} &< \frac{R_{\text{MAXIMUM}}}{\text{Length}} = \frac{0.05 \Omega}{14.0 \text{ ft}} \\ &= 3.57 \times 10^{-3} \frac{\Omega}{\text{ft}} \times \frac{1000 \text{ ft}}{1000 \text{ ft}} \\ \frac{R_{\text{WIRE}}}{1000 \text{ ft}} &< \frac{3.57 \Omega}{1000 \text{ ft}} \end{aligned}$$

Find the value of  $R_{\text{WIRE}} / 1000 \text{ ft}$  that is less than the calculated value. The wire table shows that #15 AWG is the smallest size having a resistance less than this value. (The resistance of #15 AWG wire is given as

3.1810 Ω / 1000 ft.) Select any wire size larger than this for the connections in your circuit, to ensure that the total wire resistance will be less than 0.05 Ω.

When the wire in question is not made of copper, the resistance values in the wire table should be multiplied by the ratios shown in Table 2.1 to obtain the resulting resistance. If the wire in the first example were made from nickel instead of copper, the length required for 3.5 Ω would be:

$$\begin{aligned} \text{Length} &= \frac{R_{\text{DESIRED}}}{\frac{R_{\text{WIRE}}}{1000 \text{ ft}}} \\ &= \frac{3.5 \Omega}{\frac{66.17 \Omega}{1000 \text{ ft}}} \times 5.1 = \frac{3.5 \Omega \times 1000 \text{ ft}}{66.17 \Omega \times 5.1} \\ \text{Length} &= \frac{3500 \text{ ft}}{337.5} = 10.5 \text{ ft} \end{aligned}$$

### 4.1.2 Temperature Effects on Resistors

The resistance of a conductor changes with its temperature. The resistance of practically every metallic conductor increases with increasing temperature. Carbon, however, acts in the opposite way; its resistance decreases when its temperature rises. It is seldom necessary to consider temperature in making resistance calculations for amateur work. The temperature effect is important when it is necessary to maintain a constant resistance under all conditions, however. Special materials that have little or no change in resistance over a wide temperature range are used in that case.

### 4.1.3 Component Resistors

The size and construction of resistors having the same value of resistance in ohms may

**Figure 4.1** — Examples of various resistors. At the top left is a small 10-W wirewound resistor. A single in-line package (SIP) of resistors is at the top right. At the top center is a small PC-board-mount variable resistor. A tiny surface-mount (chip) resistor is also shown at the top. Below the variable resistor is a 1-W carbon composition resistor and then a 1/2-W composition unit. The dog-bone-shaped resistors at the bottom are 1/2-W and 1/4-W film resistors. The 1/4-inch-ruled graph paper background provides a size comparison. The inset photo shows the chip resistor with a penny for size comparison.

vary considerably based on how much power they are intended to dissipate, how much voltage is expected to be applied to them, and so forth (see **Figure 4.1**). See the **Component Data and References** chapter for information on resistor value marking conventions.

## TYPES OF RESISTORS

Resistors are made in several different ways: carbon composition, metal oxide, carbon film, metal film, and wirewound. In some circuits, the resistor value may be critical. In this case, precision resistors are used. These are typically wirewound or carbon-film devices whose values are carefully controlled during manufacture. In addition, special material or construction techniques may be used to provide temperature compensation, so the value does not change (or changes in a precise manner) as the resistor temperature changes.

**Carbon composition** resistors are simply small cylinders of carbon mixed with various binding agents to produce any desired resistance. The most common sizes of “carbon comp” resistors are 1/2- and 1/4-W resistors. They are moderately stable from 0 to 60 °C (their resistance increases above and below this temperature range). They can absorb short overloads better than film-type resistors, but they are relatively noisy, and have relatively wide tolerances. Because carbon composition resistors tend to be affected by humidity and other environmental factors and because they are difficult to manufacture in surface-mount packages, they have largely been replaced by film-type resistors.

**Metal-oxide** resistors are similar to carbon composition resistors in that the resistance is

supplied by a cylinder of metal oxide. Metal-oxide resistors have replaced carbon composition resistors in higher power applications because they are more stable and can operate at higher temperatures.

**Wirewound** resistors are made from wire, which is cut to the proper length and wound on a coil form (usually ceramic). They are capable of handling high power; their values are very stable, and they are manufactured to close tolerances. The wound-wire construction creates inductance so these resistors are not suitable for ac circuits above a few kHz.

**Metal-film** resistors are made by depositing a thin film of aluminum, tungsten, or other metal on an insulating substrate. Their resistances are controlled by careful adjustments of the width, length and depth of the film. As a result, they have very tight tolerances. They are used extensively in surface-mount technology. As might be expected, their power handling capability is somewhat limited. They also produce very little electrical noise.

**Carbon-film** resistors use a film of carbon

mixed with other materials instead of metal. They are not quite as stable as other film resistors and have wider tolerances than metal-film resistors, but they are still as good as (or better than) carbon composition resistors.

**Thin-film resistors** are also available at high power ratings in a transistor-like TO-220 package. Because of their packaging, they can be mounted to heat sinks and are available with power ratings up to 50 W. These resistors also have low inductance for use in switch-mode circuits and high-frequency applications.

## THERMAL CONSIDERATIONS FOR RESISTORS

Current through a resistance causes the conductor to become heated; the higher the resistance and the larger the current, the greater the amount of heat developed. Resistors intended for carrying large currents must be physically large so the heat can be radiated quickly to the surrounding air or some type of heat sinking material. If the resistor does not dissipate the heat quickly, it may get hot enough to melt or burn.

The amount of heat a resistor can safely dissipate depends on the material, surface area and design. Typical resistors used in amateur electronics (1/2 to 2-W resistors) dissipate heat primarily through the surface area of the case, with some heat also being carried away through the connecting leads. Wirewound resistors are usually used for higher power levels. Some have finned cases for better convection cooling and/or metal cases for better conductive cooling.

The major departure of resistors from ideal behavior at low-frequencies is their *temperature coefficient* (TC). (See the chapter on **RF Techniques** for a discussion of the behavior of resistors at high frequencies.) The resistivity of most materials changes with temperature, and typical TC values for resistor materials are given in **Table 4.1**. TC values are usually expressed in parts-per-million (PPM) for each degree (centigrade) change from some nominal temperature, usually room temperature (77 °F or 27 °C). A positive TC indicates an increase in resistance with

## Component Tolerance

Resistors are manufactured with a specific *nominal* value of resistance. This is the value printed on the body of the resistor or marked with stripes of colored paint. The *actual* value of resistance varies from the nominal value because of random variations in the manufacturing process. The maximum allowable amount of variation is called the *tolerance* and it is expressed in percent. For example, a 1000 Ω resistor with a tolerance of 5% could have any value of resistance between 95% and 105% of 1000 Ω; 950 to 1050 Ω. In most circuits, this small variation doesn't have much effect, but it is important to be aware of tolerance and choose the correct value (10%, 5%, 1%, or even tighter tolerance values are available for *precision components*) of tolerance for the circuit to operate properly, no matter what the actual value of resistance. All components have this same nominal-to-actual value relationship.

**Table 4.1**

**Temperature Coefficients for Various Resistor Compositions**

1 PPM = 1 part per million = 0.0001%

Type	TC (PPM/°C)
Wire wound	±(30 - 50)
Metal Film	±(100 - 200)
Carbon Film	+350 to -800
Carbon composition	±800

increasing temperature while a negative TC indicates a decreasing resistance. For example, if a 1000-Ω resistor with a TC of +300 PPM/°C is heated to 50 °C, the change in resistance is 300 × (50 - 27) = 6900 PPM, yielding a new resistance of

$$1000 \left( 1 + \frac{6900}{1000000} \right) = 1006.9 \Omega$$

Carbon-film resistors are unique among the major resistor families because they alone have a negative temperature coefficient. They are often used to “offset” the thermal effects of the other components.

If the temperature increase is small (less than 30-40 °C), the resistance change with temperature is nondestructive — the resistor will return to normal when the temperature returns to its nominal value. Resistors that get too hot to touch, however, may be permanently damaged even if they appear normal. For this reason, be conservative when specifying power ratings for resistors. It’s common to specify a resistor rated at 200% to 400% of the expected dissipation.

**4.1.4 Voltage Dividers**

According to Kirchoff’s Voltage Law (KVL), the voltage drop across each resistor in a series circuit is directly proportional to the resistance. When connected in series, a resistor that has a value twice as large as another will have twice the voltage drop across it.

Resistors in series without any other connections form a *resistive voltage divider*. (Other types of components can form voltage

**Figure 4.2 — An example of resistors in series.**

**Digital Electronics Tutorial**

The chapter on digital basics found in previous editions has been converted to a supplemental item in this book’s downloadable supplemental material. The number of excellent book and online references have reduced the need for a separate chapter on digital electronics in this book. A set of references on digital electronics, including current ARRL publications on the use of microcontrollers for Amateur Radio projects are listed here.

dividers, too.) The voltage across any specific resistor in the divider,  $R_n$ , is equal to the voltage across the entire string of resistors multiplied by the ratio of  $R_n$  to the sum of all resistors in the string.

For example, in the circuit of **Figure 4.2**, the voltage across the 5000 Ω resistor is:

$$E1 = 250 \frac{5000}{5000 + 20000 + 8000} = 37.9 \text{ V}$$

This is a more convenient method than calculating the current through the resistor and using Ohm’s Law.

Voltage dividers can be used as a source of voltage. As long as the device connected to the output of the divider has a much higher resistance than the resistors in the divider, there will be little effect on the divider output voltage. For example, for a voltage divider with a voltage of  $E = 15 \text{ V}$  and two resistors of  $R1 = 5 \text{ k}\Omega$  and  $R2 = 10 \text{ k}\Omega$ , the voltage across  $R2$  will be 10 V measured on a high-impedance voltmeter because the measurement draws very little current from the divider. However, if the measuring device or load across  $R2$  draws significant current, it will increase the amount of current drawn through the divider and change the output voltage.

The following equations show how to calculate the voltage produced by a voltage

divider. Using the circuit in **Figure 4.3**, the *unloaded* output voltage (with  $R3$  not connected) is:

$$V_{OUT} = V_{IN} \left( \frac{R2}{R1 + R2} \right)$$

If  $R3$  is connected, the *loaded* output voltage is:

$$V_{OUT} = V_{IN} \left( \frac{R2 // R3}{R1 + R2 // R3} \right)$$

where // indicates “in parallel with.”

**Figure 4.3 — A voltage divider showing both unloaded ( $R3$  not connected) and loaded ( $R3$  connected) conditions.**

**Figure 4.4** — This photo shows examples of different styles of potentiometers. The 1/4-inch-ruled graph paper background provides a size comparison.

A good rule of thumb to keep the loaded output voltage within about 10% of the unloaded voltage is for the load resistance to be at least 10 times higher than the output resistor of the divider. As the load resistance approaches the value of the output resistor, the additional current through the load causes additional voltage drop across the divider's input resistor.

Potentiometers (variable resistors described in the next section) are often used as adjustable voltage dividers and this is how they got their name. Potential is an older name for voltage and a "potential-meter" is a device that can "meter" or adjust potential, thus potentiometer.

### 4.1.5 Current Dividers

Resistors connected in parallel form a circuit called a *resistive current divider*. For any number of resistors connected in parallel ( $R_1, R_2, R_3, \dots, R_n$ ), the current through one of the resistors,  $R_n$ , is equal to the sum of all resistor currents multiplied by the ratio of the equivalent of all parallel resistors *except*  $R_n$  to the sum of  $R_n$  and the equivalent value.

$$I_n = I_{TOT} R_{EQ} / (R_n + R_{EQ})$$

For example, in a circuit with three parallel resistors;  $R_1, R_2$ , and  $R_3$ , the current through  $R_2$  is equal to:

$$I_2 = I \frac{R_1 + R_3}{R_1 + R_2 + R_3}$$

where  $I$  is the total current through all the resistors. If  $I = 100 \text{ mA}$ ,  $R_1 = 100 \Omega$ ,  $R_2 = 50 \Omega$ , and  $R_3 = 200 \Omega$ :

$$100 \text{ mA} \frac{100 + 200}{100 + 50 + 200} = 85.7 \text{ mA}$$

### 4.1.6 Potentiometers

*Potentiometer* (pronounced po-ten-tchee-AH-meh-tur) is a formal name for a variable resistor and the common name for these components is "pots." A typical potentiometer consists of a circular *element* of resistive material which can be a carbon compound similar to that used in carbon composition resistors or a conductive plastic. One contact is made to each end of the element. A variable-position *wiper* makes contact with the element at different positions. As the wiper moves along the material, more resistance is introduced between the wiper and one of the element's contacts. The wiper is turned by a shaft to move across the material.

For higher power applications, the element may be wire wound around a core, like a wirewound resistor. Like the wirewound resistor, this type of pot is not suitable for high-frequency applications due to inductance.

A potentiometer may be used to control current, voltage, or resistance in a circuit. **Figure 4.4** shows several different types of potentiometers. **Figure 4.5** shows the schematic symbol for a potentiometer and how changing the position of the shaft changes the resistance between its three terminals. The figure shows a *panel pot*, designed to be mounted on an equipment panel and adjusted by an operator. The small rectangular *trimmer* potentiometers in **Figure 4.5** are adjusted with a screwdriver and have wire terminals.

Typical specifications for a potentiometer include element resistance, power dissipation, voltage and current ratings, number of turns (or degrees) the shaft can rotate, type and size of shaft, mounting arrangements, and resistance *taper*. Taper describes how the resistance of the element changes with position along it.

Pots with a *linear taper* have equal change in resistance with position along the element. That is, the change in resistance is the same

**Figure 4.5** — Typical potentiometer construction and schematic symbol. Rotation on the shaft moves the wiper along the element, changing the resistance between the wiper terminal and the element terminals. Moving the wiper closer to an element terminal reduces the resistance between them.

for a given number of degrees of shaft rotation anywhere along different portions of the resistive material.

Some pots have *non-linear tapers*. A typical use for a nonlinear taper is as a volume control in an audio amplifier. Since the human ear has a logarithmic response to sound, a volume control must change the amplifier output much more near one end of the element than the other (for a given amount of rotation) so that the "perceived" change in volume is about the same for a similar change in the control's position. This is commonly called an *audio taper* or *log taper* as the change in resistance per degree of rotation attempts to match the response of the human ear. Tapers can be designed to match almost any desired control function for a given application. Linear and audio tapers are the most common tapers.

## 4.2 Practical Capacitors

### 4.2.1 Component Capacitors

The ideal capacitor does not conduct any current at dc, dissipates none of the energy stored in it, has the same value at all temperatures, and operates with any amount of voltage applied across it or ac current flowing through it. As actual components, they deviate considerably from that ideal and have imperfections that must be considered when selecting capacitors and designing circuits that use capacitors. (The characteristics of capacitors at high frequencies is discussed in the **RF Techniques** chapter.)

#### LEAKAGE RESISTANCE

If we use anything other than a vacuum for the insulating layer, even air, two imperfections are created. Because there are atoms between the plates, some electrons will be available to create a current between the plates when a dc voltage is applied. The magnitude of this *leakage current* will depend on the insulator quality, and the current is usually very small. Leakage current can be modeled by a resistance  $R_L$  in parallel with the capacitance (in an ideal capacitor,  $R_L$  is infinite). **Table 4.2** shows typical dc leakage resistances for different dielectric materials. Leakage also generally increases with increasing temperature.

#### CAPACITOR LOSSES

When an ac current flows through the capacitor (even at low frequencies), capacitors dissipate some of the energy stored in the dielectric due to the electromagnetic properties of dielectric materials. This loss can be thought of as a resistance in series with the capacitor and it is often specified in the manufacturer's data for the capacitor as *effective (or equivalent) series resistance (ESR)* which is specified in ohms.

Loss can also be specified as the capacitor's *loss angle*,  $\theta$ . (Some literature uses  $\delta$  for loss angle.) Loss angle is the angle between  $X_C$  (the reactance of the capacitor without any loss) and the impedance of the capacitor (impedance is discussed later in this chapter) made up of the combination of ESR and  $X_C$ . Increasing loss increases loss angle. The loss angle is usually quite small, and is zero for an ideal capacitor.

*Dissipation Factor (DF)* or *loss tangent* is the ratio of loss resistance to reactance.

$$DF = \tan \theta = ESR / X_C$$

The loss angle of a given capacitor is relatively constant over frequency, meaning that  $ESR = (\tan \theta) / 2\pi fC$  goes down as frequency goes up. For this reason, ESR must be specified at a given frequency.

**Table 4.2**

**Typical Temperature Coefficients and Leakage Resistances for Various Capacitor Constructions**

Type	TC @ 20°C (PPM/°C)	DC Leakage Resistance ( $\Omega$ )
Ceramic Disc	$\pm 300$ (NPO) $+150/-1500$ (GP)	$> 10$ M $> 10$ M
Mica	$-20$ to $+100$	$> 100,000$ M
Polyester	$\pm 500$	$> 10$ M
Tantalum Electrolytic	$\pm 1500$	$> 10$ M $\Omega$
Small Al Electrolytic ( $\approx 100$ $\mu$ F)	$-20,000$	500 k - 1 M
Large Al Electrolytic ( $\approx 10$ mF)	$-100,000$	10 k
Vacuum (glass)	$+100$	$\approx \infty$
Vacuum (ceramic)	$+50$	$\approx \infty$

#### TOLERANCE AND TEMPERATURE COEFFICIENT

As with resistors, capacitor values vary in production, and most capacitors have a tolerance rating either printed on them or listed on a data sheet. Typical capacitor tolerances and the labeling of tolerance are described in the chapter on **Component Data and References**.

Because the materials that make up a capacitor exhibit mechanical changes with temperature, capacitance also varies with temperature. This change in capacitance with temperature is the capacitor's *temperature coefficient* or *tempco (TC)*. The lower a capacitor's TC, the less its value changes with temperature.

TC is important to consider when constructing a circuit that will carry high power levels, operate in an environment far from room temperature, or must operate consistently at different temperatures. Typical temperature coefficients for several capacitor types are given in Table 4.2. (Capacitor temperature coefficient behaviors are listed in the **Component Data and References** chapter.)

#### VOLTAGE RATINGS AND BREAKDOWN

When voltage is applied to the plates of a capacitor, force is exerted on the atoms and molecules of the dielectric by the electrostatic field between the plates. If the voltage is high enough, the atoms of the dielectric will ionize (one or more of the electrons will be pulled away from the atom), causing a large dc current to flow discharging the capacitor. This is *dielectric breakdown*, and it is generally destructive to the capacitor because it creates punctures or defects in solid dielectrics that provide permanent low-resistance current paths between the plates. (*Self-healing* dielectrics have the ability to seal off this type of

damage.) With most gas dielectrics such as air, once the voltage is removed, the arc ceases and the capacitor is ready for use again.

The *breakdown voltage* of a dielectric depends on the chemical composition and thickness of the dielectric. Breakdown voltage is not directly proportional to the thickness; doubling the thickness does not quite double the breakdown voltage. A thick dielectric must be used to withstand high voltages. Since capacitance is inversely proportional to dielectric thickness (plate spacing) for a given plate area, a high-voltage capacitor must have more plate area than a low-voltage one of the same capacitance. High-voltage, high-capacitance capacitors are therefore physically large.

*Dielectric strength* is specified in terms of a *dielectric withstanding voltage (DWV)*, given in volts per mil (0.001 inch) at a specified temperature. Taking into account the design temperature range of a capacitor and a safety margin, manufacturers specify *dc working voltage (dcwv)* to express the maximum safe limits of dc voltage across a capacitor to prevent dielectric breakdown.

For use with ac voltages, the peak value of ac voltage should not exceed the dc working voltage, unless otherwise specified in component ratings. In other words, the RMS value of sine-wave ac waveforms should be 0.707 times the dcwv value, or lower. With many types of capacitors, further derating is required as the operating frequency increases. An additional safety margin is good practice.

Dielectric breakdown in a gas or air dielectric capacitor occurs as a spark or arc between the plates. Spark voltages are generally given with the units *kilovolts per centimeter*. For air, the spark voltage or  $V_s$  may range from more than 120 kV/cm for gaps as narrow as 0.006 cm down to 28 kV/cm for gaps as wide as 10 cm. In addition, a large number of vari-

ables enter into the actual breakdown voltage in a real situation. Among the variables are the plate shape, the gap distance, the air pressure or density, the voltage, impurities in the air (or any other dielectric material) and the nature of the external circuit (with air, for instance, the humidity affects conduction on the surface of the capacitor plate).

Dielectric breakdown occurs at a lower voltage between pointed or sharp-edged surfaces than between rounded and polished surfaces. Consequently, the breakdown voltage between metal plates of any given spacing in air can be increased by buffing the edges of the plates. If the plates are damaged so they are no longer smooth, they may have to be polished or the capacitor replaced.

#### 4.2.2 Capacitor Types and Uses

Quite a variety of capacitors are used in radio circuits, differing considerably in physical size, construction and capacitance. Some of the different types are shown in Figure 4.6 and many other types and packages are available. (See the **Component Data and References** chapter for illustrations of capacitor types and labeling conventions.)

The dielectric determines many properties of the capacitor, although the construction of the plates strongly affects the capacitor's ac performance and some dc parameters. Various materials are used for different reasons such as working voltage and current, availability, cost, and desired capacitance range.

*Fixed capacitors* having a single, non-adjustable value of capacitance can also be made with metal plates and with air as the dielectric, but are usually constructed from strips of metal foil with a thin solid or liquid dielectric sandwiched between, so that a relatively large capacitance can be obtained in a small package. Solid dielectrics commonly used in fixed capacitors are plastic films, mica, paper and special ceramics. Two typical types of fixed capacitor construction are shown in Figure 4.7.

For capacitors with wire leads, there are two basic types of lead orientation; *axial* (shown in Figure 4.7A) in which the leads are aligned with the long axis of the capacitor body and *radial* (shown in Figure 4.7B) in which the leads are at right angles to the capacitor's length or width.

*Vacuum*—Both fixed and variable vacuum capacitors are available. They are rated by their maximum working voltages (3 to 60 kV)

and currents. Losses are specified as negligible for most applications. The high working voltage and low losses make vacuum capacitors widely used in transmitting applications. Vacuum capacitors are also unaffected by humidity, moisture, contamination, or dust, unlike air-dielectric capacitors discussed next. This allows them to be used in environments for which air-dielectric capacitors would be unsuitable.

*Air*—Since  $K \approx 1$  for air, air-dielectric capacitors are large when compared to those of the same value using other dielectrics. Their capacitance is very stable over a wide temperature range, leakage losses are low, and therefore a high Q can be obtained. They also can withstand high voltages. Values range from a few tens to hundreds of pF.

For these reasons (and ease of construction) most variable capacitors in tuning circuits are *air-variable* capacitors made with one set of plates movable with respect to the other set to vary the area of overlap and thus the capacitance. A *transmitting-variable* capacitor has heavy plates far enough apart to withstand the high voltages and currents encountered in a transmitter. (Air variable capacitors with more closely-spaced plates are often referred to as *receiving-variables*.)

(A)

(C)

(B)

(D)

(E)

Figure 4.6 — Fixed-value capacitors are shown in parts A and B. Aluminum electrolytic capacitors are pictured near the center of photo A. The small tear-drop units to the left of center are tantalum electrolytic capacitors. The rectangular units are silvered-mica, polystyrene film and monolithic ceramic. At the right edge is a disc-ceramic capacitor and near the top right corner is a surface-mount capacitor. B shows a large “computer-grade” electrolytic. These have very low equivalent series resistance (ESR) and are often used as filter capacitors in switch-mode power supplies, and in series-strings for high-voltage supplies of RF power amplifiers. Parts C and D show a variety of variable capacitors, including air variable capacitors and mica compression units. Part E shows a vacuum variable capacitor such as is sometimes used in high-power amplifier circuits. The 1/4-inch-ruled graph paper backgrounds provide size comparisons.

**Figure 4.7** — Two common types of capacitor construction. **A** shows the roll method for film capacitors with axial leads. **B** shows the alternating layer method for ceramic capacitors. Axial leads are shown in **A** and radial leads in **B**.

**Plastic film** — Capacitors with plastic film (such as polystyrene, polyethylene, or Mylar) dielectrics are widely used in bypassing and coupling applications up to several megahertz. They have high leakage resistances (even at high temperatures) and low TCs. Values range from tens of pF to 1  $\mu$ F. Plastic-film variable capacitors are also available.

Most film capacitors are not polarized; however, the body of the capacitor is usually marked with a color band at one end. The band indicates the terminal that is connected to the outermost plate of the capacitor. This terminal should be connected to the side of the circuit at the lower potential as a safety precaution.

Film capacitors are often made using roll construction as in Figure 4.7. This construction has relatively high inductance and the capacitor may not be suitable for RF applications.

**Mica** — The capacitance of mica capacitors is very stable with respect to time, temperature and electrical stress. Leakage and losses are very low and they are often used in transmitting equipment. Values range from 1 pF to 0.1  $\mu$ F. High working voltages are possible, but they must be derated severely as operating frequency increases. Note that many WWII-era mica capacitors are still available on the used and surplus market. Given the age of these components (now approaching 80 years) either use newer components or test them before using them in a high-power or high-voltage circuit.

**Silver-mica** — These capacitors are made by depositing a thin layer of silver on the mica dielectric. This makes the value even more stable, but it presents the possibility of silver migration through the dielectric. The migra-

tion problem worsens with increased dc voltage, temperature and humidity. Avoid using silver-mica capacitors under such conditions. Silver-mica capacitors are often used in RF circuits requiring stable capacitor values, such as oscillators and filters.

**Ceramic** — Ceramic capacitors are available with values from 1 pF to 1  $\mu$ F and with voltage ratings up to 1 kV. **Monolithic ceramic** capacitors are constructed from a stack of thin ceramic layers with a metal coating on one side. The layer is then compressed with alternating metal coatings connected together to form the capacitor's plates. The high dielectric constant makes these capacitors physically small for their capacitance, but their value is not as stable and their dielectric properties vary with temperature, applied voltage and operating frequency. They also exhibit piezoelectric behavior. Use them only in coupling and bypass roles. **Disc ceramic** capacitors are made similarly to monolithic ceramic capacitors but with a lower dielectric constant so they are larger and tend to have higher voltage ratings. Ceramic capacitors are useful into the VHF and UHF ranges.

**Transmitting ceramic** capacitors are made, like transmitting air-variables, with heavy plates and high-voltage ratings. They are relatively large (often called "doorknobs"), but very stable and have nearly as low losses as mica capacitors at HF.

**Electrolytic** — Electrolytic capacitors are constructed with plates made of aluminum-foil strips and a semi-liquid conducting chemical compound between them. They are sometimes called *aluminum electrolytics*. The actual dielectric is a very thin film of insulating material that forms on one set of plates through electrochemical action when a dc

voltage is applied to the capacitor. The capacitance of an electrolytic capacitor is very large compared to capacitors having other dielectrics, because the dielectric film is so thin — much thinner than is practical with a solid dielectric. Electrolytic capacitors are available with values from approximately 1  $\mu$ F to 1 F and with voltage ratings up to hundreds of volts.

Electrolytic capacitors are popular because they provide high capacitance values in small packages at a reasonable cost. Leakage resistance is comparatively low and they are polarized — there is a definite positive and negative plate, due to the chemical reaction that creates the dielectric. Internal inductance restricts aluminum-foil electrolytics to low-frequency applications such as power-supply filtering and bypassing in audio circuits. To maintain the dielectric film, electrolytic capacitors should not be used if the applied dc potential will be well below the capacitor working voltage.

**Supercapacitors** are a special type of electrolytic capacitor with very high capacitance (greater than 1 F) and a low working voltage (a few volts, typically). Supercapacitors have one electrode that is a porous material with an extremely high ratio of surface area to volume and is immersed in electrolyte fluid or gel. The porous electrode is contained in a metal can that forms the other electrode. The dielectric forms on the porous material's surface, similarly to foil-type electrolytics. "Supercaps" are used as short-term power sources and as filter capacitors for power connections with large, sudden, short-term current demands.

A cautionary note is warranted regarding electrolytic capacitors found in older equipment, both vacuum tube and solid-state. The chemical paste in electrolytics dries out when the component is heated and with age, causing high losses and reduced capacitance. The dielectric film also disappears when the capacitor is not used for long periods. It is possible to "reform" the dielectric by applying a low voltage to an old or unused capacitor and gradually increasing the voltage. However, old electrolytics rarely perform as well as new units. To avoid expensive failures and circuit damage, it is recommended that electrolytic capacitors in old equipment be replaced if they have not been in regular use for more than ten years.

**Tantalum** — Related to the electrolytic capacitor, *tantalum* capacitors substitute a *slug* of extremely porous tantalum (a rare-earth metallic element) for the aluminum-foil strips as one plate. As in the electrolytic capacitor, the dielectric is an oxide film that forms on the surface of the tantalum. The slug is immersed in a liquid compound contained in a metal can that serves as the other plate.

Tantalum capacitors are commonly used with values from 0.1 to several hundred  $\mu\text{F}$  and voltage ratings of less than 100 V. Tantalum capacitors are smaller, lighter and more stable, with less leakage and inductance than their aluminum-foil electrolytic counterparts but their cost is higher.

**Paper** — Paper capacitors are generally not used in new designs and are largely encountered in older equipment; capacitances from 500 pF to 50  $\mu\text{F}$  are available. High working voltages are possible, but paper-

dielectric capacitors have low leakage resistances and tolerances are no better than 10 to 20%. Paper capacitors are not available as new stock (except possible for specialty restoration applications) and should not be used in new equipment.

**Trimming capacitors** — Small-value variable capacitors are often referred to as *trimmers* because they are used for fine-tuning or frequency adjustments, called *trimming*. Trimmers have dielectrics of Teflon, air, or ceramic and generally have values of less than

100 pF. **Compression trimmers** have higher values of up to 1000 pF and are constructed with mica dielectrics.

**Oil-filled** — Oil-filled capacitors use special high-strength dielectric oils to achieve voltage ratings of several kV. Values of up to 100  $\mu\text{F}$  are commonly used in high-voltage applications such as high-voltage power supplies and energy storage. (See the chapter on **Power Sources** for additional information about the use of oil-filled and electrolytic capacitors.)

## 4.3 Practical Inductors

### 4.3.1 Component Inductors

Various facets of radio circuits make use of inductors ranging from the tiny up to the massive. Small values of inductance, such as those inductors in **Figure 4.8A**, serve mostly in RF circuits. They may be self-supporting, air-core or air-wound inductors, or the winding may be supported by nonmagnetic strips or a form. Phenolic, certain plastics and ceramics are the most common *coil forms* for air-core inductors. These inductors range in value from a few hundred  $\mu\text{H}$  for medium- and high-frequency circuits down to tenths of a  $\mu\text{H}$  at VHF and UHF.

The most common inductor in small-signal RF circuits is the *encapsulated inductor*. These components look a lot like carbon-composition or film resistors and are often marked with colored paint stripes to indicate

value. (The chapter **Component Data and References** contains information on inductor color codes and marking schemes.) These inductors have values from less than 1  $\mu\text{H}$  to a few mH. They cannot handle much current without saturating or over-heating.

It is possible to make solenoid inductors variable by inserting a moveable *slug* in the center of the inductor. (Slug-tuned inductors normally have a ceramic, plastic, or phenolic insulating form between the conductive slug and the inductor winding.) If the slug material is magnetic, such as powdered iron, the inductance increases as the slug is moved into the center of the inductor. If the slug is brass or some other nonmagnetic material, inserting the slug will reduce the inductor's inductance.

An alternative to air-core inductors for RF work are *toroidal* inductors (or *toroids*)

wound on powdered-iron or ferrite cores. The availability of many types and sizes of powdered-iron cores has made these inductors popular for low-power fixed-value service. The toroidal shape concentrates the inductor's field nearly completely inside the inductor, eliminating the need in many cases for other forms of shielding to limit the interaction of the inductor's magnetic field with the fields of other inductors. (Ferrite core materials are discussed here and in the chapter on **RF Techniques**.)

Figure 4.8B shows samples of inductors in the millihenry (mH) range. Among these inductors are multi-section RF chokes designed to block RF currents from passing beyond them to other parts of circuits. Low-frequency radio work may also use inductors in this range of values, sometimes wound with

(A)

(B)

(C)

**Figure 4.8** — Part A shows small-value air-wound inductors. Part B shows some inductors with values in the range of a few millihenrys and C shows a large inductor such as might be used in audio circuits or as power-supply chokes. The  $\frac{1}{4}$ -inch-ruled graph paper background provides a size comparison.

*litz wire*. Litz wire is a special version of stranded wire, with each strand insulated from the others, and is used to minimize losses associated with skin effect.

For audio filters, toroidal inductors with values up to 100 mH are useful. Resembling powdered-iron-core RF toroids, these inductors are wound on ferrite or molybdenum-permalloy cores having much higher permeabilities.

Audio and power-supply inductors appear in Figure 4.8C. Lower values of these iron-core inductors, in the range of a few henrys, are useful as audio-frequency chokes. Larger values up to about 20 H may be found in power supplies, as choke filters, to suppress 120-Hz ripple. Although some of these inductors are open frame, most have iron covers to confine the powerful magnetic fields they produce.

Although builders and experimenters rarely construct their own capacitors, inductor fabrication for low- and high-power RF circuits is common. In fact, it is often necessary, since commercially available units may be unavailable or expensive. Even if available, they may consist of inductor stock to be trimmed to the required value. Core materials and wire for winding both solenoid and toroidal inductors are readily available. The following information includes fundamental formulas and design examples for calculating practical inductors, along with additional data on the theoretical limits in the use of some materials.

### 4.3.2 Air-Core Inductors

Many circuits require air-core inductors using just one layer of wire. The approximate inductance of a single-layer air-core inductor may be calculated from the simplified formula:

$$L(\mu\text{H}) = \frac{d^2 n^2}{18d + 40\ell}$$

where

- L = inductance in microhenrys,
- d = inductor diameter in inches (from wire center to wire center),
- ℓ = inductor length in inches, and
- n = number of turns.

If dimensions are given in cm, the equation is:

$$L(\mu\text{H}) = \frac{d^2 n^2}{6.4(7.2d + 15.8\ell)}$$

The notation is illustrated in Figure 4.9. This formula is a close approximation for inductors having a length equal to or greater than 0.4d. (Note: Inductance varies as the square of the turns. If the number of turns is doubled, the inductance is quadrupled. This relationship is inherent in the equation, but is often overlooked. For example, to double the induc-

Figure 4.9 — Coil dimensions used in the inductance formula for air-core inductors.

tance, add additional turns equal to 1.4 times the original number of turns, or 40% more turns.)

Example: What is the inductance of an inductor if the inductor has 48 turns wound at 32 turns per inch and a diameter of 3/4 inch? In this case, d = 0.75, ℓ = 48/32 = 1.5 and n = 48.

$$L(\mu\text{H}) = \frac{0.75^2 \times 48^2}{(18 \times 0.75) + (40 \times 1.5)}$$

$$= \frac{1300}{74} = 18 \mu\text{H}$$

To calculate the number of turns of a single-layer inductor for a required value of inductance, the formula becomes:

$$n = \frac{\sqrt{L(18d + 40\ell)}}{d} \text{ (inches)}$$

$$n = \frac{\sqrt{L(7.2d + 15.8\ell)}}{d} \text{ (cm)}$$

Example: Suppose an inductance of 10.0 μH is required. The form on which the inductor is to be wound has a diameter of one inch and is long enough to accommodate an inductor of 1 1/4 inches. Then d = 1.00 inch, ℓ = 1.25 inches and L = 10.0. Substituting:

$$n = \frac{\sqrt{10.0 [(18 \times 1.0) + (40 \times 1.25)]}}{1}$$

$$= \sqrt{680} = 26.1 \text{ turns}$$

A 26-turn inductor would be close enough in practical work. Since the inductor will be 1.25 inches long, the number of turns per inch will be 26.1 / 1.25 = 20.9. Consulting the **Component Data and References** chapter, we find that #17 AWG enameled wire (or anything smaller) can be used. The proper inductance is obtained by winding the required number of turns on the form and

Figure 4.10 — Measured inductance of coils wound with #12 bare wire, eight turns to the inch. The values include half-inch leads.

then adjusting the spacing between the turns to make a uniformly spaced inductor 1.25 inches long.

Most inductance formulas lose accuracy when applied to small inductors (such as are used in VHF work and in low-pass filters built for reducing harmonic interference to televisions) because the conductor thickness is no longer negligible in comparison with the size of the inductor. **Figure 4.10** shows the measured inductance of VHF inductors and may be used as a basis for circuit design. Two curves are given; curve A is for inductors wound to an inside diameter of ½ inch; curve B is for inductors of ¾ -inch inside diameter. In both curves, the wire size is #12 AWG and the winding pitch is eight turns to the inch (½-inch turn spacing). The inductance values include leads ½-inch long.

Machine-wound inductors with the preset diameters and turns per inch are available from component distributors, under the trade names of B&W Mininductor and Airdux. Information on using such coil stock is provided in the **Component Data and References** chapter to simplify the process of designing high-quality inductors for most HF applications.

Forming a wire into a solenoid increases its inductance, but also introduces distributed capacitance. Since each turn is at a slightly different ac potential, each pair of turns effectively forms a capacitor in parallel with part of the inductor. (See the chapter on **RF Techniques** for information on the effects of these and other factors that affect the behavior of the “ideal” inductors discussed in this chapter.)

Moreover, the Q of air-core inductors is, in part, a function of the inductor shape, specifically its ratio of length to diameter. Q tends to be highest when these dimensions are nearly equal. With wire properly sized to the current carried by the inductor, and with high-caliber construction, air-core inductors can achieve Q above 200.

For a large collection of formulas useful in constructing air-core inductors of many configurations, see the “Circuit Elements” section in Terman’s *Radio Engineers’ Handbook* (listed in the References section).

### 4.3.3 Straight-Wire Inductance

At low frequencies the inductance of a straight, round, nonmagnetic wire in free space is given by:

$$L = 0.00508 b \left\{ \ln \left( \frac{2b}{a} \right) - 0.75 \right\}$$

where

L = inductance in  $\mu\text{H}$ ,  
a = wire radius in inches,

**Figure 4.11 — Inductance of various conductor sizes as straight wires.**

b = wire length in inches, and  
ln = natural logarithm =  $2.303 \times$  common logarithm (base 10).

If the dimensions are expressed in millimeters instead of inches, the equation may still be used, except replace the 0.00508 value with 0.0002.

Skin effect reduces the inductance at VHF and above. As the frequency approaches infinity, the 0.75 constant within the brackets approaches unity. As a practical matter, skin effect will not reduce the inductance by more than a few percent.

Example: What is the inductance of a wire that is 0.1575 inch in diameter and 3.9370 inches long? For the calculations, a = 0.0787 inch (radius) and b = 3.9370 inch.

$$\begin{aligned} L &= 0.00508 b \left\{ \ln \left( \frac{2b}{a} \right) - 0.75 \right\} \\ &= 0.00508 (3.9370) \times \\ &\quad \left\{ \ln \left( \frac{2 \times 3.9370}{0.0787} \right) - 0.75 \right\} \\ &= 0.20 \times [\ln (100) - 0.75] \\ &= 0.20 \times (4.60 - 0.75) \\ &= 0.20 \times 3.85 = 0.077 \mu\text{H} \end{aligned}$$

**Figure 4.11** is a graph of the inductance for wires of various radii as a function of length.

A VHF or UHF tank circuit can be fabricated from a wire parallel to a ground plane, with one end grounded. A formula for the inductance of such an arrangement is given in **Figure 4.12**.

Example: What is the inductance of a wire 3.9370 inches long and 0.0787 inch in radius, suspended 1.5748 inch above a ground plane? (The inductance is measured between the free end and the ground plane, and the formula includes the inductance of the 1.5748-inch grounding link.) To demonstrate the use of the formula in **Figure 4.12**, begin by evaluating these quantities:

$$\begin{aligned} b + \sqrt{b^2 + a^2} &= 3.9370 + \sqrt{3.9370^2 + 0.0787^2} \\ &= 3.9370 + 3.94 = 7.88 \\ b + \sqrt{b^2 + 4(h^2)} &= 3.9370 + \sqrt{3.9370^2 + 4(1.5748^2)} \end{aligned}$$

hbk05\_04-056

$$L = 0.0117b \left\{ \log_{10} \left[ \frac{2h}{a} \left( \frac{b + \sqrt{b^2 + a^2}}{b + \sqrt{b^2 + 4h^2}} \right) \right] \right\} + 0.00508 \left( \sqrt{b^2 + 4h^2} - \sqrt{b^2 + a^2} + \frac{b}{4} - 2h + a \right)$$

where

- L = inductance in  $\mu\text{H}$   
 a = wire radius in inches  
 b = wire length parallel to ground plane in inches  
 h = wire height above ground plane in inches

**Figure 4.12** — Equation for determining the inductance of a wire parallel to a ground plane, with one end grounded. If the dimensions are in millimeters, the numerical coefficients become 0.0004605 for the first term and 0.0002 for the second term.

$$= 3.9370 + \sqrt{15.50 + 4(2.480)}$$

$$= 3.9370 + \sqrt{15.50 + 9.920}$$

$$= 3.9370 + 5.0418 = 8.9788$$

$$\frac{2h}{a} = \frac{2 \times 1.5748}{0.0787} = 40.0$$

$$\frac{b}{a} = \frac{3.9370}{4} = 0.98425$$

Substituting these values into the formula yields:

$$L = 0.0117 \times 3.9370 \left\{ \log_{10} \left[ 40.0 \times \left( \frac{7.88}{8.9788} \right) \right] \right\}$$

$$+ 0.00508 \times (5.0418 - 3.94 + 0.98425 - 3.1496 + 0.0787)$$

$$L = 0.0662 \mu\text{H}$$

Another conductor configuration that is frequently used is a flat strip over a ground plane. This arrangement has lower skin-effect loss at high frequencies than round wire because it has a higher surface-area-to volume ratio. The inductance of such a strip can be found from the formula in **Figure 4.13**.

#### 4.3.4 Iron-Core Inductors

If the permeability of an iron core in an inductor is 800, then the inductance of any given air-wound inductor is increased 800 times by inserting the iron core. The inductance will be proportional to the magnetic flux through the inductor, other things being equal. The inductance of an iron-core inductor is highly dependent on the current flowing in the inductor, in contrast to an air-core inductor, where the inductance is independent of current because air does not saturate.

Iron-core inductors are used chiefly in power-supply equipment. They usually have direct current flowing through the winding, and any variation in inductance with current

$$L = 0.00508 b \left( \ln \frac{2h}{w+h} + 0.5 - 2.2235 \frac{w+h}{b} \right)$$

where

- L = inductance in  $\mu\text{H}$   
 b = length in inches  
 w = width in inches  
 h = thickness in inches

**Figure 4.13** — Equation for determining the inductance of a flat strip inductor.

is usually undesirable. Inductance variations may be overcome by keeping the flux density below the saturation point of the iron. Opening the core so there is a small air gap will achieve this goal, as discussed in the earlier section on inductors. The reluctance or magnetic resistance introduced by such a gap is very large compared with that of the iron, even though the gap is only a small fraction of an inch. Therefore, the gap — rather than the iron — controls the flux density. Air gaps in iron cores reduce the inductance, but they hold the value practically constant regardless of the current magnitude.

When alternating current flows through an inductor wound on an iron core, a voltage is induced. Since iron is a conductor, eddy currents also flow in the core as discussed earlier. Eddy currents represent lost power because they flow through the resistance of the iron and generate heat. Losses caused by eddy

currents can be reduced by laminating the core (cutting the core into thin strips). These strips or laminations are then insulated from each other by painting them with some insulating material such as varnish or shellac. Eddy current losses add to hysteresis losses, which are also significant in iron-core inductors.

Eddy-current and hysteresis losses in iron increase rapidly as the frequency of the alternating current increases. For this reason, ordinary iron cores can be used only at power-line and audio frequencies — up to approximately 15000 Hz. Even then, a very good grade of iron or steel is necessary for the core to perform well at the higher audio frequencies. Laminated iron cores become completely useless at radio frequencies because of eddy current and hysteresis losses.

#### 4.3.5 Slug-Tuned Inductors

For RF work, the losses in iron cores can be reduced to a more useful level by grinding the iron into a powder and then mixing it with a binder of insulating material in such a way that the individual iron particles are insulated from each other. Using this approach, cores can be made that function satisfactorily even into the VHF range. Because a large part of the magnetic path is through a nonmagnetic material (the binder), the permeability of the powdered iron is low compared with the values for solid iron cores used at power-line frequencies.

The slug is usually shaped in the form of a cylinder that fits inside the insulating form on which the inductor is wound. Despite the fact that the major portion of the magnetic path for the flux is in air, the slug is quite effective in increasing the inductor inductance. By pushing (or screwing) the slug in and out of the inductor, the inductance can be varied over a considerable range.

#### 4.3.6 Powdered-Iron Toroidal Inductors

For fixed-value inductors intended for use at HF and VHF, the powdered-iron toroidal core has become the standard in low- and

medium-power circuits. **Figure 4.14** shows the general outlines of a toroidal inductor on a magnetic core.

Manufacturers offer a wide variety of core materials, or *mixes*, to create conductor cores that will perform over a desired frequency range with a reasonable permeability. Permeabilities for powdered-iron cores fall in the range of 3 to 35 for various mixes. In addition, core sizes are available in the range of 0.125-inch outside diameter (OD) up to 1.06-inch OD, with larger sizes to 5-inch OD available in certain mixes. The range of sizes permits the builder to construct single-layer inductors for almost any value using wire sized to meet the circuit current demands.

The use of powdered iron in a binder reduces core losses usually associated with iron, while the permeability of the core permits a reduction in the wire length and associated resistance in forming an inductor of a given inductance. Therefore, powdered-iron-core toroidal inductors can achieve Q well above 100, often approaching or exceeding 200 within the frequency range specified for a given core. Moreover, these inductors are considered *self-shielding* since most of the magnetic flux is within the core, a fact that simplifies circuit design and construction.

Each powdered-iron core has an *inductance factor* or *index*  $A_L$  determined by the manufacturer. (See the **Component Data and References** chapter.) Amidon specifies  $A_L$  in

$\mu\text{H}$  per 100 turns-squared and other manufacturers specify  $A_L$  in  $\mu\text{H}$  or nH per turns-squared. Check the manufacturer's website or product information for the correct units for  $A_L$  and method of calculating the inductance or desired number of turns.

$$L = \frac{A_L \times N^2}{10000} \text{ (Amidon) or}$$

$$L = A_L \times N^2 \text{ (Other manufacturers)}$$

where  
 $L$  = the inductance in  $\mu\text{H}$ ,  
 $A_L$  = the inductance index (see text above)  
 $N$  = the number of turns.

The builder must then ensure that the core is capable of holding the calculated number of turns of wire of the required wire size. See the **Component Data and References** chapter for more detailed data on the range of available cores.

Example: What is the inductance of a 60-turn inductor on a core with an  $A_L$  of 55  $\mu\text{H}/100\text{-turns}^2$ ?

$$L = \frac{A_L \times N^2}{10000} = \frac{55 \times 60^2}{10000}$$

$$= \frac{198000}{10000} = 19.8 \mu\text{H}$$

Example: What is the inductance of a 20-turn inductor on a core with an  $A_L$  of 0.3  $\mu\text{H}/\text{turns}^2$ ?

$$L = A_L \times N^2 = 0.3 \times 20^2$$

$$= 0.3 \times 400 = 120 \mu\text{H}$$

To calculate the number of turns needed for a particular inductance, use the formula:

$$N = 100 \sqrt{\frac{L}{A_L}} \text{ (Amidon) or}$$

$$N = \sqrt{\frac{L}{A_L}} \text{ (Other manufacturers)}$$

Example: How many turns are needed for a 12.0- $\mu\text{H}$  inductor if the  $A_L$  for the selected core is 49  $\mu\text{H}/100\text{-turns}^2$ ?

$$N = 100 \sqrt{\frac{L}{A_L}} = 100 \sqrt{\frac{12.0}{49}}$$

$$= 100 \sqrt{0.245} = 100 \times 0.495 = 49.5 \text{ turns}$$

Example: How many turns are needed for a 300-nH inductor if the  $A_L$  for the selected core is 12 nH/turns<sup>2</sup>?

$$N = \sqrt{\frac{L}{A_L}} = \sqrt{\frac{300}{12}} = \sqrt{25} = 5 \text{ turns}$$

Count turns by each pass of the wire

through the center of the core. (*A straight wire through a toroidal core counts as a one-turn inductor.*) Fine adjustment of the inductance may be possible by spreading or compressing inductor turns.

If the value is critical, experiment by starting with an extra turn or two, then measure the inductance or test the circuit. Core characteristics may vary slightly from batch to batch and winding style has a small effect on inductance, as well.

The power-handling ability of toroidal cores depends on many variables, which include the cross-sectional area through the core, the core material, the numbers of turns in the inductor, the applied voltage and the operating frequency. Although powdered-iron cores can withstand dc flux densities up to 5000 gauss without saturating, ac flux densities from sine waves above certain limits can overheat cores. Manufacturers provide guideline limits for ac flux densities to avoid overheating. The limits range from 150 gauss at 1 MHz to 30 gauss at 28 MHz, although the curve is not linear. To calculate the maximum anticipated flux density for a particular inductor, use the formula:

$$B_{\text{max}} = \frac{E_{\text{RMS}} \times 10^8}{4.44 \times A_e \times N \times f}$$

where  
 $B_{\text{max}}$  = the maximum flux density in gauss,  
 $E_{\text{RMS}}$  = the voltage across the inductor,  
 $A_e$  = the cross-sectional area of the core in square centimeters,  
 $N$  = the number of turns in the inductor, and  
 $f$  = the operating frequency in Hz.

Example: What is the maximum ac flux density for an inductor of 15 turns if the frequency is 7.0 MHz, the RMS voltage is 25 V and the cross-sectional area of the core is 0.133 cm<sup>2</sup>?

$$B_{\text{max}} = \frac{E_{\text{RMS}} \times 10^8}{4.44 \times A_e \times N \times f}$$

$$= \frac{25 \times 10^8}{4.44 \times 0.133 \times 15 \times 7.0 \times 10^6}$$

$$= \frac{25 \times 10^8}{62 \times 10^6} = 40 \text{ gauss}$$

Since the recommended limit for cores operated at 7 MHz is 57 gauss, this inductor is well within guidelines.

### 4.3.7 Ferrite Toroidal Inductors

Although nearly identical in general appearance to powdered-iron cores, ferrite cores differ in a number of important charac-

**Figure 4.14** — A typical toroidal inductor wound on a powdered-iron or ferrite core. Some key physical dimensions are noted. Equally important are the core material, its permeability, its intended range of operating frequencies, and its  $A_L$  value. This is an 11-turn toroid.

teristics. Composed of nickel-zinc ferrites for lower permeability ranges and of manganese-zinc ferrites for higher permeabilities, these cores span a permeability range from 20 to above 10000. Nickel-zinc cores with permeabilities from 20 to 800 are useful in high-Q applications, but function more commonly in amateur applications as RF chokes. They are also useful in wide-band transformers, discussed in the chapter **RF Techniques**.

Ferrite cores are often unpainted, unlike powdered-iron toroids. Ferrite toroids and rods often have sharp edges, while powdered-iron toroids usually have rounded edges.

Because of their higher permeabilities, the  $A_L$  values for ferrite cores are higher than for powdered-iron cores. Amidon Corp. is the most common supplier of cores for amateurs (see the **Component Data and References**

chapter) and specifies  $A_L$  in mH per 1000 turns-squared. Other manufacturers specify  $A_L$  in nH per turns-squared.

To calculate the inductance of a ferrite toroidal inductor when the number of turns and the core material are known:

$$L = \frac{A_L \times N^2}{1000000} \quad (\text{Amidon})$$

where

- $L$  = the inductance in mH,
- $A_L$  = the inductance index in mH per 1000 turns-squared, and
- $N$  = the number of turns.

$$L = A_L \times N^2 \quad (\text{Other manufacturers})$$

where

- $L$  = the inductance in nH,

$A_L$  = the inductance index in nH per turns-squared, and

$N$  = the number of turns.

Calculations are performed similarly to the examples given for powdered-iron cores in the previous section. The builder must then ensure that the core is capable of holding the calculated number of turns of wire of the required wire size.

For inductors carrying both dc and ac currents, the upper saturation limit for most ferrites is a flux density of 2000 gauss, with power calculations identical to those used for powdered-iron cores. More detailed information is available on specific cores and manufacturers in the **Component Data and References** chapter.

## 4.4 Transformers

When the ac source current flows through every turn of an inductor, the generation of a counter-voltage and the storage of energy during each half cycle is said to be by virtue of self-inductance. If another inductor — not connected to the source of the original current — is positioned so the magnetic field of the first inductor intercepts the turns of the second inductor, coupling the two inductors and creating mutual inductance as described earlier, a voltage will be induced and current will flow in the second inductor. A load such as a resistor may be connected across the second inductor to consume the energy transferred magnetically from the first inductor.

**Figure 4.15** illustrates a pair of coupled inductors, showing an ac energy source connected to one, called the *primary inductor*, and a load connected to the other, called the *secondary inductor*. If the inductors are wound tightly on a magnetic core so that nearly all magnetic flux from the first inductor intersects with the turns of the second inductor, the pair is said to be *tightly coupled*. Inductors not sharing a common core and separated by a

distance would be *loosely coupled*.

The signal source for the primary inductor may be household ac power lines, audio, or other waveforms at low frequencies, or RF currents. The load may be a device needing power, a speaker converting electrical energy into sonic energy, an antenna using RF energy for communications or a particular circuit set up to process a signal from a preceding circuit. The uses of magnetically coupled energy in electronics are innumerable.

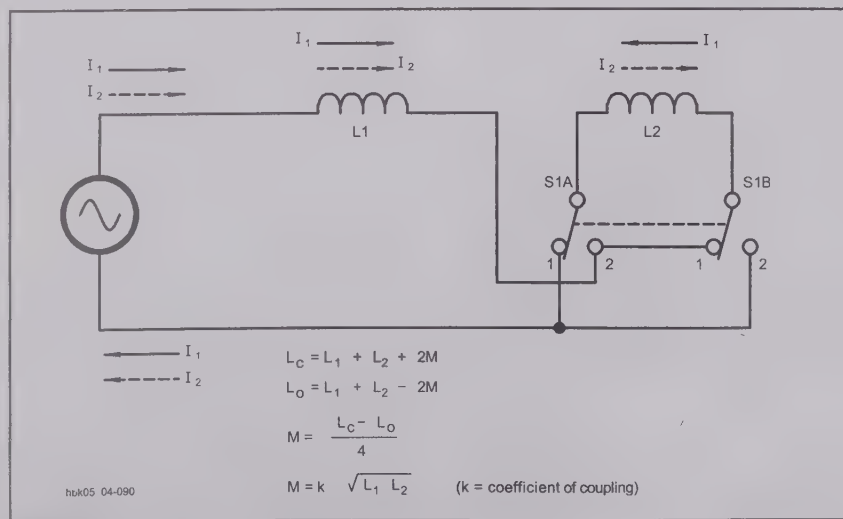

Mutual inductance ( $M$ ) between inductors is measured in henrys. Two inductors have a mutual inductance of 1 H under the following

conditions: as the primary inductor current changes at a rate of 1 A/s, the voltage across the secondary inductor is 1 V. The level of mutual inductance varies with many factors: the size and shape of the inductors, their relative positions and distance from each other, and the permeability of the inductor core material and of the space between them.

If the self-inductance values of two inductors are known (self-inductance is used in this section to distinguish it from the mutual inductance), it is possible to derive the mutual inductance by way of a simple experiment schematically represented in **Figure 4.16**.

**Figure 4.15** — A basic transformer: two inductors — one connected to an ac energy source, the other to a load — with coupled magnetic fields.

**Figure 4.16** — An experimental setup for determining mutual inductance. Measure the inductance with the switch in each position and use the formula in the text to determine the mutual inductance.

**Figure 4.17** — A transformer. A is a pictorial diagram. Power is transferred from the primary coil to the secondary by means of the magnetic field. B is a schematic diagram of an iron-core transformer, and C is an air-core transformer.

**Figure 4.18** — The conditions for transformer action: two coils that exhibit mutual inductance, an ac power source, and a load. The magnetic field set up by the energy in the primary circuit transfers energy to the secondary for use by the load, resulting in a secondary voltage and current.

Without altering the physical setting or position of two inductors, measure the total coupled inductance,  $L_C$ , of the series-connected inductors with their windings complementing each other and again with their windings opposing each other. Since, for the two inductors,  $L_C = L_1 + L_2 + 2M$ , in the complementary case, and  $L_O = L_1 + L_2 - 2M$  for the opposing case,

$$M = \frac{L_C - L_O}{4}$$

The ratio of magnetic flux set up by the secondary inductor to the flux set up by the primary inductor is a measure of the extent to which two inductors are coupled, compared to the maximum possible coupling between them. This ratio is the *coefficient of coupling* ( $k$ ) and is always less than 1. If  $k$  were to equal 1, the two inductors would have the maximum possible mutual coupling. Thus:

$$M = k \sqrt{L_1 L_2}$$

where

- $M$  = mutual inductance in henrys,
- $L_1$  and  $L_2$  = individual coupled inductors, each in henrys, and
- $k$  = the coefficient of coupling.

Using the experiment above, it is possible to solve for  $k$  with reasonable accuracy.

Any two inductors having mutual inductance comprise a *transformer* having a *primary winding* or inductor and a *secondary winding* or inductor. The word “winding” is generally dropped so that transformers are said to have “primaries” and “secondaries.”

**Figure 4.17** provides a pictorial representation of a typical iron-core transformer, along with the schematic symbols for both iron-core and air-core transformers. Conventionally, the term *transformer* is most commonly applied to coupled inductors having a magnetic core material, while coupled air-wound inductors are not called by that name. They are still transformers, however.

We normally think of transformers as ac devices, since mutual inductance only occurs when magnetic fields are changing. A transformer connected to a dc source will exhibit mutual inductance only at the instants of closing and opening the primary circuit, or on the rising and falling edges of dc pulses, because only then does the primary winding have a changing field. There are three principle uses of transformers: to physically isolate the primary circuit from the secondary circuit, to transform voltages and currents from one level to another, and to transform circuit impedances from one level to another. These functions are not mutually exclusive and have many variations.

#### 4.4.1 Basic Transformer Principles

The primary and secondary windings of a transformer may be wound on a core of magnetic material. The permeability of the magnetic material increases the inductance of the windings so a relatively small number of turns may be used to induce a given voltage value with a small current. A closed core having a continuous magnetic path, such as that shown in **Figure 4.17**, also tends to ensure that practically all of the field set up by the current in the primary winding will intercept or “cut” the turns of the secondary winding.

For power transformers and impedance-matching transformers used at audio frequencies, cores made of soft iron strips or sheets called *laminations* are most common and generally very efficient. At higher frequencies, ferrite or powdered-iron cores are more frequently used. This section deals with basic transformer operation at audio and power frequencies. RF transformer operation is discussed in the chapter on **RF Techniques**.

The following principles presume a coefficient of coupling ( $k$ ) of 1, that is, a perfect transformer. The value  $k = 1$  indicates that all the turns of both windings link with all the magnetic flux lines, so that the voltage induced per turn is the same with both windings. This condition makes the induced voltage independent of the inductance of the primary and secondary inductors. Iron-core transformers for low frequencies closely approach this ideal condition. **Figure 4.18** illustrates the conditions for transformer action.

#### VOLTAGE RATIO

For a given varying magnetic field, the voltage induced in an inductor within the field is proportional to the number of turns in the inductor. When the two windings of a transformer are in the same field (which is the case when both are wound on the same closed core), it follows that the induced voltages will be proportional to the number of turns in each winding. In the primary, the induced voltage practically equals, and opposes, the applied voltage, as described earlier. Hence:

$$E_S = E_P \left( \frac{N_S}{N_P} \right)$$

where

- $E_S$  = secondary voltage,
- $E_P$  = primary applied voltage,
- $N_S$  = number of turns on secondary, and
- $N_P$  = number of turns on primary.

Example: A transformer has a primary with 400 turns and a secondary with 2800 turns, and a voltage of 120 V is applied to the primary. What voltage appears across the secondary winding?

$$E_S = 120 \text{ V} \left( \frac{2800}{400} \right) = 120 \text{ V} \times 7 = 840 \text{ V}$$

(Notice that the number of turns is taken as a known value rather than a measured quantity, so they do not limit the significant figures in the calculation.) Also, if 840 V is applied to the 2800-turn winding (which then becomes the primary), the output voltage from the 400-turn winding will be 120 V.

Either winding of a transformer can be used as the primary, provided the winding has enough turns (enough inductance) to induce a voltage equal to the applied voltage without

requiring an excessive current. The windings must also have insulation with a voltage rating sufficient for the voltages applied or created. Transformers are called *step-up* or *step-down* transformers depending on whether the secondary voltage is higher or lower than the primary voltage, respectively.

### CURRENT OR AMPERE-TURNS RATIO

The current in the primary when no current is taken from the secondary is called the *magnetizing current* of the transformer. An ideal transformer, with no internal losses, would consume no power, since the current through the primary inductor would be 90° out of phase with the voltage. In any properly designed transformer, the power consumed by the transformer when the secondary is open (not delivering power) is only the amount necessary to overcome the losses in the iron core and in the resistance of the wire with which the primary is wound.

When power is transferred from the secondary winding to a load, the secondary current creates a magnetic field that opposes the field established by the primary current. For the induced voltage in the primary to equal the applied voltage, the original magnetizing field must be maintained. Therefore, enough additional current must flow in the primary to create a field exactly equal and opposite to the field set up by the secondary current, leaving the original magnetizing field.

In practical transformer calculations it may be assumed that the entire primary current is caused by the secondary load. This is justifiable because the magnetizing current should be very small in comparison with the primary load current at rated power output.

If the magnetic fields set up by the primary and secondary currents are to be equal, the number of ampere-turns must be equal in each winding. (See the previous discussion of magnetic fields and magnetic flux density.) Thus, primary current multiplied by the primary turns must equal the secondary current multiplied by the secondary turns.

$$I_p N_p = I_s N_s$$

and

$$I_p = I_s \left( \frac{N_s}{N_p} \right)$$

where

$I_p$  = primary current,

$I_s$  = secondary current,

$N_p$  = number of turns in the primary winding, and

$N_s$  = number of turns in the secondary winding.

Example: Suppose the secondary of the

transformer in the previous example is delivering a current of 0.20 A to a load. What will be the primary current?

$$I_p = 0.20 \text{ A} \left( \frac{2800}{400} \right) = 0.20 \text{ A} \times 7 = 1.4 \text{ A}$$

Although the secondary voltage is higher than the primary voltage, the secondary current is lower than the primary current, and by the same ratio. The secondary current in an ideal transformer is 180° out of phase with the primary current, since the field in the secondary just offsets the field in the primary. The phase relationship between the currents in the windings holds true no matter what the phase difference between the current and the voltage of the secondary. In fact, the phase difference, if any, between voltage and current in the secondary winding will be *reflected* back to the primary as an identical phase difference.

### POWER RATIO

A transformer cannot create power; it can only transfer it and change the voltage and current ratios. Hence, the power taken from the secondary cannot exceed that taken by the primary from the applied voltage source. There is always some power loss in the resistance of the windings and in the iron core, so in all practical cases the power taken from the source will exceed that taken from the secondary.

$$P_O = \eta P_I$$

where

$P_O$  = power output from secondary,

$P_I$  = power input to primary, and

$\eta$  = efficiency.

The efficiency,  $\eta$ , is always less than 1 and is commonly expressed as a percentage: if  $\eta$  is 0.65, for instance, the efficiency is 65%.

Example: A transformer has an efficiency of 85.0% at its full-load output of 150 W. What is the power input to the primary at full secondary load?

$$P_I = \frac{P_O}{\eta} = \frac{150 \text{ W}}{0.850} = 176 \text{ W}$$

A transformer is usually designed to have the highest efficiency at the power output for which it is rated. The efficiency decreases with either lower or higher outputs. On the other hand, the losses in the transformer are relatively small at low output but increase as more power is taken. The amount of power that the transformer can handle is determined by its own losses, because these losses heat the wire and core. There is a limit to the temperature rise that can be tolerated, because too high a temperature can either melt the wire or cause the insulation to break down.

A transformer can be operated at reduced output, even though the efficiency is low, because the actual loss will be low under such conditions. The full-load efficiency of small power transformers such as are used in radio receivers and transmitters usually lies between about 60 and 90%, depending on the size and design.

### IMPEDANCE RATIO

In an ideal transformer — one without losses or leakage inductance (see Transformer Losses) — the primary power,  $P_p = E_p I_p$ , and secondary power,  $P_s = E_s I_s$ , are equal. The relationships between primary and secondary voltage and current are also known. Since impedance is the ratio of voltage to current,  $Z = E/I$ , the impedances represented in each winding are related as follows:

$$Z_p = Z_s \left( \frac{N_p}{N_s} \right)^2$$

where

$Z_p$  = impedance at the primary terminals from the power source,

$Z_s$  = impedance of load connected to secondary, and

$N_p/N_s$  = turns ratio, primary to secondary.

The transformer is converting input power at one ratio of voltage to current (i.e. impedance) to output power at a different ratio of voltage to current (i.e. a different impedance).

A load of any given impedance connected to the transformer secondary will thus be transformed to a different value at the primary terminals. The impedance transformation is proportional to the square of the primary-to-secondary turns ratio. (Take care to use the primary-to-secondary turns ratio, since the secondary-to-primary ratio is more commonly used to determine the voltage transformation ratio.)

The term *looking into* is often used to mean the conditions observed from an external perspective at the terminals specified. For example, “impedance looking into” the transformer primary means the impedance measured externally to the transformer at the terminals of the primary winding.

Example: A transformer has a primary-to-secondary turns ratio of 0.6 (the primary has six-tenths as many turns as the secondary) and a load of 3000  $\Omega$  is connected to the secondary. What is the impedance looking into the primary of the transformer?

$$Z_p = 3000 \Omega \times (0.6)^2 = 3000 \Omega \times 0.36$$

$$Z_p = 1080 \Omega$$

By choosing the proper turns ratio, the impedance of a fixed load can be transformed to any desired value, within practical limits.

If transformer losses can be neglected, the transformed (reflected) impedance has the same phase angle as the actual load impedance. Thus, if the load is a pure resistance, the load presented by the primary to the power source will also be a pure resistance. If the load impedance is complex, that is, if the load current and voltage are out of phase with each other, then the primary voltage and current will have the same phase angle.

Many devices or circuits require a specific value of load resistance (or impedance) for optimum operation. The impedance of the actual load that is to dissipate the power may be quite different from the impedance of the source device or circuit, so an *impedance-matching transformer* is used to change the actual load into an impedance of the desired value. The turns ratio required is:

$$\frac{N_P}{N_S} = \sqrt{\frac{Z_P}{Z_S}}$$

where

$N_P / N_S$  = required turns ratio, primary to secondary,

$Z_P$  = primary impedance required, and

$Z_S$  = impedance of load connected to secondary.

Example: A transistor audio amplifier requires a load of  $150 \Omega$  for optimum performance, and is to be connected to a loudspeaker having an impedance of  $4.0 \Omega$ . What primary-to-secondary turns ratio is required in the coupling transformer?

$$\frac{N_P}{N_S} = \sqrt{\frac{Z_P}{Z_S}} = \sqrt{\frac{150 \Omega}{4.0 \Omega}} = \sqrt{38} = 6.2$$

The primary therefore must have 6.2 times as many turns as the secondary.

These relationships may be used in practical circuits even though they are based on an ideal transformer. Aside from the normal design requirements of reasonably low internal losses and low leakage reactance, the only other requirement is that the primary has enough inductance to operate with low magnetizing current at the voltage applied to the primary.

The primary terminal impedance of an iron-core transformer is determined wholly by the load connected to the secondary and by the turns ratio. If the characteristics of the transformer have an appreciable effect on the impedance presented to the power source, the transformer is either poorly designed or is not suited to the voltage and frequency at which it is being used. Most transformers will operate quite well at voltages from slightly above to well below the design figure.

## TRANSFORMER LOSSES

In practice, none of the formulas given so

Figure 4.19 — A transformer as a network of resistances, inductances and capacitances. Only L1 and L2 contribute to the transfer of energy.

far provides truly exact results, although they afford reasonable approximations. Transformers in reality are not simply two coupled inductors, but a network of resistances and reactances, most of which appear in Figure 4.19. Since only the terminals numbered 1 through 4 are accessible to the user, transformer ratings and specifications take into account the additional losses created by these complexities.

In a practical transformer not all of the magnetic flux is common to both windings, although in well-designed transformers the amount of flux that cuts one winding and not the other is only a small percentage of the total flux. This *leakage flux* causes a voltage by self-induction in the winding creating the flux. The effect is the same as if a small *leakage inductance* existed independently of the main windings. Leakage inductance acts in exactly the same way as inductance inserted in series with the winding. It has, therefore, a certain reactance, depending on the amount of leakage inductance and the frequency. This reactance is called *leakage reactance* and is shown as  $X_{L1}$  and  $X_{L2}$  in Figure 4.19.

Current flowing through the leakage reactance causes a voltage drop. This voltage drop increases with increasing current (or frequency); hence, it increases as more power is taken from the secondary. The resistances of the transformer windings,  $R_1$  and  $R_2$ , also cause voltage drops when there is current. Although these voltage drops are not in phase with those caused by leakage reactance, together they result in a lower secondary voltage under load than is indicated by the transformer turns ratio. Thus, in a practical transformer, the greater the secondary current, the smaller the secondary terminal voltage becomes.

At ac line frequencies (50 or 60 Hz), the voltage at the secondary, with a reasonably well-designed iron-core transformer, should not drop more than about 10% from open-circuit conditions to full load. The voltage drop may be considerably more than this in a transformer operating at audio frequencies,

because the leakage reactance increases with frequency.

In addition to wire resistances and leakage reactances, certain unwanted or “stray” capacitances occur in transformers. The wire forming the separate turns of the winding acts as the plates of a small capacitor, creating a capacitance between turns and between the windings. This *distributed capacitance* appears in Figure 4.19 as  $C_1$ ,  $C_2$ , and  $C_m$ . More-over, transformer windings can exhibit capacitance relative to nearby metal, for example, the chassis, the shield and even the core. When current flows through a winding each turn has a slightly different voltage than its adjacent turns. This voltage causes a small current to flow in these *interwinding and winding-to-winding capacitances*.

Although stray capacitances are of little concern with power and audio transformers they become important as the frequency increases. In transformers for RF use, the stray capacitance can resonate with either the leakage reactance or, at lower frequencies, with the winding reactances,  $L_1$  or  $L_2$ , especially under very light or zero loads. In the frequency region around resonance, transformers no longer exhibit the properties formulated above or the impedance properties to be described below.

Iron-core transformers also experience losses within the core itself. *Hysteresis losses* include the energy required to overcome the retentivity of the core’s magnetic material. Circulating currents through the core’s resistance are *eddy currents*, which form part of the total core losses. These losses, which add to the required magnetizing current, are equivalent to adding a resistance in parallel with  $L_1$  in Figure 4.19.

## CORE CONSTRUCTION

Audio and power transformers usually employ silicon steel as the core material. With permeabilities of 5000 or greater, these cores saturate at flux densities approaching  $10^5$  (Mx) per square inch of cross section. The cores consist of thin insulated laminations to

**Figure 4.20** — A typical transformer iron core. The E and I pieces alternate direction in successive layers to improve the magnetic path while attenuating eddy currents in the core.

**Figure 4.21** — Two common transformer constructions: shell and core.

break up potential eddy current paths.

Each core layer consists of an “E” and an “I” piece butted together, as represented in **Figure 4.20**. The butt point leaves a small gap. Each layer is reversed from the adjacent layers so that each gap is next to a continuous magnetic path so that the effect of the gaps is minimized. This is different from an air-gapped inductor in which the air gap is maintained for all layers of laminations.

Two core shapes are in common use, as shown in **Figure 4.21**. In the shell type, both windings are placed on the inner leg, while in the core type the primary and secondary windings may be placed on separate legs, if desired. This is sometimes done when it is necessary to minimize capacitance between

**Figure 4.22** — A shielded transformer cross-section: the core plus an outer shield of magnetic material contain nearly all of the magnetic field.

the primary and secondary, or when one of the windings must operate at very high voltage.

The number of turns required in the primary for a given applied voltage is determined by the size, shape and type of core material used, as well as the frequency. The number of turns required is inversely proportional to the cross-sectional area of the core. As a rough indication, windings of small power transformers frequently have about six to eight turns per volt on a core of 1-square-inch cross section and have a magnetic path 10 or 12 inches in length. A longer path or smaller cross section requires more turns per volt, and vice versa.

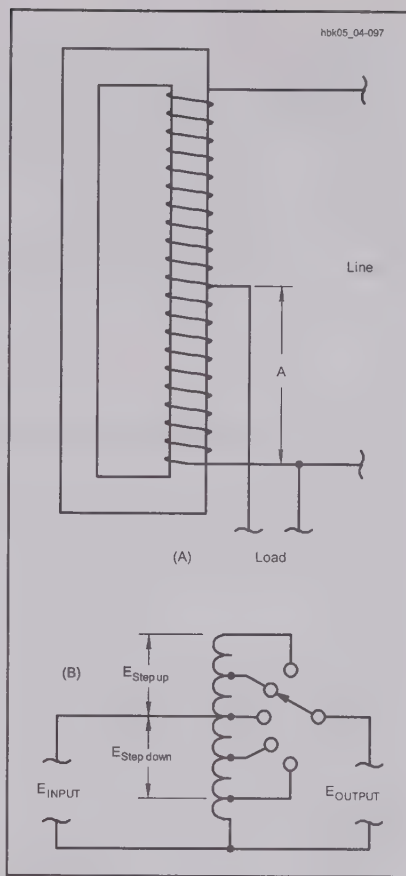

In most transformers the windings are wound in layers, with a thin sheet of treated-paper insulation between each layer. Thicker insulation is used between adjacent windings and between the first winding and the core.

## SHIELDING

Because magnetic lines of force are continuous loops, shielding requires a complete path for the lines of force of the leakage flux. The high-permeability of iron cores tends to concentrate the field, but additional shielding is often needed. As depicted in **Figure 4.22**, enclosing the transformer in a good magnetic material can restrict virtually all of the magnetic field in the outer case. The nonmagnetic material between the case and the core creates a region of high reluctance, attenuating the field before it reaches the case.

### 4.4.2 Autotransformers

The transformer principle can be used with only one winding instead of two, as shown in **Figure 4.23A**. The principles that relate voltage, current and impedance to the turns ratio also apply equally well. A one-winding trans-

**Figure 4.23** — The autotransformer is based on the transformer, but uses only one winding. The pictorial diagram at A shows the typical construction of an autotransformer. The schematic diagram at B demonstrates the use of an autotransformer to step up or step down ac voltage, usually to compensate for excessive or deficient line voltage.

former is called an *autotransformer*. The current in the common section (A) of the winding is the difference between the line (primary) and the load (secondary) currents, since these currents are out of phase. Hence, if the line and load currents are nearly equal, the common section of the winding may be wound with comparatively small wire. The line and load currents will be equal only when the primary (line) and secondary (load) voltages are not very different.

Autotransformers are used chiefly for boosting or reducing the power-line voltage by relatively small amounts. **Figure 4.23B** illustrates the principle schematically with a switched, stepped autotransformer. Continuously variable autotransformers are commercially available under a variety of trade names; Variac and Powerstat are typical examples.

Technically, tapped air-core inductors,

such as the one in the network in Figure 3.48 at the close of the discussion of resonant circuits in the chapter on **Radio Fundamentals**, are also autotransformers. The voltage from the tap to the bottom of the winding is less than the voltage across the entire winding. Likewise, the impedance of the tapped part of the winding is less than the impedance of the entire winding. Because in this case, leakage reactances are great and the coefficient of coupling is quite low, the relationships that

are true in a perfect transformer grow quite unreliable in predicting the exact values. For this reason, tapped inductors are rarely referred to as transformers. The stepped-down situation in Figure 3.48 is better approximated — at or close to resonance — by the formula

$$R_p = \frac{R_L X_{COM}^2}{X_L}$$

where

$R_p$  = tuned-circuit parallel-resonant impedance,

$R_L$  = load resistance tapped across part of the winding,

$X_{COM}$  = reactance of the portion of the winding common to both the resonant circuit and the load tap, and

$X_L$  = reactance of the entire winding.

The result is approximate and applies only to circuits with a Q of 10 or greater.

## 4.5 Practical Semiconductors

There are several different kinds of components that can be used to build circuits for analog signal processing. Bipolar semiconductors, field-effect semiconductors and integrated circuits comprise a wide spectrum of active devices used in analog signal processing. (Vacuum tubes are discussed in the chapter on **RF Power Amplifiers**, their primary application in Amateur Radio.) Several different devices can perform the same function, each with its own advantages and disadvantages based on the physical characteristics of each type of device.

Understanding the specific characteristics of each device allows you to make educated decisions about which device would be best for a particular purpose when designing analog circuitry, or understanding why an existing circuit was designed in a particular way.

### 4.5.1 Device Characteristics

#### CHARACTERISTIC CURVES

Analog devices are described most completely with their *characteristic curves*. The characteristic curve is a plot of the interrelationships between two or three variables. The vertical (y) axis parameter is the output, or result of the device being operated with an input parameter on the horizontal (x) axis. Often the output is the result of two input values. The first input parameter is represented along the X-axis and the second input parameter by several curves, each for a different value.

Almost all devices of concern are nonlinear over a wide range of operating parameters. We are often interested in using a device only in the region that approximates a linear response. Characteristic curves are used to graphically describe a device's operation in both its linear and nonlinear regions.

Figure 4.24A shows the characteristic curve for a semiconductor diode with the Y-axis showing the forward current,  $I_F$ , flowing through the diode and the X-axis showing

forward voltage,  $V_F$ , across the diode. This curve shows the relationship between current and voltage in the diode when it is conducting current. Characteristic curves showing voltage and current in two-terminal devices such as diodes are often called *I-V curves*. Char-

acteristic curves may include all four quadrants of operation in which both axes include positive and negative values. It is also common for different scales to be used in the different quadrants, so inspect the legend for the curves carefully.

The parameters plotted in a characteristic curve depend on how the device will be used so that the applicable design values can be obtained from the characteristic curve. The slope of the curve is often important because it relates changes in output to changes in input. To determine the slope of the curve, two closely-spaced points along that portion of the curve are selected, each defined by its location along the x and y axes. If the two points are defined by  $(x_1, y_1)$  and  $(x_2, y_2)$ , the slope,  $m$ , of the curve (which can be a gain, a resistance or a conductance, for example) is calculated as:

$$m = \frac{\Delta y}{\Delta x} = \frac{y_1 - y_2}{x_1 - x_2}$$

It is important to pick points that are close together or the slope will not reflect the actual behavior of the device. A device whose characteristic curve is not a straight line will not have a linear response to inputs because the slope changes with the value of the input parameter.

For a device in which three parameters interact, such as a transistor, sets of characteristic curves can be drawn. Figure 4.24B shows a set of characteristic curves for a bipolar transistor where collector current,  $I_C$ , is shown on the y axis and collector-to-emitter voltage,  $V_{CE}$ , is shown on the x axis. Because the amount of collector current also depends on base current,  $I_B$ , the curve is repeated several times for different values of  $I_B$ . From this set of curves, an amplifier circuit using this transistor can be designed to have specific values of gain.

#### BIASING

The operation of an analog signal-processing device is greatly affected by which portion

**Figure 4.24 — Characteristic curves. A forward voltage vs forward current characteristic curve for a semiconductor diode is shown at (A). (B) shows a set of characteristic curves for a bipolar transistor in which the collector current vs collector-to-emitter voltage curve is plotted for five different values of base current.**

**Figure 4.25 — Effect of biasing.** An input signal may be reproduced linearly or nonlinearly depending on the choice of bias points.

of the characteristic curve is used to do the processing. The device's *bias point* is its set of operating parameters when no input signal is applied. The bias point is also known as the *quiescent point* or *Q-point*. By changing the bias point, the circuit designer can affect the relationship between the input and output signal. The bias point can also be considered as a dc offset of the input signal. Devices that perform analog signal processing require appropriate input signal biasing.

As an example, consider the characteristic curve shown in **Figure 4.25**. (The exact types of device and circuit are unimportant.) The characteristic curve shows the relationship between an input voltage and an output current. Increasing input voltage results in an increase in output current so that an input signal is reproduced at the output. The characteristic curve is linear in the middle, but is quite nonlinear in its upper and lower regions.

In the circuit described by the figure, bias points are established by adding one of the three voltages,  $V_1$ ,  $V_2$  or  $V_3$  to the input signal. Bias voltage  $V_1$  results in an output current of  $I_1$  when no input signal is present. This is shown as Bias Point 1 on the characteristic curve. When an input signal is applied, the input voltage varies around  $V_1$  and the output current varies around  $I_1$  as shown. If the dc value of the output current is subtracted, a reproduction of the input signal is the result.

If Bias Point 2 is chosen, we can see that

the input voltage is reproduced as a changing output current with the same shape. In this case, the device is operating linearly. If either Bias Point 1 or Bias Point 3 is chosen, however, the shape of the output signal is distorted because the characteristic curve of the device is nonlinear in this region. Either the increasing portion of the input signal results in more variation than the decreasing portion (Bias Point 1) or vice versa (Bias Point 3). Proper biasing is crucial to ensure that a device operates linearly.

### MANUFACTURER'S DATA SHEETS

Manufacturer's data sheets list device characteristics, along with the specifics of the part type (polarity, semiconductor type), identity of the pins and leads (*pinouts*), and the typical use (such as small signal, RF, switching or power amplifier). The pin identification is important because, although common package pinouts are normally used, there are exceptions. Manufacturers may differ slightly in the values reported, but certain basic parameters are listed. Different batches of the same devices are rarely identical, so manufacturers specify the guaranteed limits for the parameters of their device. There are usually three values listed in the data sheet for each parameter: guaranteed minimum value, the guaranteed maximum value, and/or the typical value.

Another section of the data sheet lists ABSOLUTE MAXIMUM RATINGS, beyond which device

damage may result. For example, the parameters listed in the ABSOLUTE MAXIMUM RATINGS section for a solid-state device are typically voltages, continuous currents, total device power dissipation ( $P_D$ ) and operating- and storage-temperature ranges.

Rather than plotting the characteristic curves for each device, the manufacturer often selects key operating parameters that describe the device operation for the configurations and parameter ranges that are most commonly used. For example, a bipolar transistor data sheet might include an OPERATING PARAMETERS section. Parameters are listed in an OFF CHARACTERISTICS subsection and an ON CHARACTERISTICS subsection that describe the conduction properties of the device for dc voltages. The SMALL-SIGNAL CHARACTERISTICS section might contain a minimum Gain-Bandwidth Product ( $f_T$  or GBW), maximum output capacitance, maximum input capacitance, and the range of the transfer parameters applicable to a given device. Finally, the SWITCHING CHARACTERISTICS section might list absolute maximum ratings for Delay Time ( $t_d$ ), Rise Time ( $t_r$ ), Storage Time ( $t_s$ ), and Fall Time ( $t_f$ ). Other types of devices list characteristics important to operation of that specific device.

When selecting equivalent parts for replacement of specified devices, the data sheet provides the necessary information to tell if a given part will perform the functions of another. Lists of *cross-references* and *substitution guides* generally only specify devices that have nearly identical parameters. There are usually a large number of additional devices that can be chosen as replacements. Knowledge of the circuit requirements adds even more to the list of possible replacements. The device parameters should be compared individually to make sure that the replacement part meets or exceeds the parameter values of the original part required by the circuit. Be aware that in some applications a far superior part may fail as a replacement, however. A transistor with too much gain could easily oscillate if there were insufficient negative feedback to ensure stability.

### 4.5.2 Diodes

Although many types of semiconductor diodes are available, they share many common characteristics. The different types of diodes have been developed to optimize particular characteristics for one type of application. You will find many examples of diode applications throughout this book.

The diode symbol is shown in **Figure 4.26**. Forward current flows in the direction from anode to cathode, in the direction of the arrow. Reverse current flows from cathode to anode. (Current is considered to be conventional current as described in the **Electronic Funda-**

**Figure 4.26 — Practical semiconductor diodes.** All devices are aligned with anode on the left and cathode on the right. (A) Standard PN junction diode. (B) Point-contact or “cat’s whisker” diode. (C) PIN diode formed with heavily doped P-type (P<sup>+</sup>), undoped (intrinsic) and heavily doped N-type (N<sup>+</sup>) semiconductor material. (D) Diode schematic symbol. (E) Diode package with marking stripe on the cathode end.

mentals chapter.) The anode of a semiconductor junction diode is made of P-type material and the cathode is made of N-type material, as indicated in Figure 4.26. Most diodes are marked with a band on the cathode end.

### DIODE RATINGS

Five major characteristics distinguish standard junction diodes from one another: current handling capacity, maximum voltage rating, response speed, reverse leakage current and junction forward voltage. Each of these characteristics can be manipulated during manufacture to produce special purpose diodes.

#### Current Capacity

The ideal diode would have zero resistance in the forward direction and infinite resistance in the reverse direction. This is not the case for actual devices, which behave as shown in the plot of a diode response in Figure 4.27A. Note that the scales of the two graphs are drastically different. The inverse of the slope of the line (the change in voltage between two points on a straight portion of the line divided by the corresponding change in current) on the upper right is the resistance of the diode in the forward direction,  $R_F$ .

The range of voltages is small and the range of currents is large since the forward resistance is very small (in this example, about 2Ω). Nevertheless, this resistance causes heat dissipation according to  $P = I_F^2 \times R_F$ .

In addition, there is a forward voltage,  $V_F$ , whenever the forward current is flowing. This also results in heat dissipation as  $P = I \times V_F$ . In power applications where the average for-

**Figure 4.27 — Semiconductor diode (PN junction) characteristic curve.** (A) Forward-biased (anode voltage higher than cathode) response for Germanium (Ge) and Silicon (Si) devices. Each curve breaks away from the X-axis at its junction threshold voltage. The slope of each curve is its forward resistance. (B) Reverse-biased response. Very small reverse current increases until it reaches the reverse saturation current ( $I_0$ ). The reverse current increases suddenly and drastically when the reverse voltage reaches the reverse breakdown voltage,  $V_{BR}$ .

ward current is high, heating from forward resistance and the forward voltage drop can be significant. Since forward current determines the amount of heat dissipation, the diode’s power rating is stated as a *maximum average current*. Exceeding the current rating in a diode will cause excessive heating that leads to PN junction failure as described earlier.

#### Peak Inverse Voltage (PIV)

In Figure 4.27B, the lower left portion of the curve illustrates a much higher resistance that increases from tens of kilohms to thousands of megohms as the reverse voltage gets larger, and then decreases to near zero (a nearly vertical line) very suddenly. This sudden change occurs because the diode enters

reverse breakdown or when the reverse voltage becomes high enough to push carriers across the junction. The voltage at which this occurs is the *reverse breakdown voltage*. Unless the current is so large that the diode fails from overheating, breakdown is not destructive and the diode will again be normally when the bias is removed. The maximum reverse voltage that the diode can withstand under normal use is the *peak inverse voltage (PIV)* rating. A related effect is *avalanche breakdown* in which the voltage across a device is greater than its ability to conduct or block current flow.

### Response Speed

The speed of a diode’s response to a change in voltage polarity limits the frequency of current that the diode can rectify. The diode response in Figure 4.27 shows how that response will act at dc. As the frequency increases, the diode may not be able to turn current on or off as fast as the changing polarity of the signal.

Diode response speed mainly depends on *charge storage* in the depletion region. When forward current is flowing, electrons and holes fill the region near the junction to recombine. When the applied voltage reverses, the excess charges move away from the junction so that no recombination can take place. The reverse bias empties the depletion region of excess charge, it begins to act like a capacitor formed by the regions containing majority carriers on either side of the junction and the depletion region acting as the dielectric. This *junction capacitance* is inversely proportional to the width of the depletion region and directly proportional to the cross-sectional surface area of the junction.

The effect of junction capacitance allows current to flow for a short period after the applied voltage changes from positive to negative. To halt current flow requires that the junction capacitance be charged. Charging this capacitance takes some time; a few picoseconds for regular rectifier diodes and a few hundred nanoseconds for *fast-recovery* diodes. This is the diode’s *charge-storage time*. The amount of time required for current flow to cease is the diode’s *recovery time*.

### Reverse Leakage Current

Because the depletion region is very narrow, reverse bias causes a small amount of reverse leakage or reverse saturation current to flow from cathode to anode. This is typically microamperes or less until reverse breakdown voltage is reached. Silicon diodes have lower reverse leakage currents than diodes made from germanium materials with higher carrier mobility, as germanium.

The reverse saturation current  $I_S$  is not constant but is affected by temperature, with higher temperatures increasing the mol-

majority carriers so that more of them enter the depletion region for a given amount of reverse bias. For silicon diodes (and transistors near room temperature,  $I_s$  increases by a factor of 2 every 4.8 °C. This means that for every 4.8 °C rise in temperature, either the current doubles (if the voltage across it is constant), or if the current is held constant by resistances in the circuit, the diode voltage will decrease by  $V_T \times \ln 2 = 18$  mV. For germanium, the current doubles every 8 °C and for gallium-arsenide (GaAs), 3.7 °C. This temperature dependence is highly reproducible and may usually be exploited to produce temperature-sensing circuits.

While the change resulting from a rise of several degrees may be tolerable in a circuit design, that from 20 or 30 degrees may not. Therefore it's a good idea with diodes, just as with other components, to specify power ratings conservatively (2 to 4 times margin) to prevent self-heating.

While component derating does reduce self-heating effects, circuits must be designed for the expected operating environment. For example, mobile radios may face temperatures from -20° to +140 °F (-29° to 60 °C).

### Forward Voltage

The amount of voltage required to cause majority carriers to enter the depletion region and recombine, creating full current flow, is called a diode's *forward voltage*,  $V_F$ . It depends on the type of material used to create the junction and the amount of current. For silicon diodes at normal currents,  $V_F = 0.7$  V, for germanium diodes,  $V_F = 0.3$  V. As we saw earlier,  $V_F$  also affects power dissipation in the diode.

### POINT-CONTACT DIODES

One way to decrease charge storage time in the depletion region is to form a metal-semiconductor junction for which the depletion region is very thin. This can be accomplished with a *point-contact diode*, where a thin piece of aluminum wire, often called a *whisker*, is pressed in contact with one face of a piece of lightly doped N-type material. In fact, the point-contact diodes used for detecting radio signals ("cat's whisker diodes") were made with a metal wire in contact with a crystal of impure germanium (galena). Point-contact diodes have high response speed, but poor PIV and current-carrying ratings. The 1N34 germanium point-contact diode is the best-known example of a point-contact diode still in common use.

### SCHOTTKY DIODES

An improvement to point-contact diodes, the *shot-carrier diode* is similar to a point-contact diode, but with more ideal characteristics attained by using more efficient metals, such as platinum and gold, that act to lower

forward resistance and increase PIV. This type of contact is known as a *Schottky barrier*, and diodes made this way are called *Schottky diodes*. The junctions of Schottky diodes, being smaller, store less charge and as a result, have shorter switching times and junction capacitances than standard PN-junction diodes. Their forward voltage is also lower, typically 0.3 to 0.4 V. In most other respects they behave similarly to PN diodes.

### PIN DIODES

The PIN diode, shown in Figure 4.26C is a *slow response* diode that is capable of passing RF and microwave signals when it is forward biased. This device is constructed with a layer of intrinsic (undoped) semiconductor placed between very highly doped P-type and N-type material (called P<sup>+</sup>-type and N<sup>+</sup>-type material to indicate the extra amount of doping), creating a *PIN junction*. These devices provide very effective switches for RF signals and are often used in transmit-receive switches in transceivers and amplifiers. The majority carriers in PIN diodes have longer than normal lifetimes before recombination, resulting in a slow switching process that causes them to act more like resistors than diodes at high radio frequencies. The amount of resistance can be controlled by the amount of forward bias applied to the PIN diode and this allows them to act as current-controlled attenuators. (For additional discussion of PIN diodes and projects in which they are used, see the chapters on **Transmitting, RF Power Amplifiers, and Test Equipment and Measurements.**)

### VARACTOR DIODES

Junction capacitance can be used as a circuit element by controlling the reverse bias voltage across the junction, creating a small variable capacitor. Junction capacitances are small, on the order of pF. As the reverse bias voltage on a diode increases, the width of the depletion region increases, decreasing its capacitance. A *varactor* (also known by the trade name Varicap diode) is a diode with a junction specially formulated to have a relatively large range of capacitance values for a modest range of reverse bias voltages (**Figure 4.28**).

As the reverse bias applied to a diode changes, the width of the depletion layer, and therefore the capacitance, also changes. The diode junction capacitance ( $C_j$ ) under a reverse bias of  $V$  volts is given by

$$C_j = \frac{C_{j0}}{\sqrt{V_{on} - V}}$$

where  $C_{j0}$  = measured capacitance with zero applied voltage.

Note that the quantity under the radical is a large *positive* quantity for reverse bias. As seen from the equation, for large reverse

**Figure 4.28 — Varactor diode. (A) Schematic symbol. (B) Equivalent circuit of the reverse biased varactor diode.  $R_S$  is the junction resistance,  $R_J$  is the leakage resistance and  $C_J$  is the junction capacitance, which is a function of the magnitude of the reverse bias voltage. (C) Plot of junction capacitance,  $C_J$ , as a function of reverse voltage,  $V_R$ , for three different varactor devices. Both axes are plotted on a logarithmic scale.**

biases  $C_j$  is inversely proportional to the square root of the voltage.

Although special forms of varactors are available from manufacturers, other types of diodes may be used as inexpensive varactor diodes, but the relationship between reverse voltage and capacitance is not always reliable.

When designing with varactor diodes, the reverse bias voltage must be absolutely free of noise since any variations in the bias voltage will cause changes in capacitance. For example, if the varactor is used to tune an oscillator, unwanted frequency shifts or instability will result if the reverse bias voltage is noisy. It is possible to frequency modulate a signal by adding the audio signal to the reverse bias on a varactor diode used in the carrier oscillator. (For examples of the use of varactors in oscillators and modulators, see the chapters on **Transmitting and Oscillators and Synthesizers.**)

### ZENER DIODES

When the PIV of a reverse-biased diode is exceeded, the diode begins to conduct current as it does when it is forward biased. This current will not destroy the diode if it is limited to less than the device's maximum allow-

able value. By using heavy levels of doping during manufacture, a diode's PIV can be precisely controlled to be at a specific level, called the *Zener voltage*, creating a type of voltage reference. These diodes are called Zener diodes after their inventor, American physicist Clarence Zener.

When the Zener voltage is reached, the reverse voltage across the Zener diode remains constant even as the current through it changes. With an appropriate series current-limiting resistor, the Zener diode provides an accurate voltage reference (see **Figure 4.29**).

Zener diodes are rated by their reverse-breakdown voltage and their power-handling capacity, where  $P = V_Z \times I_Z$ . Since the same current must always pass through the resistor to drop the source voltage down to the reference voltage, with that current divided between the Zener diode and the load, this type of power source is very wasteful of current.

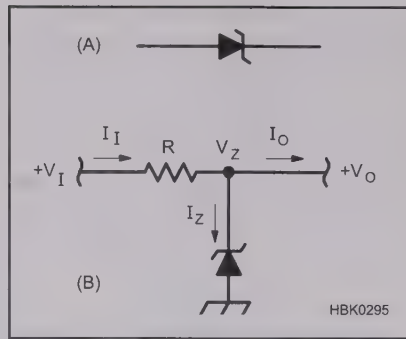

The Zener diode does make an excellent and efficient voltage reference in a larger voltage regulating circuit where the load current is provided from another device whose voltage is set by the reference. (See the **Power Sources** chapter for more information about using Zener diodes as voltage regulators.) When operating in the breakdown region, Zener diodes can be modeled as a simple voltage source.

The primary sources of error in Zener-diode-derived voltages are the variation with load current and the variation due to heat. Temperature-compensated Zener diodes are available with temperature coefficients as low as 5 parts per million per °C. If this is unacceptable, voltage reference integrated circuits based on Zener diodes have been developed that include additional circuitry to counteract temperature effects.

A variation of Zener diodes, *transient voltage suppressor (TVS)* diodes are designed to dissipate the energy in short-duration, high-voltage transients that would otherwise damage equipment or circuits. TVS diodes have large junction cross-sections so that they can handle large currents without damage. These diodes are also known by the trade name TransZorbs. Since the polarity of the transient can be positive, negative, or both, transient protection circuits can be designed with two devices connected with opposite polarities.

## RECTIFIERS

The most common application of a diode is to perform rectification; that is, permitting current flow in only one direction. Power rectification converts ac current into pulsating dc current. There are three basic forms of power rectification using semiconductor diodes: half wave (1 diode), full-wave center-tapped (2 diodes) and full-wave bridge (4 diodes). These applications are shown in

**Figure 4.29 — Zener diode.** (A) Schematic symbol. (B) Basic voltage regulating circuit.  $V_Z$  is the Zener reverse breakdown voltage. Above  $V_Z$ , the diode draws current until  $V_1 - I_1 R = V_Z$ . The circuit design should select  $R$  so that when the maximum current is drawn,  $R < (V_1 - V_Z) / I_O$ . The diode should be capable of passing the same current when there is no output current drawn.

**Figure 4.30A, B and C** and are more fully described in the **Power Sources** chapter.

The most important diode parameters to consider for power rectification are the PIV and current ratings. The peak negative voltages that are blocked by the diode must be smaller in magnitude than the PIV and the peak current through the diode when it is forward biased must be less than the maximum average forward current.

Rectification is also used at much lower current levels in modulation and demodulation and other types of analog signal processing circuits. For these applications, the diode's response speed and junction forward voltage are the most important ratings.

## 4.5.3 Bipolar Junction Transistors (BJT)

The bipolar junction transistor is a *current-controlled device* with three basic terminals; *emitter*, *collector* and *base*. The current between the emitter and the collector is controlled by the current between the base and emitter. The convention when discussing transistor operation is that the three currents into the device are positive ( $I_c$  into the collector,  $I_b$  into the base and  $I_e$  into the emitter). Kirchhoff's Current Law applies to transistors just as it does to passive electrical networks: the total current entering the device must be zero. Thus, the relationship between the currents into a transistor can be generalized as

$$I_c + I_b + I_e = 0$$

which can be rearranged as necessary. For example, if we are interested in the emitter current,

**Figure 4.30 — Diode rectifier circuits.** (A) Half wave rectifier circuit. Only when the ac voltage is positive does current pass through the diode. Current flows only during half of the cycle. (B) Full-wave center-tapped rectifier circuit. Center-tap on the transformer secondary is grounded and the two ends of the secondary are 180° out of phase. (C) Full-wave bridge rectifier circuit. In each half of the cycle two diodes conduct.

$$I_e = -(I_c + I_b)$$

The back-to-back diode model shown in Figure 2.36 is appropriate for visualization of transistor construction. In actual transistors, however, the relative sizes of the collector, base and emitter regions differ. A common transistor configuration that spans a distance

mm between the collector and emitter acts typically has a base region that is 25  $\mu\text{m}$  across.

The operation of the bipolar transistor is described graphically by characteristic curves shown in **Figure 4.31**. These are similar to the I-V characteristic curves for the two-terminal devices described in the preceding sections. The parameters shown by the curves depend on the type of circuit in which they are measured, such as common emitter or common collector. The output characteristic consists of a set of curves for either collector or emitter current versus collector-emitter voltage at various values of input current (either base or emitter). The input characteristic shows the voltage between the input and common terminals (such as base-emitter) versus input current for different values of output voltage.

### CURRENT GAIN

Two parameters describe the relationships between the three transistor currents at low frequencies:

$$\frac{\Delta I_C}{\Delta I_E} = 1$$

$$\frac{\Delta I_C}{\Delta I_B}$$

The relationship between  $\alpha$  and  $\beta$  is defined

$$\frac{\beta}{1 + \beta}$$

Another designation for  $\beta$  is often used:

$h_{FE}$ , the *forward dc current gain*. (The “h” refers to “h parameters,” a set of transfer parameters for describing a two-port network and described in more detail in the **RF Techniques** chapter.) The symbol,  $h_{fe}$ , in which the subscript is in lower case, is used for the forward current gain of ac signals.

### OPERATING REGIONS

Current conduction between collector and emitter is described by *regions* of the transistor’s characteristic curves in **Figure 4.31**. (References such as *common-emitter* or *common-base* refer to the configuration of the circuit in which the parameter is measured.) The transistor is in its *active* or *linear region* when the base-collector junction is reverse biased and the base-emitter junction is forward biased. The slope of the output current,  $I_O$ , versus the output voltage,  $V_O$ , is virtually flat, indicating that the output current is nearly independent of the output voltage. In this region, the output circuit of the transistor can be modeled as a constant-current source controlled by the input current. The slight slope that does exist is due to base-width modulation (known as the *Early effect*).

When both the junctions in the transistor are forward biased, the transistor is said to be in its *saturation region*. In this region,  $V_O$  is nearly zero and large changes in  $I_O$  occur for very small changes in  $V_O$ . Both junctions in the transistor are reverse-biased in the *cutoff region*. Under this condition, there is very little current in the output, only the nanoamperes or microamperes that result from the very small leakage across the input-to-output

junction. Finally, if  $V_O$  is increased to very high values, avalanche breakdown begins as in a PN-junction diode and output current increases rapidly. This is the *breakdown region*, not shown in **Figure 4.31**.

These descriptions of junction conditions are the basis for the use of transistors. Various configurations of the transistor in circuitry make use of the properties of the junctions to serve different purposes in analog signal processing.

### OPERATING PARAMETERS

A typical general-purpose bipolar-transistor data sheet lists important device specifications. Parameters listed in the ABSOLUTE MAXIMUM RATINGS section are the three junction voltages ( $V_{CEO}$ ,  $V_{CBO}$  and  $V_{EBO}$ ), the continuous collector current ( $I_C$ ), the total device power dissipation ( $P_D$ ) and the operating and storage temperature range. Exceeding any of these parameters is likely to cause the transistor to be destroyed. (The “O” in the suffixes of the junction voltages indicates that the remaining terminal is not connected, or open.)

In the OPERATING PARAMETERS section, three guaranteed minimum junction breakdown voltages are listed  $V_{(BR)CEO}$ ,  $V_{(BR)CBO}$  and  $V_{(BR)EBO}$ . Exceeding these voltages is likely to cause the transistor to enter avalanche breakdown, but if current is limited, permanent damage may not result.

Under ON CHARACTERISTICS are the guaranteed minimum dc current gain ( $\beta$  or  $h_{FE}$ ), guaranteed maximum collector-emitter saturation voltage,  $V_{CE(SAT)}$ , and the guaranteed maximum base-emitter on voltage,  $V_{BE(ON)}$ . Two guaranteed maximum collector cutoff currents,  $I_{CEO}$  and  $I_{CBO}$ , are listed under OFF CHARACTERISTICS.

The next section is SMALL-SIGNAL CHARACTERISTICS, where the guaranteed minimum current gain-bandwidth product,  $BW$  or  $f_T$ , the guaranteed maximum output capacitance,  $C_{obo}$ , the guaranteed maximum input capacitance,  $C_{ibo}$ , the guaranteed range of input impedance,  $h_{ie}$ , the small-signal current gain,  $h_{fe}$ , the guaranteed maximum voltage feedback ratio,  $h_{re}$  and output admittance,  $h_{oe}$  are listed.

Finally, the SWITCHING CHARACTERISTICS section lists absolute maximum ratings for delay time,  $t_d$ ; rise time,  $t_r$ ; storage time,  $t_s$ ; and fall time,  $t_f$ .

**Figure 4.31** — Transistor response curve output characteristics. The X-axis is the output voltage, and the Y-axis is the output current. Different curves are plotted for various values of input current. The three regions of the transistor are its cutoff region, where no current flows in any terminal, its active region, where the output current is nearly independent of the output voltage and there is a linear relationship between the input current and the output current, and the saturation region, where the output current has little change for small changes in output voltage.

### 4.5.4 Field-Effect Transistors (FET)

FET devices are controlled by the voltage level of the input rather than the input current, as in the bipolar transistor. FETs have three basic terminals, the *gate*, the *source* and the *drain*. They are analogous to bipolar transistor terminals: the gate to the base, the source

to the emitter, and the drain to the collector. Symbols for the various forms of FET devices are pictured in **Figure 4.32**.

The FET gate has a very high impedance, so the input can be modeled as an open circuit. The voltage between gate and source,  $V_{GS}$ , controls the resistance of the drain-source channel,  $r_{DS}$ , and so the output of the FET

is modeled as a current source, whose output current is controlled by the input voltage.

The action of the FET channel is so nearly ideal that, as long as the JFET gate does not become forward biased and inject current from the base into the channel, the drain and source currents are virtually identical. For JFETs the *gate leakage current*,  $I_G$ , is a function of  $V_{GS}$  and this is often expressed with an *input curve* (see **Figure 4.33**). The point at which there is a significant increase in  $I_G$  is called the *junction breakpoint voltage*. Because the gate of MOSFETs is insulated from the channel, gate leakage current is insignificant in these devices.

The dc channel resistance,  $r_{DS}$ , is specified in data sheets to be less than a maximum value when the device is biased on ( $r_{DS(on)}$ ). When

the gate voltage is maximum ( $V_{GS} = 0$  for JFET),  $r_{DS(on)}$  is minimum. This describes the effectiveness of the device as an analog switch. Channel resistance is approximately the same for ac and dc signals until at high frequencies the capacitive reactances inherent in the FET structure become significant.

FETs also have strong similarities to vacuum tubes in that input voltage between the grid and cathode controls an output current between the plate and cathode. (See the chapter on **RF Power Amplifiers** for more information on vacuum tubes.)

### FORWARD TRANSCONDUCTANCE

The change in FET drain current caused by a change in gate-to-source voltage is called *forward transconductance*,  $g_m$ .

$$g_m = \frac{\Delta I_{DS}}{\Delta V_{GS}}$$

or

$$\Delta I_{DS} = g_m \Delta V_{GS}$$

The input voltage,  $V_{GS}$ , is measured between the FET gate and source and drain current,  $I_{DS}$ , flows from drain to source. Analogous to a bipolar transistor's current gain, the units of transconductance are siemens (S) because it is the ratio of current to voltage. (Both  $g_m$  and  $g_{fs}$  are used interchangeably to indicate transconductance. Some sources specify  $g_m$  as the *common-source forward transconductance*. This chapter uses  $g_m$ , the most common convention in the reference literature.)

### OPERATING REGIONS

The most useful relationships for FETs are the output and transconductance response characteristic curves in **Figure 4.34**. (Refer

**Figure 4.32** — FET schematic symbols.

**Figure 4.33** — JFET input leakage curves for common source amplifier configuration. Input voltage ( $V_{GS}$ ) on the X-axis versus input current ( $I_G$ ) on the Y-axis, with two curves plotted for different operating temperatures, 25 °C and 125 °C. Input current increases greatly when the gate voltage exceeds the junction breakpoint voltage.

**Figure 4.34** — JFET output and transconductance response curves for common source amplifier configuration. (A) Output voltage ( $V_{DS}$ ) on the X-axis versus output current ( $I_D$ ) on the Y-axis, with different curves plotted for various values of input voltage ( $V_{GS}$ ). (B) Transconductance curve with the same three variables rearranged:  $V_{GS}$  on the X-axis,  $I_D$  on the Y-axis and curves plotted for different values of  $V_{DS}$ .

es such as *common-source* or *common-emitter* refer to the configuration of the circuit (which the parameter is measured.) Transconductance curves relate the drain current,  $I_D$ , to gate-to-source voltage,  $V_{GS}$ , at various drain-source voltages,  $V_{DS}$ . The FET's forward transconductance,  $g_m$ , is the slope of the curves in the forward transconductance curve. The same parameters are interrelated in a different way in the output characteristic, in which  $I_D$  is shown versus  $V_{DS}$  for different values of  $V_{GS}$ .

Like the bipolar transistor, FET operation can be characterized by regions. The *ohmic region* is shown at the left of the FET output characteristic curve in **Figure 4.35** where  $I_D$  is increasing nearly linearly with  $V_{DS}$  and the FET is acting like a resistance controlled by  $V_{GS}$ . As  $V_{DS}$  continues to increase,  $I_D$  saturates and becomes nearly constant. This is the FET's *saturation region* in which the channel of the FET can be modeled as a constant-current source.  $V_{DS}$  can become so large that  $V_{GS}$  no longer controls the conduction of the device and avalanche breakdown occurs as in bipolar transistors and PN-junction diodes. This is the *breakdown region*, shown in **Figure 4.35** where the curves for  $I_D$  break sharply upward. If  $V_{GS}$  is less than  $V_P$ , so that transconductance is zero, the FET is in the *cut-off region*.

## OPERATING PARAMETERS

A typical FET data sheet gives ABSOLUTE MAXIMUM RATINGS for  $V_{DS}$ ,  $V_{DG}$ ,  $V_{GS}$  and  $I_D$ , along with the usual device dissipation ( $P_D$ ) and storage temperature range. Exceeding these limits usually results in destruction of the FET.

Under OPERATING PARAMETERS the OFF CHARACTERISTICS list the gate-source breakdown voltage,  $V_{GS(BR)}$ , the reverse gate current,  $I_{GSS}$  and the gate-source cutoff voltage,  $V_{GS(OFF)}$ . Exceeding  $V_{GS(BR)}$  will not permanently damage the device if current is limited. The primary ON CHARACTERISTIC parameters are the channel resistance,  $r_{DS}$ , and the zero-voltage drain current ( $I_{DSS}$ ). An FET's channel resistance,  $r_{DS}$ , is specified in data sheets to be less than a maximum value when the device is biased on ( $r_{DS(on)}$ ). For ac signals,  $r_{DS(on)}$  is not necessarily the same as  $r_{DS(on)}$ , but it is not very different as long as the frequency is not so high that capacitive reactance of the FET becomes significant.

The SMALL SIGNAL CHARACTERISTICS include the forward transfer admittance,  $y_{fs}$ , the output admittance,  $y_{os}$ , the static drain-source resistance,  $r_{ds(on)}$  and various capacitances such as input capacitance,  $C_{iss}$ , reverse transfer capacitance,  $C_{rss}$ , the drain-substrate capacitance,  $C_{d(sub)}$ . FUNCTIONAL CHARACTERISTICS include the noise figure, NF, and common source power gain,  $G_{ps}$ .

**Figure 4.35 — JFET operating regions.** At the left,  $I_D$  is increasing rapidly with  $V_{GS}$  and the JFET can be treated as resistance ( $R_{DS}$ ) controlled by  $V_{GS}$ . In the saturation region, drain current,  $I_D$ , is relatively independent of  $V_{GS}$ . As  $V_{DS}$  increases further, avalanche breakdown begins and  $I_D$  increases rapidly.

## MOSFETS

As described earlier, the MOSFET's gate is insulated from the channel by a thin layer of nonconductive oxide, doing away with any appreciable gate leakage current. Because of this isolation of the gate, MOSFETs do not need input and reverse transconductance curves. Their output curves (**Figure 4.36**) are similar to those of the JFET. The gate acts as a small capacitance between the gate and both the source and drain.

The output and transconductance curves in **Figure 4.36A** and **4.36B** show that the depletion-mode N-channel MOSFET's transconductance is positive at  $V_{GS} = 0$ , like that of the N-channel JFET. Unlike the JFET, however, increasing  $V_{GS}$  does not forward-bias

the gate-source junction and so the device can be operated with  $V_{GS} > 0$ .

In the enhancement-mode MOSFET, transconductance is zero at  $V_{GS} = 0$ . As  $V_{GS}$  is increased, the MOSFET enters the ohmic region. If  $V_{GS}$  increases further, the saturation region is reached and the MOSFET is said to be *fully-on*, with  $r_{DS}$  at its minimum value. The behavior of the enhancement-mode MOSFET is similar to that of the bipolar transistor in this regard.

The relatively flat regions in the MOSFET

**Figure 4.36 — MOSFET output [(A) and (C)] and transconductance [(B) and (D)] response curves.** Plots (A) and (B) are for an N-channel depletion mode device. Note that  $V_{GS}$  varies from negative to positive values. Plots (C) and (D) are for an N-channel enhancement mode device.  $V_{GS}$  has only positive values.

output curves are often used to provide a constant current source. As is plotted in these curves, the drain current,  $I_D$ , changes very little as the drain-source voltage,  $V_{DS}$ , varies in this portion of the curve. Thus, for a fixed gate-source voltage,  $V_{GS}$ , the drain current can be considered to be constant over a wide range of drain-source voltages.

Multiple gate MOSFETs are also available. Due to the insulating layer, the two gates are isolated from each other and allow two signals to control the channel simultaneously with virtually no loading of one signal by the other. A common application of this type of device is an automatic gain control (AGC) amplifier. The signal is applied to one gate and a rectified, low-pass filtered form of the output (the AGC voltage) is fed back to the other gate. Another common application is as a mixer in which the two input signals are applied to the pair of gates.

### MOSFET Gate Protection

The MOSFET is constructed with a very thin layer of  $\text{SiO}_2$  for the gate insulator. This layer is extremely thin in order to improve the transconductance of the device but this makes it susceptible to damage from high voltage levels, such as *electrostatic discharge* (ESD) from static electricity. If enough charge accumulates on the gate terminal, it can *punch through* the gate insulator and destroy it. The insulation of the gate terminal is so good that virtually none of this potential is eased by leakage of the charge into the device. While this condition makes for nearly ideal input impedance (approaching infinity), it puts the device at risk of destruction from even such seemingly innocuous electrical sources as static electrical discharges from handling.

Some MOSFET devices contain an internal Zener diode with its cathode connected to the gate and its anode to the substrate. If the voltage at the gate rises to a damaging level the Zener diode junction conducts, bleeding excess charges off to the substrate. When voltages are within normal operating limits the Zener has little effect on the signal at the gate, although it may decrease the input impedance of the MOSFET.

This solution will not work for all MOSFETs. The Zener diode must always be reverse biased to be effective. In the enhancement-mode MOSFET,  $V_{GS} > 0$  for all valid uses of the part, keeping the Zener reverse biased. In depletion mode devices however,  $V_{GS}$  can be both positive and negative; when negative, a gate-protection Zener diode would be forward biased and the MOSFET gate would not be driven properly. In some depletion mode MOSFETs, back-to-back Zener diodes are used to protect the gate.

MOSFET devices are at greatest risk of damage from static electricity when they are out of circuit. Even though an electrostatic

discharge is capable of delivering little energy, it can generate thousands of volts and high peak currents. When storing MOSFETs, the leads should be placed into conductive foam. When working with MOSFETs, it is a good idea to minimize static by wearing a grounded wrist strap and working on a grounded workbench or mat. A humidifier may help to decrease the static electricity in the air. Before inserting a MOSFET into a circuit board it helps to first touch the device leads with your hand and then touch the circuit board. This serves to equalize the excess charge so that little excess charge flows when the device is inserted into the circuit board.

### Power MOSFETs

Power MOSFETs are designed for use as switches, with extremely low values of  $r_{DS(on)}$ ; values of 50 milliohms ( $\text{m}\Omega$ ) are common. The largest devices of this type can switch tens of amps of current with  $V_{DS}$  voltage ratings of hundreds of volts. The **Component Data and References** chapter includes a table of power FET ratings. The schematic symbol for power MOSFETs (see Figure 4.30) includes a *body diode* that allows the FET to conduct in the reverse direction, regardless of  $V_{GS}$ . This is useful in many high-power switching applications. Power MOSFETs used for RF amplifiers are discussed in more detail in the **RF Power Amplifiers** chapter.

While the maximum ratings for current and voltage are high, the devices cannot withstand both high drain current and high drain-to-source voltage at the same time because of the power dissipated;  $P = V_{DS} \times I_D$ . It is important to drive the gate of a power MOSFET such that the device is fully on or fully off so that either  $V_{DS}$  or  $I_D$  is at or close to zero. When switching, the device should spend as little time as possible in the linear region where both current and voltage are nonzero because their product ( $P$ ) can be substantial. This is not a big problem if switching only takes place occasionally, but if the switching is repetitive (such as in a switching power supply) care should be taken to drive the gate properly and remove excess heat from the device.

Because the gate of a power MOSFET is capacitive (up to several hundred pF for large devices), charging and discharging the gate quickly results in short current peaks of more than 100 mA. Whatever circuit is used to drive the gate of a power MOSFET must be able to handle that current level, such as an integrated circuit designed for driving the capacitive load an FET gate presents.

The gate of a power MOSFET should not be left open or connected to a high-impedance circuit. Use a pull-down or pull-up resistor connected between the gate and the appropriate power supply to ensure that the gate is placed at the right voltage when not being driven by the gate drive circuit.

### GaAsFETs

FETs made from gallium-arsenide (GaAs) material are used at UHF and microwave frequencies because they have gain at these frequencies and add little noise to the signal. The reason GaAsFETs have gain at these frequencies is the high mobility of the electrons in GaAs material. Because the electrons are more mobile than in silicon, they respond to the gate-source input signal more quickly than silicon FETs, providing gain at higher frequencies ( $f_T$  is directly proportional to electron mobility). The higher electron mobility also reduces thermally-generated noise generated in the FET, making the GaAsFET especially suitable for weak-signal preamps.

Because electron mobility is always higher than hole mobility, N-type material is used for GaAsFETs to maximize high-frequency gain. Since P-type material is not used to make a gate-channel junction, a metal Schottky junction is formed by depositing metal directly on the surface of the channel. This type of device is also called a *MESFET* (metal-semiconductor field-effect transistor).

### 4.5.5 Comparison of BJT and FET Devices

Analog signal processing deals with changing a signal to a desired form. The three primary types of devices — bipolar transistors, field-effect transistors and integrated circuits — perform similar functions, each with specific advantages and disadvantages. The vacuum tube, once the dominant signal processing component, is relegated to high-power amplifier and display applications and is found only in the **RF Power Amplifiers** chapter of this *Handbook*. *Cathode-ray tubes* (CRTs) are covered in a separate article in this book's downloadable supplement material.

Bipolar transistors, when treated properly, can have virtually unlimited life spans. They are relatively small and, if they do not handle high currents, do not generate much heat. They make excellent high-frequency amplifiers. Compared to MOSFET devices they are less susceptible to damage from electrostatic discharge. Bipolar transistors and ICs like all semiconductors, are susceptible to damage from power and lightning transients.

There are many performance advantages to FET devices, particularly MOSFETs. Their extremely low gate currents allow the design of analog stages with nearly infinite input resistance. Signal distortion due to loading is minimized in this way. FETs are less expensive to fabricate in ICs and so are gradually replacing bipolar transistors in many IC applications.

RF amplifiers are now designed almost

sively using some variety of MOSFET or final amplifiers. The transistors are integrated into modules (a.k.a. "pallets") that include circuitry to protect the transistors from the high voltages generated by reflections under high SWR conditions. See the **RF Power Amplifier** chapter for information on advances in RF amplification technology.

An important consideration in the use of integrated components is the future availability of parts. At an ever increasing rate, as new components are developed to replace older technology, the older components are discontinued by the manufacturers and become unavailable for future use. ASIC and PGA technology, discussed along with integrated circuits, brings the power of custom electronics to the radio, but can make it nearly impossible to repair by replacing an IC, even if the design is known. If field repair and service at the component level are to be performed, it is important to use standard ICs wherever possible. Even so, when demand for a particular component drops, a manufacturer will discontinue its production. This happens on an ever-decreasing timeline.

Another further consideration is the trend toward digital signal processing and software-defined radio systems. (See the chapter on **RF and SDR Fundamentals**.) More and more analog functions are being performed by digital microprocessors and the analog signals are converted to digital at higher and higher frequencies. It is now common practice to interface the incoming RF signal directly at the antenna system interface.

There will always be a need for analog components, but the balance point between analog and digital is accelerating towards the digital side.

In future years, radio and test equipment will consist of a powerful, general-purpose digital signal processor, surrounded by the necessary analog circuitry to convert the signals to digital form and supply the processor with power.

## 6 Optical Semiconductors

In addition to electrical energy and heat energy, light energy also affects the behavior of semiconductor materials. If a device is designed to allow photons of light to strike the surface of the semiconductor material, the energy absorbed by electrons disrupts the bonds between atoms, creating free electrons and holes. This increases the conductivity of the material (*photoconductivity*). The photon also transfers enough energy to an electron to allow it to cross a PN junction's depletion region as current flow through the semiconductor (*photoelectricity*).

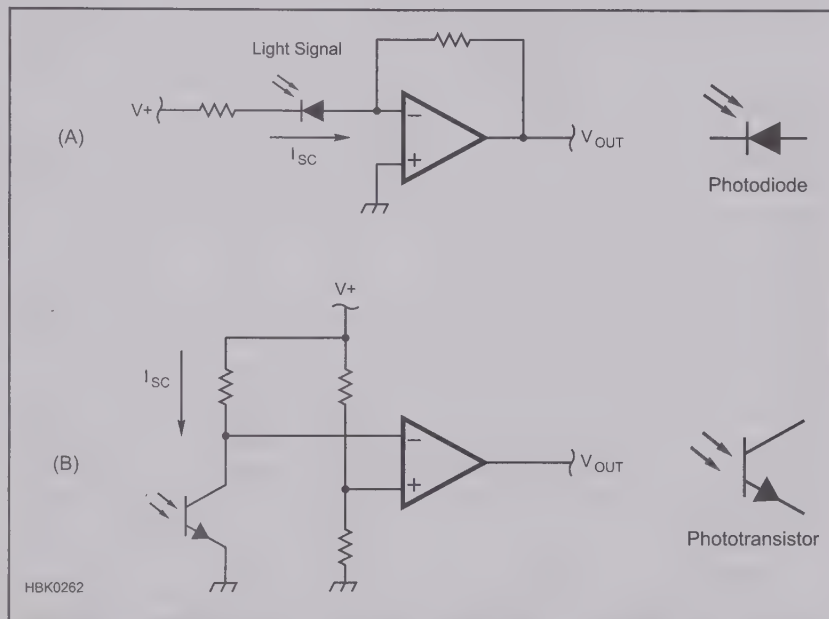

### PHOTOCONDUCTORS

Commercial *photoconductors* (also

called *photoresistors*) the resistance can change by as much as several kilohms for a light intensity change of 100 ft-candles. The most common material used in photoconductors is cadmium sulfide (CdS), with a resistance range of more than 2 MΩ in total darkness to less than 10 Ω in bright light. Other materials used in photoconductors respond best at specific colors. Lead sulfide (PbS) is most sensitive to infrared light and selenium (Se) works best in the blue end of the visible spectrum.

### PHOTODIODES

A similar effect is used in some diodes and transistors so that their operation can be controlled by light instead of electrical current biasing. These devices, shown in **Figure 4.37**, are called *photodiodes* and *phototransistors*. The flow of minority carriers across the reverse biased PN junction is increased by light falling on the doped semiconductor material. In the dark, the junction acts the same as any reverse biased PN junction, with a very low current,  $I_{SC}$ , (on the order

**Figure 4.37** — The photodiode (A) is used to detect light. An amplifier circuit changes the variations in photodiode current to a change in output voltage. At (B), a phototransistor conducts current when its base is illuminated. This causes the voltage at the collector to change causing the amplifier's output to switch between ON and OFF.

**Figure 4.38** — Photodiode I-V curve. Reverse voltage is plotted on the X-axis and current through diode is plotted on the Y-axis. Various response lines are plotted for different illumination. Except for the zero illumination line, the response does not pass through the origin since there is current generated at the PN junction by the light energy. A load line is shown for a 50-kΩ resistor in series with the photodiode.

of  $10\ \mu\text{A}$ ) that is nearly independent of reverse voltage. The presence of light not only increases the current but also provides a resistance-like relationship (reverse current increases as reverse voltage increases). See **Figure 4.38** for the characteristic response of a photodiode. Even with no reverse voltage applied, the presence of light causes a small reverse current, as indicated by the points at which the lines in Figure 4.38 intersect the left side of the graph.

Photoconductors and photodiodes are generally used to produce light-related analog signals that require further processing. For example, a photodiode is used to detect infrared light signals from remote control devices as in Figure 4.37A. The light falling on the reverse-biased photodiode causes a change in  $I_{SC}$  that is detected as a change in output voltage.

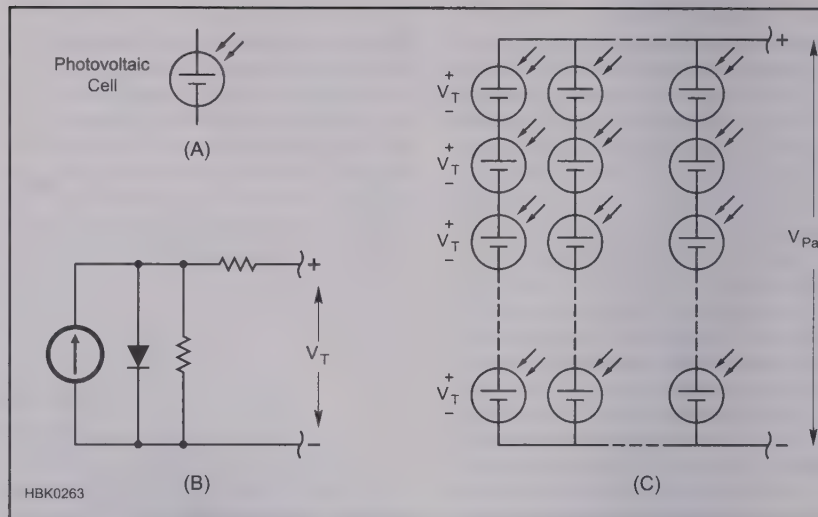

Light falling on the phototransistor acts as base current to control a larger current between the collector and emitter. Thus the phototransistor acts as an amplifier whose input signal is light and whose output is current. Phototransistors are more sensitive to light than the other devices. Phototransistors have lots of light-to-current gain, but photodiodes normally have less noise, so they make more sensitive detectors. The phototransistor in Figure 4.37B is being used as a detector. Light falling on the phototransistor causes collector current to flow, dropping the collector voltage below the voltage at the amplifier's + input and causing a change in  $V_{OUT}$ .

### PHOTOVOLTAIC CELLS

When illuminated, the reverse-biased photodiode has a reverse current caused by excess minority carriers. As the reverse voltage is reduced, the potential barrier to the forward flow of majority carriers is also reduced. Since light energy leads to the generation of both majority and minority carriers, when the resistance to the flow of majority carriers is decreased these carriers form a forward current. The voltage at which the forward current equals the reverse current is called the *photovoltaic potential* of the junction. If the illuminated PN junction is not connected to a load, a voltage equal to the photovoltaic potential can be measured across it as the *terminal voltage*,  $V_T$ , or *open-circuit voltage*,  $V_{OC}$ .

Devices that use light from the sun to produce electricity in this way are called *photovoltaic (PV)* or *solar cells* or *solar batteries*. The symbol for a photovoltaic cell is shown in **Figure 4.39A**. The electrical equivalent circuit of the cell is shown in Figure 4.39B. The cell is basically a large, flat diode junction exposed to light. Metal electrodes on each side of the junction collect the current generated.

When illuminated, the cell acts like a cur-

**Figure 4.39** — A photovoltaic cell's symbol (A) is similar to a battery. Electrically, the cell can be modeled as the equivalent circuit at (B). Solar panels (C) consist of arrays of cells connected to supply power at a convenient voltage.

rent source, with some of the current flowing through a diode (made of the same material as the cell), a shunt resistance for leakage current and a series resistor that represents the resistance of the cell. Two quantities define the electrical characteristics of common silicon photovoltaic cells. These are an open-circuit voltage,  $V_{OC}$  of 0.5 to 0.6 V and the output *short-circuit current*,  $I_{SC}$  as above, that depends on the area of the cell exposed to light and the degree of illumination. A measure of the cell's effectiveness at converting light into current is the *conversion efficiency*. Typical silicon solar cells have a conversion efficiency of 10 to 15% although special cells with stacked junctions or using special light-absorbing materials have shown efficiencies as high as 40%.

Solar cells are primarily made from single-crystal slices of silicon, similar to diodes and transistors, but with a much greater area. *Polycrystalline silicon* and *thin-film* cells are less expensive, but have lower conversion efficiency. Technology is advancing rapidly in the field of photovoltaic energy and there are a number of different types of materials and fabrication techniques that have promise in surpassing the effectiveness of the single-junction silicon cells.

Solar cells are assembled into arrays called *solar panels*, shown in Figure 4.39C. Cells are connected in series so that the combined output voltage is a more useful voltage, such as 12 V. Several strings of cells are then connected in parallel to increase the available output current. Solar panels are available with output powers from a few watts to hundreds of watts. Note that unlike batteries, strings of solar cells can be connected directly in paral-

el because they act as sources of constant current instead of voltage. (More information on the use of solar panels for powering radio equipment can be found in the chapter **Power Sources**.)

### LIGHT EMITTING DIODES AND LASER DIODES

In the photodiode, energy from light falling on the semiconductor material is absorbed to create additional electron-hole pairs. When the electrons and holes recombine, the same amount of energy is given off. In normal diodes the energy from recombination of carriers is given off as heat. In certain forms of semiconductor material, the recombination energy is given off as light with a mechanism called *electroluminescence*. Unlike the incandescent light bulb, electroluminescence is a cold (non-thermal) light source that typically operates with low voltages and currents (such as 1.5 V and 10 mA). Devices made for this purpose are called *light emitting diodes (LEDs)*. They have the advantages of low power requirements, fast switching times (in the order of 10 ns) and narrow spectra (relatively pure color).

The LED emits light when it is forward biased and excess carriers are present. As carriers recombine, light is produced with a color that depends on the properties of the semiconductor material used. Gallium-arsenide (GaAs) generates light in the infrared region, gallium-phosphide (GaP) gives off light when doped with oxygen or green light when doped with nitrogen. Orange light is attained with a mixture of GaAs and GaP (GaAsP). Silicon-carbide (SiC) creates a blue LED.

**Figure 4.40** — A light-emitting diode (LED) emits light when conducting forward current. A series current-limiting resistor is used to set the current through the LED according to the equation.

**Figure 4.41** — The optoisolator consists of an LED (input) that illuminates the base of a phototransistor (output). The phototransistor then conducts current in the output circuit. CTR is the optoisolator's current transfer ratio.

White LEDs are made by coating the inside of the LED lens with a white-light emitting phosphor and illuminating the phosphor with light from a single-color LED. White LEDs are currently approaching the cost of compact fluorescent (CFL) bulbs and will eventually replace CFL technology for lighting, just as LEDs are replacing the incandescent bulb.

The LED, shown in **Figure 4.40**, is very simple to use. It is connected across a voltage source ( $V$ ) with a series resistor ( $R$ ) that limits the current to the desired level ( $I_F$ ) for the amount of light to be generated.

$$R = \frac{V - V_F}{I_F}$$

where  $V_F$  is the forward voltage of the LED. The cathode lead is connected to the lower potential, and is specially marked as shown on the manufacturer's data sheet. LEDs may be connected in series for additional light, with the same current flowing in all of the LEDs. Diodes connected in parallel without current-limiting resistors for each diode are likely to share the current unequally, thus the

series connection is preferred.

The laser diode operates by similar principles to the LED except that all of the light produced is *monochromatic* (of the same color and wavelength) and it is *coherent*, meaning that all of the light waves emitted by the device are in phase. Laser diodes generally require higher current than an LED and will not emit light until the *lasing current* level is reached. Because the light is monochromatic and coherent, laser diodes can be used for applications requiring precise illumination and modulation, such as high-speed data links, and in data storage media such as CD-ROM and DVD. LEDs are not used for high-speed or high-frequency analog modulation because of recovery time limitations, just as in regular rectifiers.

## OPTOISOLATORS

An interesting combination of optoelectronic components proves very useful in many analog signal processing applications. An *optoisolator* consists of an LED optically coupled to a phototransistor, usually in an enclosed package (see **Figure 4.41**). The optoisolator, as its name suggests, isolates different circuits from each other. Typically, isolation resistance is on the order of  $10^{11} \Omega$  and isolation capacitance is less than 1 pF. Maximum voltage isolation varies from 1000 to 10,000 V ac. The most common optoisolators are available in 6-pin DIP packages.

Optoisolators are primarily used for voltage level shifting and signal isolation. Voltage level shifting allows signals (usually digital signals) to pass between circuits operating at greatly different voltages. The isolation has two purposes: to protect circuitry (and operators) from excessive voltages and to isolate noisy circuitry from noise-sensitive circuitry.

Optoisolators also cannot transfer signals with high power levels. The power rating of the LED in a 4N25 device is 120 mW. Optoisolators have a limited frequency response due to the high capacitance of the LED. A typical bandwidth for the 4N25 series is 300 kHz. Optoisolators with bandwidths of several MHz are available, but are somewhat expensive.

As an example of voltage level shifting, an optoisolator can be used to allow a low-voltage, solid-state electronic Morse code keyer to activate a vacuum-tube grid-block keying circuit that operates at a high negative voltage (typically about  $-100$  V) but low current. No common ground is required between the two pieces of equipment.

Optoisolators can act as input protection for circuits that are exposed to high voltages or transients. For example, a short 1000-V transient that can destroy a semiconductor circuit will only saturate the LED in the optoisolator, preventing damage to the circuit.

The worst that will happen is the LED in the optoisolator will be destroyed, but that is usually quite a bit less expensive than the circuit it is protecting.

Optoisolators are also useful for isolating different ground systems. The input and output signals are totally isolated from each other, even with respect to the references for each signal. A common application for optoisolators is when a computer is used to control radio equipment. The computer signal, and even its ground reference, typically contains considerable wide-band noise caused by the digital circuitry. The best way to keep this noise out of the radio is to isolate both the signal and its reference; this is easily done with an optoisolator.

The design of circuits with optoisolators is not greatly different from the design of circuits with LEDs and with transistors. On the input side, the LED is forward-biased and driven with a series current-limiting resistor whose value limits current to less than the maximum value for the device (for example, 60 mA is the maximum LED current for a 4N25). This is identical to designing with standalone LEDs.

On the output side, instead of current gain for a transistor, the optoisolator's *current transfer ratio (CTR)* is used. CTR is a ratio given in percent between the amount of current through the LED to the output transistor's maximum available collector current. For example, if an optoisolator's CTR = 25%, then an LED current of 20 mA results in the output transistor being able to conduct up to  $20 \times 0.25 = 5$  mA of current in its collector circuit.

If the optoisolator is to be used for an analog signal, the input signal must be appropriately dc shifted so that the LED is always forward biased. A phototransistor with all three leads available for connection (as in **Figure 4.41**) is required. The base lead is used for biasing, allowing the optical signal to create variations above and below the transistor's operating point. The collector and emitter leads are used as they would be in any transistor amplifier circuit. (There are also linear optoisolators that include built-in linearizing circuitry.) The use of linear optoisolators is not common.

## FIBER OPTICS

An interesting variation on the optoisolator is the *fiber-optic* connection. Like the optoisolator, the input signal is used to drive an LED or laser diode that produces modulated light (usually light pulses). The light is transmitted in a fiber optic cable, an extruded glass fiber that efficiently carries light over long distances and around fairly sharp bends. The signal is recovered by a photo detector (photoresistor, photodiode or phototransistor). Because the fiber optic cable is nonconduc-

tive, the transmitting and receiving systems are electrically isolated.

Fiber optic cables generally have far less loss than coaxial cable transmission lines. They do not leak RF energy, nor do they pick up electrical noise. Fiber optic cables are virtually immune to electromagnetic interference! Special forms of LEDs and phototransistors are available with the appropriate optical couplers for connecting to fiber optic cables. These devices are typically designed for higher frequency operation with gigahertz bandwidth.

### 4.5.7 Integrated Circuits (ICs)

If you look inside a transistor, the actual size of the semiconductor is quite small compared to the size of the packaging. For most semiconductors, the packaging takes considerably more space than the actual semiconductor device. Thus, an obvious way to reduce the physical size of circuitry is to combine more of the circuit inside a single package.

#### HYBRID INTEGRATED CIRCUITS

It is easy to imagine placing several small semiconductor chips in the same package. This is known as *hybrid circuitry*, a technology in which several semiconductor chips are placed in the same package and miniature wires are connected between them to make complete circuits.

Hybrid circuits miniaturize analog or analog/digital electronic circuits by eliminating much of the packaging and interconnections inherent in discrete electronics. The term *discrete* refers to the use of individual compo-

nents to make a circuit, each in its own package. The individual components are attached together on a small circuit board or with bonding wires. Manufacturers often use hybrids when small size and specialized techniques are needed, but there is insufficient volume to justify the expense of a custom IC.

A current application for hybrid circuitry is UHF and microwave amplifiers — they are in wide use by the mobile phone industry. For example, the Motorola MW4IC915N Wideband Integrated Power Amplifier in **Figure 4.42** is a complete 15-W transmitting module. Its TO-272 package is only about 1 inch long by 3/8-inch wide. This particular device is designed for use between 750 and 1000 MHz and can be adapted for use on the amateur 902 MHz band. Other devices available as hybrid circuits include oscillators, signal processors, preamplifiers and so forth. Surplus hybrids can be hard to adapt to amateur use unless they are clearly identified with manufacturing identification such that a data sheet can be obtained.

#### MONOLITHIC INTEGRATED CIRCUITS

In order to build entire circuits on a single piece of semiconductor, it must be possible to fabricate resistors and capacitors, as well as transistors and diodes. Only then can the entire circuit be created on one piece of silicon called a *monolithic integrated circuit*. The following description is a relatively simplified view of monolithic IC structure and fabrication techniques. IC technology is advancing on many directions at a very rapid rate. Giving a comprehensive description of current ICs — even the limited number of types used in Amateur Radio — is well beyond the scope of this book. References on specific technologies are given at the end of each chapter for the interested reader to pursue.

An integrated circuit (IC) or “chip” is fabricated in layers. An example of a semiconductor circuit schematic and its implementation in an IC is pictured in **Figure 4.43**. The base layer of the circuit, the *substrate*, is made of P-type semiconductor material. Although less common, the polarity of the substrate can also be N-type material. Since the mobility of electrons is about three times higher than that of holes, bipolar transistors made with N-type collectors and FETs made with N-type channels are capable of higher speeds and power handling. Thus, P-type substrates are far more common. For devices with N-type substrates, all polarities in the ensuing discussion would be reversed.

Other substrates have been used, one of the most successful of which is the *silicon-on-sapphire* (SOS) construction that has been used to increase the bandwidth of integrated circuitry. Its relatively high manufacturing cost has impeded its use, however, except for

the demanding military and aerospace applications. Many other types of substrates are employed in various special applications.

On top of the P-type substrate is a thin layer of N-type material in which the active and passive components are built. Impurities are diffused into this layer to form the appropriate component at each location. To prevent random diffusion of impurities into the N-layer, its upper surface must be protected. This is done by covering the N-layer with a layer of silicon dioxide ( $\text{SiO}_2$ ). Wherever diffusion of impurities is desired, the  $\text{SiO}_2$  is etched away. The precision of placing components on the semiconductor material depends mainly on the fineness of the etching. The fourth layer of an IC is made of aluminum (copper is used in some high-speed digital ICs) and is used to make the interconnections between the components.

Different components are made in a single piece of semiconductor material by first diffusing a high concentration of acceptor impurities into the layer of N-type material. This process creates P-type semiconductor regions often referred to as P<sup>+</sup>-type semiconductor because of its high concentration of acceptor atoms — that isolates regions of N-type material. Each of these regions is then further processed to form single components.

A component is produced by the diffusion of a lesser concentration of acceptor atoms into the middle of each isolation region. This results in an N-type *isolation well* that contains P-type material, is surrounded on all sides by P<sup>+</sup>-type material and has P-type material (substrate) below it. The cross section in **Figure 4.41B** illustrates the various layers. Connections to the metal layer are often made by diffusing high concentrations of donor atoms into small regions of the N-type well and the P-type material in the well. The material in these small regions is N<sup>+</sup>-type and facilitates electron flow between the metal contact and the semiconductor. In some configurations, it is necessary to connect the metal directly to the P-type material in the well.

#### Fabricating Resistors and Capacitors

An isolation well can be made into a resistor by making two contacts into the P-type semiconductor in the well. Resistance is inversely proportional to the cross-sectional area of the well. An alternate type of resistor that can be integrated in a semiconductor circuit is a *thin-film resistor*, where a metal film is deposited on the  $\text{SiO}_2$  layer, masked on its upper surface by more  $\text{SiO}_2$  and then etched to make the desired geometry, then adjusting the resistance.

There are two ways to form capacitors on a semiconductor. One is to make use of a PN junction between the N-type well and

**Figure 4.42** — The TO-272 is typical of packages used for hybrid IC RF amplifier modules at UHF and microwave frequencies.

**Figure 4.43 — Integrated circuit construction.** (A) Circuit containing two diodes, a resistor, a capacitor, an NPN transistor and an N-channel MOSFET. Labeled leads are D for diode, R for resistor, DC for diode-capacitor, E for emitter, S for source, CD for collector-drain and G for gate. (B) Integrated circuit that is identical to circuit in (A). Same leads are labeled for comparison. Circuit is built on a P-type semiconductor substrate with N-type wells diffused into it. An insulating layer of SiO<sub>2</sub> is above the semiconductor and is etched away where aluminum metal contacts are made with the semiconductor. Most metal-to-semiconductor contacts are made with heavily doped N-type material (N<sup>+</sup>-type semiconductor).

P-type material that fills it. Much like a varactor diode, when this junction is reverse biased a capacitance results. Since a bias voltage is required, this type of capacitor is polarized, like an electrolytic capacitor. Nonpolarized capacitors can also be formed in an integrated circuit by using thin film technology. In this case, a very high concentration of donor ions is diffused into the well, creating an N<sup>+</sup>-type region. A thin metallic film is deposited over the SiO<sub>2</sub> layer covering the well and the capacitance is created between the metallic film and the well. The value of the capacitance is adjusted by varying the thickness of the SiO<sub>2</sub> layer and the cross-sectional size of the well. This type of thin film capacitor is also known as a metal oxide semiconductor (MOS) capacitor.

Unlike resistors and capacitors, it is very difficult to create inductors in integrated circuits. Generally, RF circuits that need induc-

tance require external inductors to be connected to the IC. In some cases, particularly at lower frequencies, the behavior of an inductor can be mimicked by an amplifier circuit. In many cases the appropriate design of IC amplifiers can reduce or eliminate the need for external inductors. As the frequency of operation increases, however, the amount of inductance needed falls for an equivalent amount of reactance. This had led to several innovative techniques for creating small inductors using the metallization layers of the IC.

**Fabricating Diodes and Transistors**

The simplest form of diode is generated by connecting to an N<sup>+</sup>-type connection point in the well for the cathode and to the P-type well material for the anode. Diodes are often converted from NPN transistor configurations. Integrated circuit diodes made this way can

either short the collector to the base or leave the collector unconnected. The base contact is the anode and the emitter contact is the cathode.

Transistors are created in integrated circuitry in much the same way that they are fabricated in their discrete forms. The NPN transistor is the easiest to make since the wall of the well, made of N-type semiconductor, forms the collector, the P-type material in the well forms the base and a small region of N<sup>+</sup>-type material formed in the center of the well becomes the emitter. A PNP transistor is made by diffusing donor ions into the P-type semiconductor in the well to make a pattern with P-type material in the center (emitter) surrounded by a ring of N-type material that connects all the way down to the well material (base), and this is surrounded by another ring of P-type material (collector). This configuration results in a

large base width separating the emitter and collector, causing these devices to have much lower current gain than the NPN form. This is one reason why integrated circuitry is designed to use many more NPN transistors than PNP transistors.

FETs can also be fabricated in IC form as shown in Figure 4.43C. Due to its many functional advantages, the MOSFET is the most common form used for digital ICs. MOSFETs are made in a semiconductor chip much the same way as MOS capacitors, described earlier. In addition to the signal processing advantages offered by MOSFETs over other transistors, the MOSFET device can be fabricated in 5% of the physical space required for bipolar transistors. CMOS ICs can contain 20 times more circuitry than bipolar ICs with the same chip size, making the devices more powerful and less expensive than those based

on bipolar technology. CMOS is the most popular form of integrated circuit.

The final configuration of the switching circuit is CMOS as described in a previous section of this chapter. CMOS gates require two FETs, one of each form (NMOS and PMOS as shown in the figure). NMOS requires fewer processing steps, and the individual FETs have lower on-resistance than PMOS. The fabrication of NMOS FETs is the same as for individual semiconductors; P+ wells form the source and drain in a P-type substrate. A metal gate electrode is formed on top of an insulating SiO<sub>2</sub> layer so that the channel forms in the P-type substrate between the source and drain. For the PMOS FET, the process is similar, but begins with an N-type well in the P-type substrate.

MOSFETs fabricated in this manner also

have bias (B) terminals connected to the positive power supply to prevent destructive *latch-up*. This can occur in CMOS gates because the two MOSFETs form a *parasitic SCR*. If the SCR mode is triggered and both transistors conduct at the same time, large currents can flow through the FET and destroy the IC unless power is removed. Just as discrete MOSFETs are at risk of gate destruction, IC chips made with MOSFET devices have a similar risk. They should be treated with the same care to protect them from static electricity as discrete MOSFETs.

While CMOS is the most widely used technology, integrated circuits need not be made exclusively with MOSFETs or bipolar transistors. It is common to find IC chips designed with both technologies, taking advantage of the strengths of each.

## 4.6 Amplifiers

By far, the most common type of analog circuit is the amplifier. The basic component of most electronics — the transistor — is an amplifier in which a small input signal controls a larger signal. Most of modern electronics, both analog and digital, are based on the transistor amplifier or switch, regardless of whether the input signal is amplified at the output.

### 4.6.1 Amplifier Configurations

Amplifier configurations are described by the *common* part of the device. The word “common” is used to describe the connection of a lead directly to a reference that is used by both the input and output ports of the circuit. The most common reference is ground, but positive and negative power sources are also valid references.

The type of circuit reference used depends on the type of device (transistor [NPN or PNP] or FET [P-channel or N-channel]), which lead is chosen as common, and the range of signal levels. Once a common lead is chosen, the other two leads are used for signal input and output. Based on the biasing conditions, there is only one way to select these leads. Thus, there are three possible amplifier configurations for each type of three-lead device. (Vacuum tube amplifiers are discussed in the chapter on **RF Power Amplifiers**.)

DC power sources are usually constructed so that ac signals at the output terminals are bypassed to ground through a very low impedance. This allows the power source to be treated as an *ac ground*, even though it may be supplying dc voltages to the circuit. When

a circuit is being analyzed for its ac behavior, ac grounds are usually treated as ground, since dc bias is ignored in the ac analysis. Thus, a transistor’s collector can be considered the “common” part of the circuit, even though in actual operation, a dc voltage is applied to it.

**Figure 4.44** shows the three basic types of bipolar transistor amplifiers: the common-base, common-emitter, and common-collector. The common terminal is shown connected to ground, although as mentioned earlier, a dc bias voltage may be present. Each type of amplifier is described in the following sections. Following the description of the amplifier, additional discussion of biasing transistors and their operation at high frequencies and for large signals is presented.

### 4.6.2 Transistor Amplifiers

Creating a useful transistor amplifier depends on using an appropriate model for the transistor itself, choosing the right configuration of the amplifier, using the design equations for that configuration and insuring that the amplifier operates properly at different temperatures. This section follows that sequence, first introducing simple transistor models and then extending that knowledge to the point of design guidelines for common circuits that use bipolar and FETs.

#### DEVICE MODELS AND CLASSES

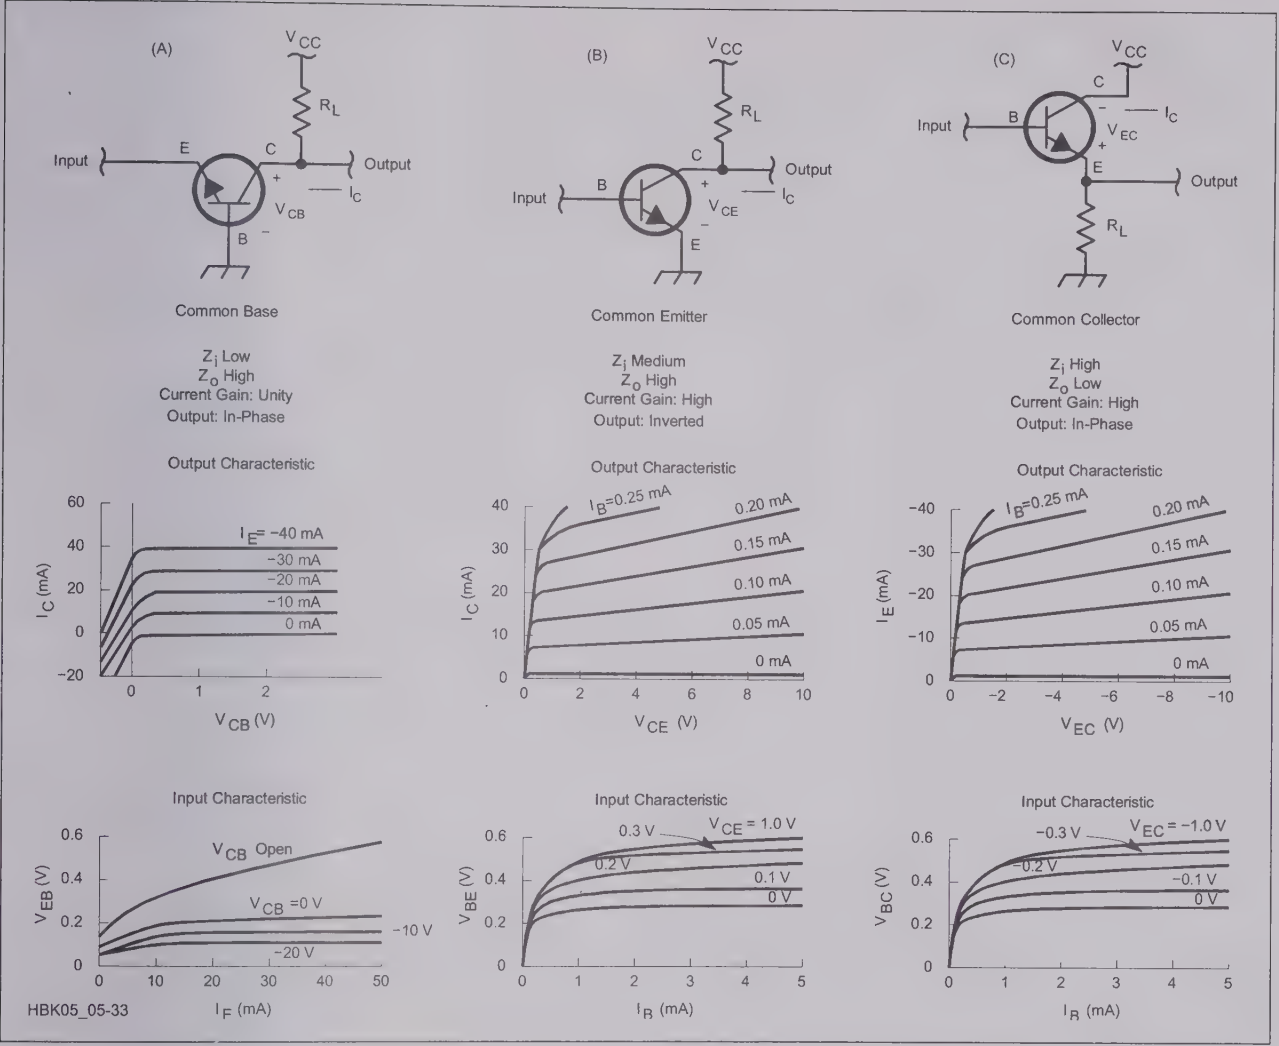

Semiconductor circuit design is based on equivalent circuits that describe the physics of the devices. These circuits, made up of voltage and current sources and passive components such as resistors, capacitors and

inductors, are called models. A complete model that describes a transistor exactly over a wide frequency range is a fairly complex circuit. As a result, simpler models are used in specific circumstances. For example, the *small-signal model* works well when the device is operated close to some nominal set of characteristics such that current and voltage interact fairly linearly. The *large-signal model* is used when the device is operated so that it enters its saturation or cut-off regions, for example.

Different frequency ranges also require different models. The *low-frequency models* used in this chapter can be used to develop circuits for dc, audio and very low RF applications. At higher frequencies, small capacitances and inductances that can be ignored at low frequencies begin to have significant effects on device behavior, such as gain or impedance. In addition, the physical structure of the device also becomes significant as gain begins to drop or phase shifts between input and output signals start to grow. In this region, *high-frequency models* are used.

Amplifiers are also grouped by their *operating class* that describes the way in which the input signal is amplified. There are several classes of analog amplifiers; A, B, AB, AB1, AB2 and C.

The analog class designators specify over how much of the input cycle the active device is conducting current. A class-A amplifier’s active device conducts current for 100 percent of the input signal cycle, such as shown in Figure 4.25. A class-B amplifier conducts during one-half of the input cycle, class-AB, AB1, and AB2 some fraction between 50 and

**Figure 4.44** — The three configurations of bipolar transistor amplifiers. Each has a table of its relative impedance and current gain. The output characteristic curve is plotted for each, with the output voltage along the X-axis, the output current along the Y-axis and various curves plotted for different values of input current. The input characteristic curve is plotted for each configuration with input current along the X-axis, input voltage along the Y-axis and various curves plotted for different values of output voltage. (A) Common base configuration with input terminal at the emitter and output terminal at the collector. (B) Common emitter configuration with input terminal at the base and output terminal at the collector. (C) Common collector with input terminal at the base and output terminal at the emitter.

100 percent of the input cycle, and class-C for less than 50 percent of the input signal cycle.

Digital amplifiers, in which the active device is operated as a switch that is either fully-on or fully-off, similarly to switchmode power supplies, are also grouped by classes beginning with the letter D and beyond. Each different class uses a different method of converting the switch's output waveform to the desired RF waveform.

Amplifier classes, models and their use at high-frequencies are discussed in more detail in the chapter on **RF Techniques**. In addition, the use of models for circuit simulation is

discussed at length in the **Computer-Aided Circuit Design** chapter.

**4.6.3 Bipolar Transistor Amplifiers**

In this discussion, we will focus on simple models for bipolar transistors (BJTs). This discussion is centered on NPN BJTs but applies equally well to PNP BJTs if the bias voltage and current polarities are reversed. This section assumes the small-signal, low-frequency models for the transistors.

**SMALL-SIGNAL BJT MODEL**

The transistor is usually considered as a

*current-controlled* device in which the base current controls the collector current:

$$I_c = \beta I_b$$

where

- $I_c$  = collector current
- $I_b$  = base current
- $\beta$  = common-emitter current gain, beta.

(The term "common-emitter" refers to the type of transistor circuit described below in which the transistor operates with base current as its input and collector circuit as its output.) Current is positive if it flows *into* a device terminal.

The transistor can also be treated as a voltage-controlled device in which the transistor's emitter current,  $I_e$ , is controlled by the base-emitter voltage,  $V_{be}$ :

$$I_c = I_{es} [e^{(qV_{be}/kT)} - 1] \approx I_{es} e^{(qV_{be}/kT)}$$

where

- q = electronic charge
- k = Boltzmann's constant
- T = temperature in degrees Kelvin (K)
- $I_{es}$  = emitter saturation current, typically  $1 \times 10^{-13}$  A.

The subscripts for voltages indicate the direction of positive voltage, so that  $V_{be}$  indicates positive is from the base to the emitter. It is simpler to design circuits using the current-controlled device, but accounting for the transistor's behavior with temperature requires an understanding of the voltage-controlled model.

Transistors are usually driven by both biasing and signal voltages. Both equations above for collector current apply to both transistor dc biasing and signal design. Both of these equations are approximations of the more complex behavior exhibited by actual transistors. The second equation applies to a simplification of the first *Ebers-Moll model* (see references). More sophisticated models for BJTs are described by Getreu (see references). Small-signal models treat only the signal components. We will consider bias later.

The next step is to use these basic equations to design circuits. We will begin with small-signal amplifier design and the limits of where the techniques can be applied. Later, we'll discuss large-signal amplifier design and the distortion that arises from operating the transistor in regions where the relationship between the input and output signals is nonlinear.

### Common-Emitter Model

Figure 4.45 shows a BJT amplifier connected in the common-emitter configuration. (The emitter, shown connected to ground, is common to both the input circuit with the voltage source and the output circuit with the transistor's collector.) The performance of this circuit is adequately described by the simple equation  $I_c = \beta I_b$ . Figure 4.46 shows the most common of all transistor small-signal models, a controlled current source with emitter resistance.

There are two variations of the model shown in the figure. Figure 4.46B shows the base as a direct connection to the junction of a current-controlled current source ( $I_c = \beta I_b$ ) and a resistance,  $r_e$ , the *dynamic emitter resistance* representing the change in  $V_{be}$  with  $I_e$ . This resistance also changes with emitter current:

$$r_e = \frac{kT}{qI_c} \approx \frac{26}{I_c}$$

where  $I_e$  is the dc bias current in milliamperes.

The simplified approximation only applies at a typical ambient temperature of 300 K because  $r_e$  increases with temperature. In Figure 4.46A, the emitter resistance has been moved to the base connection, where it has the value  $(\beta+1)r_e$ . These models are electrically equivalent.

The transistor's output resistance (the Thevenin or Norton equivalent resistance between the collector and the grounded emit-

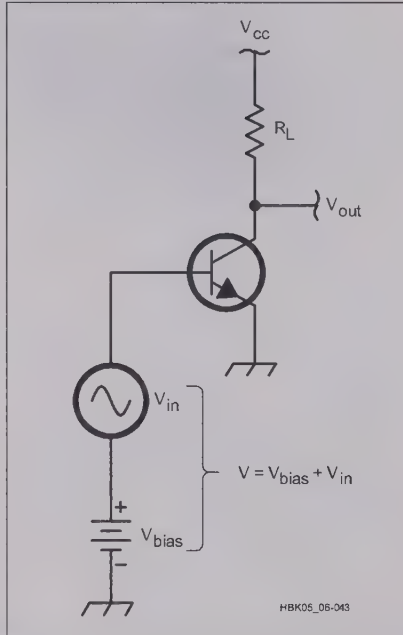

Figure 4.45 — Bipolar transistor with voltage bias and input signal.

Figure 4.46 — Simplified low-frequency model for the bipolar transistor, a "beta generator with emitter resistance."  $r_e = 26 / I_e$  (mA dc).

ter) is infinite because of the current source. This is a good approximation for most silicon transistors at low frequencies (well below the transistor's gain-bandwidth product,  $F_T$ ) and will be used for the design examples that follow.

As frequency increases, the capacitance inherent in BJT construction becomes significant and the *hybrid-pi model* shown in Figure 4.47 is used, adding  $C_\pi$  in parallel with the input resistance. In this model the transfer parameter  $h_{ie}$  often represents the input impedance, shown here as a resistance at low frequencies.

### THREE BASIC BJT AMPLIFIERS

Figure 4.48 shows a small-signal model applied to the three basic bipolar junction transistor (BJT) amplifier circuits: *common-emitter* (CE), *common-base* (CB) and *common-collector* (CC), more commonly known as the *emitter-follower* (EF). As defined earlier, the word "common" indicates that the referenced terminal is part of both the input and output circuits.

In these simple models, transistors in both the CE and CB configurations have infinite output resistance because the collector current source is in series with the output current. (The amplifier circuit's output impedance must include the effects of  $R_L$ .) The transistor connected in the EF configuration, on the other hand, has a finite output resistance because the current source is connected in parallel with the base circuit's equivalent resistance. Calculating the EF amplifier's output resistance requires including the input voltage source,  $V_s$ , and its impedance.

The three transistor amplifier configurations are shown as simple circuits in Figure 4.42. Each circuit includes the basic characteristics of the amplifier and characteristic curves for a typical transistor in each configuration. Two sets of characteristic curves are presented: one describing the input behavior and the other describing the output behavior in each amplifier configuration. The different transistor amplifier configurations have different gains, input and output imped-

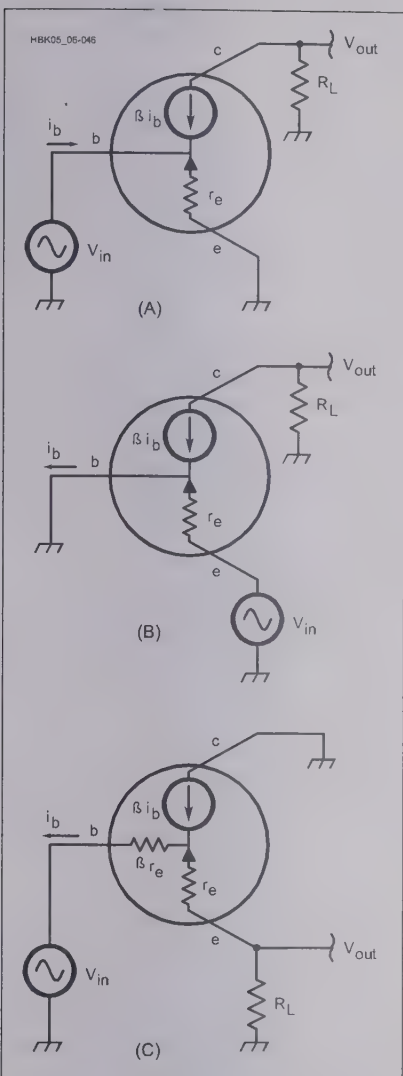

Figure 4.47 — The hybrid-pi model for the bipolar transistor.

**Figure 4.48** — Application of small-signal models for analysis of (A) the CE amplifier, (B) the CB and (C) the EF (CC) bipolar junction transistor amplifiers.

ances and phase relationships between the input and output signals.

Examining the performance needs of the amplifier (engineers refer to these as the circuit's *performance requirements*) determines which of the three circuits is appropriate. Then, once the amplifier configuration is chosen, the equations that describe the circuit's behavior are used to turn the performance requirements into actual circuit component values.

This text presents design information for the CE amplifier in some detail, then summarizes designs for the CC and CB amplifiers. Detailed design analysis for all three amplifiers is described in the texts listed in the reference section for this chapter. All of the analysis in the following sections assume the

**Figure 4.49** — A load line. A circuit's load line shows all of the possible operating points with the specific component values chosen. If there is no input signal, the operating point is the quiescent or Q-point.

small-signal, low-frequency model and ignore the effects of the coupling capacitors. High-frequency considerations are discussed in the **RF Techniques** chapter and some advanced discussion of biasing and large signal behavior of BJT amplifiers is available in the downloadable supplemental content.

### LOAD LINES AND Q-POINT

The characteristic curves in Figure 4.44 show that the transistor can operate with an infinite number of combinations of current (collector, emitter and base) and voltage (collector-emitter, collector-base or emitter-collector). The particular combination at which the amplifier is operating is its *operating point*. The operating point is controlled by the selection of component values that make up the amplifier circuit so that it has the proper combination of gain, linearity and so forth. The result is that the operating point is restricted to a set of points that fall along a *load line*. The operating point with no input signal applied is the circuit's *quiescent point* or *Q-point*. As the input signal varies, the operating point moves along the load line, but returns to the Q-point when the input signal is removed.

**Figure 4.49** shows the load line and Q-point for an amplifier drawn on a transistor's set of characteristic curves for the CE amplifier circuit. The two end-points of the load line correspond to transistor saturation ( $I_{Csat}$  on the  $I_C$  current axis) and cutoff ( $V_{CC}$  on the  $V_{CE}$  voltage axis).

When a transistor is in saturation, further increases in base current do not cause a further increase in collector current. In the CE amplifier, this means that  $V_{CE}$  is very close to zero and  $I_C$  is at a maximum. In the circuit of Figure 4.42B, imagine a short circuit across the collector-to-emitter so that all of

$V_{CC}$  appears across  $R_L$ . Increasing base current will not result in any additional collector current. At cutoff, base current is so small that  $V_{CE}$  is at a maximum because no collector current is flowing and further reductions in base current cause no additional increase in  $V_{CE}$ .

In this simple circuit,  $V_{CE} = V_{CC} - I_C R_L$  and the relationship between  $I_C$  and  $V_{CE}$  is a straight line between saturation and cutoff. This is the circuit's *load line* and it has a slope of  $R_L = (V_{CC} - V_{CE}) / I_C$ . No matter what value of base current is flowing in the transistor, the resulting combination of  $I_C$  and  $V_{CE}$  will be somewhere on the load line.

With no input signal to this simple circuit, the transistor is at cutoff where  $I_C = 0$  and  $V_{CE} = V_{CC}$ . As the input signal increases so that base current gets larger, the operating point begins to move along the load line to the left, so that  $I_C$  increases and the voltage drop across the load,  $I_C R_L$ , increases, reducing  $V_{CE}$ . Eventually, the input signal will cause enough base current to flow that saturation is reached, where  $V_{CE} \approx 0$  (typically 0.1 to 0.3 V for silicon transistors) and  $I_C \approx V_{CC} / R_L$ . If  $R_L$  is made smaller, the load line will become steeper and if  $R_L$  increases, the load line's slope is reduced.

This simple circuit cannot reproduce negative input signals because the transistor is already in cutoff with no input signal. In addition, the shape and spacing of the characteristic curves show that the transistor responds nonlinearly when close to saturation and cutoff (the nonlinear regions) than it does in the middle of the curves (the linear or active region). Biasing is required so that the circuit does not operate in nonlinear regions, distorting the signal as shown in Figure 4.25.

If the circuit behaves differently for ac signals than for dc signals, a separate *ac load line* can be drawn as discussed below in the section "AC Performance" for the common-emitter amplifier. For example, in the preceding circuit, if  $R_L$  is replaced by a circuit that includes inductive or capacitive reactance, ac collector current will result in a different voltage drop across the circuit than will dc collector current. This causes the slope of the ac load line to be different than that of the dc load line.

The ac load line's slope will also vary with frequency, although it is generally treated as constant over the range of frequencies for which the circuit is designed to operate. The ac and dc load lines intersect at the circuit's Q-point because the circuit's ac and dc operation is the same if the ac input signal is zero.

### COMMON-EMITTER AMPLIFIER

The *common-emitter amplifier (CE)* is the most common amplifier configuration of all

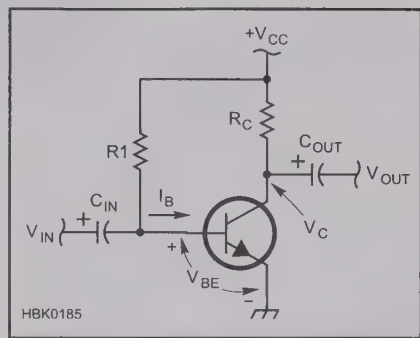

Figure 4.50 — Fixed-bias is the simplest common-emitter (CE) amplifier circuit.

— found in analog and digital circuits, from dc through microwaves, made of discrete components and fabricated in ICs. If you understand the CE amplifier, you've made a good start in electronics.

The CE amplifier is used when modest voltage gain is required along with an *input impedance* (the load presented to the circuit supplying the signal to be amplified) of a few hundred to a few kΩ. The current gain of the CE amplifier is the transistor's current gain,  $\beta$ .

The simplest practical CE amplifier circuit is shown in **Figure 4.50**. This circuit includes both coupling and biasing components. The capacitors at the input ( $C_{IN}$ ) and output ( $C_{OUT}$ ) block the flow of dc current to the load or to the circuit driving the amplifier. This is an ac-coupled design. These capacitors also cause the gain at very low frequencies to be reduced — gain at dc is zero, for example, because dc input current is blocked by  $C_{IN}$ . Resistor  $R_1$  provides a path for bias current to flow into the base, offsetting the collector current from zero and establishing the Q-point for the circuit.

As the input signal swings positive, more current flows into the transistor's base through  $C_{IN}$ , causing more current to flow from the collector to emitter. This causes more voltage drop across  $R_L$  and so the voltage at the collector also drops. The reverse is true when the input signal swings negative. Thus, the output from the CE amplifier is inverted from its input.

Kirchoff's Voltage Law is used to analyze the circuit. We'll start with the collector circuit and treat the power supply as a voltage source.

$$V_{cc} = I_c R_c + V_{ce}$$

We can determine the circuit's voltage gain,  $A_V$ , from the variation in output voltage caused by variations in input voltage. The output voltage from the circuit at the transistor collector is

$$V_c = V_{CC} - I_c R_c = V_{CC} - \beta I_B R_c$$

Figure 4.51 — Emitter degeneration. Adding  $R_E$  produces negative feedback to stabilize the bias point against changes due to temperature. As the bias current increases, the voltage drop across  $R_E$  also increases and causes a decrease in  $V_{BE}$ . This reduces bias current and stabilizes the operating point.

It is also necessary to determine how base current varies with input voltage. Using the transistor's equivalent circuit of **Figure 4.46A**,

$$I_B = \frac{V_B}{(\beta + 1) r_e}$$

so that

$$V_c = V_{CC} - V_B \frac{\beta}{\beta + 1} \times \frac{R_C}{r_e}$$

We can now determine the circuit's *voltage gain*, the variation in output voltage,  $\Delta V_C$ , due to variations in input voltage,  $\Delta V_B$ . Since  $V_{CC}$  is constant and  $\beta$  is much greater than 1 in our model:

$$A_V \approx -\frac{R_C}{r_e}$$

Because  $r_e$  is quite small (typically a few ohms, see the equation for  $r_e$  in the section on the Common-Emitter Model),  $A_V$  for this circuit can be quite high.

The circuit load line's end-points are  $V_{CE} = V_{CC}$  and  $I_C = V_{CC}/R_C$ . The circuit's Q-point is determined by the collector resistor,  $R_C$ , and resistor  $R_1$  that causes bias current to flow into the base. To determine the Q-point, again use KVL starting at the power source and assuming that  $V_{BE} = 0.7$  V for a silicon transistor's PN junction when forward-biased.

$$V_{CC} - I_B R_1 = V_B = V_{BE} = 0.7$$

so

$$I_B = \frac{V_{CC} - 0.7V}{R_1}$$

And the Q-point is therefore

$$V_{CEQ} = V_{CC} - \beta I_B R_C$$

and

$$I_{CQ} = \beta I_B$$

The actual  $V_{BE}$  of silicon transistors will vary from 0.6–0.75 V, depending on the level of base current, but 0.7 V is a good compromise value and widely used in small-signal, low-frequency design. Use 0.6 V for very low-power amplifiers and 0.75 V (or more) for high-current switch circuits.

This simple *fixed-bias* circuit is a good introduction to basic amplifiers, but is not entirely practical because the bias current will change due to the change of  $V_{BE}$  with temperature, leading to thermal instability. In addition, the high voltage gain can lead to instability due to positive feedback at high frequencies.

To stabilize the dc bias, **Figure 4.51** adds  $R_E$ , a technique called *emitter degeneration* because the extra emitter resistance creates negative feedback: as base current rises, so does  $V_E$ , the voltage drop across  $R_E$ . This reduces the base-emitter voltage and lowers base current. The benefit of emitter degeneration comes from stabilizing the circuit's dc behavior with temperature, but there is a reduction in gain because of the increased resistance in the emitter circuit. Ignoring the effect of  $R_L$  for the moment,

$$A_V \approx -\frac{R_C}{R_E}$$

In effect, the load resistor is now split between  $R_C$  and  $R_E$ , with part of the output voltage appearing across each because the changing current flows through both resistors. While somewhat lower than with the emitter connected directly to ground, voltage gain becomes easy to control because it is the ratio of two resistances.

### Biasing the CE Amplifier

**Figure 4.52** adds  $R_1$  and  $R_2$  from a voltage divider that controls bias current by fixing the base voltage at:

$$V_B = V_{CC} \frac{R_2}{R_1 + R_2}$$

Since

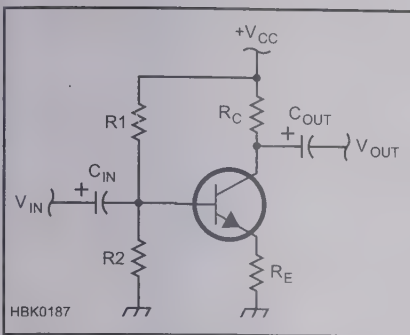

$$V_B = V_{BE} + (I_B + I_C) R_E = 0.7V + (\beta + 1) I_B R_E$$

base current is

$$I_B = \frac{V_B - 0.7V}{(\beta + 1) R_E}$$

and Q-point collector current becomes for high values of  $\beta$

$$I_{CQ} = \beta I_B \approx \frac{V_{CC} \frac{R_2}{R_1 + R_2} - 0.7}{R_E}$$

**Figure 4.52 — Self-bias or self-emitter bias.** R1 and R2 form a voltage divider to stabilize  $V_B$  and bias current. A good rule of thumb is for current flow through R1 and R2 to be 10 times the desired bias current. This stabilizes bias against changes in transistor parameters and component values.

This is referred to as *self-bias* or *self-emitter bias* in which the Q-point is much less sensitive to variations in temperature that affect  $\beta$  and  $V_{BE}$ .

A good rule-of-thumb for determining the sum of  $R_1$  and  $R_2$  is that the current flowing through the voltage divider,  $V_{CC}/(R_1+R_2)$ , should be at least 10 times the bias current,  $I_B$ . This keeps  $V_B$  relatively constant even with small changes in transistor parameters and temperature.

Q-point  $V_{CEQ}$  must now also account for the voltage drop across both  $R_C$  and  $R_E$ ,

$$V_{CEQ} \approx V_{CC} - \beta I_B (R_C + R_E)$$

More sophisticated techniques for designing the bias networks of bipolar transistor circuits are described in reference texts listed at the end of this chapter.

### Input and Output Impedance

With  $R_E$  in the circuit, the small changes in input current,  $I_B$ , when multiplied by the transistor's current gain,  $\beta$ , cause a large voltage change across  $R_E$  equal to  $\beta I_B R_E$ . This is the same voltage drop as if  $I_B$  was flowing through a resistance equal to  $\beta R_E$ . Thus, the effect of  $\beta$  on impedance at the base is to multiply the emitter resistance,  $R_E$  by  $\beta$ , as well. At the transistor's base,

$$Z_B \approx (\beta + 1) R_E$$

The input source doesn't just drive the base, of course, it also has to drive the combination of  $R_1$  and  $R_2$ , the biasing resistors. From an ac point of view, both  $R_1$  and  $R_2$  can be considered as connected to ac ground and they can be treated as if they were connected in parallel. When  $R_1//R_2$  are considered along with the transistor base impedance,  $Z_B$ , the impedance presented to the input signal

source is:

$$Z_{IN} = R_1 // R_2 // (\beta + 1) R_E$$

where  $//$  designates "in parallel with."

For both versions of the CE amplifier, the collector output impedance is high enough that

$$Z_{OUT} \approx R_C$$

### CE Amplifier Design Example

The general process depends on the circuit's primary performance requirements, including voltage gain, impedances, power consumption and so on. The most common situation in which a specific voltage gain is required and the circuit's Q-point has been selected based on the transistor to be used, and using the circuit of Figure 4.52, is as follows:

1) Start by determining the circuit's design constraints and assumptions: power supply  $V_{CC} = 12$  V, transistor  $\beta = 150$  and  $V_{BE} = 0.7$  V. State the circuit's design requirements:  $|A_V| = 5$ , Q-point of  $I_{CQ} = 4$  mA and  $V_{CEQ} = 5$  V. (A  $V_{CEQ} \approx \frac{1}{2} V_{CC}$  allows a wide swing in output voltage with the least distortion.)

2) Determine the values of  $R_C$  and  $R_E$ :  $R_C + R_E = (V_{CC} - V_{CEQ})/I_{CQ} = 1.75$  k $\Omega$

3)  $A_V = -5$ , so  $R_C = 5 R_E$ , thus  $6R_E = 1.75$  k $\Omega$  and  $R_E = 270$   $\Omega$

4) Determine the base bias current,  $I_B = I_{CQ}/\beta = 27$   $\mu$ A. By the rule of thumb, current through  $R_1$  and  $R_2 = 10 I_B = 270$   $\mu$ A

5) Find the voltage across  $R_2 = V_B = V_{BE} + I_C R_E = 0.7 + 4$  mA (0.27 k $\Omega$ ) = 1.8 V. Thus,  $R_2 = 1.8$  V / 270  $\mu$ A = 6.7 k $\Omega$

6) The voltage across  $R_1 = V_{CC} - V_{R2} = 12 - 1.8 = 10.2$  V and  $R_1 = 10.2$  V / 270  $\mu$ A = 37.8 k $\Omega$

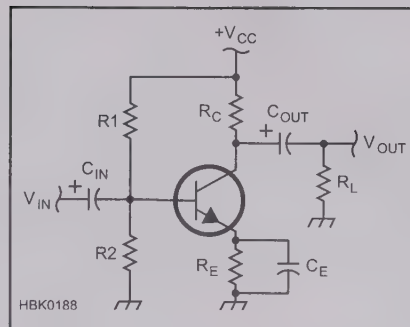

Use the nearest standard values ( $R_E = 270$   $\Omega$ ,  $R_1 = 39$  k $\Omega$ ,  $R_2 = 6.8$  k $\Omega$ ) and circuit behavior will be close to predicted performance.

### AC Performance

To achieve high gains for ac signals while maintaining dc bias stability, the *emitter-bypass capacitor*,  $C_E$ , is added in **Figure 4.53** to provide a low impedance path for ac signals around  $R_E$ . In addition, a more accurate formula for ac gain includes the effect of adding  $R_L$  through the dc blocking capacitor at the collector. In this circuit, the ac voltage gain is

$$A_V \approx \frac{R_C // R_L}{r_e}$$

Because of the different signal paths for ac

**Figure 4.53 — Emitter bypass.** Adding  $C_E$  allows ac currents to flow "around"  $R_E$ , returning ac gain to the value for the fixed-bias circuit while allowing  $R_E$  to stabilize the dc operating point.

and dc signals, the ac performance of the circuit is different than its dc performance. This is illustrated in **Figure 4.54** by the intersecting load lines labeled "AC Load Line" and "DC Load Line." The load lines intersect at the Q-point because at that point dc performance is the same as ac performance if no ac signal is present.

The equation for ac voltage gain assumes that the reactances of  $C_{IN}$ ,  $C_{OUT}$ , and  $C_E$  are small enough to be neglected (less than one-tenth that of the components to which they are connected at the frequency of interest). At low frequencies, where the capacitor reactances become increasingly large, voltage gain is reduced. Neglecting  $C_{IN}$  and  $C_{OUT}$ , the low-frequency 3 dB point of the amplifier,  $f_L$ , occurs where  $X_{C_E} = 0.414 r_e$ ,

$$f_L = \frac{2.42}{2\pi r_e C_E}$$

This increases the emitter circuit impedance such that  $A_V$  is lowered to 0.707 of its mid-band value, lowering gain by 3 dB. (This ignores the effects of  $C_{IN}$  and  $C_{OUT}$ , which will also affect the low-frequency performance of the circuit.)

The ac input impedance of this version of the CE amplifier is lower because the effect of  $R_E$  on ac signals is removed by the bypass capacitor. This leaves only the internal emitter resistance,  $r_e$ , to be multiplied by the current gain,

$$Z_{IN} \approx R_1 // R_2 // \beta r_e$$

and

$$Z_{OUT} \approx R_C$$

again neglecting the reactance of the three capacitors.

The power gain,  $A_P$ , for the emitter-bypassed CE amplifier is the ratio of output

**Figure 4.54 — Amplifier biasing and ac and dc load lines.** (A) Fixed bias. Input signal is ac coupled through  $C_i$ . The output has a voltage that is equal to  $V_{CC} - I_C \times R_C$ . This signal is ac coupled to the load,  $R_L$ , through  $C_o$ . For dc signals, the entire output voltage is based on the value of  $R_C$ . For ac signals, the output voltage is based on the value of  $R_C$  in parallel with  $R_L$ . (B) Characteristic curve for the transistor amplifier pictured in (A). The slope of the dc load line is equal to  $-1/R_C$ . For ac signals, the slope of the ac load line is equal to  $-1/(R_C \parallel R_L)$ . The quiescent-point,  $Q$ , is based on the base bias current with no input signal applied and the point where this characteristic line crosses the dc load line. The ac load line must also pass through point  $Q$ . (C) Self-bias. Similar to fixed bias circuit with the base bias resistor split into two:  $R_1$  connected to  $V_{CC}$  and  $R_2$  connected to ground. Also an emitter bias resistor,  $R_E$ , is included to compensate for changing device characteristics. (D) This is similar to the characteristic curve plotted in (B) but with an additional “bias curve” that shows how the base bias current varies as the device characteristics change with temperature. The operating point,  $Q$ , moves along this line and the load lines continue to intersect it as it changes. If  $C_E$  was added as in Figure 4.53, the slope of the ac load line would increase further.

power,  $V_O^2/Z_{OUT}$ , to input power,  $V_I^2/Z_{IN}$ . Since  $V_O = V_I A_V$ ,

$$A_P = A_V^2 \frac{R_1 \parallel R_2 \parallel \beta r_e}{R_C}$$

### COMMON-COLLECTOR (EMITTER-FOLLOWER) AMPLIFIER

The common-collector (CC) amplifier in **Figure 4.55** is also known as the *emitter-follower* (EF) because the emitter voltage “follows” the input voltage. In fact, the amplifier has no voltage gain (voltage gain  $\approx 1$ ), but is used as a buffer amplifier to isolate sensitive circuits such as oscillators or to drive

low-impedance loads, such as coaxial cables. As in the CE amplifier, the current gain of the emitter-follower is the transistor’s current gain,  $\beta$ . It has relatively high input impedance with low output impedance and good power gain.

The collector of the transistor is connected directly to the power supply without a resistor and the output signal is created by the voltage drop across the emitter resistor. There is no  $180^\circ$  phase shift as seen in the CE amplifier; the output voltage follows the input signal with  $0^\circ$  phase shift because increases in the input signal cause increases in emitter current and the voltage drop across the emitter resistor.

**Figure 4.55 — Emitter follower (EF) amplifier.** The voltage gain of the EF amplifier is unity. The amplifier has high input impedance and low output impedance, making it a good choice for use as a buffer amplifier.

The EF amplifier has high input impedance: following the same reasoning as for the CE amplifier with an unbypassed emitter resistor,

$$Z_{IN} = R_1 \parallel R_2 \parallel (\beta + 1) R_E$$

The impedance at the EF amplifier’s output consists of the emitter resistance,  $R_E$ , in parallel with the series combination of the internal emitter resistance,  $r_e$ , the parallel combination of biasing resistors  $R_1$  and  $R_2$ , and the internal impedance of the source providing the input signal. In this case, current gain acts to *reduce* the effect of the input circuit’s impedance on output impedance:

$$Z_{OUT} = \left[ \frac{R_S \parallel R_1 \parallel R_2}{(\beta + 1)} \right] \parallel R_E$$

In practice, with transistor  $\beta$  of 100 or more,  $Z_{OUT} \approx R_S/\beta$ . However, if a very high impedance source is used, such as a crystal microphone element or photodetector, the effects of the biasing and emitter resistors must be considered.

Because the voltage gain of the EF amplifier is unity, the power gain is simply the ratio of input impedance to output impedance,

$$A_P \approx \frac{R_1 \parallel R_2 \parallel (\beta + 1) R_E}{R_E}$$

### EF Amplifier Design Example

The following procedure is similar to the design procedure in the preceding section for the CE amplifier, except  $A_V = 1$ .

1) Start by determining the circuit’s design constraints and assumptions:  $V_{CC} = 12\text{ V}$  (the power supply voltage), a transistor’s  $\beta$  of 150 and  $V_{BE} = 0.7\text{ V}$ . State the circuit’s design requirements:  $Q$ -point of  $I_{CQ} = 5\text{ mA}$  and  $V_{CEQ} = 6\text{ V}$ .

$$2) R_E = (V_{CC} - V_{CEQ})/I_{CQ} = 1.2\text{ k}\Omega$$

3) Base current,  $I_B = I_{CQ}/\beta = 33 \mu\text{A}$

4) Current through R1 and R2 =  $10 I_B = 330 \mu\text{A}$  (10  $I_B$  rule of thumb as with the CE amplifier)

5) Voltage across R2 =  $V_{BE} + I_C R_E = 0.7 + 5 \text{ mA} (1.2 \text{ k}\Omega) = 6.7 \text{ V}$  and  $R2 = 6.7 \text{ V} / 330 \mu\text{A} = 20.3 \text{ k}\Omega$  (use the standard value 22 k $\Omega$ )

6) Voltage across R1 =  $V_{CC} - 6.7 \text{ V} = 5.3 \text{ V}$

7)  $R1 = 5.3 \text{ V} / 330 \mu\text{A} = 16.1 \text{ k}\Omega$  (use 16 k $\Omega$ )

8)  $Z_{IN} = R1 // R2 // R_E(\beta + 1) \approx 8.5 \text{ k}\Omega$

### COMMON-BASE AMPLIFIER

The common-base (CB) amplifier of **Figure 4.56** is used where low input impedance is needed, such as for a receiver preamp with a coaxial feed line as the input signal source. Complementary to the EF amplifier, the CB amplifier has unity current gain and high output impedance.

Figure 4.56A shows the CB circuit as it is usually drawn, without the bias circuit resistors connected and with the transistor symbol turned on its side from the usual orientation so that the emitter faces the input. In order to better understand the amplifier's function, Figure 4.56B reorients the circuit in a more familiar style. We can now clearly see that the input has just moved from the base circuit to the emitter circuit.

Placing the input in the emitter circuit allows it to cause changes in the base-emitter current as for the CE and EF amplifiers, except that for the CB amplifier a positive change in input amplitude reduces base current by lowering  $V_{BE}$  and raising  $V_C$ . As a result, the CB amplifier is noninverting, just like the EF, with output and input signals in-phase.

A practical circuit for the CB amplifier is shown in **Figure 4.57**. From a dc point of view (replace the capacitors with open circuits), all of the same resistors are there as in the CE amplifier. The input capacitor,  $C_{IN}$ , allows the dc emitter current to bypass the ac input signal source and  $C_B$  places the base at ac ground while allowing a dc voltage for biasing. (All voltages and currents are labeled to aid in understanding the different orientation of the circuit.)

The CB amplifier's current gain,

$$A_I = \frac{i_C}{i_E} = \frac{\beta}{\beta + 1}$$

is relatively independent of input and output impedance, providing excellent isolation between the input and output circuits. Output impedance does not affect input impedance, allowing the CB amplifier to maintain stable input impedance, even with a changing load.

Following reasoning similar to that for the CE and EF amplifiers for the effect of current gain on  $R_E$ , we find that input impedance for the CB amp is

$$Z_{IN} = R_E // (\beta + 1) r_e$$

With high-gain transistors having a  $\beta > 100$ , for typical values of  $r_e$  (about 1 k $\Omega$ ) the input impedance is approximately  $R_E$ . If  $R_E$  is chosen to be 50  $\Omega$ , the result will be a good input impedance match to 50  $\Omega$  feed lines and signal sources.

The output impedance for the CB amplifier is approximately

$$Z_{OUT} = R_C // \frac{1}{h_{oe}} \approx R_C$$

where  $h_{oe}$  is the transistor's collector output admittance. The reciprocal of  $h_{oe}$  is in the range of 100 k $\Omega$  at low frequencies.

Voltage gain for the CB amplifier is

$$A_V \approx \frac{R_C // R_L}{r_e}$$

As a result, the usual function of the CB amplifier is to convert input current from a low-impedance source into output voltage at a higher impedance.

Power gain for the CB amplifier is approximately the ratio of output to input impedance,

$$A_P \approx \frac{R_C}{R_E // (\beta + 1) r_e}$$

### CB Amplifier Design Example

Because of its usual function as a current-to-voltage converter, the design process for the CB amplifier begins with selecting  $R_E$  and  $A_V$ , assuming that  $R_L$  is known.

1) Start by determining the circuit's design constraints and assumptions:  $V_{CC} = 12 \text{ V}$  (the power supply voltage), a transistor's  $\beta$  of 150 and  $V_{BE} = 0.7 \text{ V}$ . State the circuit's design requirements:  $R_E = 50 \Omega$ ,  $R_L = 1 \text{ k}\Omega$ ,  $I_{CQ} = 5 \text{ mA}$ ,  $V_{CEQ} = 6 \text{ V}$ .

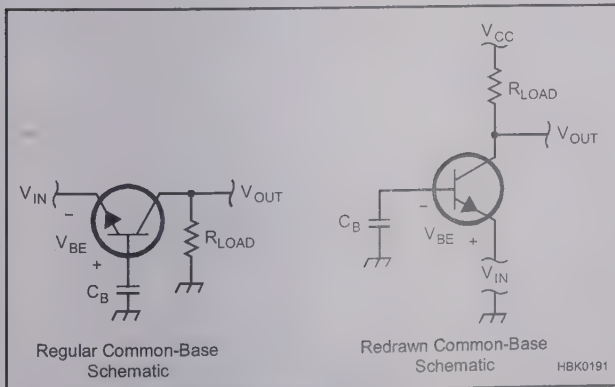

2) Base current,  $I_B = I_{CQ}/\beta = 33 \mu\text{A}$

3) Current through R1 and R2 =  $10 I_B = 330 \mu\text{A}$  (10  $I_B$  rule of thumb as with the CE amplifier)

4) Voltage across R2 =  $V_{BE} + I_C R_E = 0.7 + 5 \text{ mA} (50 \Omega) = 0.95 \text{ V}$  and  $R2 = 0.95 \text{ V} / 330 \mu\text{A} = 2.87 \text{ k}\Omega$  (use the standard value 2.7 k $\Omega$ )

5) Voltage across R1 =  $V_{CC} - 0.95 \text{ V} = 11.05 \text{ V}$

6)  $R1 = 11.05 \text{ V} / 330 \mu\text{A} = 33.5 \text{ k}\Omega$  (use 33 k $\Omega$ )

**Figure 4.56** — The common-base (CB) amplifier is often drawn in an unfamiliar style (A), but is more easily understood when drawn similarly to the CE and EF amplifiers (B). The input signal to the CB amplifier is applied to the emitter instead of the base.

**Figure 4.57** — A practical common-base (CB) amplifier. The current gain of the CB amplifier is unity. It has low input impedance and high output impedance, resulting in high voltage gain. The CB amplifier is used to amplify signals from low-impedance sources, such as coaxial cables.

$$7) R_C = (V_{CC} - I_{CQ} R_E - V_{CEQ}) / I_{CQ} = (12 - 0.25 - 6) / 5 \text{ mA} = 1.15 \text{ k}\Omega \text{ (use } 1.2 \text{ k}\Omega)$$

$$8) A_v = (1.2 \text{ k}\Omega // 1 \text{ k}\Omega) / (26 \text{ mV} / I_E) = 105$$

#### 4.6.4 FET Amplifiers

The field-effect transistor (FET) is widely used in radio and RF applications. There are many types of FETs, with JFETs (junction FET) and MOSFETs (metal-oxide-semiconductor FET) being the most common types. In this section we will discuss JFETs, with the understanding that the use of MOSFETs is similar. (This discussion is based on N-channel JFETs, but the same discussion applies to P-channel devices if the bias voltages and currents are reversed.)

##### SMALL-SIGNAL FET MODEL

While bipolar transistors are most commonly viewed as current-controlled devices, the JFET, however, is purely a voltage-controlled device — at least at low frequencies. The input gate is treated as a reverse-biased diode junction with virtually no current flow. As with the bipolar transistor amplifier circuits, the circuits in this section are very basic and more thorough treatments of FET amplifier design can be found in the references at the end of the chapter.

The operation of an N-channel JFET for both biasing and signal amplification can be characterized by the following equation:

$$I_D = I_{DSS} \left( \frac{1 - V_{SG}}{V_P} \right)^2$$

where

$I_{DSS}$  = drain saturation current

$V_{GS}$  = the gate-source voltage

$V_P$  = the pinch-off voltage.

$I_{DSS}$  is the maximum current that will flow between the drain and source for a given value of drain-to-source voltage,  $V_{DS}$ . Note that the FET is a *square-law* device in which output current is proportional to the square of an input voltage. (The bipolar transistor's output current is an exponential function of input current.)

Also note that  $V_{GS}$  in this equation has the opposite sense of the bipolar transistor's  $V_{BE}$ . For this device, as  $V_{GS}$  increases (making the source more positive than the gate), drain current decreases until at  $V_P$  the channel is completely "pinched-off" and no drain current flows at all. This equation applies only if  $V_{GS}$  is between 0 and  $V_P$ . JFETs are seldom used with the gate-to-channel diode forward-biased ( $V_{GS} < 0$ ).

None of the terms in this equation depend explicitly on temperature. Thus, the FET is relatively free of the thermal instability exhibited by the bipolar transistor. As temperature increases, the overall effect on the JFET is to

**Figure 4.58 — Small-signal FET model.** The FET can be modeled as a voltage-controlled current source in its saturation region. The gate is treated as an open-circuit due to the reverse-biased gate-channel junction.

reduce drain current and to stabilize the operation.

The small-signal model used for the JFET is shown in **Figure 4.58**. The drain-source channel is treated as a current source whose output is controlled by the gate-to-source voltage so that  $I_D = g_m V_{GS}$ . The high input impedance allows the input to be modeled as an open circuit (at low frequencies). This simplifies circuit modeling considerably as biasing of the FET gate can be done by a simple voltage divider without having to consider the effects of bias current flowing in the JFET itself.

The FET has characteristic curves as shown in **Figure 4.34** that are similar to those of a bipolar transistor. The output characteristic curves are similar to those of the bipolar transistor, with the horizontal axis showing  $V_{DS}$  instead of  $V_{CE}$  and the vertical axis showing  $I_D$  instead of  $I_C$ . Load lines, both ac and dc, can be developed and drawn on the output characteristic curves in the same way as for bipolar transistors.

The set of characteristic curves in **Figure 4.34** are called *transconductance response curves* and they show the relationship between input voltage ( $V_{GS}$ ), output current ( $I_D$ ) and output voltage ( $V_{DS}$ ). The output characteristic curves show  $I_D$  and  $V_{DS}$  for different values of  $V_{GS}$  and are similar to the BJT output characteristic curve. The input characteristic curves show  $I_D$  versus  $V_{GS}$  for different values of  $V_{DS}$ .

MOSFETs act in much the same way as JFETs when used in an amplifier. They have a higher input impedance, due to the insulation between the gate and channel. The insulated gate also means that they can be operated with the polarity of  $V_{GS}$  such that a JFET's gate-channel junction would be forward biased, beyond  $V_P$ . Refer to the discussion of depletion- and enhancement-mode MOSFETs in the previous section on Practical Semiconductors.

#### THREE BASIC FET AMPLIFIERS

Just as for bipolar transistor amplifiers, there are three basic configurations of ampli-

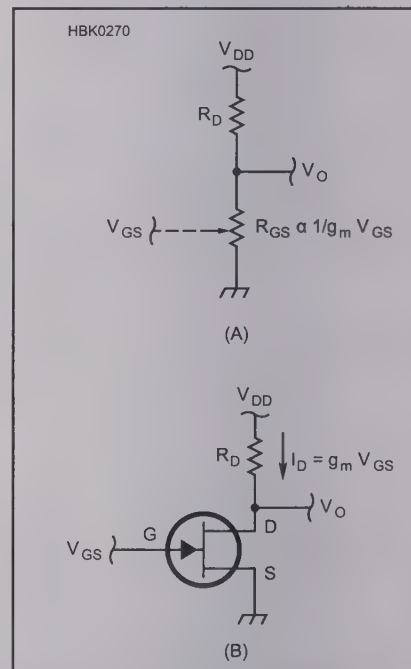

fiers using FETs; the *common-source* (CS) (corresponding to the common-emitter), *common-drain* (CD) or *source-follower* (corresponding to the emitter-follower) and the *common-gate* (CG) (corresponding to the common base). Simple circuits and design methods are presented here for each, assuming low-frequency operation and a simple, voltage-controlled current-source model for the FET. Discussion of the FET amplifier at high frequencies is available in the **RF Techniques** chapter and an advanced discussion of biasing FET amplifiers and their large-signal behavior is contained in this book's downloadable supplemental information.

##### COMMON-SOURCE AMPLIFIER

The basic circuit for a common-source FET amplifier is shown in **Figure 4.59**. In the ohmic region (see the previous discussion on FET characteristics), the FET can be treated as a variable resistance as shown in **Figure 4.59A** where  $V_{GS}$  effectively varies the resistance between drain and source. However, most FET amplifiers are designed to operate in the saturation region and the model of **Figure 4.58** is used in the circuit of **Figure 4.59B** in which,

$$I_D = g_m V_{GS}$$

where  $g_m$  is the FET's forward transconductance.

**Figure 4.59 — In the ohmic region (A), the FET acts like a variable resistance,  $R_{DS}$ , with a value controlled by  $V_{GS}$ . The alpha symbol ( $\alpha$ ) means "is proportional to". In the saturation region (B), the drain-source channel of the FET can be treated like a current source with  $I_D = g_m V_{GS}$ .**

If  $V_O$  is measured at the drain terminal (just as the common-emitter output voltage is measured at the collector), then

$$\Delta V_O = -g_m \Delta V_{GS} R_D$$

The minus sign results from the output voltage decreasing as drain current and the voltage drop across  $R_D$  increases, just as in the CE amplifier. Like the CE amplifier, the input and output voltages are thus 180° out of phase. Voltage gain of the CS amplifier in terms of transconductance and the drain resistance is:

$$A_V = -g_m R_D$$

As long as  $V_{GS} < 0$ , this simple CS amplifier's input impedance at low frequencies is that of a reverse-biased diode — nearly infinite with a very small leakage current. Output impedance of the CS amplifier is approximately  $R_D$  because the FET drain-to-source channel acts like a current source with very high impedance.

$$Z_{IN} = \infty \text{ and } Z_{OUT} \approx R_D$$

As with the BJT, biasing is required to create a Q-point for the amplifier that allows reproduction of ac signals. The practical circuit of Figure 4.59B is used to allow control of  $V_{GS}$  bias. A load line is drawn on the JFET output characteristic curves, just as for a bipolar transistor circuit. One end point of the load line is at  $V_{DS} = V_{DD}$  and the other at  $I_{DS} = V_{DD} / R_D$ . The Q-point for the CS amplifier at  $I_{DQ}$  and  $V_{DSQ}$  is thus determined by the dc value of  $V_{GS}$ .

The practical JFET CS amplifier shown in Figure 4.60 uses self-biasing in which the voltage developed across the source resistor,  $R_S$ , raises  $V_S$  above ground by  $I_D R_S$  volts and  $V_{GS} = -I_D R_S$  since there is no dc drop across  $R_G$ . This is also called *source degeneration*. The presence of  $R_S$  changes the equation of voltage gain to

$$A_V = -\frac{g_m R_D}{1 + g_m R_S} \approx -\frac{R_D}{R_S}$$

The value of  $R_S$  is obtained by substituting  $V_{GS} = I_D R_S$  into the small-signal model's equation for  $I_D$  and solving for  $R_S$  as follows:

$$R_S = \frac{-V_P}{I_{DQ}} \left( 1 - \sqrt{\frac{I_{DQ}}{I_{DSS}}} \right)$$

Once  $R_S$  is known, the equation for voltage gain can be used to find  $R_D$ .

The input impedance for the circuit of Figure 4.60 is essentially  $R_G$ . Since the gate of the JFET is often ac coupled to the input source through a dc blocking capacitor,  $C_{IN}$ ,

Figure 4.60 — Common-source (CS) amplifier with self-bias.

a value of 100 kΩ to 1 MΩ is often used for  $R_G$  to provide a path to ground for gate leakage current. If  $R_G$  is omitted in an ac-coupled JFET amplifier, a dc voltage can build up on the gate from leakage current or static electricity, affecting the channel conductivity.

$$Z_{IN} = R_G$$

Because of the high impedance of the drain-source channel in the saturation region, the output impedance of the circuit is:

$$Z_{OUT} \approx R_D$$

### Designing the Common-Source Amplifier

The design of the CS amplifier begins with selection of a Q-point  $I_{DQ} < I_{DSS}$ . Because of variations in  $V_P$  and  $I_{DSS}$  from JFET to JFET, it may be necessary to select devices individually to obtain the desired performance.

1) Start by determining the circuit's design constraints and assumptions:  $V_{DD} = 12$  V (the power supply voltage) and the JFET has an  $I_{DSS}$  of 35 mA and a  $V_P$  of  $-3.0$  V, typical of small-signal JFETs. State the circuit's design requirements:  $|A_V| = 10$  and  $I_{DQ} = 10$  mA.

2) Use the equation above to find  $R_S = 139 \Omega$

3) Since  $|A_V| = 10$ ,  $R_D = 10 R_S = 1390 \Omega$ . Use standard values for  $R_S = 150 \Omega$  and  $R_D = 1.5$  kΩ.

### AC Performance

As with the CE bipolar transistor amplifier, a bypass capacitor can be used to increase ac gain while leaving dc bias conditions unchanged as shown in Figure 4.61. In the case of the CS amplifier, a *source bypass capacitor* is placed across  $R_S$  and the load,  $R_L$ , connected through a dc blocking capacitor. In this circuit voltage gain becomes:

$$A_V = -g_m (R_D // R_L)$$

Figure 4.61 — Common-source amplifier with source bypass capacitor,  $C_S$ , to increase voltage gain without affecting the circuit's dc performance.

Assuming  $C_{IN}$  and  $C_{OUT}$  are large enough to ignore their effects, the low-frequency cut-off frequency of the amplifier,  $f_L$ , is approximately where  $X_{CS} = 0.707 (R_D // R_L)$ ,

$$f_L = \frac{1.414}{2\pi (R_D // R_L) C_S}$$

as this reduces  $A_V$  to 0.707 of its mid-band value, resulting in a 3 dB drop in output amplitude.

The low-frequency ac input and output impedances of the CS amplifier remain

$$Z_{IN} = R_G \text{ and } Z_{OUT} \approx R_D$$

### COMMON-DRAIN (SOURCE-FOLLOWER) AMPLIFIER

The *common-drain* amplifier in Figure 4.62 is also known as a *source-follower* (SF) because the voltage gain of the amplifier is unity, similar to the emitter follower (EF) bipolar transistor amplifier. The SF amplifier is used primarily as a buffer stage and to drive low-impedance loads.

At low frequencies, the input impedance of the SF amplifier remains nearly infinite.

Figure 4.62 — Similar to the EF amplifier, the common-drain (CD) amplifier has a voltage gain of unity, but makes a good buffer with high input and low output impedances.

The SF amplifier's output impedance is the source resistance,  $R_S$ , in parallel with the impedance of the controlled current source,  $1/g_m$ .

$$Z_{OUT} = R_S // \frac{1}{g_m}$$

$$= \frac{R_S}{g_m R_S + 1} \approx \frac{1}{g_m} \text{ for } g_m R_S \gg 1$$

Design of the SF amplifier follows essentially the same process as the CS amplifier, with  $R_D = 0$ .

### THE COMMON-GATE AMPLIFIER

The *common-gate* amplifier in **Figure 4.63** has similar properties to the bipolar transistor common-base (CB) amplifier; unity current gain, high voltage gain, low input impedance and high output impedance. (Refer to the discussion of the CB amplifier regarding placement of the input and how the circuit schematic is drawn.) It is used as a voltage amplifier, particularly for low-impedance sources, such as coaxial cable inputs.

The CG amplifier's voltage gain is

$$A_V = g_m (R_D // R_L)$$

The output impedance of the CG amplifier is very high, we must take into account the output resistance of the controlled current source,  $r_o$ . This is analogous to the appearance of  $h_{oe}$  in the equation for output impedance of the bipolar transistor CG amplifier.

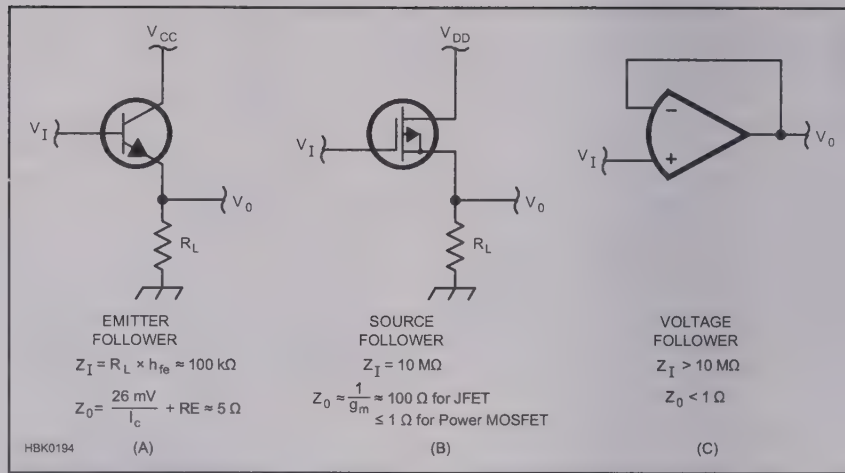

$$Z_O \approx r_o (g_m R_S + 1) // R_D$$

The CG amplifier input impedance is approximately

$$Z_I = R_S // \frac{1}{g_m}$$

Because the input impedance is quite low, the cascode circuit described later in the section on buffers is often used to present a higher-impedance input to the signal source.

Occasionally, the value of  $R_S$  must be fixed in order to provide a specific value of input

**Figure 4.64** — Common buffer stages and some typical input ( $Z_I$ ) and output ( $Z_O$ ) impedances. (A) Emitter follower, made with an NPN bipolar transistor; (B) Source follower, made with an FET; and (C) Voltage follower, made with an operational amplifier. All of these buffers are terminated with a load resistance,  $R_L$ , and have an output voltage that is approximately equal to the input voltage (gain  $\approx 1$ ).

impedance. Solving the small-signal FET model equation for  $I_{DQ}$  results in the following equation:

$$I_{DQ} = \frac{V_P}{2R_S^2 I_{DSS}} \left( V_P + \sqrt{V_P^2 - 4R_S I_{DSS} V_P} \right) - \frac{V_P}{R_S}$$

### Designing the Common-Gate Amplifier

Follow the procedure for designing a CS amplifier, except determine the value of  $R_D$  as shown in the equation above for voltage gain,  $A_V$ .

1) Start by determining the circuit's design constraints and assumptions:  $V_{DD} = 12 \text{ V}$  (the power supply voltage) and the JFET has a  $g_m$  of  $15 \text{ mA/V}$ , an  $I_{DSS}$  of  $60 \text{ mA}$  and  $V_P = -6 \text{ V}$ . State the circuit's design requirements:  $A_V = 10$ ,  $R_L = 1 \text{ k}\Omega$  and  $R_S = 50 \Omega$ .

2) Solve the  $A_V$  equation for  $R_D$ :  $10 = 0.015 \times R_D // R_L$ , so  $R_D // R_L = 667 \Omega$ .  $R_D = 667 R_L / (R_L - 667) = 2 \text{ k}\Omega$ .

3) Use the equation above to find  $I_{DQ} = 10 \text{ mA}$ . If  $I_{DQ}$  places the Q-point in the ohmic region, reduce  $A_V$  and repeat the calculations.

### 4.6.5 Buffer Amplifiers

**Figure 4.64** shows common forms of buffers with low-impedance outputs: the *emitter follower* using a bipolar transistor, the *source follower* using a field-effect transistor and the *voltage follower*, using an operational amplifier. (The operational amplifier is discussed later in this chapter.) These circuits are called "followers" because the output "follows" the input very closely with approximately the same voltage and little phase shift between the input and output signals.

### 4.6.6 Cascaded Buffers

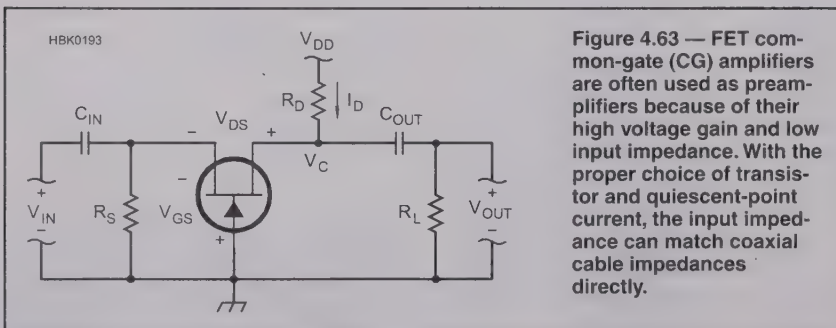

#### THE DARLINGTON PAIR

Buffer stages that are made with single active devices can be more effective if cascaded. Two types of such buffers are in common use. The *Darlington pair* is a cascade of two transistors connected as emitter followers as shown in **Figure 4.65**. The current gain of the Darlington pair is the product of the current gains for the two transistors,  $\beta_1 \times \beta_2$ .

What makes the Darlington pair so useful is that its input impedance is equal to the load impedance times the current gain, effectively multiplying the load impedance;

$$Z_I = Z_{LOAD} \times \beta_1 \times \beta_2$$

For example, if a typical bipolar transistor has  $\beta = 100$  and  $Z_{LOAD} = 15 \text{ k}\Omega$ , a pair of these transistors in the Darlington-pair configuration would have:

**Figure 4.63** — FET common-gate (CG) amplifiers are often used as preamplifiers because of their high voltage gain and low input impedance. With the proper choice of transistor and quiescent-point current, the input impedance can match coaxial cable impedances directly.

HBK05\_05-05

**Figure 4.65** — Darlington pair made with two emitter followers. Input impedance,  $Z_I$ , is far higher than for a single transistor and output impedance,  $Z_O$ , is nearly the same as for a single transistor. DC biasing has been omitted for simplicity.

$$Z_I = 15 \text{ k}\Omega \times 100 \times 100 = 150 \text{ M}\Omega$$

This impedance places almost no load on the circuit connected to the Darlington pair's input. The shunt capacitance at the input of real transistors can lower the actual impedance as the frequency increases.

Drawbacks of the Darlington pair include lower bandwidth and switching speed. The extremely high dc gain makes biasing very sensitive to temperature and component tolerances. For these reasons, the circuit is usually used as a switch and not as a linear amplifier.

### CASCODE AMPLIFIERS

A common-emitter amplifier followed by a common-base amplifier is called a *cascode buffer*, shown in its simplest form in **Figure 4.66**. (Biasing and dc blocking components are omitted for simplicity — replace the transistors with the practical circuits described earlier.) Cascode stages using FETs follow a common-source amplifier with a common-gate configuration. The input impedance and current gain of the cascode amplifier are approximately the same as those of the first stage. The output impedance of the common-base or -gate stage is much higher than that of the common-emitter or common-source amplifier. The power gain of the cascode amplifier is the product of the input stage current gain and the output stage voltage gain.

As an example, a typical cascode buffer

HBK05\_05-06

**Figure 4.66** — Cascode buffer made with two NPN bipolar transistors has a medium input impedance and high output impedance. DC biasing has been omitted for simplicity.

made with BJTs has moderate input impedance ( $Z_{IN} = 1 \text{ k}\Omega$ ), high current gain ( $h_{fe} = 50$ ), and high output impedance ( $Z_{OUT} = 1 \text{ M}\Omega$ ). Cascode amplifiers have excellent input/output isolation (very low unwanted internal feedback), resulting in high gain with good stability. Because of its excellent isolation, the cascode amplifier has little effect on external tuning components. Cascode circuits are often used in tuned amplifier designs for these reasons.

### 4.6.7 Using the Transistor as a Switch

When designing amplifiers, the goal was to make the transistor's output a replica of its input, requiring that the transistor stay within its linear region, conducting some current at all times. A switch circuit has completely different properties — its output current is either zero or some maximum value. **Figure 4.67** shows both a bipolar and metal-oxide semiconductor field-effect transistor (or MOSFET) switch circuit. Unlike the linear amplifier circuits, there are no bias resistors in either circuit. When using the bipolar transistor as a switch, it should operate in saturation or in cutoff. Similarly, an FET switch should be either fully-on or fully-off. The figure shows the waveforms associated with both types of switch circuits.

This discussion is written with power control in mind, such as to drive a relay or motor or lamp. The concepts, however, are equally applicable to the much lower-power circuits that control logic-level signals. The switch should behave just the same — switch

See the **RF Techniques** chapter for more information on transistor amplifier RF design, including a list of RF Amplifier Design resources in the References section.

between on and off quickly and completely — whether large or small.

### DESIGNING SWITCHING CIRCUITS

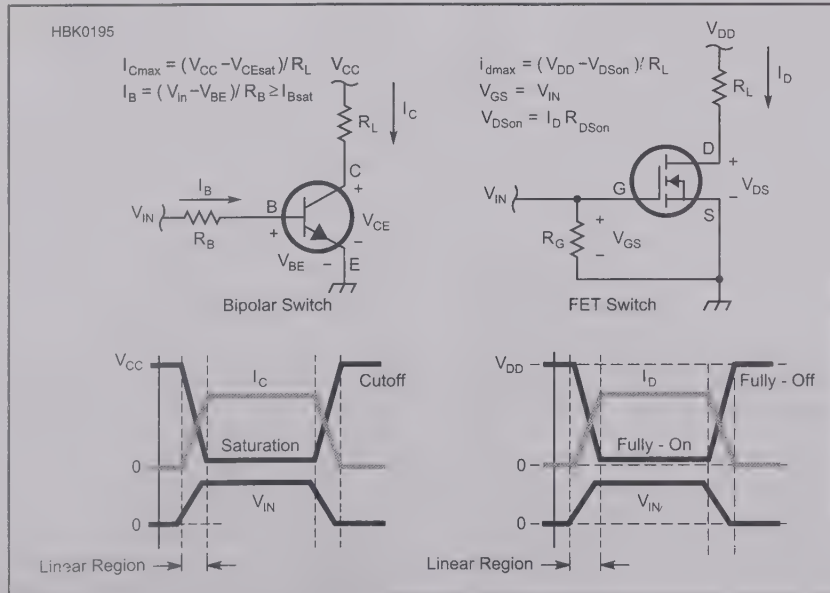

First, select a transistor that can handle the load current and dissipate whatever power is dissipated as heat. Second, be sure that the input signal source can supply an adequate input signal to drive the transistor to the required states, both on and off. Both of these conditions must be met to insure reliable driver operation.

To choose the proper transistor, the load current and supply voltage must both be known. Supply voltage may be steady, but sometimes varies widely. For example, a car's 12 V power bus may vary from 9 to 18 V, depending on battery condition. The transistor must withstand the maximum supply voltage,  $V_{MAX}$ , when off. The load resistance,  $R_L$ , must also be known. The maximum steady-state current the switch must handle is:

$$I_{MAX} = \frac{V_{MAX}}{R_L}$$

If you are using a bipolar transistor, calculate how much base current is required to drive the transistor at this level of collector current. You'll need to inspect the transistor's data sheet because  $\beta$  decreases as collector current

HBK0195

**Figure 4.67** — A pair of transistor driver circuits using a bipolar transistor and a MOSFET. The input and output signals show the linear, cutoff and saturation regions.

increases, so use a value for  $\beta$  specified at a collector current at or above  $I_{MAX}$ .

$$I_B = \frac{I_{MAX}}{\beta}$$

Now inspect the transistor's data sheet values for  $V_{CEsat}$  and make sure that this value of  $I_B$  is sufficient to drive the transistor fully into saturation at a collector current of  $I_{MAX}$ . Increase  $I_B$  if necessary — this is  $I_{Bsat}$ . The transistor must be fully saturated to minimize heating when conducting load current.

Using the *minimum* value for the input voltage, calculate the value of  $R_B$ :

$$R_B = \frac{V_{IN(min)} - V_{BE}}{I_{Bsat}}$$

The minimum value of input voltage must be used to accommodate the *worst-case* combination of circuit voltages and currents.

Designing with a MOSFET is a little easier because the manufacturer usually specifies the value  $V_{GS}$  must have for the transistor to be fully on,  $V_{GS(on)}$ . The MOSFET's gate, being insulated from the conducting channel, acts like a small capacitor of a few hundred pF and draws very little dc current.  $R_G$  in Figure 4.67 is required if the input voltage source does not actively drive its output to zero volts when off, such as a switch connected to a positive voltage. The MOSFET won't turn off reliably if its gate is allowed to "float."  $R_G$  pulls the gate voltage to zero when the input is open-circuited.

Power dissipation is the next design hurdle. Even if the transistors are turned completely on, they will still dissipate some heat. Just as for a resistor, for a bipolar transistor switch the power dissipation is:

$$P_D = V_{CE} I_C = V_{CE(sat)} I_{MAX}$$

where  $V_{CE(sat)}$  is the collector-to-emitter voltage when the transistor is saturated.

Power dissipation in a MOSFET switch is:

$$P_D = V_{DS} I_D = R_{DS(on)} I_{MAX}^2$$

$R_{DS(on)}$  is the resistance of the channel from drain to source when the MOSFET is on. MOSFETs are available with very low on-resistance, but still dissipate a fair amount of power when driving a heavy load. The transistor's data sheet will contain  $R_{DS(on)}$  specification and the  $V_{GS}$  required for it to be reached.

Power dissipation is why a switching transistor needs to be kept out of its linear region. When turned completely off or on, either current through the transistor or voltage across it are low, also keeping the product of voltage and current (the power to be dissipated) low. As the waveform diagrams in

Figure 4.67 show, while in the linear region, both voltage and current have significant values and so the transistor is generating heat when changing from off to on and vice versa. It's important to make the transition through the linear region quickly to keep the transistor cool.

The worst-case amount of power dissipated during each on-off transition is approximately

$$P_{transition} = \frac{1}{4} V_{MAX} I_{MAX}$$

assuming that the voltage and current increase and decrease linearly. If the circuit turns on and off at a rate of  $f$ , the total average power dissipation due to switching states is:

$$P_D = \frac{f}{2} V_{MAX} I_{MAX}$$

since there are two on-off transitions per switching cycle. This power must be added to the power dissipated when the switch is conducting current.

Once you have calculated the power the switch must dissipate, you must check to see whether the transistor can withstand it. The manufacturer of the transistor will specify a *free-air dissipation* that assumes no heat-sink and room temperature air circulating freely around the transistor. This rating should be at least 50% higher than your calculated power dissipation. If not, you must either use a larger transistor or provide some means of getting rid of the heat, such as heat sink. Methods of dissipating heat are discussed in this chapter's section on Heat Management.

## INDUCTIVE AND CAPACITIVE LOADS

Voltage transients for inductive loads, such as solenoids or relays can easily reach dozens of times the power supply voltage when load current is suddenly interrupted. To protect the transistor, the voltage transient must be clamped or its energy dissipated. Where switching is frequent, a series-RC *snubber* circuit (see Figure 4.68A) is connected across the load to dissipate the transient's energy as heat. The most common method is to employ a "kickback" diode that is reverse-biased when the load is energized as shown in Figure 4.68B. When the load current is interrupted, the diode routes the energy back to the power supply, clamping the voltage at the power supply voltage plus the diode's forward voltage drop. (If the solenoid or relay is going to be used in an amateur station, add a small bypass capacitor (0.001 – 0.01  $\mu$ F, value is not critical) across the diode to prevent it generating harmonics or mixing products from strong RF.)

Capacitive loads such as heavily filtered power inputs may temporarily act like short circuits when the load is energized or de-

**Figure 4.68** — The snubber RC circuit at (A) absorbs energy from transients with fast rise- and fall-times. At (B) a kickback diode protects the switching device when current is interrupted in the inductive load, causing a voltage transient, by conducting the energy back to the power source. See section on Analog-Digital Interfacing regarding bypassing kickback diodes.

energized. The surge current is only limited by the internal resistance of the load capacitance. The transistor will have to handle the temporary overloads without being damaged or overheating. The usual solution is to select a transistor with an  $I_{MAX}$  rating greater to the surge current. Sometimes a small current-limiting resistor can be placed in series with the load to reduce the peak surge current at the expense of dissipating power continuously when the load is drawing current.

## HIGH-SIDE AND LOW-SIDE SWITCHING

The switching circuits shown in Figure 4.68 are *low-side switches*. This means the switch is connected between the load and ground. A *high-side switch* is connected between the power source and the load. The same concerns for power dissipation apply, but the methods of driving the switch change because of the voltage of the emitter or source of the switching device will be at or near the power supply voltage when the switch is on.

To drive an NPN bipolar transistor or an N-channel MOSFET in a high-side circuit requires the switch input signal to be at least  $V_{BE(sat)}$  or  $V_{GS(on)}$  above the voltage supplied to the load. If the load expects to see the full power supply voltage, the switch input signal will have to be *greater* than the power supply voltage. A small step-up or boost dc-to-dc converter is often used to supply the extra voltage needed for the driver circuit.

One alternate method of high-side switching is to use a PNP bipolar transistor as the switching transistor. A small input transistor turns the main PNP transistor on by controlling the larger transistor's base current. Sim-

ilarly, a P-channel MOSFET could also be employed with a bipolar transistor or FET acting as its driver. P-type material generally does not have the same high conductivity as N-type material and so these devices dissipate somewhat more power than N-type devices under the same load conditions.

#### 4.6.8 Choosing a Transistor

With all the choices for transistors — web-

sites and catalogs can list hundreds — selecting a suitable transistor can be intimidating. Start by determining the maximum voltage ( $V_{CE0}$  or  $V_{DS(MAX)}$ ), current ( $I_{MAX}$ ) and power dissipation ( $P_{D(MAX)}$ ) the transistor must handle. Determine what dc current gain,  $\beta$ , or transconductance,  $g_m$ , is required. Then determine the highest frequency at which full gain is required and multiply it by either the voltage or current gain to obtain  $f_T$  or  $h_{fe}$ . This

will reduce the number of choices dramatically.

The chapter on **Component Data and References** has tables of parameters for popular transistors that tend to be the lowest-cost and most available parts, as well. You will find that a handful of part types satisfy the majority of your building needs. Only in very special applications will you need to choose a corresponding special part.

## 4.7 Operational Amplifiers

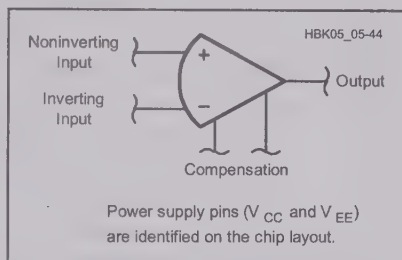

An *operational amplifier*, or *op amp*, is one of the most useful linear devices. While it is possible to build an op amp with discrete components, and early versions were, the symmetry of the circuit demanded for high performance requires a close match of many components. It is more effective, and much easier, to implement as an integrated circuit. (The term “operational” comes from the op amp’s origin in analog computers where it was used to implement mathematical operations.)

The op amp’s performance approaches that of an ideal analog circuit building block: an infinite input impedance ( $Z_i$ ), a zero output impedance ( $Z_o$ ) and an open loop voltage gain ( $A_v$ ) of infinity. Obviously, practical op amps do not meet these specifications, but they do come closer than most other types of amplifiers. These attributes allow the circuit designer to implement many different functions with an op amp and only a few external components.

### 4.7.1 Characteristics of Practical Op-Amps

An op amp has three signal terminals (see **Figure 4.69**). There are two input terminals, the *noninverting input* marked with a + sign and the *inverting input* marked with a – sign. Voltages applied to the noninverting input cause the op amp output voltage to change with the same polarity.

The output of the amplifier is a single terminal with the output voltage referenced to the external circuit’s reference voltage. Usually, that reference is ground, but the op amp’s internal circuitry allows all voltages to *float*, that is, to be referenced to any arbitrary voltage between the op amp’s power supply voltages. The reference can be negative, ground or positive. For example, an op amp powered from a single power supply voltage amplifies just as well if the circuit reference voltage is halfway between ground and the supply voltage.

**Figure 4.69** — Operational amplifier schematic symbol. The terminal marked with a + sign is the noninverting input. The terminal marked with a – sign is the inverting input. The output is to the right. On some op amps, external compensation is needed and leads are provided, pictured here below the device. Usually, the power supply leads are not shown on the op amp itself but are specified in the data sheet.

### GAIN-BANDWIDTH PRODUCT AND COMPENSATION

An ideal op amp would have infinite frequency response, but just as transistors have an  $f_T$  that marks their upper frequency limit, the op amp has a *gain-bandwidth product* (GBW or BW). GBW represents the maximum product of gain and frequency available to any signal or circuit: voltage gain  $\times$  frequency = GBW. If an op-amp with a GBW of 10 MHz is connected as a  $\times 50$  voltage amplifier, the maximum frequency at which that gain could be guaranteed is  $GBW / \text{gain} = 10 \text{ MHz} / 50 = 200 \text{ kHz}$ . GBW is an important consideration in high-performance filters and signal processing circuits whose design equations require high-gain at the frequencies over which they operate.

Older operational amplifiers, such as the LM301, have an additional two connections for *compensation*. To keep the amplifier from oscillating at very high gains it is often neces-

sary to place a capacitor across the compensation terminals. This also decreases the frequency response of the op amp but increases its stability by making sure that the output signal cannot have the right phase to create positive feedback at its inputs. Most modern op amps are internally compensated and do not have separate pins to add compensation capacitance. Additional compensation can be created by connecting a capacitor between the op amp output and the inverting input.

### CMRR AND PSRR

One of the major advantages of using an op amp is its very high *common mode rejection ratio* (CMRR). *Common mode* signals are those that appear equally at all terminals. For example, if both conductors of an audio cable pick up a few tenths of a volt of 60 Hz signal from a nearby power transformer, that 60 Hz signal is a common-mode signal to whatever device the cable is connected. Since the op amp only responds to *differences* in voltage at its inputs, it can ignore or reject common mode signals. CMRR is a measure of how well the op amp rejects the common mode signal. High CMRR results from the symmetry between the circuit halves. CMRR is important when designing circuits that process low-level signals, such as microphone audio or the mV-level dc signals from sensors or thermocouples.

The rejection of power-supply imbalance is also an important op amp parameter. Shifts in power supply voltage and noise or ripple on the power supply voltages are coupled directly to the op amp’s internal circuitry. The op amp’s ability to ignore those disturbances is expressed by the *power supply rejection ratio* (PSRR). A high PSRR means that the op amp circuit will continue to perform well even if the power supply is imbalanced or noisy.

## INPUT AND OUTPUT VOLTAGE LIMITS

The op amp is capable of accepting and amplifying signals at levels limited by the power supply voltages, also called *rails*. The difference in voltages between the two rails limits the range of signal voltages that can be processed. The voltages can be symmetrical positive and negative voltages ( $\pm 12\text{ V}$ ), a positive voltage and ground, ground and a negative voltage or any two different, stable voltages.

In most op amps the signal levels that can be handled are one or two diode forward voltage drops (0.7 V to 1.4 V) away from each rail. Thus, if an op amp has 15 V connected as its upper rail (usually denoted  $V^+$ ) and ground connected as its lower rail ( $V^-$ ), input signals can be amplified to be as high as 13.6 V and as low as 1.4 V in most amplifiers. Any values that would be amplified beyond those limits are clamped (output voltages that should be 1.4 V or less appear as 1.4 V and those that should be 13.6 V or more appear as 13.6 V). This clamping action was illustrated in Figure 3.49 in the **Radio Fundamentals** chapter.

“Rail-to-rail” op amps have been developed to handle signal levels within a few tens of mV of rails (for example, the MAX406, from Maxim Integrated Products processes signals to within 10 mV of the power supply voltages). Rail-to-rail op-amps are often used in battery-powered products to allow the circuits to operate from low battery voltages for as long as possible.

## INPUT BIAS AND OFFSET

The inputs of an op amp, while very high impedance, still allow some input current to flow. This is the *input bias current* and it is in the range of nA in modern op amps. Slight asymmetries in the op amp’s internal circuitry result in a slight offset in the op amp’s output voltage, even with the input terminals shorted together. The amount of voltage difference between the op amp’s inputs required to cause the output voltage to be exactly zero is the *input offset voltage*, generally a few mV or less. Some op amps, such as the LM741, have special terminals to which a potentiometer can be connected to *null* the offset by correcting the internal imbalance. Introduction of a small dc correction voltage to the noninverting terminal is sometimes used to apply an offset voltage that counteracts the internal mismatch and centers the signal in the rail-to-rail range.

DC offset is an important consideration in op amps for two reasons. Actual op amps have a slight mismatch between the inverting and noninverting terminals that can become a substantial dc offset in the output, depending on the amplifier gain. The op amp output

voltage must not be too close to the clamping limits or distortion will occur.

## A TYPICAL OP AMP

As an example of typical values for these parameters, one of today’s garden-variety op amps, the TL084, which contains both JFET and bipolar transistors, has a guaranteed minimum CMRR of 80 dB, an input bias current guaranteed to be below 200 pA (1 pA = 1 millionth of a  $\mu\text{A}$ ) and a gain-bandwidth product of 3 MHz. Its input offset voltage is 3 mV. CMRR and PSRR are 86 dB, meaning that an unwanted signal or power supply imbalance of 1 V will only result in a 2.5 nV change at the op amp’s output! All this for less than 50 cents even purchased in single quantities and there are four op-amps per package — that’s a lot of performance.

## 4.7.2 Basic Op-Amp Circuits

If a signal is connected to the input terminals of an op amp without any other circuitry attached, it will be amplified at the device’s *open-loop gain* (typically 200,000 for the TL084 at dc and low frequencies, or 106 dB). This will quickly saturate the output at the power supply rails. Such large gains are rarely used. In most applications, negative feedback is used to limit the circuit gain by providing a feedback path from the output terminal to the inverting input terminal. The resulting *closed-loop gain* of the circuit depends solely on the values of the passive components used to form the loop (usually resistors and, for frequency-selective circuits, capacitors). The higher the op-amp’s open-loop gain, the closer the circuit’s actual gain will approach that predicted from the component values. Note that the gain of the op amp itself has not changed — it is the configuration of the external components that determines the overall gain of the circuit. Some examples of different circuit configurations that manipulate the closed-loop gain follow.

## INVERTING AND NONINVERTING AMPLIFIERS

The op amp is often used in either an *inverting* or a *noninverting* amplifier circuit as shown in Figure 4.70. (Inversion means that the output signal is inverted from the input signal about the circuit’s voltage reference as described below.) The amount of amplification is determined by the two resistors: the feedback resistor,  $R_f$ , and the input resistor,  $R_i$ .

In the noninverting configuration shown in Figure 4.70A, the input signal is connected to the op-amp’s noninverting input. The feedback resistor is connected between the output and the inverting input terminal. The inverting input terminal is connected to  $R_i$ , which is connected to ground (or the circuit reference voltage).

Figure 4.70 — Operational amplifier circuits. (A) Noninverting configuration. (B) Inverting configuration.

This circuit illustrates how op amp circuits use negative feedback, the high open-loop gain of the op amp itself, and the high input impedance of the op amp inputs to create a stable circuit with a fixed gain. The signal applied to the noninverting input causes the output voltage of the op-amp to change with the same polarity. That is, a positive input signal causes a positive change in the op amp’s output voltage. This voltage causes current to flow in the voltage divider formed by  $R_f$  and  $R_i$ . Because the current into the inverting input is so low, the current through  $R_f$  is the same as  $R_i$ .

The voltage at the *summing junction*, the connection point for the two resistors and the inverting terminal,  $V_{INV}$ , is:

$$V_{INV} = V_O \left( \frac{R_i}{R_i + R_f} \right)$$

The op amp’s output voltage will continue to rise until the *loop error signal*, the difference in voltage between the inverting and noninverting inputs, is close to zero. At this point, the voltage at the inverting terminal is approximately equal to the voltage at the noninverting terminal,  $V_{in}$ , so that  $V_{INV} = V_{in}$ . Substituting in equation for  $V_{INV}$ , the gain of this circuit is:

$$\frac{V_O}{V_{in}} = \left( 1 + \frac{R_f}{R_i} \right)$$

where

$$V_O = \text{the output voltage}$$

$$V_{in} = \text{the input voltage.}$$

The higher the op amp’s open-loop gain, the closer will be the voltages at the inverting

and noninverting terminals when the circuit is balanced and the more closely the circuit's closed-loop gain will equal that in the equation. So the negative feedback creates an electronic balancing act with the op amp increasing its output voltage so that the input error signal is as small as possible.

In the inverting configuration of Figure 4.70B, the input signal ( $V_{in}$ ) is connected through  $R_i$  to the inverting terminal. The feedback resistor is again connected between the inverting terminal and the output. The noninverting terminal is connected to ground (or the circuit reference voltage). In this configuration the feedback action results in the output voltage changing to whatever value is needed such that the current through  $R_i$  is balanced by an equal and opposite current through  $R_f$ . The gain of this circuit is:

$$\frac{V_O}{V_{in}} = -\frac{R_f}{R_{in}}$$

where  $V_{in}$  represents the voltage input to  $R_{in}$ .

For the remainder of this section, "ground" or "zero voltage" should be understood to be the circuit reference voltage. That voltage may not be "earth ground potential." For example, if a single positive supply of 12 V is used, 6 V may be used as the circuit reference voltage. The circuit reference voltage is a fixed dc voltage that can be considered to be an ac ground because of the reference source's extremely low ac impedance.

The negative sign in the voltage gain equation indicates that the signal is inverted. For ac signals, inversion represents a 180° phase shift. The gain of the noninverting configuration can vary from a minimum of 1 to the maximum of which the op amp is capable, as indicated by  $A_v$ , for dc signals, or the gain-bandwidth product for ac signals. The gain of the inverting configuration can vary from a minimum of 0 (gains from 0 to 1 attenuate the signal while gains of 1 and higher amplify the signal) to the maximum of which the device is capable.

The inverting amplifier configuration results in a special condition at the op amp's inverting input called *virtual ground*. Because the op amp's high open-loop gain drives the two inputs to be very close together, if the noninverting input is at ground potential, the inverting input will be very close to ground as well and the op amp's output will change with the input signal to maintain the inverting input at ground. Measured with a voltmeter, the input appears to be grounded, but it is merely maintained at ground potential by the action of the op amp and the feedback loop. This point in the circuit may not be connected to any other ground connection or circuit point because the resulting additional current flow will upset the balance of the circuit.

The *voltage follower* or *unity-gain buffer*

**Figure 4.71 — Voltage follower.** This operational amplifier circuit makes a nearly ideal buffer with a voltage gain of about one, and with extremely high input impedance and extremely low output impedance.

circuit of **Figure 4.71** is commonly used as a buffer stage. The voltage follower has the input connected directly to the noninverting terminal and the output connected directly to the inverting terminal. This configuration has unity gain because the circuit is balanced when the output and input voltages are the same (error voltage equals zero). It also provides the maximum possible input impedance and the minimum possible output impedance of which the device is capable.

### Differential and Difference Amplifier

A *differential amplifier* is a special application of an operational amplifier (see **Figure 4.72**). It amplifies the difference between two analog signals and is very useful to cancel noise under certain conditions. For instance, if an analog signal and a reference signal travel over the same cable they may pick up noise, and it is likely that both signals will have the same amount of noise. When the differential amplifier subtracts them, the signal will be unchanged but the noise will be completely removed, within the limits of the CMRR. The equation for differential amplifier operation is

$$V_O = \frac{R_f}{R_i} \left[ \frac{1}{\frac{R_n}{R_g} + 1} \left( \frac{R_i}{R_f} + 1 \right) V_n - V_i \right]$$

which, if the ratios  $R_i/R_f$  and  $R_n/R_g$  are equal, simplifies to:

$$V_O = \frac{R_f}{R_i} (V_n - V_i)$$

Note that the differential amplifier gain is identical to the inverting amplifier gain if the voltage applied to the noninverting terminal is equal to zero. If the voltage applied to the inverting terminal ( $V_i$ ) is zero, the analysis is a little more complicated but it is possible to derive the noninverting amplifier gain from the differential amplifier gain by taking into account the influence of  $R_n$  and  $R_g$ . If all four resistors have the same value the *difference*

**Figure 4.72 — Difference amplifier.** This operational amplifier circuit amplifies the difference between the two input signals.

*amplifier* is created and  $V_O$  is just the difference of the two voltages.

$$V_O = V_n - V_i$$

### Instrumentation Amplifier

Just as the symmetry of the transistors making up an op amp leads to devices with high values of  $Z_i$ ,  $A_v$ , and CMRR and a low value of  $Z_o$ , a symmetric combination of op amps is used to further improve these parameters. This circuit, shown in **Figure 4.73** is called an *instrumentation amplifier*. It has three parts; each of the two inputs is connected to a noninverting buffer amplifier with a gain of  $1 + R_2/R_1$ . The outputs of these buffer amplifiers are then connected to a differential amplifier with a gain of  $R_4/R_3$ .  $V_2$  is the circuit's inverting input and  $V_1$  the noninverting input.

The three amplifier modules are usually all part of the same integrated circuit. This means that they have essentially the same temperature and the internal transistors and resistors are very well matched. This causes the subtle gain and tracking errors caused by temperature differences and mismatched components between individual op amps to be cancelled out or dramatically reduced. In addition, the external resistors using the same designators ( $R_2$ ,  $R_3$ ,  $R_4$ ) are carefully matched as well, sometimes being part of a single integrated *resistor pack*. The result is a circuit with better performance than any single-amplifier circuit over a wider temperature range.

### Summing Amplifier

The high input impedance of an op amp makes it ideal for use as a *summing amplifier*. In either the inverting or noninverting configuration, the single input signal can be replaced by multiple input signals that are connected together through series resistors, as shown in **Figure 4.74**. For the inverting summing amplifier, the gain of each input signal can be calculated individually using

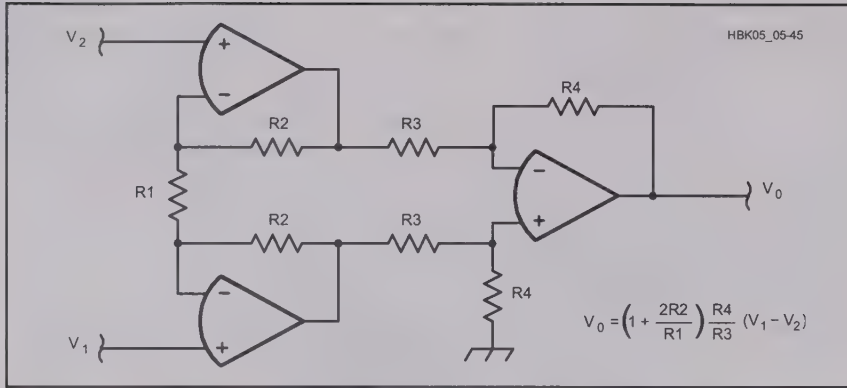

Figure 4.73 — Operational amplifiers arranged as an instrumentation amplifier. The balanced and cascaded series of op amps work together to perform differential amplification with good common-mode rejection and very high input impedance (no load resistor required) on both the inverting ( $V_1$ ) and noninverting ( $V_2$ ) inputs.

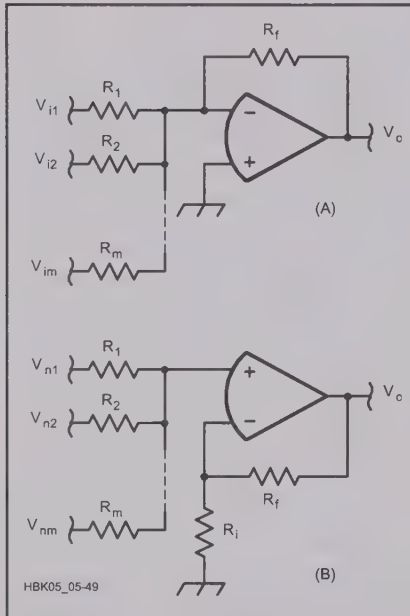

Figure 4.74 — Summing operational amplifier circuits. (A) Inverting configuration. (B) Noninverting configuration.

the equation for inverting amplifier gain and, because of the superposition property of linear circuits, the output is the sum of each input signal multiplied by its gain. In the noninverting configuration, the output is the gain times the weighted sum of the  $m$  different input signals:

$$V_n = V_{n1} \frac{R_{p1}}{R_1 + R_{p1}} + V_{n2} \frac{R_{p2}}{R_2 + R_{p2}} + \dots + V_{nm} \frac{R_{pm}}{R_m + R_{pm}}$$

where  $R_{pm}$  is the parallel resistance of

all  $m$  resistors excluding  $R_m$ . For example, with three signals being summed,  $R_{p1}$  is the parallel combination of  $R_2$  and  $R_3$ .

## Comparators

A *voltage comparator* is another special form of op amp circuit, shown in Figure 4.75. It has two analog signals as its inputs and its output is either TRUE or FALSE depending on whether the noninverting or inverting signal voltage is higher, respectively. Thus, it “compares” the input voltages. TRUE generally corresponds to a positive output voltage and FALSE to a negative or zero voltage. The circuit in Figure 4.75 uses external resistors to generate a reference voltage, called the *setpoint*, to which the input signal is compared. A comparator can also compare two variable voltages.

A standard operational amplifier can be made to act as a comparator by connecting the two input voltages to the noninverting and inverting inputs with no input or feedback resistors. If the voltage of the noninverting input is higher than that of the inverting input, the output voltage will be driven to the positive clamping limit. If the inverting input is at a higher potential than the noninverting input, the output voltage will be driven to the negative clamping limit. If the comparator is comparing an unknown voltage to a known voltage, the known voltage is called the *setpoint* and the comparator output indicates whether the unknown voltage is above or below the setpoint.

An op amp that has been intended for use as a comparator, such as the LM311, is optimized to respond quickly to the input signals. In addition, comparators often have *open-collector outputs* that use an external *pull-up resistor*,  $R_{OUT}$ , connected to a positive power supply voltage. When the comparator output is TRUE, the output transistor is turned off and

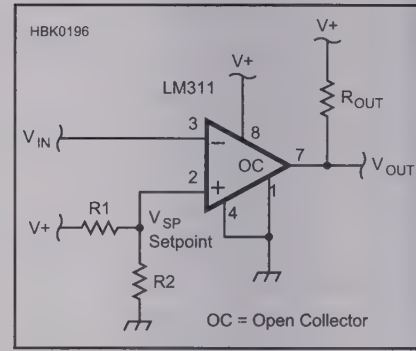

Figure 4.75 — A comparator circuit in which the output voltage is low when voltage at the inverting input is higher than the setpoint voltage at the noninverting input.

the pull-up resistor “pulls up” the output voltage to the positive power supply voltage. When the comparator output is FALSE, the transistor is driven into the saturation and the output voltage is the transistor’s  $V_{CE(sat)}$ .

## Hysteresis

Comparator circuits also use *hysteresis* to prevent “chatter” — the output of the comparator switching rapidly back and forth when the input voltage is at or close to the setpoint voltage. There may be noise on the input signal, as shown in Figure 4.76A, that causes the input voltage to cross the setpoint threshold repeatedly. The rapid switching of the output can be confusing to the circuits monitoring the comparator output.

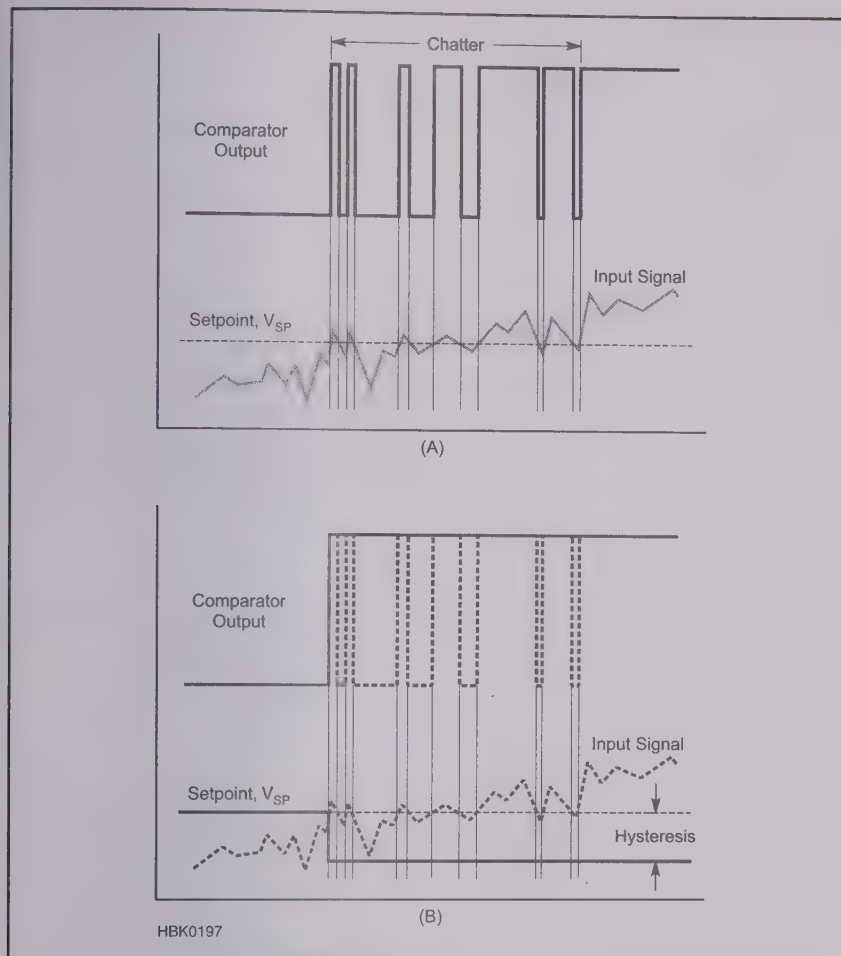

Hysteresis is a form of positive feedback that “moves” the setpoint by a few mV in the direction *opposite* to that in which the input signal crossed the setpoint threshold. As shown in Figure 4.76B, the slight shift in the setpoint tends to hold the comparator output in the new state and prevents switching back to the old state. Figure 4.77 shows how the output of the comparator is fed back to the positive input through resistor  $R_3$ , adding or subtracting a small amount of current from the divider and shifting the setpoint. If  $V_{HYS}$  is the amount of hysteresis desired (the shift in the setpoint voltage):

$$V_{HYS} \approx (V_{OH})(R_1 \parallel R_2) / [R_3 + (R_1 \parallel R_2)]$$

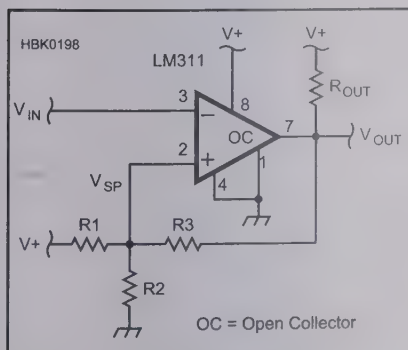

where  $V_{OH}$  is the high-level output voltage with the comparator’s output is off. Solving for  $R_3$  if the other values are known:

$$R_3 \approx [(V_{OH})(R_1 \parallel R_2) / V_{HYS}] - (R_1 \parallel R_2)$$

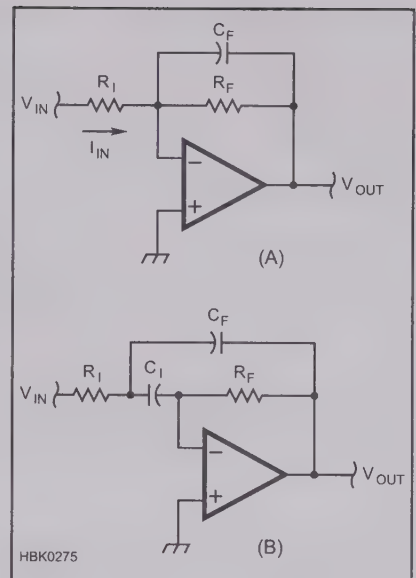

Some applications of a voltage comparator are a zero crossing detector, a signal squarer (which turns other cyclical wave forms into

**Figure 4.76** — Chatter (A) is caused by noise when the input signal is close to the setpoint. Chatter can also be caused by voltage shifts that occur when a heavy load is turned on and off. Hysteresis (B) shifts the setpoint a small amount by using positive feedback in which the output pulls the setpoint farther away from the input signal after switching.

**Figure 4.77** — Comparator circuit with hysteresis.  $R_3$  causes a shift in the comparator setpoint by allowing more current to flow through  $R_1$  when the comparator output is low.

**Figure 4.78** — Op amp active filters. The circuit at (A) has a low-pass response identical to an RC filter. The  $-3$  dB frequency occurs when the reactance of  $C_F$  equals  $R_F$ . The band-pass filter at (B) is a multiple-feedback filter.

the reactance of the feedback capacitor decreases with frequency, requiring less output voltage to balance the voltages of the inverting and noninverting inputs.

The *multiple-feedback* circuit in Figure 4.78B results in a band-pass response while using only resistors and capacitors. This circuit is just one of many different types of active filters. Active filters are discussed in the **Analog and Digital Filtering** chapter.

## RECTIFIERS AND PEAK DETECTORS

The high open-loop gain of the op amp can also be used to simulate the I-V characteristics of an ideal diode. A *precision rectifier* circuit is shown in **Figure 4.79** along with the I-V characteristics of a real (dashed lines) and ideal (solid line) diode. The high gain of the op amp compensates for the  $V_F$  forward voltage drop of the real diode in its feedback loop with an output voltage equal to the input voltage plus  $V_F$ . Remember that the op amp's output increases until its input voltages are balanced. When the input voltage is negative, which would reverse-bias the diode, the op amp's output can't balance the input because the diode blocks any current flow through the feedback loop. The resistor at the output holds the voltage at zero until the input voltage is positive once again. Precision half-wave and full-wave rectifier circuits are shown in **Figure 4.80** and their operation is described in

square waves) and a peak detector. An amateur station application: Circuits that monitor the CI-V band data output voltage from ICOM HF radios use a series of comparators to sense the level of the voltage and indicate on which band the radio is operating.

## FILTERS

One of the most important type of op amp circuits is the *active filter*. Two examples of op amp filter circuits are shown in **Figure 4.78**. The simple noninverting low-pass filter in Figure 4.78A has the same response as a passive single-pole RC low-pass filter, but unlike the passive filter, the op amp filter circuit has a very high input impedance and a very low output impedance so that the filter's frequency and voltage response are relatively unaffected by the circuits connected to the filter input and output. This circuit is a low-pass filter because

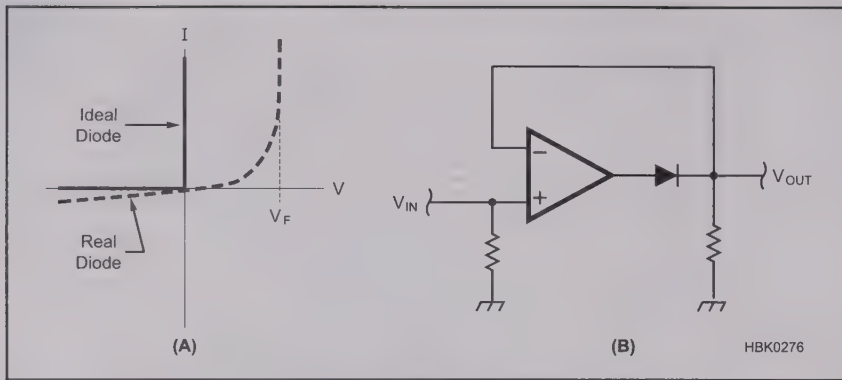

Figure 4.79 — Ideal and real diode I-V characteristics are shown at (A). The op amp precision rectifier circuit is shown at (B).

many reference texts.

One application of the precision rectifier circuit useful in radio is the *peak detector*, shown in **Figure 4.81**. A precision rectifier is used to charge the output capacitor which holds the peak voltage. The output resistor sets the time constant at which the capacitor discharges. The resistor can also be replaced by a transistor acting as a switch to reset the detector. This circuit is used in AGC loops, spectrum analyzers, and other instruments that measure the peak value of ac waveforms.

### LOG AMPLIFIER

There are a number of applications in radio in which it is useful for the gain of an amplifier to be higher for small input signals than for large input signals. For example, an audio compressor circuit is used to reduce the variations in a speech signal's amplitude so that the average power output of an AM or SSB transmitter is increased. A *log amplifier* circuit whose gain for large signals is proportional to the logarithm of the input signal's amplitude is shown in **Figure 4.82**. The log amp circuit is used in compressors and limiter circuits.

At signal levels that are too small to cause

significant current flow through the diodes, the gain is set as in a regular inverting amplifier,  $A_V = -R_f/R_i$ . As the signal level increases, however, more current flows through the diode according to the Fundamental Diode Equation (see the **Electronic Fundamentals** chapter). That means the op amp output voltage has to increase less (lower gain) to cause enough current to flow through  $R_i$  such that the input voltages balance. The larger the input voltage, the more the diode conducts and the lower the gain of the circuit. Since the diode's current is exponential in response to voltage, the gain of the circuit for large input signals is logarithmic.

### Voltage-Current Converters

Another pair of useful op amp circuits convert voltage into current and current into voltage. These are frequently used to convert currents from sensors and detectors into voltages that are easier to measure. **Figure 4.83A** shows a voltage-to-current converter in which the output current is actually the current in the feedback loop. Because the op amp's high open-loop gain insures that its input voltages are equal, the current  $I_{R1} = V_{IN}/R1$ . Certainly, this could also be achieved with a resistor and

Figure 4.81 — Peak detector. Coupling a precision diode with a capacitor to store charge creates a peak detector. The capacitor will charge to the peak value of the input voltage. R discharges the capacitor with a time constant of  $\tau = RC$  and can be omitted if it is desired for the out-

Figure 4.82 — Log amplifier. At low voltages, the gain of the circuit is  $-R_f/R_i$ , but as the diodes begin to conduct for higher-voltage signals, the gain changes to  $-\ln(V_{in})$  in because of the diode's exponential current as described in the Fundamental Diode Equation.

Ohm's Law, but the op amp circuit's high input impedance means there is little interaction between the input voltage source and the output current.

Going the other way, **Figure 4.83B** is a

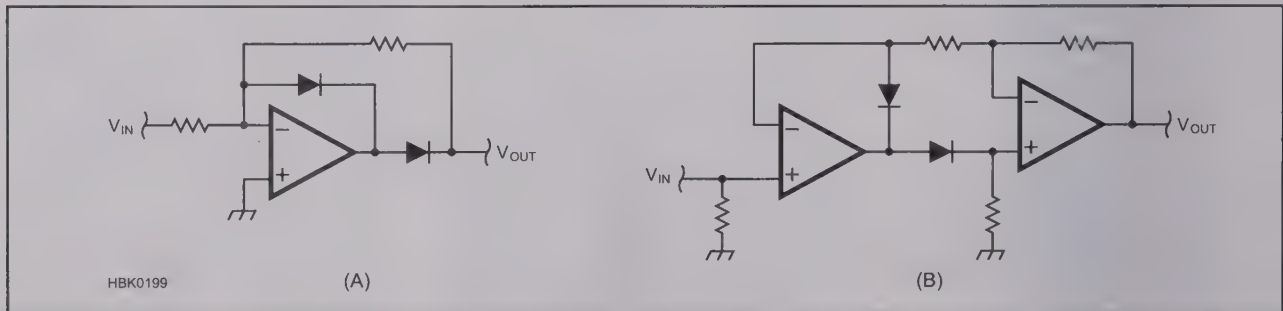

Figure 4.80 — Half-wave precision rectifier (A). The extra diode at the output of the op amp prevents the op amp from saturating on negative half-cycles and improves response time. The precision full-wave rectifier circuit at (B) reproduces both halves of the input waveform.

**Figure 4.83 — Voltage-current converters.** The current through R1 in (A) equals  $V_{IN}/R1$  because the op amp keeps both input terminals at approximately the same voltage. At (B), input current is balanced by the op amp, resulting in  $V_{OUT} = I_{IN} \cdot R1$ . Current through a photodiode (C) can be converted into a voltage in this way.

current-to-voltage converter. The op amp's output will change so that the current through the feedback resistor, R1, exactly equals the input current, keeping the inverting terminal at ground potential. The output voltage,  $V_O$

$= I_{IN} R1$ . Again, this could be done with just a resistor, but the op amp provides isolation between the source of input current and the output voltage. Figure 4.83C shows an application of a current-to-voltage converter in

which the small currents from a photodiode are turned into voltage. This circuit can be used as a detector for amplitude modulated light pulses or waveforms.

## 4.8 Miscellaneous Analog ICs

The three main advantages of designing a circuit into an IC are to take advantage of the matched characteristics of its components, to make highly complex circuitry more economical, and to miniaturize the circuit and reduce power consumption. As circuits standardize and become widely used, they are often converted from discrete components to integrated circuits. Along with the op amp described earlier, there are many such classes of linear ICs.

mination resistors, diode bridges and Darlington pair transistors. A nearly infinite number of possibilities exists for these combinations of components and many of these are available in arrays.

Driver arrays, such as the ULN2000-series devices shown in **Figure 4.84** are very useful in creating an interface between low-power circuits such as microprocessors and higher-power loads and indicators. Each driver consists of a Darlington pair switching circuit as described earlier in this chapter. There are different versions with different types and arrangements of resistors and diodes.

Many manufacturers offer driver arrays. They are available with built-in kickback diodes to allow them to drive inductive loads, such as relays, and are heavy enough to source or sink current levels up to 1 A. (All of the drivers in the array cannot operate at full load at the same time, however. Read the data sheet carefully to determine what limitations on current and power dissipation may exist.)

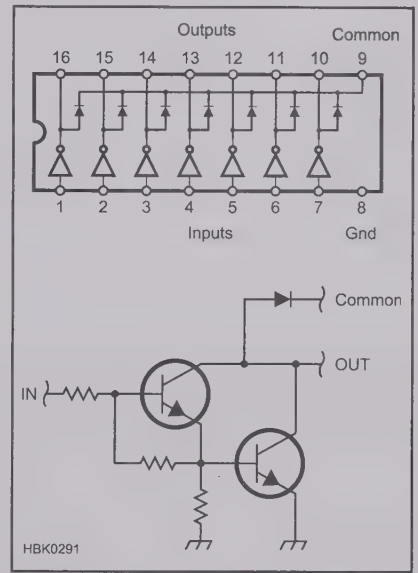

### 4.8.1 Transistor and Driver Arrays

The most basic form of linear integrated circuit and one of the first to be implemented is the component array. The most common of these are the resistor, diode and transistor arrays. Though capacitor arrays are also possible, they are used less often. Component arrays usually provide space saving but this is not the major advantage of these devices. They are the least densely packed of the integrated circuits because each device requires a separate off-chip connection. While it may be possible to place over a million transistors on a single semiconductor chip, individual access to these would require a total of three million pins and this is beyond the limits of practicability. More commonly, resistor and diode arrays contain from five to 16 individual devices and transistor arrays contain from three to six individual transistors. The advantage of these arrays is the very close matching of component values within the array. In a circuit that needs matched components, the component array is often a good method of obtaining this feature. The components within an array can be internally combined for special functions, such as ter-

### 4.8.2 Voltage Regulators and References

One of the most popular linear ICs is the voltage regulator. There are two basic types, the three-terminal regulator and the regulator controller. Examples of both are described in the **Power Sources** chapter.

The three-terminal regulator (input, ground, output) is a single package designed to perform all of the voltage regulation functions. The output voltage can be fixed, as in the 7800-series of regulators, or variable, as in the LM317 regulator. It contains a voltage reference, comparator circuits, current and temperature sensing protective circuits, and the main pass element. These ICs are usually

**Figure 4.84 — Typical ULN2000-series driver array configuration and internal circuit.** The use of driver array ICs is very popular as an interface between microprocessor or other low-power digital circuits and loads such as relays, solenoids or lamps.

contained in the same packages as power transistors and the same techniques of thermal management are used to remove excess heat.

Regulator controllers, such as the popular 723 device, contain all of the control and voltage reference circuitry, but require external components for the main pass element, current sensing, and to configure some of their control functions.

Voltage references such as the Linear Tech-

nology LT1635 are special semiconductor diodes that have a precisely controlled I-V characteristic. A buffer amplifier isolates the sensitive diode and provides a low output impedance for the voltage signal. Voltage references are used as part of power regulators and by analog-digital converter circuits.

### 4.8.3 Timers (Multivibrators)

A *multivibrator* is a circuit that oscillates between two states, usually with a square wave or pulse train output. The frequency of oscillation is accurately controlled with the addition of appropriate values of external resistance and capacitance. The most common multivibrator

in use today is the 555 timer IC (NE555 by Signetics [now Philips] or LM555 by National Semiconductor). This very simple eight-pin device has a frequency range from less than one hertz to several hundred kilohertz. Such a device can also be used in *monostable* operation, where an input pulse generates an output pulse of a different duration, or in a *stable* or *free-running* operation, where the device oscillates continuously. Other applications of a multivibrator include a frequency divider, a delay line, a pulse width modulator and a pulse position modulator. (These can be found in the IC's data sheet or in the reference listed at the end of this chapter.)

Figure 4.85 shows the basic components

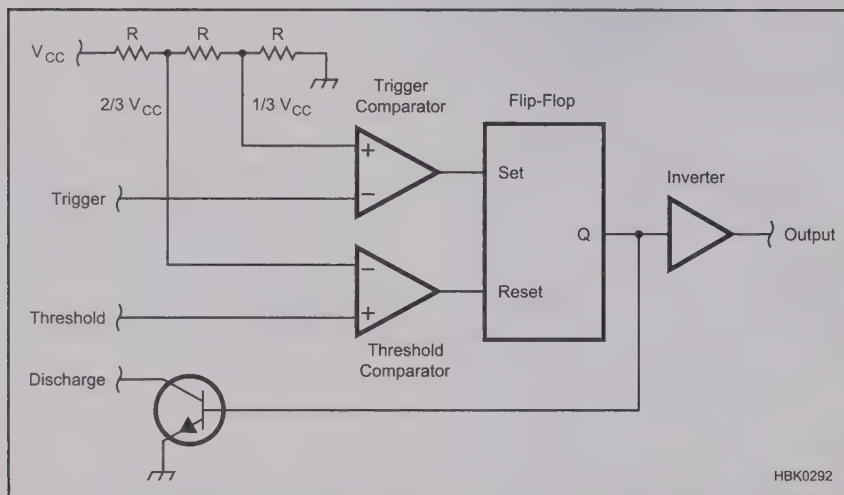

Figure 4.85 — Internal NE555 timer components. This simple array of components combines to make one of the most popular analog ICs. The 555 timer IC uses ratios of internal resistors to generate a precise voltage reference for generating time intervals based on charging and discharging a capacitor.

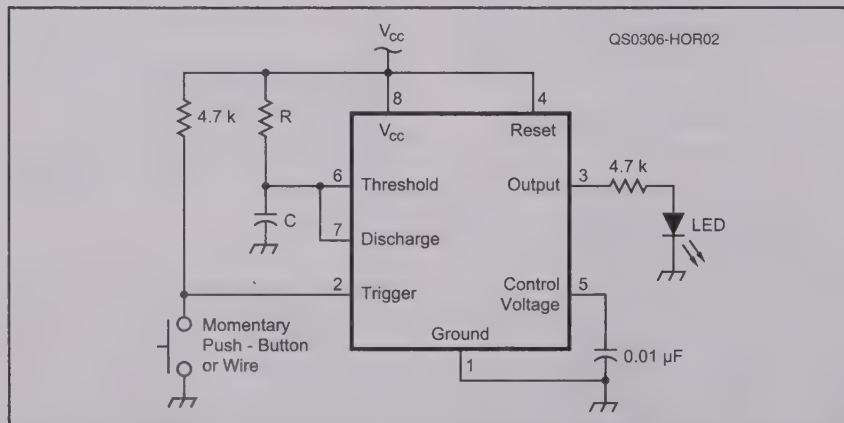

Figure 4.86 — Monostable timer. The timing capacitor is discharged until a trigger pulse initiates the charging process and turns the output on. When the capacitor has charged to  $2/3 V_{CC}$ , the output is turned off, the capacitor is discharged and the timer awaits the next trigger pulse.

of a 555. Connected between power input ( $V_{CC}$ ) and ground, the three resistors labeled “R” at the top left of the figure form a *voltage divider* that divides  $V_{CC}$  into two equal steps—one at  $2/3 V_{CC}$  and one at  $1/3 V_{CC}$ . These serve as reference voltages for the rest of the circuit.

Connected to the reference voltages are blocks labeled *trigger comparator* and *threshold comparator*. (Comparators were discussed in a preceding section.) The trigger comparator in the 555 is wired so that its output is high whenever the trigger input is *less* than  $1/3 V_{CC}$  and vice versa. Similarly, the threshold comparator output is high whenever the threshold input is *greater* than  $2/3 V_{CC}$ .

These two outputs control a digital *flip-flop* circuit with an output, *Q*, that changes to high or low when the state of its *set* and *reset* inputs changes. The *Q* output stays high or low (it *latches* or *toggles*) until the opposite input changes. When the set input changes from low to high, *Q* goes low. When reset changes from low to high, *Q* goes high. The flip-flop ignores any other changes. An inverter makes the 555 output high when *Q* is low and vice versa — this makes the timer circuit easier to interface with external circuits.

The transistor connected to *Q* acts as a switch. When *Q* is high, the transistor is on and acts as a closed switch connected to ground. When *Q* is low, the transistor is off and the switch is open. These simple building blocks — voltage divider, comparator, flip-flop and switch — build a surprising number of useful circuits.

### THE MONOSTABLE OR “ONE-SHOT” TIMER

The simplest 555 circuit is the monostable circuit. This configuration will output one fixed-length pulse when triggered by an input pulse. Figure 4.86 shows the connections for this circuit.

Starting with capacitor *C* discharged, the flip-flop output, *Q*, is high, which keeps the discharge transistor turned on and the voltage on *C* below  $2/3 V_{CC}$ . The circuit is in its stable state, waiting for a trigger pulse.

When the voltage at the trigger input drops below  $1/3 V_{CC}$ , the trigger comparator output changes from low to high, which causes *Q* to toggle to the low state. This turns off the transistor (opens the switch) and allows *C* to begin charging toward  $V_{CC}$ .

When *C* reaches  $2/3 V_{CC}$ , this causes the threshold comparator to switch its output from low to high and that resets the flip-flop. *Q* returns high, turning on the transistor and discharging *C*. The circuit has returned to its stable state. The output pulse length for the monostable configuration is:

$$T = 1.1R C_1$$

Notice that the timing is independent of the absolute value of  $V_{CC}$  — the output pulse width is the same with a 5 V supply as it is with a 15 V supply. This is because the 555 design is based on ratios and not absolute voltage levels.

### THE ASTABLE MULTIVIBRATOR

The complement to the monostable circuit is the astable circuit in **Figure 4.87**. Pins 2, 6 and 7 are configured differently and timing resistor is now split into two resistors, R1 and R2.

Start from the same state as the monostable circuit, with C completely discharged. The monostable circuit requires a trigger pulse to initiate the timing cycle. In the astable circuit, the trigger input is connected directly to the capacitor, so if the capacitor is discharged, then the trigger comparator output must be high. Q is low, turning off the discharge transistor, which allows C to immediately begin charging.

C charges toward  $V_{CC}$ , but now through the combination of R1 and R2. As the capacitor voltage passes  $2/3 V_{CC}$ , the threshold comparator output changes from low to high, resetting Q to high. This turns on the discharge transistor and the capacitor starts to discharge through R2. When the capacitor is discharged below  $1/3 V_{CC}$ , the trigger comparator changes from high to low and the cycle begins again, automatically. This happens over and over, causing a train of pulses at the output while C charges and discharges between  $1/3$  and  $2/3 V_{CC}$  as seen in the figure.

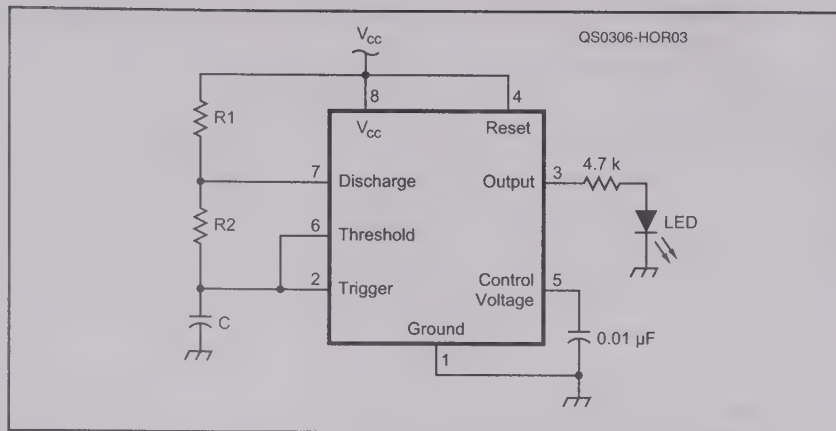

The total time it takes for one complete cycle is the charge time,  $T_c$ , plus the discharge time,  $T_d$ :

$$T = T_c + T_d = 0.693(R_1 + R_2)C + 0.693 R_2 C = 0.693 (R_1 + 2R_2)C$$

and the output frequency is:

$$f = \frac{1}{T} = \frac{1.443}{(R_1 + 2R_2)C}$$

When using the 555 in an application in or around radios, it is important to block any RF signals from the IC power supply or timing control inputs. Any unwanted signal present on these inputs, especially the Control Voltage input, will upset the timer's operation and cause it to operate improperly. The usual practice is to use a  $0.01 \mu\text{F}$  bypass capacitor (shown on pin 5 in both **Figure 4.86** and **4.87**) to bypass ac signals such as noise or RF to ground. Abrupt changes in  $V_{CC}$  will also cause changes in timing and these may be prevented by connecting filter capacitors at the  $V_{CC}$  input to ground.

**Figure 4.87** — Astable timer. If the capacitor discharge process initiates the next charge cycle, the timer will output a pulse train continuously.

### 4.8.4 Analog Switches and Multiplexers

Arrays of analog switches, such as the Maxim MAX312-series, allow routing of audio through lower frequency RF signals without mechanical switches. There are several types of switch arrays. Independent switches have isolated inputs and outputs and are turned on and off independently. Both SPST and SPDT configurations are available. Multiple switches can be wired with common control signals to implement multiple-pole configurations.

Use of analog switches at RF through microwave frequencies requires devices specifically designed for those frequencies. The Analog Devices ADG901 is a switch usable to 2.5 GHz. It absorbs the signal when off, acting as a terminating load. The ADG902 instead reflects the signal as an open circuit when off. Arrays of three switches called “tee-switches” are used when very high isolation between the input and output is required.

*Multiplexers* or “muxes” are arrays of SPST switches configured to act as a multi-position switch that connects one of four to sixteen input signals to a single output. Demultiplexers (“demuxes”) have a single input and multiple outputs. Multiplexer ICs are available as single N-to-1 switches (the MAX4617 is an 8-to-1 mux) or as groups of N-to-1 switches (the MAX4618 is a dual 4-to-1 mux).

*Crosspoint* switch arrays are arranged so that any of four to sixteen signal inputs can be connected to any of four to sixteen output signal lines. The Analog Devices AD8108 is an 8-by-8 crosspoint switch with eight inputs and eight outputs. These arrays are used when it is necessary to switch multiple signal

sources among multiple signal receivers. They are most commonly used in telecommunications.

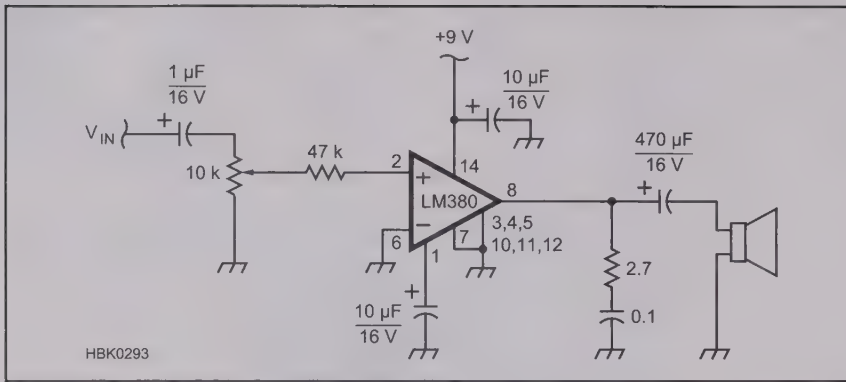

All analog switches use FET technology as the switching element. To switch ac signals, most analog switches require both positive and negative voltage power supplies. An alternative is to use a single power supply voltage and ground, but bias all inputs and output at one-half the power supply voltage. This requires dc blocking capacitors in all signal paths, both input and output, and loading resistors may be required at the device outputs. The blocking capacitors can also introduce low-frequency roll-off.

The impedance of the switching element varies from a few ohms to more than 100 ohms. Check the switch data sheet to determine the limits for how much power and current the switches can handle. Switch arrays, because of the physical size of the array, can have significant coupling or *crossstalk* between signal paths. Use caution when using analog switches for high-frequency signals as coupling generally increases with frequency and may compromise the isolation required for high selectivity in receivers and other RF signal processing equipment.

### 4.8.5 Audio Output Amplifiers

While it is possible to use op amps as low power audio output drivers for headphones, they generally have output impedances that are too high for most audio transducers such as speakers and headphones. The LM380 series of audio driver ICs has been used in radio circuits for many years and a simple schematic for a speaker driver is shown in **Figure 4.88**.

The popularity of personal music players

**Figure 4.88 — Speaker driver.** The LM380-series of audio output drivers are well-suited for low-power audio outputs, such as for headphones and small speakers. When using IC audio output drivers, be sure to refer to the manufacturer's data sheet for layout and power supply guidelines.

has resulted in the creation of many new and inexpensive audio driver ICs, such as the National Semiconductor LM4800- and LM4900-series. Drivers that operate from voltages as low as 1.5 V for battery-powered devices and up to 18 V for use in vehicles are now available.

When choosing an audio driver IC for communications audio, the most important

parameters to evaluate are its power requirements and power output capabilities. An overloaded or underpowered driver will result in distortion. Driver ICs intended for music players have frequency responses well in excess of the 3000 Hz required for communications. This can lead to annoying and fatiguing hiss unless steps are taken to reduce

the circuit's frequency response.

Audio power amplifiers should also be carefully decoupled from the power supply and the manufacturer may recommend specific circuit layouts to prevent oscillation or feedback. Check the device's data sheet for this information.

#### 4.8.6 Temperature Sensors

Active temperature sensors use the temperature-dependent properties of semiconductor devices to create voltages that correspond to absolute temperature in degrees Fahrenheit (LM34) or degrees Celsius (LM35). These sensors (of which many others are available than the two examples given here) are available in small plastic packages, both leaded and surface-mount, that respond quickly to temperature changes. They are available with 1% and better accuracy, requiring only a source of voltage at very low current and ground. Complete application information is available in the manufacturer data sheets. Thermistors, a type of passive temperature sensor, are discussed in the Thermal Management section of this chapter. Temperature sensors are used in radio mostly in cooling and temperature control circuits.

# 4.9 Analog-Digital Interfacing

Quite often, logic circuits must either drive or be driven from non-logic sources. A very common requirement is sensing the presence or absence of a high (as compared to +5 V) voltage or perhaps turning on or off a 120 V ac device or moving the motor in an antenna rotator. A similar problem occurs when two different units in the shack must be interfaced because induced ac voltages or ground loops can cause problems with the desired signals.

A slow speed but safe way to interface such circuits is to use a relay. This provides absolute isolation between the logic circuits and the load. **Figure 4.89A** shows the correct way to provide this connection. The relay coil is selected to draw less than the available current from the driving logic circuit. The diode is called a *kickback* or *flyback diode* that clamps the *back EMF* switching transient generated when current through the

coil is interrupted. Voltage at the switching transistor from the transient can reach several hundred volts and damage or destroy the transistor. Use a 1N4148 for small relays or a 1N4001 for larger coils which generate higher surge currents. The use of a kickback diode can increase the turn-off time of the relay. If the turn-off time is an important part of the design, a Zener diode in series with the kickback diode can be used. The Zener voltage should be approximately twice the supply voltage (a 1N5252 is a 24V Zener). This will still result in some turn-off delay. Experimentation may be necessary to find the best trade-off between Zener voltage and turn-off time for critical circuits. Transzorb and MOVs can also be used. MOVs may change clamping voltages after extended use. A thorough discussion of relay drive protection can be found in STMicroelectronics Application Note AN-319, "Relay Drive Protection" which is available online from several sources.

For applications in which the relay is connected to circuits where strong RF might be present, such as antenna switches, rotator control cables, or tuning circuits, add a 0.01 to 0.001  $\mu\text{F}$  ceramic capacitor (rated at 50 V or more) in parallel with the coil to prevent the diode(s) or clamping devices from generating mixing products or harmonics. It is often not possible to find a relay that meets the load requirements *and* has a coil that can be driven directly from the logic output. **Figure 4.89B** shows two methods of using transistors to allow the use of higher power relays with logic gates.

Electro-optical couplers such as optoisolators and solid state relays can also be used for this circuit interfacing. **Figure 4.89C** uses an optoisolator to interface two sets of logic circuits that must be kept electrically isolated, and **Figure 4.89D** uses a solid state relay to control an ac line supply to a high current load. Note that this example uses a solid state relay with internal current limiting on the input side; the LED input has an impedance of approximately 300  $\Omega$ . Some devices may need a series resistor to set the LED current; always consult the device data sheet to avoid exceeding device limits of the relay or the processor's I/O pin. For safely using signals with voltages higher than logic levels as inputs, the same simple resistor and Zener diode circuit similar to that shown in **Figure 4.29** can be used to clamp the input voltage to an acceptable level. Care must be used to choose a resistor value that will not load the input signal unacceptably.

**Figure 4.89** — Interface circuits for logic driving real-world loads. (A) driving a relay from a logic output; (B) using a bipolar transistor or MOSFET to boost current capacity; (C) using an optoisolator for electrical isolation; (D) using a solid-state relay for switching ac loads.

## 4.10 Analog Device and Circuits Glossary

**AC ground** — A circuit connection point that presents a very low impedance to ac signals.

**Active** — A device that requires power to operate.

**Active region** — The region in the characteristic curve of an analog device in which it is capable of processing the signal linearly.

**Amplification** — The process by which amplitude of a signal is increased. Gain is the amount by which the signal is amplified.

**Analog signal** — A signal that can have any amplitude (voltage or current) value and exists at any point in time.

**Anode** — The element of an analog device that accepts electrons or toward which electrons flow.

**Attenuation** — The process of reducing the amplitude of a signal.

**Avalanche breakdown** — Current flow through a semiconductor device in response to an applied voltage beyond the device's ability to control or block current flow.

**Base** — The terminal of a bipolar transistor in which control current flows.

**Beta** ( $\beta$ ) — The dc current gain of a bipolar transistor, also designated  $h_{FE}$ .

**Biasing** — The addition of a dc voltage or current to a signal at the input of an analog device, changing or controlling the position of the device's operating point on the characteristic curve.

**Bipolar transistor** — An analog device made by sandwiching a layer of doped semiconductor between two layers of the opposite type: PNP or NPN.

**Black box** — Circuit or equipment that is analyzed only with regards to its external behavior.

**Bode plot** — Graphs showing amplitude response in dB and phase response in degrees versus frequency on a logarithmic scale.

**Buffer** — An analog stage that prevents loading of one analog stage by another.

**Carrier** — (1) Free electrons and holes in semiconductor material. (2) An unmodulated component of a modulated signal.

**Cascade** — Placing one analog stage after another to combine their effects on the signal.

**Cathode** — The element of an analog device that emits electrons or from which electrons are emitted or repelled.

**Characteristic curve** — A plot of the relative responses of two or three analog-device parameters, usually of an output with respect to an input. (Also called *I-V* or *V-I curve*.)

**Class (amplifier)** — For analog amplifiers (Class A, B, AB, C), a categorization of the fraction of the input signal cycle during which the amplifying device is active. For digital or switching amplifiers (Class D and above), a categorization of the method by which the signal is amplified.

**Clipping** — A nonlinearity in amplification in which the signal's amplitude can no longer be increased, usually resulting in distortion of the waveform. (Also called *clamping* or *limiting*.)

**Closed-loop gain** — Amplifier gain with an external feedback circuit connected.

**Collector** — The terminal of a bipolar transistor from which electrons are removed.

**Common** — A terminal shared by more than one port of a circuit or network.

**Common mode** — Signals that appear equally on all terminals of a signal port.

**Comparator** — A circuit, usually an amplifier, whose output indicates the relative amplitude of two input signals.

**Compensation** — The process of counteracting the effects of signals that are inadvertently fed back from the output to the input of an analog system. Compensation increases stability and prevents oscillation.

**Compression** — Reducing the dynamic range of a signal in order to increase the average power of the signal or prevent excessive signal levels.

**Conversion efficiency** — The amount of light energy converted to electrical energy by a photoelectric device, expressed in percent.

**Coupling (ac or dc)** — The type of connection between two circuits. DC coupling allows dc current to flow through the connection. AC coupling blocks dc current while allowing ac current to flow.

**Cutoff frequency** — Frequency at which a circuit's amplitude response is reduced to one-half its mid-band value (also called *half-power* or *corner frequency*).

**Cutoff (region)** — The region in the characteristic curve of an analog device in which there is no current through the device. Also called the OFF region.

**Degeneration (emitter or source)** — Negative feedback from the voltage drop across an emitter or source resistor in order to stabilize a circuit's bias and operating point.

**Depletion mode** — An FET with a channel that conducts current with zero gate-to-source voltage and whose conductivity is progressively reduced as reverse bias is applied.

**Depletion region** — The narrow region at a

PN junction in which majority carriers have been removed. (Also called *space-charge* or *transition region*.)

**Diode** — A two-element semiconductor with a cathode and an anode that conducts current in only one direction.

**Drain** — The connection at one end of a field-effect-transistor channel from which electrons are removed.

**Dynamic range** — The range of signal levels over which a circuit operates properly. Usually refers to the range over which signals are processed linearly.

**Emitter** — The terminal of a bipolar transistor into which electrons are injected.

**Enhancement mode** — An FET with a channel that does not conduct with zero gate-to-source voltage and whose conductivity is progressively increased as forward bias is applied.

**Feedback** — Routing a portion of an output signal back to the input of a circuit. Positive feedback causes the input signal to be reinforced. Negative feedback results in partial cancellation of the input signal.

**Field-effect transistor (FET)** — An analog device with a semiconductor channel whose width can be modified by an electric field. (Also called *unipolar transistor*.)

**Forward bias** — Voltage applied across a PN junction in the direction to cause current flow.

**Forward voltage** — The voltage required to cause forward current to flow through a PN junction.

**Free electron** — An electron in a semiconductor crystal lattice that is not bound to any atom.

**Frequency response** — A description of a circuit's gain (or other behavior) with frequency.

**Gain** — see *Amplification*.

**Gain-bandwidth product** — The relationship between amplification and frequency that defines the limits of the ability of a device to act as a linear amplifier. In many amplifiers, gain times bandwidth is approximately constant.

**Gate** — The control electrode of a field-effect transistor.

**High-side** — A switch or controlling device connecting between a power source and load.

**Hole** — A positively charged carrier that results when an electron is removed from an atom in a semiconductor crystal structure.

**Hysteresis** — In a comparator circuit, the practice of using positive feedback to shift the input setpoint in such a way as

- to minimize output changes when the input signal(s) are near the setpoint.
- Integrated circuit (IC)** — A semiconductor device in which many components, such as diodes, bipolar transistors, field-effect transistors, resistors and capacitors are fabricated to make an entire circuit.
- Isolation** — Eliminating or reducing electrical contact between one portion of a circuit and another or between pieces of equipment.
- Junction FET (JFET)** — A field-effect transistor whose gate electrode forms a PN junction with the channel.
- Linearity** — Processing and combining of analog signals independently of amplitude.
- Load line** — A line drawn through a family of characteristic curves that shows the operating points of an analog device for a given load or circuit component values.
- Loading** — The condition that occurs when the output behavior of a circuit is affected by the connection of another circuit to that output.
- Low-side** — A switch or controlling device connected between a load and ground.
- Metal-oxide semiconductor (MOSFET)** — A field-effect transistor whose gate is insulated from the channel by an oxide layer. (Also called *insulated gate FET* or *IGFET*)
- Multivibrator** — A circuit that oscillates between two states.
- NMOS** — N-channel MOSFET.
- N-type impurity** — A doping atom with an excess of valence electrons that is added to semiconductor material to act as a source of free electrons.
- Network** — General name for any type of circuit.
- Noise** — Any unwanted signal, usually random in nature.
- Open-loop gain** — Gain of an amplifier with no feedback connection.
- Operating point** — Values of a set of circuit parameters that specify a device's operation at a particular time.
- Operational amplifier (op amp)** — An integrated circuit amplifier with high open-loop gain, high input impedance, and low output impedance.
- Optoisolator** — A device in which current in a light-emitting diode controls the operation of a phototransistor without a direct electrical connection between them.
- Oscillator** — A circuit whose output varies continuously and repeatedly, usually at a single frequency.
- P-type impurity** — A doping atom with a shortage of valence electrons that is added to semiconductor material to create an excess of holes.
- Passive** — A device that does not require power to operate.
- Peak inverse voltage (PIV)** — The highest voltage that can be tolerated by a reverse biased PN junction before current is conducted. (See also *avalanche breakdown*.)
- Photoconductivity** — Phenomenon in which light affects the conductivity of semiconductor material.
- Photoelectricity** — Phenomenon in which light causes current to flow in semiconductor material.
- PMOS** — P-channel MOSFET.
- PN junction** — The structure that forms when P-type semiconductor material is placed in contact with N-type semiconductor material.
- Pole** — Frequency at which a circuit's transfer function becomes infinite.
- Port** — A pair of terminals through which a signal is applied to or output from a circuit.
- Quiescent (Q-) point** — Circuit or device's operating point with no input signal applied. (Also called *bias point*.)
- Pinch-off** — The condition in an FET in which the channel conductivity has been reduced to zero.
- Rail** — Power supply voltage(s) for a circuit.
- Range** — The total span of analog values that can be processed by an analog-to-digital conversion.
- Recombination** — The process by which free electrons and holes are combined to produce current flow across a PN junction.
- Recovery time** — The amount of time required for carriers to be removed from a PN junction device's depletion region, halting current flow.
- Rectify** — Convert ac to pulsating dc.
- Resolution** — Smallest change in an analog value that can be represented in a conversion between analog and digital quantities. (Also called *step size*.)
- Reverse bias** — Voltage applied across a PN junction in the direction that does not cause current flow.
- Reverse breakdown** — The condition in which reverse bias across a PN junction exceeds the ability of the depletion region to block current flow. (See also *avalanche breakdown*.)
- Roll-off** — Change in a circuit's amplitude response per octave or decade of frequency.
- Safe operating area (SOA)** — The region of a device's characteristic curve in which it can operate without damage.
- Saturation (region)** — The region in the characteristic curve of an analog device in which the output signal can no longer be increased by the input signal. See *Clipping*.
- Schottky barrier** — A metal-to-semiconductor junction at which a depletion region is formed, similarly to a PN junction.
- Semiconductor** — (1) An element such as silicon with bulk conductivity between that of an insulator and a metal. (2) An electronic device whose function is created by a structure of chemically-modified semiconductor materials.
- Signal-to-noise ratio (SNR)** — The ratio of the strength of the desired signal to that of the unwanted signal (noise), usually expressed in dB.
- Slew rate** — The maximum rate at which a device can change the amplitude of its output.
- Small-signal** — Conditions under which the variations in circuit parameters due to the input signal are small compared to the quiescent operating point and the device is operating in its active region.
- Source** — The connection at one end of the channel of a field-effect transistor into which electrons are injected.
- Stage** — One of a series of sequential signal processing circuits or devices.
- Substrate** — Base layer of material on which the structure of a semiconductor device is constructed.
- Superposition** — Process in which two or more signals are added together linearly.
- Total harmonic distortion (THD)** — A measure of how much noise and distortion are introduced by a signal processing function.
- Thermal runaway** — The condition in which increasing device temperature increases device current in a positive feedback cycle.
- Transconductance** — Ratio of output current to input voltage, with units of Siemens (S).
- Transfer characteristics** — A set of parameters that describe how a circuit or network behaves at and between its signal interfaces.
- Transfer function** — A mathematical expression of how a circuit modifies an input signal.
- Unipolar transistor** — see *Field-effect transistor (FET)*.
- Virtual ground** — Point in a circuit maintained at ground potential by the circuit without it actually being connected to ground.
- Zener diode** — A heavily-doped PN-junction diode with a controlled reverse breakdown voltage, used as a voltage reference or regulator.
- Zero** — Frequency at which a circuit's transfer function becomes zero.

# 4.11 Heat Management

While not strictly an electrical fundamental, managing the heat generated by electronic circuits is important in nearly all types of radio equipment. Thus, the topic is included in this chapter. Information on the devices and circuits discussed in this section may be found in other chapters.

Any actual energized circuit consumes electric power because any such circuit contains components that convert electricity into other forms of energy. This dissipated power appears in many forms. For example, a loudspeaker converts electrical energy into sound, the motion of air molecules. An antenna (or a light bulb) converts electricity into electromagnetic radiation. Charging a battery converts electrical energy into chemical energy (which is then converted back to electrical energy upon discharge). But the most common transformation by far is the conversion, through some form of resistance, of electricity into heat.

Sometimes the power lost to heat serves a useful purpose — toasters and hair dryers come to mind. But most of the time, this heat represents a power loss that is to be minimized wherever possible or at least taken into account. Since all real circuits contain resistance, even those circuits (such as a loudspeaker) whose primary purpose is to convert electricity to some *other* form of energy also convert some part of their input power to heat. Often, such losses are negligible, but sometimes they are not.

If unintended heat generation becomes significant, the involved components will get warm. Problems arise when the temperature increase affects circuit operation by either

- causing the component to fail, by explosion, melting, or other catastrophic event, or, more subtly,
- causing a slight change in the properties of the component, such as through a temperature coefficient (TC).

In the first case, we can design conservatively, ensuring that components are rated to safely handle two, three or more times the maximum power we expect them to dissipate. In the second case, we can specify components with low TCs, or we can design the circuit to minimize the effect of any one component. Occasionally we even exploit temperature effects (for example, using a resistor, capacitor or diode as a temperature sensor). Let's look more closely at the two main categories of thermal effects.

Not surprisingly, heat dissipation (more correctly, the efficient removal of generated heat) becomes important in medium- to high-power circuits: power supplies, transmitting circuits and so on. While these are not the only examples where elevated temperatures

and related failures are of concern, the techniques we will discuss here are applicable to all circuits.

## 4.11.1 Thermal Resistance

The transfer of heat energy, and thus the change in temperature, between two ends of a block of material is governed by the following heat flow equation and illustrated in **Figure 4.90**:

$$P = \frac{kA}{L} \Delta T = \frac{\Delta T}{\theta}$$

where

P = power (in the form of heat) conducted between the two points

k = *thermal conductivity*, measured in W/(m °C), of the material between the two points, which may be steel, silicon, copper, PC board material and so on

L = length of the block

A = area of the block, and

**Figure 4.90** — Physical and “circuit” models for the heat-flow equation.

**Table 4.3**  
**Thermal Conductivities of Various Materials**

Gases at 0 °C, Others at 25 °C; from *Physics*, by Halliday and Resnick, 3rd Ed.

Material	k in units of W/m°C
Aluminum	200
Brass	110
Copper	390
Lead	35
Silver	410
Steel	46
Silicon	150
Air	0.024
Glass	0.8

$\Delta T$  = *difference* in temperature between the two points.

Thermal conductivities of various common materials at room temperature are given in **Table 4.3**.

The heat flow equation has the same form as the variation of Ohm's Law relating current flow to the ratio of a difference in potential to resistance;  $I = E/R$ . In this case, what's flowing is heat (P), the difference in potential is a temperature difference ( $\Delta T$ ), and what's resisting the flow of heat is the *thermal resistance*;

$$\theta = \frac{L}{kA}$$

with units of °C/W. (The units of resistance are equivalent to V/A.) The analogy is so apt that the same principles and methods apply to heat flow problems as circuit problems. The following correspondences hold:

- Thermal conductivity W/(m °C) ↔ Electrical conductivity (S/m).
- Thermal resistance (°C/W) ↔ Electrical resistance (Ω).
- Thermal current (heat flow) (W) ↔ Electrical current (A).
- Thermal potential (T) ↔ Electrical potential (V).
- Heat source ↔ Power source.

For example, calculate the temperature of a 2-inch (0.05 m) long piece of #12 copper wire at the end that is being heated by a 25 W (input power) soldering iron, and whose other end is clamped to a large metal vise (assumed to be an infinite heat sink), if the ambient temperature is 25 °C (77 °F).

First, calculate the thermal resistance of the copper wire (diameter of #12 wire is 2.052 mm, cross-sectional area is  $3.31 \times 10^{-6} \text{ m}^2$ )

$$\theta = \frac{L}{kA} = \frac{(0.05 \text{ m})}{(390 \text{ W / (m °C)}) \times (3.31 \times 10^{-6} \text{ m}^2)} = 38.7 \text{ °C/W}$$

Then, rearranging the heat flow equation above yields (after assuming the heat energy actually transferred to the wire is around 10 W)

$$\Delta T = P \theta = (10 \text{ W}) \times (38.7 \text{ °C/W}) = 387 \text{ °C}$$

So the wire temperature at the hot end is  $25 \text{ °C} + \Delta T = 412 \text{ °C}$  (or 774 °F). If this sounds a little high, remember that this is for the steady state condition, where you've been holding the iron to the wire for a long time.

From this example, you can see that things can get very hot even with application of moderate power levels. For this reason, circuits

that generate sufficient heat to alter, not necessarily damage, the components must employ some method of cooling, either active or passive. Passive methods include heat sinks or careful component layout for good ventilation. Active methods include forced air (fans) or some sort of liquid cooling (in some high-power transmitters).

#### 4.11.2 Heat Sink Selection and Use

The purpose of a heat sink is to provide a high-power component with a large surface area through which to dissipate heat. To use the models above, it provides a low thermal-resistance path to a cooler temperature, thus allowing the hot component to conduct a large “thermal current” away from itself.

Power supplies probably represent one of the most common high-power circuits amateurs are likely to encounter. Everyone has certainly noticed that power supplies get warm or even hot if not ventilated properly. Performing the thermal design for a properly cooled power supply is a very well-defined process and is a good illustration of heat-flow concepts.

This material was originally prepared by ARRL Technical Advisor Dick Jansson, KD1K, during the design of a 28-V, 10-A power supply. (Power Sources chapter has more information on power supply design.) An outline of the design procedure shows the logic applied:

1. Determine the expected power dissipation ( $P_{in}$ ).
2. Identify the requirements for the dissipating elements (maximum component temperature).
3. Estimate heat-sink requirements.
4. Rework the electronic device (if necessary) to meet the thermal requirements.
5. Select the heat exchanger (from heat sink data sheets).

The first step is to estimate the filtered, unregulated supply voltage under full load. Since the transformer secondary output is 32 V ac (RMS) and feeds a full-wave bridge rectifier, let's estimate 40 V as the filtered dc output at a 10-A load.

The next step is to determine our critical components and estimate their power dissipations. In a regulated power supply, the pass transistors are responsible for nearly all the power lost to heat. Under full load, and allowing for some small voltage drops in the power-transistor emitter circuitry, the output of the series pass transistors is about 29 V for a delivered 28 V under a 10-A load. With an unregulated input voltage of 40 V, the total energy heat dissipated in the pass transistors is  $(40\text{ V} - 29\text{ V}) \times 10\text{ A} = 110\text{ W}$ . The heat sink for this power supply must be able to handle that amount of dissipation and still

Figure 4.91 — Resistive model of thermal conduction in a power transistor and associated heat sink. See text for calculations.

keep the transistor junctions below the specified safe operating temperature limits. It is a good rule of thumb to select a transistor that has a maximum power dissipation of twice the desired output power.

Now, consider the ratings of the pass transistors to be used. This supply calls for 2N3055s as pass transistors. The data sheet shows that a 2N3055 is rated for 15-A service and 115-W dissipation. But the design uses four in parallel. Why? Here we must look past the big, bold type at the top of the data sheet to such subtle characteristics as the junction-to-case thermal resistance,  $\theta_{jc}$ , and the maximum allowable junction temperature,  $T_j$ .

The 2N3055 data sheet shows  $\theta_{jc} = 1.52\text{ }^\circ\text{C/W}$ , and a maximum allowable case (and junction) temperature of  $220\text{ }^\circ\text{C}$ . While it seems that one 2N3055 could barely, on paper at least, handle the electrical requirements — at what temperature would it operate?

To answer that, we must model the entire “thermal circuit” of operation, starting with the transistor junction on one end and ending at some point with the ambient air. A reasonable model is shown in Figure 4.91. The ambient air is considered here as an infinite

heat sink; that is, its temperature is assumed to be a constant  $25\text{ }^\circ\text{C}$  ( $77\text{ }^\circ\text{F}$ ).  $\theta_{jc}$  is the thermal resistance from the transistor junction to its case.  $\theta_{cs}$  is the resistance of the mounting interface between the transistor case and the heat sink.  $\theta_{sa}$  is the thermal resistance between the heat sink and the ambient air. In this “circuit,” the generation of heat (the “thermal current source”) occurs in the transistor at  $P_{in}$ .

Proper mounting of most TO-3 package power transistors such as the 2N3055 requires that they have an electrical insulator between the transistor case and the heat sink. However, this electrical insulator must at the same time exhibit a low thermal resistance. To achieve a quality mounting, use thin polyimide or mica formed washers and a suitable thermal compound to exclude air from the interstitial space. “Thermal greases” are commonly available for this function. Any silicone grease may be used, but filled silicone oils made specifically for this purpose are better.

Using such techniques, a conservatively high value for  $\theta_{cs}$  is  $0.50\text{ }^\circ\text{C/W}$ . Lower values are possible, but the techniques needed to achieve them are expensive and not generally available to the average amateur. Further-

Figure 4.92 — Thermal resistance vs heat-sink volume for natural convection cooling and  $50\text{ }^\circ\text{C}$  temperature rise. The graph is based on engineering data from Wakefield Thermal Solutions, Inc.

more, this value of  $\theta_{cs}$  is already much lower than  $\theta_{jc}$ , which cannot be lowered without going to a somewhat more exotic pass transistor.

Finally, we need an estimate of  $\theta_{sa}$ . **Figure 4.92** shows the relationship of heat-sink volume to thermal resistance for natural-convection cooling. This relationship presumes the use of suitably spaced fins (0.35 inch or greater) and provides a “rough order-of-magnitude” value for sizing a heat sink. For a first calculation, let’s assume a heat sink of roughly  $6 \times 4 \times 2$  inch (48 cubic inches). From **Figure 4.92**, this yields a  $\theta_{sa}$  of about  $1 \text{ }^\circ\text{C/W}$ .

Returning to **Figure 4.91**, we can now calculate the approximate temperature increase of a single 2N3055:

$$\begin{aligned} \delta T &= P \theta_{\text{total}} \\ &= 110 \text{ W} \times (1.52 \text{ }^\circ\text{C/W} + 0.5 \text{ }^\circ\text{C/W} + 1.0 \text{ }^\circ\text{C/W}) \\ &= 332 \text{ }^\circ\text{C} \end{aligned}$$

Given the ambient temperature of  $25 \text{ }^\circ\text{C}$ , this puts the junction temperature  $T_j$  of the 2N3055 at  $25 + 332 = 357 \text{ }^\circ\text{C}$ ! This is clearly too high, so let’s work backward from the air end and calculate just how many transistors we need to handle the heat.

First, putting more 2N3055s in parallel means that we will have the thermal model illustrated in **Figure 4.93**, with several identical  $\theta_{jc}$  and  $\theta_{cs}$  in parallel, all funneled through the same  $\theta_{sa}$  (we have one heat sink).

Keeping in mind the physical size of the project, we could comfortably fit a heat sink of approximately 120 cubic inches ( $6 \times 5 \times 4$  inches), well within the range of commercially available heat sinks. Furthermore, this application can use a heat sink where only “wire access” to the transistor connections is required. This allows the selection of a more efficient design. In contrast, RF designs

require the transistor mounting surface to be completely exposed so that the PC board can be mounted close to the transistors to minimize parasitics. Looking at **Figure 4.92**, we see that a 120-cubic-inch heat sink yields a  $\theta_{sa}$  of  $0.55 \text{ }^\circ\text{C/W}$ . This means that the temperature of the heat sink when dissipating 110 W will be  $25 \text{ }^\circ\text{C} + (110 \text{ W} \times 0.55 \text{ }^\circ\text{C/W}) = 85.5 \text{ }^\circ\text{C}$ .

Industrial experience has shown that silicon transistors suffer substantial failure when junctions are operated at highly elevated temperatures. Most commercial and military specifications will usually not permit design junction temperatures to exceed  $125 \text{ }^\circ\text{C}$ . To arrive at a safe figure for our maximum allowed  $T_j$ , we must consider the intended use of the power supply. If we are using it in a 100% duty-cycle transmitting application such as RTTY or FM, the circuit will be dissipating 110 W continuously. For a lighter duty-cycle load such as CW or SSB, the “key-down” temperature can be slightly higher as long as the average is less than  $125 \text{ }^\circ\text{C}$ . In this intermittent type of service, a good conservative figure to use is  $T_j = 150 \text{ }^\circ\text{C}$ .

Given this scenario, the temperature rise across each transistor can be  $150 - 85.5 = 64.5 \text{ }^\circ\text{C}$ . Now, referencing **Figure 2.4.93**, remembering the total  $\theta$  for each 2N3055 is  $1.52 + 0.5 = 2.02 \text{ }^\circ\text{C/W}$ , we can calculate the maximum power each 2N3055 can safely dissipate:

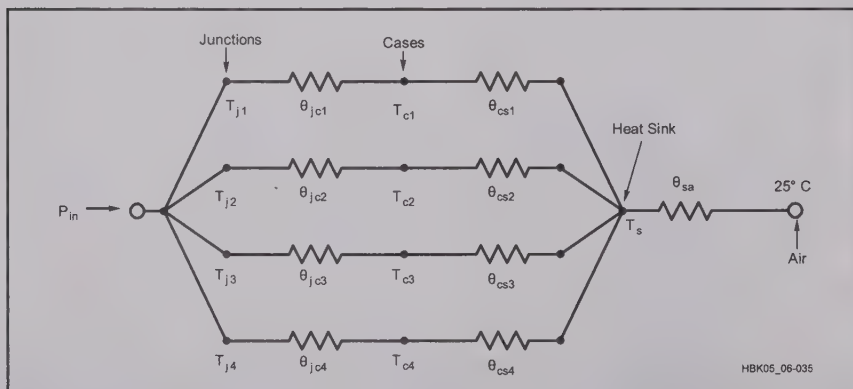

$$P = \frac{\delta T}{\theta} = \frac{64.5 \text{ }^\circ\text{C}}{2.02 \text{ }^\circ\text{C/W}} = 31.9 \text{ W}$$

Thus, for 110 W full load, we need four 2N3055s to meet the thermal requirements of the design. Now comes the big question: What is the “right” heat sink to use? We have already established its requirements: it must be capable of dissipating 110 W, and have a  $\theta_{sa}$  of  $0.55 \text{ }^\circ\text{C/W}$  (see above).

A quick consultation with several manufacturer’s catalogs reveals that Wakefield

Thermal Solutions, Inc. model nos. 441 and 435 heat sinks meet the needs of this application. A Thermalloy model no. 6441 is suitable as well. Data published in the catalogs of these manufacturers show that in natural-convection service, the expected temperature rise for 100 W dissipation would be just under  $60 \text{ }^\circ\text{C}$ , an almost perfect fit for this application. Moreover, the No. 441 heat sink can easily mount four TO-3-style 2N3055 transistors as shown in **Figure 4.94**. Remember: heat sinks should be mounted with the fins and transistor mounting area vertical to promote convection cooling.

The design procedure just described is applicable to any circuit where heat buildup is a potential problem. By using the thermal-resistance model, we can easily calculate

**Figure 4.93** — Thermal model for multiple power transistors mounted on a common heat sink.

**Figure 4.94** — A Wakefield 441 heat sink with four 2N3055 transistors mounted.

whether or not an external means of cooling is necessary, and if so, how to choose it. Aside from heat sinks, forced air cooling (fans) is another common method. In commercial transceivers, heat sinks with forced-air cooling are common.

### 4.11.3 Semiconductor Temperature Effects

The number of excess holes and electrons in semiconductor material is increased as the temperature of a semiconductor increases. Since the conductivity of a semiconductor is related to the number of excess carriers, this also increases with temperature. With respect to resistance, semiconductors have a negative temperature coefficient. The resistance of silicon *decreases* by about 8% per °C and by about 6% per °C for germanium. Semiconductor temperature properties are the opposite of most metals, which *increase* their resistance by about 0.4% per °C. These opposing temperature characteristics permit the design of circuits with opposite temperature coefficients that cancel each other out, making a temperature insensitive circuit.

Semiconductor devices can experience an effect called *thermal runaway* as the current causes an increase in temperature. (This is primarily an issue with bipolar transistors.) The increased temperature decreases resistance and may lead to a further increase in current (depending on the circuit) that leads to an additional temperature increase. This sequence of events can continue until the semiconductor destroys itself, so circuit design must include measures that compensate for the effects of temperature.

### Semiconductor Failure Caused by Heat

There are several common failure modes for semiconductors that are related to heat. The semiconductor material is connected to the outside world through metallic *bonding leads*. The point at which the lead and the semiconductor are connected is a common place for the semiconductor device to fail. As the device heats up and cools down, the materials expand and contract. The rate of expansion and contraction of semiconductor material is different from that of metal. Over many cycles of heating and cooling the bond between the semiconductor and the metal can break. Some experts have suggested that the lifetime of semiconductor equipment can be extended by leaving the devices powered on all the time, but this requires removal of the heat generated during normal operation.

A common failure mode of semiconductors is caused by the heat generated during semiconductor use. If the temperatures of the PN junctions remain at high enough levels for long enough periods of time, the impurities

resume their diffusion across the PN junctions. When enough of the impurity atoms cross the depletion region, majority carrier recombination stops functioning properly and the semiconductor device fails permanently.

Excessive temperature can also cause failure anywhere in the semiconductor from heat generation within any current-carrying conductor, such as an FET channel or the bonding leads. Integrated circuits with more than one output may have power dissipation limits that depend on how many of the outputs are active at one time. The high temperature can cause localized melting or cracking of the semiconductor material, causing a permanent failure.

Another heat-driven failure mode, usually not fatal to the semiconductor, is excessive leakage current or a shift in operating point that causes the circuit to operate improperly. This is a particular problem in complex integrated circuits — analog and digital — dissipating significant amounts of heat under normal operating conditions. Computer microprocessors are a good example, often requiring their own cooling systems. Once the device cools, normal operation is usually restored.

To reduce the risk of thermal failures, the designer must comply with the limits stated in the manufacturer's data sheet, devising an adequate heat removal system. (Thermal issues are discussed in the **Electrical Fundamentals** chapter.)

### 4.11.4 Safe Operating Area (SOA)

Devices intended for use in circuits handling high currents or voltages are specified to have a *safe operating area (SOA)*. This refers to the area drawn on the device's characteristic curve containing combinations of voltage and current that the device can be expected to control without damage under specific conditions. The SOA combines a number of limits — voltage, current, power, temperature and various breakdown mechanisms — in order to simplify the design of protective circuitry. The SOA is also specified to apply to specific durations of use — steady-state, long pulses, short pulses and so forth. The device may have separate SOAs for resistive and inductive loads.

You may also encounter two specialized types of SOA for turning the device on and off. *Reverse bias safe operating area (RBSOA)* applies when the device is turning off. *Forward bias safe operating area (FBSOA)* applies when turning the device on. These SOAs are used because the high rate-of-change of current and voltage places additional stresses on the semiconductor.

### 4.11.5 Semiconductor Derating

Maximum ratings for power transistors are usually based on a case temperature of 25 °C. These ratings will decrease with increasing operating temperature. Manufacturer's data sheets usually specify a *derating* figure or curve that indicates how the maximum ratings change per degree rise in temperature. If such information is not available (or even if it is!), it is a good rule of thumb to select a power transistor with a maximum power dissipation of at least twice the desired output power.

### RECTIFIERS

Diodes are physically quite small, and they operate at high current densities. As a result their heat-handling capabilities are somewhat limited. Normally, this is not a problem in high-voltage, low-current supplies in which rectifiers in axial-lead DO-type packages are used. (See the **Component Data and References** chapter for information on device packages.) The use of high-current (2 A or greater) rectifiers at or near their maximum ratings, however, requires some form of heat sinking. The average power dissipated by a rectifier is

$$P = I_{AVG} \times V_F$$

where

$I_{AVG}$  is the average current, and  
 $V_F$  is the forward voltage drop.

Average current must account for the conduction duty cycle and the forward voltage drop must be determined at the average current level.

Rectifiers intended for such high-current applications are available in a variety of packages suitable for mounting to flat surfaces. Frequently, mounting the rectifier on the main chassis (directly, or with thin mica insulating washers) will suffice. If the diode is insulated from the chassis, thin layers of thermal compound or thermal insulating washers should be used to ensure good heat conduction. Large, high-current rectifiers often require special heat sinks to maintain a safe operating temperature. Forced-air cooling is sometimes used as a further aid.

### 4.11.6 RF Heating

RF current often causes component heating problems where the same level of dc current may not. An example is the tank circuit of an RF oscillator. If several small capacitors are connected in parallel to achieve a desired capacitance, skin effect will be reduced and the total surface area available for heat dissipation will be increased, thus significantly reducing the RF heating effects as compared

to a single large capacitor. This technique can be applied to any similar situation; the general idea is to divide the heating among as many components as possible.

#### 4.11.7 Forced-Air and Water Cooling

In Amateur Radio today, forced-air cooling is most commonly found in vacuum-tube circuits or in power supplies built in small enclosures, such as those in solid-state transceivers or computers. Fans or blowers are commonly specified in cubic feet per minute (CFM). While the nomenclature and specifications differ from those used for heat sinks, the idea remains the same: to offer a low thermal resistance between the inside of the enclosure and the (ambient) exterior.

For forced air cooling, we basically use the “one resistor” thermal model of Figure 4.90. The important quantity to be determined is heat generation,  $P_{in}$ . For a power supply, this can be easily estimated as the difference between the input power, measured at the transformer primary, and the output power at full load. For variable-voltage supplies, the worst-case output condition is minimum voltage with maximum current. A discussion of forced-air cooling for vacuum tube equipment appears in the **RF Power Amplifiers** chapter. For an in-depth discussion of fan cooling, see the References entry for Rabassa’s February 2019 *QST* article.

Dust build-up is a common problem for forced-air cooling systems, even with powerful blowers and fans. If air intake grills and vents are not kept clean and free of lint and debris, air flow can be significantly reduced, leading to excessive equipment temperature and premature failure. Cleaning of air passageways should be included in regular equipment maintenance for good performance and maximum equipment life.

Water cooling systems are much less common in amateur equipment, used primarily for high duty cycle operating, such as RTTY, and at frequencies where the efficiency of the amplifier is relatively low, such as UHF and microwaves. In these situations, water cooling is used because water can absorb and transfer more than 3000 times as much heat as the same volume of air!

The main disadvantage of water cooling is that it requires pumps, hoses, and reservoirs whereas a fan or blower is all that is required for forced-air cooling. For high-voltage circuits, using water cooling also requires special insulation techniques and materials to allow water to circulate in close contact with the heat source while remaining electrically isolated.

Nevertheless, the technique can be effective. The increased availability of inexpensive materials designed for home sprinkler and

other low-pressure water distribution systems make water-cooling less difficult to implement. It is recommended that the interested reader review articles and projects in the amateur literature to observe the successful implementation of water cooling systems.

#### 4.11.8 Heat Pipe Cooling

A heat pipe is a device containing a *working fluid* in a reservoir where heat is absorbed and a channel to a second reservoir where heat is dissipated. Heat pipes work by *evaporative cooling*. The heat-absorbing reservoir is placed in thermal contact with the heat source which transfers heat to the working fluid, usually a liquid substance with a boiling point just above room temperature. The working fluid vaporizes and the resulting vapor pressure pushes the hot vapor through the channel to the cooling reservoir.

In the cooling reservoir, the working fluid gives up its heat of vaporization, returning to the fluid state. The cooled fluid then flows back through the channel to the heat-absorbing reservoir where the process is repeated.

Heat pipes require no fans or pumps — movement of the working fluid is driven entirely from the temperature difference between the two reservoirs. The higher the temperature difference between the absorbing and dissipating reservoirs, the more effective the heat pump becomes, up to the limit of the dissipating reservoir to dissipate heat.

The principle application for heat pipes is for space operations. Heat pipe applications in terrestrial applications are limited due to the gravity gradient sensitivity of heat pipes. At present, the only amateur equipment making use of heat pipes are computers and certain amplifier modules. Nevertheless, as more general-purpose products become available, this technique will become more common.

#### 4.11.9 Thermoelectric Cooling

Thermoelectric cooling makes use of the *Peltier effect* to create heat flow across the junction of two different types of materials. This process is related to the *thermoelectric effect* by which thermocouples generate voltages based on the temperature of a similar junction. A *thermoelectric cooler* or *TEC* (also known as a *Peltier cooler*) requires only a source of dc power to cause one side of the device to cool and the other side to warm. TECs are available with different sizes and power ratings for different applications.

TECs are not available with sufficient heat transfer capabilities that they can be used in high-power applications, such as RF amplifiers. However, they can be useful in lowering the temperature of sensitive receiver circuits,

such as preamplifiers used at UHF and microwave frequencies, or imaging devices, such as charge-coupled devices (CCDs). Satellites use TECs as *radiative coolers* that dissipate heat directly as thermal or infrared radiation. TECs are also found in some computing equipment where they are used to remove heat from microprocessors and other large integrated circuits.

#### 4.11.10 Temperature Compensation

Aside from catastrophic failure, temperature changes may also adversely affect circuits if the temperature coefficient (TC) of one or more components is too large. If the resultant change is not too critical, adequate temperature stability can often be achieved simply by using higher-precision components with low TCs (such as NP0/C0G capacitors or metal-film resistors). For applications where this is impractical or impossible (such as many solid-state circuits), we can minimize temperature sensitivity by *compensation* or *matching* — using temperature coefficients to our advantage.

Compensation is accomplished in one of two ways. If we wish to keep a certain circuit quantity constant, we can interconnect pairs of components that have equal but opposite TCs. For example, a resistor with a negative TC can be placed in series with a positive TC resistor to keep the total resistance constant. Conversely, if the important point is to keep the *difference* between two quantities constant, we can use components with the *same* TC so that the pair “tracks.” That is, they both change by the same amount with temperature.

An example of this is a Zener reference circuit. Since a diode is strongly affected by operating temperature, circuits that use diodes or transistors to generate stable reference voltages must use some form of temperature compensation. Since, for a constant current, a reverse-biased PN junction has a negative voltage TC while a forward-biased junction has a positive voltage TC, a good way to temperature-compensate a Zener reference diode is to place one or more forward-biased diodes in series with it.

#### 4.11.11 Thermistors

Thermistors can be used to control temperature and improve circuit behavior or protect against excessive temperatures, hot or cold. Circuit temperature variations can affect gain, distortion or control functions like receiver AGC or transmitter ALC. Thermistors can be used in circuits that compensate for temperature changes.

A *thermistor* is a small bit of intrinsic (no N or P doping) metal-oxide semiconductor compound material between two wire leads.

As temperature increases, the number of liberated hole/electron pairs increases exponentially, causing the resistance to decrease exponentially. You can see this in the resistance equation:

$$R(T) = R(T_0)e^{-\beta(1/T_0 - 1/T)}$$

where T is some temperature in Kelvins and T<sub>0</sub> is a reference temperature, usually 298 K (25°C), at which the manufacturer specifies R(T<sub>0</sub>).

The constant β is experimentally deter-

mined by measuring resistance at various temperatures and finding the value of β that best agrees with the measurements. A simple way to get an approximate value of β is to make two measurements, one at room temperature, say 25 °C (298 K) and one at 100 °C (373 K) in boiling water. Suppose the resistances are 10 kΩ and 938 Ω.

$$\beta = \frac{\ln\left(\frac{R(T)}{R(T_0)}\right)}{\frac{1}{T} - \frac{1}{T_0}} = \frac{\ln\left(\frac{938}{1000}\right)}{\frac{1}{373} - \frac{1}{298}} = 3507$$

With the behavior of the thermistor known — either by equation or calibration table — its change in resistance can be used to create an electronic circuit whose behavior is controlled by temperature in a known fashion. Such a circuit can be used for controlling temperature or detecting specific temperatures.

See “Thermistors in Homebrew Projects” by Bill Sabin, WØIYH, and “Thermistor Based Temperature Controller” by Bill Sabin, WØIYH in this book’s downloadable supplemental information for practical projects using thermistors.

# RF Techniques

This chapter is a compendium of material from ARRL publications and other sources. It assumes the reader is familiar with the concepts introduced in the **Electrical Fundamentals**, **Radio Fundamentals**, and **Circuits and Components** chapters. The topics and techniques discussed here are associated with the special demands of circuit design in the HF and VHF ranges. The material is collected from previous editions of this book written by Leonard Kay, K1NU; *Introduction to Radio Frequency Design* by Wes Hayward, W7ZOI; and *Experimental Methods in RF Design* by Wes Hayward, W7ZOI, Rick Campbell, KK7B, and Bob Larkin, W7PUA. Material on ferrites is drawn from publications by Jim Brown, K9YC. The section on Noise was written by Paul Wade, W1GHZ, with contributions from Joe Taylor, K1JT.

## 5.1 Introduction

When is an inductor not an inductor? When it's a capacitor! This statement may seem odd, but it suggests the main message of this chapter. In the earlier chapter, **Electrical Fundamentals**, the basic components of electronic circuits were introduced. As you may know from experience, those simple component pictures are ideal. That is, an ideal component (or element) by definition behaves exactly like the mathematical equations that describe it, and only in that fashion. For example, the current through an ideal capacitor is equal to the capacitance times the rate of change of the voltage across it without consideration of the materials or techniques by which a real capacitor is manufactured.

It is often said that, "Parasitics are anything you don't want," meaning that the component is exhibiting some behavior that detracts from or compromises its intended use. Real components only approximate ideal components, although sometimes quite closely. Any deviation from ideal behavior a component exhibits is called *non-ideal*, *parasitic*, or *stray*. One way of thinking about parasitic and stray effects — although this is by no means universal — is that parasitic effects are intrinsic to the component and stray effects include both parasitics and environmental effects such as coupling to nearby materials. Since most of what we'll discuss in the following sections deals with the characteristics of actual components, we'll use the term parasitic. Remember that stray and parasitic are often treated as interchangeable terms.

The important thing to realize is that *every* component has parasitic aspects that become significant when it is used in certain ways. This chapter deals with parasitic effects that are commonly encountered at radio frequencies. Knowing to what extent and under what conditions real components cease to behave like their ideal counterparts, and what can be done to account for these behaviors, allows the circuit designer or technician to work with circuits at radio frequencies. We will explore how and why the real components behave differently from ideal components, how we can account for those differences when analyzing circuits and how to select components to minimize, or exploit, non-ideal behaviors.

## 5.2 Lumped-Element versus Distributed Characteristics

Most electronic circuits that we use every day are inherently and mathematically considered to be composed of *lumped elements*. That is, we assume each component acts at a single point in space, and the wires that connect these lumped elements are assumed to be perfect conductors (with zero resistance and insignificant length). This concept is illustrated in **Figure 5.1**. These assumptions are perfectly reasonable for many applications, but they have limits. Lumped element models break down when:

- Circuit impedance is so low that the small, but non-zero, resistance in the wires is important. (A significant portion of the circuit power may be lost to heat in the conductors.)
- Lead and interconnection inductance is high enough (or the frequency is high enough) that the additional reactance affects circuit behavior.
- Operating frequency is high enough that the length of the connecting wires is a significant

**Figure 5.1 — The lumped element concept.** Ideally, the circuit at A is assumed to be as shown at B, where the components are isolated points connected by perfect conductors. Many components exhibit nonideal behavior when these assumptions no longer hold.

fraction ( $>0.1$ ) of the wavelength causing the propagation delay along the conductor or radiation from it to affect the circuit in which it is used.

- Transmission lines are used as conductors. (Their characteristic impedance is usually significant, and impedances connected to them are transformed as a function of the line length. See the **Transmission Lines** chapter for more information.)

Effects such as these are called *distributed*, and we talk of *distributed elements* or effects to contrast them to lumped elements.

To illustrate the differences between lumped and distributed elements, consider the two resistors in **Figure 5.2**, which are both 12 inches long. The resistor at A is a uniform rod of carbon. The second “resistor” B is made of two 6-inch pieces of silver rod (or other highly conductive material), with a small resistor soldered between them. Now imagine connecting the two probes of an ohmmeter to each of the two resistors, as in the figure. Starting with the probes at the far ends, as we slide the probes toward the center, the carbon rod will display a constantly decreasing resistance on the ohmmeter. This represents a distributed

**Figure 5.2 — Distributed (A) and lumped (B) resistances.** See text for discussion.

resistance. On the other hand, the ohmmeter connected to the other 12-inch “resistor” will display a constant resistance as long as one probe remains on each side of the small resistance and as long as we neglect the resistance of the silver rods! This represents a lumped resistance connected by perfect conductors.

Lumped elements also have the very desirable property that they introduce no phase shift resulting from propagation delay through the element. (Although combinations of lumped elements can produce phase shifts by virtue of their R, L and C properties.) Consider a lumped element that is carrying a sinusoidal current, as in **Figure 5.3A**. Since the element has negligible length, there is no phase difference in the current between the two sides of the element — *no matter how high the frequency* — precisely *because* the element length is negligible. If the physical length of

**Figure 5.3 — The effects of distributed resistance on the phase of a sinusoidal current.** There is no phase delay between ends of a lumped element.

the element were long, say  $0.25$  wavelength ( $0.25 \lambda$ ) as shown in **Figure 5.3B**, the current phase would *not* be the same from end to end. In this instance, the current is delayed by 90 electrical degrees as it moves along the element. The amount of phase difference depends on the circuit’s electrical length.

Because the relationship between the physical size of a circuit and the wavelength of an ac current present in the circuit will vary as the frequency of the ac signal varies, the ideas of lumped and distributed effects actually occupy two ends of a spectrum. At HF (30 MHz and below), where  $\lambda \geq 10$  m, the lumped element concept is almost always valid. In the UHF and microwave region (300 MHz and above), where  $\lambda \leq 1$  m and physical component size can represent a significant fraction of a wavelength, nearly all components and wiring exhibits distributed effects to one degree or another. From roughly 30 to 300 MHz, whether the distributed effects are significant must be considered on a case-by-case basis.

Of course, if we could make resistors, capacitors, inductors and so on, very small, we could treat them as lumped elements at much higher frequencies. For example, surface-mount components, which are manufactured in very small, leadless packages, can be used at much higher frequencies than leaded components and with fewer non-ideal effects.

It is for these reasons that circuits and equipment are often specified to work within specific frequency ranges. Outside of these ranges the designer’s assumptions about the physical characteristics of the components and the methods and materials of the circuit’s assembly become increasingly invalid. At frequencies sufficiently removed from the design range, circuit behavior often changes in unpredictable ways.

## 5.3 Effects of Parasitic (Stray) Characteristics

Parasitic effects can be important at almost any frequency where performance is held to tight specifications. Stray reactances can have a big effect even at audio frequencies, for example. Lightning protection is very sensitive to grounding conductor inductance. Power connections to high-current solid-state amplifiers must have very low resistance, and so on. At HF and above (where we do much of our circuit design) these considerations become very important, in some cases dominant, in the models we use to describe our components. To understand what happens to circuits at RF we turn to a brief discussion of some electromagnetic and microwave theory concepts.

Parasitic effects due to component leads, packaging, leakage and so on are relatively common to all components. When working at frequencies where many or all of the parasitics become important, a complex but completely general model such as that in **Figure 5.4** can be used for just about any component, with the actual component placed in the box marked \*. Parasitic capacitance,  $C_p$ , and leakage conductance,  $G_L$ , appear in parallel across the device, while series resistance,  $R_s$ , and parasitic inductance,  $L_s$ , appear in series with it. Package capacitance,  $C_{pkg}$ , appears as an additional capacitance in parallel across the whole device.

These small parasitics can significantly affect frequency responses of RF circuits. Either take steps to minimize or eliminate them, or use simple circuit theory to predict and anticipate changes. This maze of effects may seem overwhelming, but remember that it is very seldom necessary to consider all parasitics at all frequencies and for all applications. The **Computer-Aided Circuit Design** chapter shows how to incorporate the effect of multiple parasitics into circuit design and performance modeling. Files for the *LTSpice* simulation package that include parasitic characteristics for a resistor, capacitor and inductor are provided in the downloadable supplemental information for this *Handbook*.

### 5.3.1 Parasitic Inductance

Maxwell's equations — the basic laws of electromagnetism that govern the propagation of electromagnetic waves and the operation of all electronic components — tell us that any wire carrying a current that changes with time (one example is a sine wave) develops a changing magnetic field around it. This changing magnetic field in turn induces an opposing voltage, or *back EMF*, on the wire. The back EMF is proportional to how fast the current changes (see **Figure 5.5**).

We exploit this phenomenon when we make an inductor. The reason we typically form inductors in the shape of a coil is to concentrate the magnetic field and thereby maxi-

**Figure 5.4** — A general model for electrical components at VHF frequencies and above. The box marked \* represents the component. See text for discussion.

**Figure 5.5** — Inductive consequences of Maxwell's equations. At A, any wire carrying a changing current develops a voltage difference along it. This can be mathematically described as an effective inductance. B adds parasitic inductance to a generic component model.

**Figure 5.6** — A plot of inductance vs length for straight conductors in several wire sizes.

mize the inductance for a given physical size. However, *all* wires carrying varying currents have these inductive properties. This includes the wires we use to connect our circuits, and even the *leads* of capacitors, resistors and so on. The inductance of a straight, round, nonmagnetic wire in free space is given by:

$$L = 0.00508 b \left[ \ln \left( \frac{2b}{a} \right) - 0.75 \right] \quad (1)$$

where

- L = inductance, in  $\mu\text{H}$
- a = wire radius, in inches
- b = wire length, in inches
- ln = natural logarithm ( $2.303 \times \log_{10}$ )

Skin effect (discussed below) changes this formula slightly at VHF and above. As the frequency approaches infinity, the value 0.75 in the above equation increases to approach 1. This effect usually causes a change of no more than a few percent.

As an example, let's find the inductance of a typical #18 wire (diameter = 0.0403 inch and a = 0.0201) that is 4 inches long (b = 4):

$$L = 0.00508 (4) \left[ \ln \left( \frac{8}{0.0201} \right) - 0.75 \right]$$

$$= 0.0203 [5.98 - 0.75] = 0.106 \mu\text{H}$$

Wire of this diameter has an inductance of about 25 nH per inch of length. In circuits operating at VHF and higher frequencies, including high-speed digital circuits, the inductance of component leads can become sig-

nificant. (The #24 AWG wire typically used for component leads has an inductance on the order of 20 nH per inch.) At these frequencies, lead inductance can affect circuit behavior, making the circuit hard to reproduce or repair. Good design and construction practice is to minimize the effects of lead inductance by using surface-mount components or trimming the leads to be as short as possible.

The impact of reactance due to parasitic inductance is usually very small; at AF or LF, parasitic inductive reactance of most components is practically zero. To use this example, the reactance of a 0.106  $\mu\text{H}$  inductor even at 10 MHz is only 6.6  $\Omega$ . **Figure 5.6** shows a graph of the inductance for wires of various gauges (radii) as a function of length. Whether the reactance is significant or not depends on the application and the frequency of use.

We can represent parasitic inductance in component models by adding an inductor of appropriate value in series with the component since the wire leads are in series with the element. This (among other reasons) is why minimizing lead lengths and interconnecting wires becomes very important when designing circuits for VHF and above.

### PARASITIC INDUCTANCE IN RESISTORS

The basic construction of common resistor types is shown in **Figure 5.7**. The primary parasitic effect associated with resistors is parasitic inductance. (Some parasitic capacitance exists between the leads or electrodes due to packaging.) **Figure 5.8** shows some more

accurate circuit models for resistors at low to medium frequencies. The type of resistor with the most parasitic inductance are wire-wound resistors, essentially inductors used as resistors. Their use is therefore limited to dc or low-frequency ac applications where their reactance is negligible. Remember that this inductance will also affect switching transient waveforms, because the component will act as an RL circuit. The inductive effects of wire-wound resistors begin to become significant in the audio range above a few kHz.

As an example, consider a 1- $\Omega$  wire-wound resistor formed from 300 turns of #24 wire closely-wound in a single layer 6.3 inches long on a 0.5-inch diameter form. What is its approximate inductance? From the inductance formula for air-wound coils in the **Electrical Fundamentals** chapter:

$$L = \frac{d^2 n^2}{18d + 40l} = \frac{0.5^2 \times 300^2}{(18 \times 0.5) + (40 \times 6.3)} = 86 \mu\text{H}$$

If we want the inductive reactance to be less than 10% of the resistor value, then this resistor cannot be used above  $f = 0.1 / (2\pi \times 86 \mu\text{H}) = 185 \text{ Hz}$ ! Real wire-wound resistors have multiple windings layered over each other to minimize both size and parasitic inductance (by winding each layer in opposite directions, much of the inductance is canceled). If we assume a five-layer winding, the length is reduced to 1.8 inches and the inductance to approximately 17  $\mu\text{H}$ , so the resistor can then be used below 937 Hz. (This has the effect of increasing the resistor's parasitic capacitance, however.)

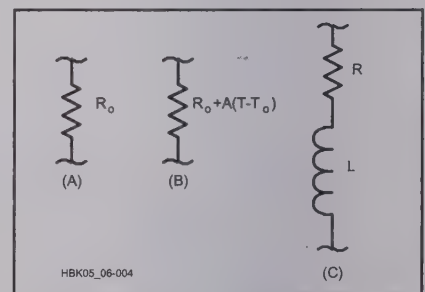

The resistance of certain types of tubular film resistors is controlled by inscribing a spiral path through the film on the inside of the tube. This creates a small inductance that may be significant at and above the higher audio frequencies.

### NON-INDUCTIVE RESISTORS

The resistors with the least amount of parasitic inductance are the bulk resistors, such

**Figure 5.7** — The electrical characteristics of different resistor types are strongly affected by their construction. Reactance from parasitic inductance and capacitance strongly impacts the resistor's behavior at RF.

**Figure 5.8** — Circuit models for resistors. The wire-wound model with associated inductance is shown at C. B includes the effect of temperature (T). For designs at VHF and higher frequencies, the model at C can be used with L representing lead inductance.

as carbon-composition, metal-oxide, and ceramic resistors. These resistors are made from a single linear cylinder, tube or block of resistive material so that inductance is minimized. Each type of resistor has a maximum usable frequency, above which parasitic capacitance and inductance begin to become significant. Review the manufacturer's data sheet for the component to learn about its performance at high frequencies.

Some resistors advertised as "noninductive" are actually wire-wound resistors with a special winding technique that minimizes inductance. These resistors are intended for use at audio frequencies and are not suitable for use at RF. If you are not sure, ask the vendor if the resistors are suitable for use in RF circuits.

Because resistors are manufactured with an insulating coating, it can be difficult to determine their internal structure and thus estimate their parasitic inductance. In cases where a surplus or used component is to be included, it is recommended that you test the component with an impedance meter or make some other type of reactance measurement if you are unable to access the manufacturer's specifications for the resistor.

**PARASITIC INDUCTANCE IN CAPACITORS**

The size and shape of a capacitor's plates and the leads used to connect them to circuits create parasitic inductance, often referred to as *equivalent series inductance (ESL)* by capacitor manufacturers. **Figs 5.9** and **5.10** show reasonable models for capacitors that are good up to VHF.

**Figure 5.11** shows a roll-type capacitor made of two strips of very thin metal foil and separated by a dielectric. After leads are attached to the foil strips, the sandwich is rolled up and either placed in a metal can or coated with plastic. *Radial leads* both stick out of one end of the roll and *axial leads* from both ends along the roll's axis. Because of the rolled strips, the ESL is high. Electrolytic and many types of film capacitors are made with roll construction. As a result, they are generally not useful in RF circuits.

In the stack capacitor, thin sheets of dielectric are coated on one side with a thin metal layer. A stack of the sheets is placed under pressure and heated to make a single solid unit. Metal side caps with leads attached contact the metal layers. The ESL of stack capacitors is very low and so they are useful at high frequencies. Ceramic and mica capacitors are the most common stack-style capacitor.

Parallel-plate air and vacuum capacitors used at RF have relatively low parasitic inductance, but transmitting capacitors made to withstand high voltages and current are large enough that parasitic inductance becomes significant, limiting their use to low-VHF and

**Figure 5.9 — A simple capacitor model for frequencies well below self-resonance.**

**Figure 5.10 — A capacitor model for VHF and above including series resistance and distributed inductance.**

lower frequencies. Adjustable capacitors (air variables and compression or piston trimmer capacitors) for tuning low-power circuits are much smaller and so have correspondingly lower parasitic inductance.

It is difficult for a single capacitor to work well over a very wide frequency range, so capacitors are often placed in parallel as discussed in the section below on Bypassing and Decoupling. It is often suggested that different types of capacitors be connected in parallel to avoid the effects of parasitic inductance at different frequencies, but without testing and careful modeling the results are often unpredictable or even counterproductive as the referenced discussion shows.

**5.3.2 Parasitic Capacitance**

Maxwell's equations also tell us that if the voltage between any two points changes with time, a displacement current is generated between these points as illustrated in **Figure 5.12**. This *displacement current* results from the propagation of the electromagnetic field between the two points and is not to be confused with *conduction current*, which is the movement of electrons. Displacement current is directly proportional to the rate at which the voltage is changing.

When a capacitor is connected to an ac voltage source, a steady ac current can flow because taken together, conduction current and displacement current "complete the loop" from the positive source terminal, across the plates of the capacitor, and back to the negative terminal.

In general, parasitic capacitance shows up *wherever* the voltage between two points is changing with time, because the laws of

**Figure 5.11 — Two common types of capacitor construction. (A) Roll construction uses two strips of foil separated by a strip of dielectric. (B) Stack construction layers dielectric material (such as ceramic or film), one side coated with metal. Leads are attached and the assembly coated with epoxy resin.**

**Figure 5.12 — Capacitive consequences of Maxwell's equations. A: Any changing voltage between two points, for example along a bent wire, generates a displacement current running between them. This can be treated mathematically as a capacitance. B adds parasitic capacitance to a generic component model.**

electromagnetics require a displacement current to flow. Since this phenomenon represents an *additional* current path from one point in space to another, we can add this parasitic capacitance to our component models by adding a capacitor of appropriate value in *parallel* with the component. These parasitic capacitances are typically less than 1 pF, so that below VHF they can be treated as open circuits (infinite reactances) and thus neglected.

## PACKAGE CAPACITANCE

Another source of capacitance, also in the 1-pF range and therefore important only at VHF and above, is the packaging of the com-

**Figure 5.13 — Unexpected stray capacitance. The mounting tab of TO-220 transistors is often connected to one of the device leads. Because one lead is connected to the chassis, small capacitances from the other lead to the chassis appear as additional package capacitance at the device. Similar capacitance can appear at any device with a conductive package.**

ponent itself. For example, a power transistor packaged in a TO-220 case (see **Figure 5.13**), often has either the emitter or collector connected to the metal tab itself. This introduces an extra *inter-electrode capacitance* across the junctions.

The copper traces on a PC board also create capacitance with the circuit components, to other traces, and to power and ground planes. Double-sided PC boards have a certain capacitance per square inch between the layers of copper on each side of the board. (Multi-layer PC boards have higher values of capacitance due to the smaller separation between layers.) It is possible to create capacitors by leaving unetched areas of copper on both sides of the board. The dielectric constant of inexpensive PC board materials intended for use at low-frequencies is not well-controlled, however, leading to significant variations in capacitance. For this reason, the copper on one side of a double-sided board should be completely removed under frequency-determining circuits such as VFOs.

*Stray capacitance* (a general term used for any "extra" capacitance that exists due to physical construction) appears in any circuit where two metal surfaces exist at different voltages. Such effects can be modeled as an extra capacitor in parallel with the given points in the circuit. A rough value can be obtained with the parallel-plate formula given in the chapter on **Electrical Fundamentals**. Similar to parasitic inductance, *any* circuit component that has wires attached to it, or is fabricated from wire, or is near or attached to metal, will have a parasitic capacitance associated with it, which again, becomes important only at RF.

Stray capacitance can be difficult to account for in circuit design because it exists *between* components and other circuit structures, depending on the physical orientation of the component. Its presence may allow signals to flow in ways that disrupt the normal operation of a circuit and may have a greater affect in a high-impedance circuit because the capacitive reactance may be a greater percentage of the circuit impedance. Also, because stray capacitance often appears in parallel with the circuit, the stray capacitor may bypass more of the desired signal at higher frequencies. Careful physical design of an RF circuit and selection of components can minimize the effects of stray capacitance.

## 5.3.3 Self-Resonance

Because of parasitic effects, a capacitor or inductor — all by itself — exhibits the properties of a resonant RLC circuit at frequencies for which the parasitic effects are significant. Figs 5.10 and 5.14 illustrate RF models for the capacitor and inductor, which are based on the general model in Figure 5.4, leaving

out the packaging capacitance. Note the slight difference in configuration; the pairs  $C_p$ - $R_p$  and  $L_s$ - $R_s$  are in series in the capacitor but in parallel in the inductor. This is because of the different physical structure of the component.

At some sufficiently high frequency, both inductors and capacitors become *self-resonant* when the parasitic reactance cancel or equals the intended reactance, creating a series-resonant circuit. Similar to a series-resonant circuit made of discrete components, above the self-resonant frequency a capacitor will appear inductive, and an inductor will appear capacitive.

For an example, let's calculate the approximate self-resonant frequency of a 470-pF capacitor whose leads are made from #20 AWG wire (0.032-inch diameter), with a total length of 1 inch. Using equation 1, we calculate the approximate parasitic inductance

$$L (\mu\text{H}) = 0.00508 (1) \left[ \ln \left( \frac{2(1)}{(0.032/2)} \right) - 0.75 \right]$$

$$= 0.021 \mu\text{H}$$

and the self-resonant frequency is roughly

$$f = \frac{1}{2\pi\sqrt{LC}} = 50.6 \text{ MHz}$$

Similarly, an inductor can also have a parallel self-resonance.

The purpose of making these calculations is to provide a feel for actual component values. They could be used as a rough design guideline, but should not be used quantitatively. Other factors such as lead orientation, shielding and so on, can alter the parasitic effects to a large extent. Large-value capacitors tend to have higher parasitic inductances (and therefore a lower self-resonant frequency) than small-value capacitors.

Self-resonance becomes critically important at VHF and UHF because the self-resonant frequency of many common components is at or below the frequency where the component will be used. In this case, either special techniques can be used to construct components to operate at these frequencies by reducing the parasitic effects, or else the idea of lumped elements must be abandoned altogether in favor of microwave techniques such as striplines and waveguides.

## 5.3.4 Inductors and RF Chokes at Radio Frequencies

Inductors are perhaps the component with the most significant parasitic effects. Where there are many different varieties of form for capacitors and resistors, most inductors are fundamentally similar: a coil of wire on a tubular or toroidal form. As such, they are affected by both parasitic resistance and capacitance as shown in the simple inductor

Figure 5.14 — General model for inductor with parasitic capacitance and resistance. The parasitic capacitance represents the cumulative effect of the capacitance between the different turns of wire. Parasitic resistance,  $R_S$ , depends on frequency due to the skin effect.  $R_P$  represents leakage resistance. At low frequencies, parasitic capacitance,  $C_P$ , can be neglected.

Model of Figure 5.14.

While the leakage conductance of a capacitor is usually negligible, the series resistance of an inductor often is not. This is caused by the long lengths of thin wire needed to create typical inductance values used in RF circuits and the skin effect (discussed below). Consider a typical air-core inductor, with  $L = 33 \mu\text{H}$  and minimum  $Q$  of 30 measured at 2.5 MHz. This would indicate a series resistance of  $R_S = 2\pi fL/Q = 17 \Omega$  that could significantly alter the bandwidth of a circuit. The skin effect also results in parasitic resistance in the upper HF ranges and above. To minimize losses due to the skin effect, inductors at these frequencies, particularly those intended for use in transmitters and amplifiers and that are expected to carry significant currents, are often made from large-diameter wire or tubing or even flat strap to maximize the surface area for current flow.

For coils with many turns for which large inductors are impractical, *Litz wire* is sometimes used. Litz wire is made of many fine insulated strands woven together, each with diameter smaller than the skin depth at the expected frequency of use, thus presenting a larger surface area than a solid wire or normal stranded wire. This creates multiple resistive inductors in parallel, which reduces the total impedance. The reduction is not proportional to the number of parallel paths, however, because they are inductively coupled.

If an inductor is wound on a magnetic core, the core itself can have losses that are treated as parasitic resistance. Each type of core — iron, powdered iron or ferrite — has a frequency range over which it is designed for maximum efficiency. Outside of that range, the core may have significant losses, raising the parasitic resistance of the inductor.

Parasitic capacitance is a particular con-

Figure 5.15 — Coils have distributed capacitance (A) between windings and from the coil to adjacent structures. This forms a parallel tuned circuit as shown in B with a resonant frequency,  $f_r$ . The coil's impedance and reactance vary with frequency as at C and D. Below resonance, the reactance is inductive and above resonance, the reactance is capacitive.

cern for inductors because of their construction. Consider the inductor in Figure 5.15. If this coil has  $n$  turns, then the ac voltage between identical points of two neighboring turns is  $1/n$  times the ac voltage across the entire coil. When this voltage changes due to an ac current passing through the coil, the effect is that of many small capacitors acting in parallel with the inductance of the coil. Thus, in addition to the capacitance resulting from the leads, inductors have higher parasitic capacitance due to their physical shape.

These various effects illustrate why inductor construction has such a large effect on performance. As an example, assume you're working on a project that requires you to wind a  $5 \mu\text{H}$  inductor. Looking at the coil inductance formula in the **Electrical Fundamentals** chapter, it comes to mind that many combinations of length and diameter could yield the desired inductance. If you happen to have

both 0.5- and 1-inch coil forms, why should you select one over the other? To eliminate some other variables, let's make both coils 1 inch long, close-wound, and give them 1-inch leads on each end.

Let's calculate the number of turns required for each. On a 0.5-inch-diameter form:

$$n = \frac{\sqrt{L(18d + 40l)}}{d} = \frac{\sqrt{5[(18 \times 0.5) + (40 \times 1)]}}{0.5} = 31.3 \text{ turns}$$

This means coil 1 will be made from #20 AWG wire (29.9 turns per inch). Coil 2, on the 1-inch form, yields

$$n = \frac{\sqrt{5[(18 \times 1) + (40 \times 1)]}}{1} = 17 \text{ turns}$$

which requires #15 AWG wire in order to be close-wound.

What are the series resistances associated with each? For coil 1, the total wire length is 2 inches +  $(31.3 \times \pi \times 0.5) = 51$  inches, which at  $10.1 \Omega/1000$  ft gives  $R_s = 0.043 \Omega$  at dc. Coil 2 has a total wire length of 2 inches +  $(17.0 \times \pi \times 1) = 55$  inches, which at  $3.18 \Omega/1000$  ft gives a dc resistance of  $R_s = 0.015 \Omega$ , or about  $\frac{1}{3}$  that of coil 1. Furthermore, at RF, coil 1 will begin to suffer from skin effect at a frequency about 3 times lower than coil 2 because of its smaller conductor diameter. Therefore, if Q were the sole consideration, it would be better to use the larger diameter coil.

Q is not the only concern, however. Such coils are often placed in shielded enclosures. A common rule of thumb says that to prevent the enclosure from affecting the inductor, the enclosure should be at least one coil diameter from the coil on all sides. That is,  $3 \times 3 \times 2$  inches for the large coil and  $1.5 \times 1.5 \times 1.5$  for the small coil, a volume difference of over 500%.

## RF CHOKES

An RF choke is an inductor intended to pass low-frequency ac and dc power while presenting a high impedance to RF. They are not intended for use in tuned circuits, filters, or other high-Q applications. (A detailed online article "How to Select R.F. Chokes" is available on the RF Café website, [www.rfcafe.com/references/electronics-world/select-rf-chokes-may-1966-electronics-world.htm](http://www.rfcafe.com/references/electronics-world/select-rf-chokes-may-1966-electronics-world.htm).)

Miniature and subminiature chokes are similar in size to resistors, both through-hole and SMT. They use a small ferrite core and very fine wire. Chokes with a metal shield around them to reduce coupling (see next section) are available. DC current ratings for these chokes are fairly low — typically tens of mA at most. Inductance values range from nanohenries to millihenries for use in low-power audio and RF circuits or for managing EMI.

Power supplies often use high-current chokes wound on ferrite rods to block common-mode RF from getting into or out of equipment. Inductance of  $10 \mu\text{H}$  to several hundred  $\mu\text{H}$  and current ratings up to 10 A are typical, with wire windings using heavy solid enameled wires.

Medium-duty chokes of several hundred  $\mu\text{H}$  to several mH are often wound on ceramic forms in several sections to minimize distributed capacitance. Each section is made of multiple turns formed into a small disk. The disks look a bit like a pie so these chokes are called "pie-wound" (also "pi-wound"). These are common in older tube equipment and high-power RF circuits. A photo of this type of RF choke is shown in the **Electrical Fundamentals** chapter's section on inductors.

Heavy-duty transmitting chokes used in tube equipment are usually employed in the plate circuit to block RF from getting back into the high-voltage supply. Values of 100

$\mu\text{H}$  to several hundred  $\mu\text{H}$  are typical with ratings of several amps for plate chokes used at HF. Filament chokes have to handle many amps of low-voltage ac with the same range of inductance values.

An RF choke performs best well below its self-resonant frequency (SRF) but it can be used throughout the range for which it has an acceptably high impedance. The choke's impedance will be inductive below the SRF and capacitive above the SRF (see Figure 5.15). If the choke is going to be used in a high-power transmitting circuit, resonances may produce very high voltages at one or more points along the coil. This can cause arcing and damage to the choke. These chokes are often specially wound to minimize the effect of resonances but this must be done to suit the exact application since distributed capacitance to the enclosure and other components affects the SRF.

Tom Rauch, W8JI, has written an informative paper about SRF and plate chokes which can be viewed at [www.w8ji.com/rf\\_](http://www.w8ji.com/rf_)

Figure 5.16 — Unshielded coils in close proximity should be mounted perpendicular to each other to minimize coupling.

Figure 5.17 — Result of light coupling ( $k = 0.05$ ) between two identical circuits of Figure 5.19A on their frequency responses.

**plate\_choke.htm**. His companion web page on inductors used in high-power RF circuits ([www.w8ji.com/loading\\_inductors.htm](http://www.w8ji.com/loading_inductors.htm)) is also very informative.

Selecting the right type of choke is important to the success of the circuit. Like capacitors, there are many types of chokes with different characteristics. A reliable guide is to inspect well-engineered commercial equipment of the same type and frequency range to see what type of inductors are used. Handbooks and articles on equipment and choke design are also helpful, particularly for high-power applications. Manufacturer application notes and selection guides, such as the Coilcraft "RF Inductor Design Center" ([www.coilcraft.com/rfdc.cfm](http://www.coilcraft.com/rfdc.cfm)) are also helpful for lower-power circuits.

When selecting the choke, your choke will need to be rated adequately for the dc current load with a low dc voltage drop. The SRF should be higher than the frequency of use or at least have a high impedance. Be sure the Q is high enough to avoid excessive RF power dissipation. Finally, any magnetic core (powdered iron or ferrite) should be intended for the frequency of use.

## INDUCTOR COUPLING

Mutual inductance (see the **Electrical Fundamentals** chapter) will also have an effect on the resonant frequency and Q of RF circuits. For this reason, inductors in frequency-critical circuits should always be oriented and with sufficient spacing to minimize coupling. For example, mount coils near each other with their axes perpendicular as in Figure 5.16. The use of ferrous core

o tends to keep magnetic fields within the  
re, reducing unwanted coupling.

As an example, assume we build an oscil-  
lator circuit that has both input and output  
onant circuits. If we are careful to keep the  
o coils in these circuits uncoupled, the fre-  
quency response of either of the two circuits  
shown by the solid line in **Figure 5.17**.

If the two coils are coupled either through  
reless placement or improper shielding, the  
onant frequency and Q will be affected.  
The dashed line in Figure 5.17 shows the  
frequency response that results from a  
coupling coefficient of  $k = 0.05$ , a reasonable  
value for air-wound inductors mounted  
perpendicularly in close proximity on a circuit  
assis. Note the resonant frequency shifted  
om 10.06 to 9.82 MHz, or 2.4%. The Q has  
me up slightly from 30.0 to 30.8 as a result  
of the slightly higher inductive reactance at  
the resonant frequency.

Capacitance between coils can also affect a  
circuit's frequency response. Using shielded  
inductors or can-mounted coils reduces  
the effects of stray capacitance between  
components.

### 3.5 Skin Effect

The resistance of a conductor to ac is dif-  
ferent than its value for dc because of the  
y ac fields interact with the conductor. As  
result, thick, near-perfect conductors (such  
as metals) conduct ac only to a certain *skin*  
*depth*,  $\delta$ , inversely proportional to the square  
root of the frequency of the current. Called the  
*skin effect*, this decreases the effective cross-  
section of the conductor at high frequencies  
and thus increases its resistance.

$$R = \frac{1}{\sqrt{\pi f \mu \sigma}} \quad (2)$$

where  
 $\mu$  is the conductor's permeability, and  
 $\sigma$  is the conducting material's conduc-  
tance.

The increase in resistance caused by the  
skin effect is insignificant at and below audio  
frequencies, but beginning around 1 MHz  
(depending on the size of the conductor) it is  
pronounced that practically all the current  
flows in a very thin layer near the conductor's  
surface. For example, at 10 MHz, the skin  
depth of a copper conductor is about 0.02  
in (0.00079 inch). For this reason, at RF a  
low tube and a solid rod of the same di-  
ameter and made of the same metal will have  
the same resistance and the RF resistance of  
the conductor is often much higher than its dc  
resistance. A rough estimate of the frequency  
above which a nonmagnetic wire (one made  
of nonferrous metal) will begin to show ap-  
preciable skin effect can be calculated from

$$f = \frac{124}{d^2} \quad (3)$$

where

$f$  = frequency, in MHz

$d$  = diameter in mils (a mil is 0.001 inch)

Above this frequency, increase the resis-  
tance of the wire by 10× for every  
2 decades of frequency (roughly 3.2× for ev-  
ery decade). For example, say we wish to find  
the RF resistance of a 2-inch length of  
#18 AWG copper wire at 100 MHz. From the  
wire tables in the **Component Data and Ref-  
erences** chapter, we see that this wire has a  
dc resistance of 2 inches  $\times$  6.386  $\Omega$ /1000 ft  
= 1.06 m $\Omega$ . From the above formula, the fre-  
quency is found to be  $124 / 40.3^2 = 76$  kHz.  
Since 100 MHz is roughly three decades  
above this (100 kHz to 100 MHz), the RF  
resistance will be approximately  $1.06 \text{ m}\Omega \times$   
 $3.2^3 = 1.06 \text{ m}\Omega \times 32.8 = 34.8 \text{ m}\Omega$ . Again,  
values calculated in this manner are approxi-  
mate and should be used qualitatively — like  
when you want an answer to a question such  
as, "Can I neglect the RF resistance of this  
length of connecting wire at 100 MHz?" Sev-  
eral useful charts regarding skin effect are  
available in *Reference Data for Engineers*,  
listed in the References section of this chapter.

Losses associated with skin effect can be  
reduced by increasing the surface area of the  
conductor carrying the RF current. Flat, solid  
strap and tubing are often used for that reason.  
In addition, because the current-carrying  
layer is so thin at UHF and microwave fre-  
quencies, a thin highly conductive layer at  
the surface of the conductor, such as silver  
plating, can lower resistance. Silver plating  
is too thin to improve HF conductivity sig-  
nificantly, however.

### 5.3.6 RF Heating

RF current often causes component heating  
problems where the same level of dc or low  
frequency ac current may not. These losses  
result from both the skin effect and from di-  
electric losses in insulating material, such as  
a capacitor dielectric.

An example is the tank circuit of an RF  
oscillator. If several small capacitors are  
connected in parallel to achieve a desired  
capacitance, skin effect will be reduced and  
the total surface area available for heat dis-  
sipation will be increased, thus significantly  
reducing the RF heating effects as compared  
to a single large capacitor. This technique can  
be applied to any similar situation; the general  
idea is to divide the heating among as many  
components as possible.

An example is shown in the circuit block  
in **Figure 5.18**, which is representative of the  
input tank circuit used in many HF VFOs.  
Along with L,  $C_{\text{main}}$ ,  $C_{\text{trim}}$ , C1 and C3 set

**Figure 5.18** — A tank circuit of the type commonly used in VFOs. Several capacitors are used in parallel to distribute the RF current, which reduces temperature effects.

the oscillator frequency. Therefore, tempera-  
ture effects are critical in these components.  
By using several capacitors in parallel, the  
RF current (and resultant heating, which is  
proportional to the square of the current) is  
reduced in each component. Parallel combi-  
nations are used for the feedback capacitors  
for the same reason.

At high power levels, losses due to RF  
heating — either from resistive or dielectric  
losses — can be significant. Insulating materi-  
als may exhibit dielectric losses even though  
they are excellent insulators. For example,  
nylon plastic insulators may work very well  
at low frequencies, but being quite lossy at  
and above VHF, they are unsuitable for use  
in RF circuits at those frequencies. To deter-  
mine whether material is suitable for use as  
an insulator at RF, a quick test can be made  
by heating the material in a microwave oven for  
a few seconds and measuring its temperature  
rise. (Take care to avoid placing parts or mate-  
rials containing any metal in the microwave!)  
Insulating materials that heat up are lossy and  
thus unsuitable for use in RF circuits.

### 5.3.7 Effect on Q

Recall from the **Electrical Fundamen-  
tals** chapter that circuit Q, a useful figure of  
merit for tuned RLC circuits, can be defined  
in several ways:

$$Q = \frac{X_L \text{ or } X_C}{R} \quad (4)$$

$$= \frac{\text{energy stored per cycle}}{\text{energy dissipated per cycle}}$$

Q is also related to the bandwidth of a tuned  
circuit's response by

$$Q = \frac{f_0}{\text{BW}_{3\text{dB}}} \quad (5)$$

Parasitic inductance, capacitance and resistance can significantly alter the performance and characteristics of a tuned circuit if the design frequency is close to the self-resonant frequencies of the components.

As an example, consider the resonant circuit of **Figure 5.19A**, which could represent the frequency-determining resonant circuit of an oscillator. Neglecting any parasitics,

$$f_0 = \frac{1}{2\pi\sqrt{LC}} = 10.06 \text{ MHz}$$

As in many practical cases, assume the resistance arises entirely from the inductor series resistance. The data sheet for the inductor specified a minimum Q of 30, so assuming  $Q = 30$  yields an R value of

$$\frac{X_L}{Q} = \frac{2\pi(10.06 \text{ MHz})(5 \mu\text{H})}{30} = 10.5 \Omega$$

Next, let's include the parasitic inductance of the capacitor (**Figure 5.19B**). A reasonable assumption is that this capacitor has the same physical size as the example from the section on Parasitic Inductance for which we calculated  $L_s = 0.106 \mu\text{H}$ . This would give the capacitor a self-resonant frequency of 434 MHz — well above our frequency of interest. However, the added parasitic inductance does account for an extra  $0.106/5.0 = 2\%$  inductance. Since this circuit is no longer strictly series or parallel, we must convert it to an equivalent form before calculating the new  $f_0$ .

An easier and faster way is to *simulate* the altered circuit by computer. This analysis was performed on a desktop computer using *SPICE*, a standard circuit simulation program described in the **Computer-Aided Circuit Design** chapter. The voltage response

of the circuit (given an input current of 1 mA) was calculated as a function of frequency for both cases, with and without parasitics. The results are shown in the plot in **Figure 5.19C**, where we can see that the parasitic circuit has an  $f_0$  of 9.96 MHz (a shift of 1%) and a Q (measured from the -3 dB point) of 31.5. For comparison, the simulation of the unaltered circuit does in fact show  $f_0 = 10.06 \text{ MHz}$  and  $Q = 30$ .

### 5.3.8 Dielectric Breakdown and Arcing

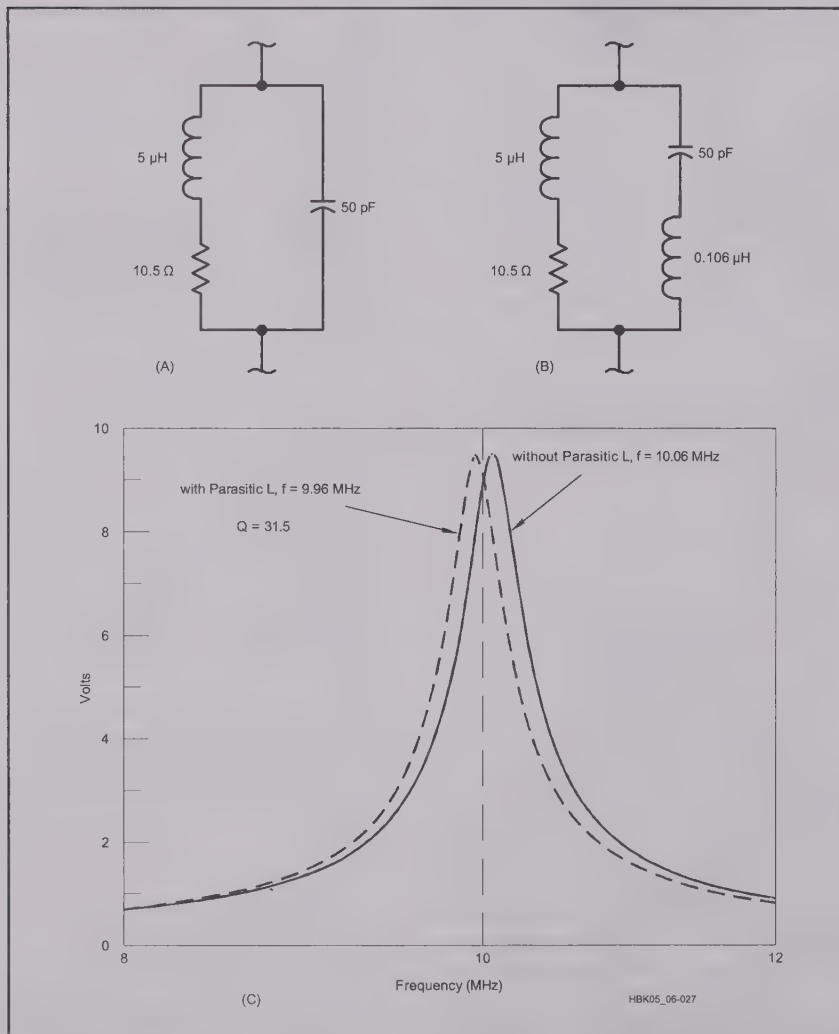

Anyone who has ever seen an arc form across a transmitting capacitor's plates, seen static discharges jump across an antenna insulator or touched a metal doorknob on a dry day has experienced the effects of dielectric breakdown.

In the ideal world, we could take any two conductors and put as large a voltage as we want across them, no matter how close together they are. In the real world, there is a voltage limit (*dielectric strength*, measured in kV/cm and determined by the insulating material between the two conductors) above which the insulator will break down.

Because they are charged particles, the electrons in the atoms of a dielectric material feel an attractive force when placed in an electric field. If the field is sufficiently strong, the force will strip the electron from the atom. This electron is available to conduct current, and furthermore, it is traveling at an extremely high velocity. It is very likely that this electron will hit another atom, and free another electron. Before long, there are many stripped electrons producing a large current forming an *arc*. When this happens, we say the dielectric has suffered *breakdown*. Arcing in RF circuits is most common in transmitters and transmission line components where high voltages are common, but it is possible anywhere two components at significant different voltage levels are closely spaced.

If the dielectric is liquid or gas, it will repair itself when the applied voltage is removed and the molecules in the dielectric return to their normal state. A solid dielectric, however, cannot repair itself because its molecules are fixed in place and the low-resistance path created by the arc is permanent. A good example of this is a CMOS integrated circuit. When exposed to the very high voltages associated with static electricity, the electric field across the very thin gate oxide layer exceeds the dielectric strength of silicon dioxide, and the device is permanently damaged by the resulting hole created in the oxide layer.

The breakdown voltage of a dielectric layer depends on its composition and thickness (see **Table 5.1**). The variation with thickness is not linear; doubling the thickness does not quite double the breakdown voltage. Break-

**Figure 5.19** — A is a tank circuit, neglecting parasitics. B is the same circuit including  $L_p$  on capacitor. C is the frequency response curves for A and B. The solid line represents the unaltered circuit (also see **Figure 5.17**) while the dashed line shows the effects of adding parasitic inductance.

**Table 5.1 Dielectric Constants and Breakdown Voltages**

Material	Dielectric Constant*	Puncture Voltage**
Aluminum nitride	7.5	240
Alumina	9.7	240
Alumina, mica filled	4.7	325-375
Cellulose acetate	3.3-3.9	250-600
Epoxy	5-7.5	150-180
Formica	4.6-4.9	450
Glass, window	7.6-8	200-250
Glass, Pyrex	4.8	335
Glass, ruby	5.4	3800-5600
Polycarbonate	2.9	250
Paper, Royalgrey	3.0	200
Pyrex	2.8	990
Polystyrene	2.3	1200
Polystyrene	2.6	500-700
Porcelain	5.1-5.9	40-100
Quartz, fused	3.8	1000
Teatite, low loss	5.8	150-315
Teflon	2.1	1000-2000

\* At 1 MHz  
 \*\* In volts per mil (0.001 in.)

own voltage is also a function of geometry: because of electromagnetic considerations, the breakdown voltage between two conductors separated by a fixed distance is less if the surfaces are pointed or sharp-edged than if they are smooth or rounded. Therefore, a simple way to help prevent breakdown in many projects is to file and smooth the edges of conductors. (See the **Power Sources** and **RF Power Amplifier** chapters for additional information on high voltage applications.)

Capacitors are, by nature, the component most often associated with dielectric failure. To prevent damage, the working voltage of a capacitor — and there are separate dc and ac ratings — should ideally be two or three times the expected maximum voltage in the circuit. Capacitors that are not air-insulated or have a self-healing dielectric should be replaced if a dielectric electric breakdown occurs.

Resistors and inductors also have voltage ratings associated with breakdown of their insulating coating. High-value resistors, in particular, can be bypassed by leakage current flowing along the surface of the resistor. High-voltage resistors often have elongated bodies to create a long leakage path to present high resistance to leakage current. Cleaning the bodies of resistors and inductors in high-voltage circuits helps prevent arcs from forming and minimizes leakage current.

### 5.3.9 Radiative Losses

Any conductor placed in an electromagnetic field will have a current induced in it. We put this principle to good use when we make an antenna. The unwelcome side of this law of nature is the phrase “any conductor”; even

Figure 5.20 — Model for a bypass capacitor.

Figure 5.21 — Test set for home lab measurement of a bypass capacitor.

conductors we don’t intend to act as antennas will respond this way.

Fortunately, the efficiency of such “antennas” varies with conductor length. They will be of importance only if their length is a significant fraction of a wavelength. When we make an antenna, we usually choose a length on the order of  $\lambda/2$ . Therefore, when we don’t want an antenna, we should be sure that the conductor length is *much less* than  $\lambda/2$ , no more than  $0.1 \lambda$ . This will ensure a very low-efficiency antenna. This is why even unpaired 60-Hz power lines do not lose a significant fraction of the power they carry — at 60 Hz,  $0.1 \lambda$  is about 300 miles!

In addition, we can use shielded cables. Such cables do allow some penetration of EM fields if the shield is not solid, but even 95% coverage is usually sufficient, especially if some sort of RF choke is used to reduce shield current.

Radiative losses and coupling can also be reduced by using twisted or parallel pairs of conductors — the fields tend to cancel. In some applications, such as audio cables, this may work better than shielding. Critical stages such as tuned circuits should be placed in shielded compartments where possible.

This argument also applies to large components — remember that a component or long wire can both radiate and receive RF energy. Measures that reduce radiative losses will also reduce unwanted RF pickup. See the **RF Interference** chapter for more information.

### 5.3.10 Bypassing and Decoupling

#### BYPASSING

Circuit models showing ac behavior often show ground connections that are not at dc ground. Bias voltages and currents are neglected in order to show how the circuit

Figure 5.22 — Test fixture for measuring self-resonant frequency of capacitors.

responds to ac signals. Rather, those points are “signal grounded” through bypass capacitors. Obtaining an effective bypass can be difficult and is often the route to design difficulty. The problem is parasitic inductance. Although we label and model parts as “capacitors,” a more complete model is needed. The better model is a series RLC circuit, shown in **Figure 5.20**. Capacitance is close to the marked value while inductance is a small value that grows with component lead length. Resistance is a loss term, usually controlled by the Q of the parasitic inductor. Even a leadless SMT (surface-mount technology) component will display inductance commensurate with its dimensions. As shown in the Parasitic Inductance section, wire component leads have an inductance of about 1 nH per mm of length (20-25 nH per inch).

Bypass capacitor characteristics can be measured in the home lab with the test setup of **Figure 5.21**. **Figure 5.22** shows a test fixture with an installed 470-pF leaded capacitor. The fixture is used with a signal generator and spectrum analyzer to evaluate capacitors. Relatively long capacitor leads were required to interface to the BNC con-

**Figure 5.23 — Network analyzer measurement of 470-pF shunt capacitors. Both SMT and leaded parts are studied.**

nectors, even though the capacitor itself was small. The signal generator was tuned over its range while examining the spectrum analyzer response, showing a minimum at the series resonant frequency. Parasitic inductance is calculated from this frequency. The C value was measured with a low-frequency LC meter. Additional test instruments and techniques are discussed in the **Test Equipment and Measurement** chapter.

The measured 470-pF capacitor is modeled as 485 pF in series with an inductance of 7.7 nH. The L is larger than we would see with shorter leads. A 0.25-inch 470-pF ceramic disk capacitor with zero lead length will show a typical inductance closer to 3 nH. The measured capacitor Q was 28 at its self-resonance of 82 MHz but is higher at lower frequency. Data from a similar measurement, but with a network analyzer is shown in **Figure 5.23**. Two 470-pF capacitors are measured, one surface mounted and the other a leaded part with 0.1-inch leads.

**Figure 5.24 — The classic technique of paralleling bypass capacitors of two values, here 470 pF and 0.01 μF. This is a terrible bypass! See text.**

It is often suggested that the bandwidth for bypassing can be extended by paralleling a capacitor that works well at one frequency with another to accommodate a different part of the spectrum. Hence, paralleling the 470 pF with a 0.01-μF capacitor should extend the bypassing to lower frequencies. The calculations are shown in the plots of **Figure 5.24**. The results are terrible! While the low frequency bypassing is indeed improved, a high impedance response is created at 63 MHz. This complicated behavior is again the result of inductance. Each capacitor was assumed to have a series inductance of 7 nH. A parallel resonance is approximately formed between the L of the larger capacitor and the C of the smaller. The Smith Chart plot shows us that the impedance is nearly 50 Ω at 63 MHz. Impedance would be even higher with greater capacitor Q.

**Figure 5.25 — Paralleling bypass capacitors of nearly the same value. This results in improved bypassing without complicating resonances.**

Bypassing can be improved by paralleling capacitors. However, the capacitors should be approximately identical. **Figure 5.25** shows the result of paralleling two capacitors of about the same value. They differ slightly at 390 and 560 pF, creating a hint of resonance. This appears as a small perturbation in the reactance plot and a tiny loop on the Smith Chart. These anomalies disappear as the C values become equal. Generally, paralleling is the scheme that produces the best bypassing. The ideal solution is to place an SMT capacitor on each side of a printed circuit trace or wire at a point that is to be bypassed.

Matched capacitor pairs form an effective bypass over a reasonable frequency range. Two 0.01-μF disk capacitors have a reactance magnitude less than 5 Ω from 2 to 265 MHz. A pair of the 0.1-μF capacitors was even better, producing the same bypassing impedance from 0.2 to 318 MHz. The 0.1-μF capacitors are chip-style components with attached wire leads. Even better results

can be obtained with multi-layer ceramic chip capacitors. Construction with multiple layers creates an integrated paralleling.

Some applications (for example, IF amplifiers) require effective bypassing at even lower frequencies. Modern tantalum electrolytic capacitors are surprisingly effective through the RF spectrum while offering high enough C to be useful at audio. In critical applications, however, the parts should be tested to be sure of their effectiveness.

## DECOUPLING

The bypass capacitor usually serves a dual role, first creating the low impedance needed to generate a “signal” ground. It also becomes part of a decoupling low-pass filter that passes dc while attenuating signals. The attenuation must function in both directions, suppressing noise in the power supply that might reach an amplifier while keeping amplifier signals from reaching the power supply. A low-pass filter is formed with alternating series and parallel component connections. A parallel bypass is followed by a series impedance, ideally a resistor.

Additional shunt elements can then be added, although this must be done with care. An inductor between shunt capacitors should have high inductance. It will resonate with the shunt capacitors to create high impedances just like those that came from parasitic inductance in the bypasses. This makes it desirable to have an inductance that is high enough that any resonance is below the band of interest. But series inductors have their own problems; they have parasitic capacitance, creating their own self-resonance. As an example, a pair of typical RF chokes (RFCs) were measured (now as series elements) as described earlier. A 2.7- $\mu\text{H}$  molded choke was parallel resonant at 200 MHz, indicating a parallel capacitance of 0.24 pF. The Q at 20 MHz was 52. A 15- $\mu\text{H}$  molded choke was parallel resonant at 47 MHz, yielding a parallel C of 0.79 pF. This part had a Q of 44 at 8 MHz.

Large inductors can be fabricated from series connections of smaller ones. The best wideband performance will result only when all inductors in a chain have about the same value. The reasons for this (and the mathematics that describe the behavior) are identical with those for paralleling identical capacitors.

Low inductor Q is often useful in decoupling applications, encouraging us to use inductors with ferrite cores. Inductors using the Fair-Rite Type #43 material have low Q in the 4 to 10 range over the HF spectrum. One can also create low-Q circuits by paralleling a series inductor of modest Q with a resistor.

Figure 5.26 shows a decoupling network and the resulting impedance when viewed from the “bypass” end. The 15- $\mu\text{H}$  RFC resonates with a 0.1- $\mu\text{F}$  capacitor to destroy the bypass effect just above 0.1 MHz. A low-value parallel resistor fixes the problem.

Figure 5.26 — Two different resistor values parallel a decoupling choke. The lower, 30- $\Omega$  value is more effective. See text.

A major reason for careful wideband bypassing and decoupling is the potential for amplifier oscillation. Instability that allows oscillations is usually suppressed by low impedance terminations. The base and collector (or gate and drain) should both “see” low impedances to ensure stability. But that must be true at all frequencies where the device can produce gain. It is never enough to merely consider the operating frequency for the amplifier. A parallel resonance in the base or collector circuits can be a disaster. When wideband bypassing is not possible, negative feedback that enhances wideband stability is often used.

Emitter bypassing is often a critical application. As demonstrated in the **Circuits and Components** chapter, a few extra ohms of impedance in the emitter circuit can drastically alter amplifier performance. A parallel-resonant emitter bypass could be a profound difficulty while a series-resonant one can be especially effective.

Capacitors also appear in circuits as blocking elements. A blocking capacitor, for example, appears between stages, creating a near short circuit for ac signals while accommodating different dc voltages on the two sides. A blocking capacitor is not as critical as a bypass, for the impedances on either side will usually be higher than that of the block.

With parasitic effects having the potential to strongly affect circuit performance, the circuit designer must account for them wherever they are significant. The additional complexity of including parasitic elements can result in a design too complex to be analyzed manually. Clearly, detailed modeling is the answer to component selection and the control of parasitic effects.

### 5.3.11 Effects on Filter Performance

LC bandpass filters perform a critical

Figure 5.27 — The amplitude of a chime’s ring after being struck by a hammer. Units are arbitrary.

function in determining the performance of a typical RF system such as a receiver. An input filter, usually a bandpass, restricts the frequency range that the receiver must process. Transmitters use LC filters to reduce harmonic output. Audio and LF filters may also use LC elements. The LC filters we refer to in this section are narrow with a bandwidth from 1 to 20% of the center frequency. Even narrower filters are built with resonators having higher Q; the quartz crystal filter discussed in the **Analog and Digital Filtering** chapter is used where bandwidths of less than a part per thousand are possible. The basic concepts that we examine with LC circuits will transfer to the crystal filter.

## LOSSES IN FILTERS AND Q

The key elements in narrow filters are tuned circuits made from inductor-capacitor pairs, quartz crystals, or transmission line sections. These resonators share the property that they store energy, but they have losses. A chime is an example. Striking the chime with a hammer produces the waveform of Figure 5.27. The rate at which the amplitude decreases with time after the hammer strike is determined by the filter’s Q, which is discussed in the chapter on **Circuits and Components**. The

higher the  $Q$ , the longer it takes for the sound to disappear. The oscillator amplitude would not decrease if it were not for the losses that expend energy stored in the resonator. The mere act of observing the oscillation will cause some energy to be dissipated.

A chime is an acoustic resonator, but the same behavior occurs in electric resonators. A pulse input to an LC circuit causes it to ring; losses cause the amplitude to diminish. The most obvious loss in an LC circuit is conductor resistance, including that in the inductor wire. This resistance is higher than the dc value owing to the skin effect, which forces high frequency current toward the conductor surface. Other losses might result from hysteresis losses in an inductor core or dielectric losses in a capacitor.

An inductor is modeled as an ideal part with a series or a parallel resistance. The resistance will depend on the  $Q$  if the inductor was part of a resonator with that quality. The two resistances are shown in **Figure 5.28**.

$$R_{\text{Series}} = \frac{2\pi f L}{Q} \quad \text{and}$$

$$R_{\text{Parallel}} = Q \times 2\pi f L \quad (6)$$

The higher the inductor  $Q$ , the smaller the series resistance, or the larger the parallel resistance is needed to model that  $Q$ . It does not matter which configuration is used. The  $Q$  of a resonator is related to the bandwidth of the tuned circuit by

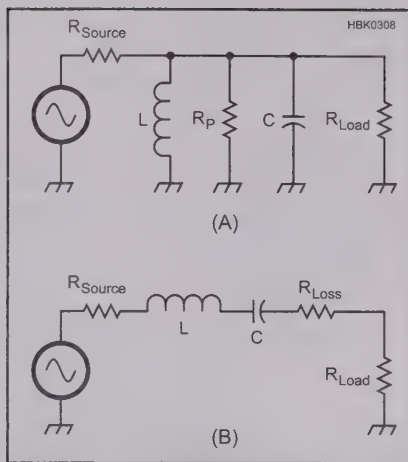

$$BW = \frac{f_c}{Q} \quad (7)$$

where  $f_c$  is the tuned circuit's center frequency. This is also the  $Q$  of an inductor in a tuned circuit if the capacitor is lossless.

The single-tuned circuit is presented in two different forms in **Figure 5.29**. In the top, a parallel tuned circuit consisting of  $L$  and  $C$  has loss modeled by three resistors. The resistor  $R_p$  is the parallel loss resistance representing the non-ideal nature of the inductor. (Another might be included to represent capacitor losses.) But the LC is here paralleled by three resistors: the source, the load and the loss element.  $R_p$  would disappear if the tuned circuit was built from perfect components.

**Figure 5.28** — Inductor  $Q$  may be modeled with either a series or a parallel resistance.

**Figure 5.29** — Two simple forms of the single-tuned circuit.

The source and load remain; they represent the source resistance that must be present if power is available and a load resistance that must be included if power is to be extracted.

Equation 6 and 7 can be applied in several ways. If the resonator is evaluated with only its intrinsic loss resistance (in either series or parallel form) the resulting  $Q$  is called the *unloaded*  $Q$ , or  $Q_u$ . If, however, the net resistance is used, which is the parallel combination of the load, the source, and the loss in the parallel tuned circuit, the resulting  $Q$  is called the *loaded*  $Q$ ,  $Q_L$ . If we were working with the series tuned circuit form, the loaded  $Q$  would be related to the total series  $R$ .

Consider an example, a parallel tuned circuit (Figure 5.29A) with a  $2\text{-}\mu\text{H}$  inductor tuned to 5 MHz with a 507-pF capacitor. Assume the parallel loss resistor was 12.57 k $\Omega$ . The unloaded  $Q$  calculated from equation 6 is 200. The unloaded bandwidth would be 5 MHz/200 = 25 kHz. Assume that the source and load resistors were equal, each 2 k $\Omega$ . The net resistance paralleling the LC would then be the combination of the three resistors, 926  $\Omega$ . The loaded  $Q$  becomes 14.7 with a loaded bandwidth of 339 kHz. The loaded  $Q$  is also the filter  $Q$ , for it describes the bandwidth of the single-tuned circuit, the simplest of band-pass filters.

This filter also has *insertion loss* (IL). This is illustrated in **Figure 5.30** which shows the parallel-resonant LC combination removed (at resonance, the LC combination has infinite impedance), leaving only the loss resistance of 12.57 k $\Omega$ . We use an arbitrary open circuit source voltage of 2. The available power to a load is then 1 V across a resistance equaling the 2-k $\Omega$  source. If the resonator had no internal losses, this available power would be delivered to the 2-k $\Omega$  load. However, the loss  $R$  parallels the load, causing the output voltage to be 0.926 V, a bit less than the ideal 1 V. Calculation of the output power into the

**Figure 5.30** — Simplified parallel tuned circuit at resonance. The effect of loss is illustrated by removing the parallel-LC combination which at resonance has infinite impedance.

**Figure 5.31** — Test setup for measuring the  $Q$  of a resonator. The source and load impedances,  $R_O$ , are assumed to be identical. The two coupling capacitors are adjusted to be equal to each other. The output signal is measured with an appropriate ac voltmeter, an oscilloscope or a spectrum analyzer.

2-k $\Omega$  load resistance and the available power shows that the insertion loss is 0.67 dB.

This exercise illustrates two vital points that are general for all bandpass filters. First, the bandwidth of any filter must always be larger than the unloaded bandwidth of the resonators used to build the filter. Second, any filter built from real-world components will have an insertion loss. The closer the  $Q$  of the filter approaches the unloaded resonator  $Q$ , the greater the insertion loss becomes. A parallel tuned circuit illustrated these ideas; the series tuned filter would have produced identical results. Generally, the insertion loss of a single-tuned circuit relates to loaded and unloaded  $Q$  by

$$IL(\text{dB}) = -20 \log \left( 1 - \frac{Q_L}{Q_U} \right) \quad (8)$$

The  $Q$  of a tuned LC circuit is easily measured with a signal generator of known output impedance (usually 50  $\Omega$ ) and a sensitive detector, again with a known impedance level, often equal to that of the generator. The test configuration is shown in **Figure 5.31**. It uses equal loads and equal capacitors to couple from the terminations to the resonator. Equal capacitors, C1 and C2 guarantees that each termination contributes equally to the resonator parallel load resistance. The voltmeter across the load is calibrated in dB.

To begin measurement we remove the tuned circuit and replace it with a direct connection

from generator to load. The available power delivered to the load is calculated after the voltage is measured. The resonator is then inserted between the generator and load, and the generator is tuned for a peak. The measured power is less than that available from the source, with the difference being the insertion loss for the simple filter. Capacitors C1 and C2 are adjusted until the loss is 30 dB or more. With loss this high, the intrinsic loss resistance of the resonator will dominate the loss. The generator is now tuned first to

one side of the peak, and then to the other, noting the frequencies where the response is lower than the peak by 3 dB. The unloaded bandwidth,  $\Delta F$ , is the difference between the two 3 dB frequencies. The unloaded Q is calculated as

$$Q_U = \frac{F}{\Delta F} \quad (9)$$

## 5.4 Semiconductor Circuits at RF

The models used in the **Circuits and Components** chapter are reasonably accurate at low frequencies, and they are of some use at RF, but more sophisticated models are required for consistent results at higher frequencies. This section notes several areas in which the simple models must be enhanced. Circuit design using models accurate at RF, particularly for large signals, is performed today using design software as described in the **Computer-Aided Circuit Design** chapter of this book. In-depth discussions of the elements of RF circuit design appear in Hayward's *Introduction to Radio Frequency Design*, an excellent text for the beginning RF designer (see the References section). See also the section of RF Amplifier Design papers and application notes in the References section of this chapter.

### 5.4.1 The Diode at High Frequencies

#### A DIODE AC MODEL

At high frequencies, the diode's behavior becomes less like a switch, especially for small signals that do not cause the diode's operating point to move by large amounts. In this case, the diode's small-signal dynamic behavior becomes important.

**Figure 5.32** shows a simple resistor-diode circuit to which is applied a dc bias voltage plus an ac signal. Assuming that the voltage drop across the diode is 0.6 V and  $R_f$  is negligible, we can calculate the bias current to be  $I = (5 - 0.6) / 1 \text{ k}\Omega = 4.4 \text{ mA}$ . This point is marked on the diodes I-V curve in **Figure 5.32**. If we draw a line tangent to this point, as shown, the slope of this line represents the *dynamic resistance* of the diode,  $R_d$ , experienced by a small ac signal. At room temperature, dynamic resistance is approximately

$$R_d = \frac{25}{I} \Omega \quad (10)$$

where  $I$  is the diode current in mA. Note that this resistance changes with bias current and should not be confused with the dc forward resistance discussed in the **Circuits and Components** chapter, which has a similar value but represents a different concept. **Figure 5.33** shows a low-frequency ac model for the diode, including the dynamic resistance and junction capacitance. This model should only be used when the diode's dc operating parameters can be neglected.

**Figure 5.32** — A simple resistor-diode circuit used to illustrate dynamic resistance. The ac input voltage “sees” a diode resistance whose value is the slope of the line at the Q-point, shown in B.

This method for Q measurement is quite universal, being effective for audio tuned circuits, simple LC RF circuits, VHF helical resonators, or microwave resonators. The form of the variable capacitors, C1 and C2, may be different for the various parts of the spectrum, but the concepts are general. Indeed, it is not even important how the coupling occurs. The Q measurement normally determines an unloaded value, but loaded values are also of interest when testing filters.

**Figure 5.33** — An ac model for diodes.  $R_d$  is the dynamic resistance and  $C_j$  is the junction capacitance.

#### SWITCHING TIME

If you change the polarity of a signal applied to the ideal diode, current flow stops or starts instantaneously. Current in a real diode cannot do this, as a finite amount of time is required to move electrons and holes in or out of the diode as it changes states. Effectively, the diode junction capacitance,  $C_j$ , in **Figure 5.33** must be charged or discharged. As a result, diodes have a maximum useful frequency when used in switching applications.

The operation of diode switching circuits can often be modeled by the circuit in **Figure 5.34**. The approximate switching time (in seconds) for this circuit is given by

$$t_s = \tau_p \left( \frac{V_1}{R_1} \right) = \tau_p \frac{I_1}{I_2} \quad (11)$$

where  $\tau_p$  is the minority carrier lifetime of the diode, a material constant determined during manufacture, on the order of 1 ms.  $I_1$  and  $I_2$  are currents that flow during the switching process. The minimum time in which a diode

can switch from one state to the other and back again is therefore  $2t_s$ , and thus the maximum usable switching frequency is  $f_{sw} \text{ (Hz)} = 1/(2t_s)$ . It is usually a good idea to stay below this by a factor of two. Diode data sheets usually give typical switching times and show the circuit used to measure them.

Note that  $f_{sw}$  depends on the forward and reverse currents, determined by  $I_1$  and  $I_2$  (or equivalently  $V_1$ ,  $V_2$ ,  $R_1$ , and  $R_2$ ). Within a reasonable range, the switching time can be reduced by manipulating these currents. Of course, the maximum power that other circuit elements can handle places an upper limit on switching currents.

Figure 5.34 — Circuit used for computation of diode switching time.

Figure 5.35 — (A) The Ebers-Moll model of the bipolar junction transistor (BJT) is used at dc and low frequencies when the transistor is in its active region. (B) The hybrid-pi model includes frequency dependence.

## 5.4.2 The Transistor at High Frequencies

The development and selection of suitable models for active devices at RF is an involved and nuanced process. This section presents a few of the models used for bipolar junction transistors (BJT) and field-effect transistors (FET) as examples of the issues involved. For more information on model details, start with the *SPICE* home page at [bwrc.eecs.berkeley.edu/classes/icbook/spice](http://bwrc.eecs.berkeley.edu/classes/icbook/spice) and the user's manual for the simulation software you intend to use.

### GAIN VERSUS FREQUENCY

The circuit design equations in **Circuits and Components** generally assumed that current gain in the bipolar transistor was independent of frequency. As signal frequency increases, however, current gain decreases. The low-frequency current gain,  $\beta_0$ , is constant through the audio spectrum, but it eventually decreases, and at some high frequency it will drop by a factor of 2 for each doubling of signal frequency. (The h-parameter  $[h_{FE}]$

is often substituted for  $\beta$  at dc and  $h_{FE}$  for current gain. H-parameters are discussed later in this chapter.) A transistor's frequency vs current gain relationship is specified by the *gain-bandwidth product* (GBW), or  $F_T$ , the frequency at which the current gain is 1. Common transistors for lower RF applications might have  $\beta_0 = 100$  and  $F_T = 500 \text{ MHz}$ , a frequency at which current gain equals 1, called  $F_b$  and is related to  $F_T$  by  $F_b = F_T/\beta_0$ .

The *Ebers-Moll model* for the bipolar transistor, shown in **Figure 5.35A**, is a "large-signal model." It is used when the transistor is in its active mode and gives good results for dc collector and emitter currents. This would be a poor model to use when designing a pass-transistor voltage regulator circuit, for example.

The frequency dependence of current gain is modeled by adding a capacitor across the base resistor of **Figure 5.35B**, the hybrid-pi model results. The capacitor's reactance should equal the low-frequency input resistance,  $(\beta + 1)r_e$ , at  $F_b$ . This simulates frequency-dependent current gain.

Similar considerations affect the trans

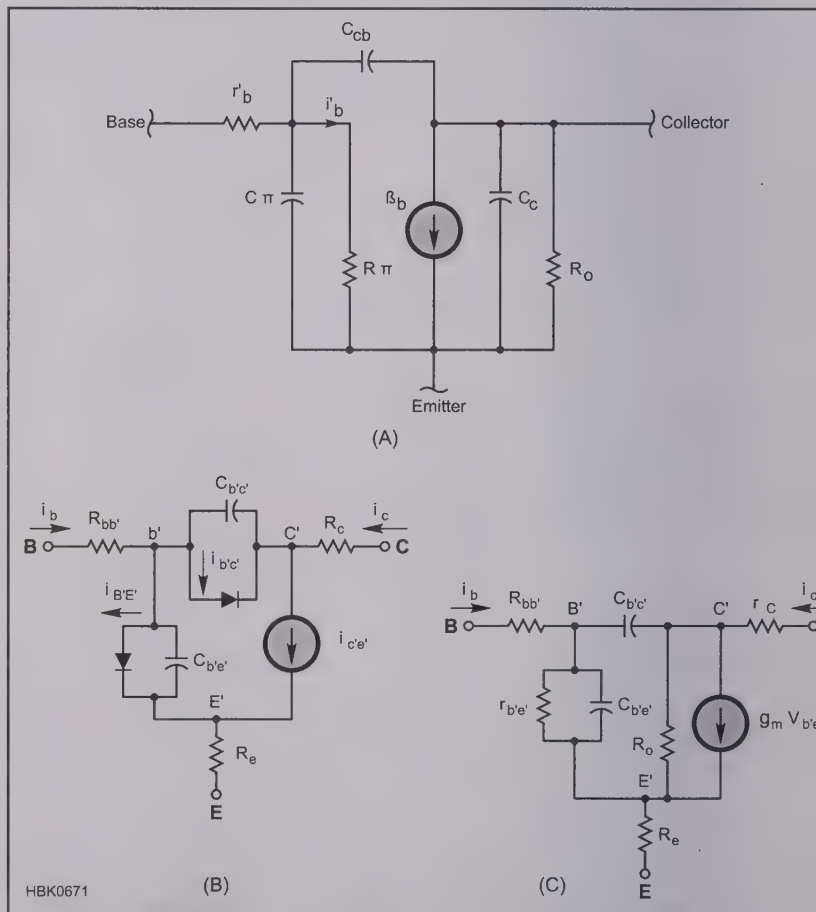

Figure 5.36 — High-frequency models for the bipolar junction transistor. (A) An improved version of the hybrid-pi model including additional device capacitances. (B) is the large-signal Gummel-Poon model used at dc and low-frequencies — the standard used for bipolar transistors by simulators based on *SPICE3* and (C) is the small-signal ac versus

uctance of FETs as the gate-to-source and gate-to-drain capacitances act to reduce high-frequency gain. Instead of  $F_T$ , most FETs designed for amplifier use specify input and output transconductance, susceptance, and power gain at different frequencies.

Recognizing that transistor gain varies with frequency, it is important to know the conditions under which the simpler model is useful. Calculations show that the simple model is valid, with  $\beta = F_T/F$ , for frequencies well above  $F_b$ . The approximation worsens, however, as the operating frequency ( $f_0$ ) approaches  $F_T$ .

## SMALL-SIGNAL DESIGN AT RF

The simplified hybrid- $\pi$  model of Figure 5.35B is often suitable for non-critical designs, but Figure 5.36A shows a better small-signal model for RF design that expands on the hybrid- $\pi$ . Consider the physical aspects of a real transistor: There is some capacitance across each of the PN junctions ( $C_{cb}$  and  $C_p$ ) and capacitance from collector to emitter ( $C_c$ ). There are also capacitances between the device leads ( $C_e$ ,  $C_b$  and  $C_c$ ). There is a resistance in each current path, emitter to base and collector. From emitter to base, there is  $r_{\pi}$  from the hybrid- $\pi$  model and  $r_b$ , the “base spreading” resistance. From emitter to collector is  $R_Q$ , the output resistance. The leads that attach the silicon die to the external circuit present inductive inductances.

Manual circuit analysis with this model is best tackled with the aid of a computer and specialized software. Other methods are presented in Hayward’s *Introduction to Radio Frequency Design*. Surprisingly accurate results may be obtained, even at RF, from the simple models. Simple models also give a better “feel” for device characteristics that might be obscured by the mathematics of a more rigorous treatment. Use the simplest model that describes the important features of the device and circuit at hand.

The *Gummel-Poon model* shown in Figs 5.36B and 5.36C is the standard used by simulation software based on *SPICE3*. By adding additional parasitic elements, such as lead inductance and lead-to-package capacitances, the small-signal ac model can be used accurately at high frequencies. Note how the model becomes progressively more sophisticated from Figure 5.35A through 5.36C.

## HIGH FREQUENCY FET MODELS

At low frequencies the FET can be treated as a simple current source controlled by the gate-to-source voltage as in Figure 3.49 in the *Circuits and Components* chapter. As frequency increases, the inter-electrode capacitances become significant and must be included, such as in the model in Figure 5.37A. As with the BJT, separate models are used for small-signal and large-signal applications. Figure

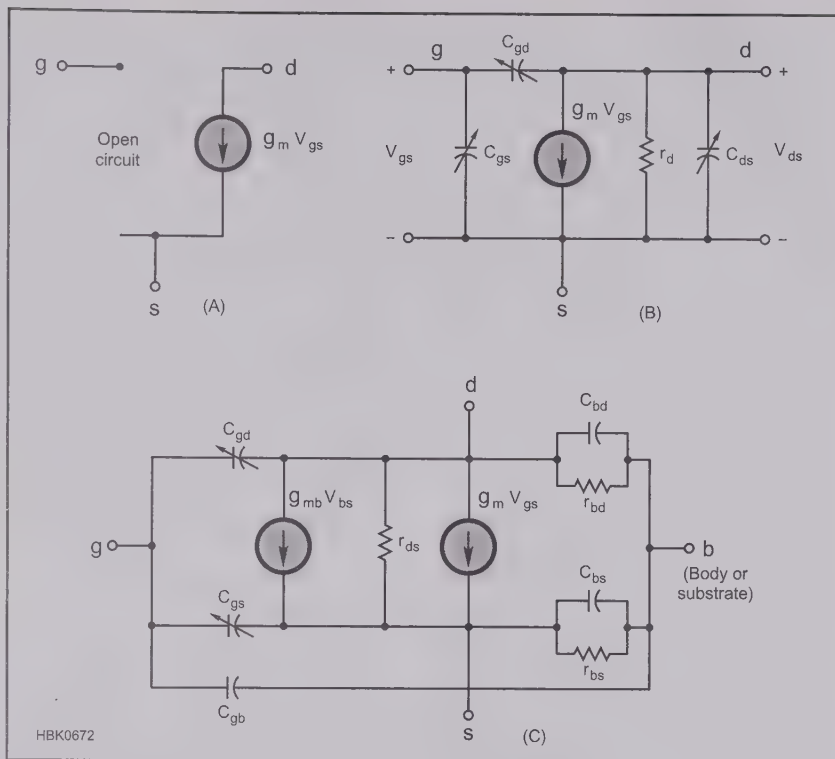

Figure 5.37 — Small-signal models for the field-effect transistor (FET). (A) is a simple low-frequency model. (B) is a common *SPICE3* large-signal model and (C) is a typical high-frequency model for the JFET.

5.37B shows a small-signal *SPICE3* simulation model for the JFET. All of the model’s capacitances vary with temperature and device operating characteristics. Figure 5.37C shows a typical high-frequency MOSFET model used by *SPICE3* (there are several) that includes the effect of the body or substrate elements.

The advances in CMOS integrated circuit technology have resulted in transistors (and capacitors and inductors) with sufficient performance for use in RF design work. In fact, most radio transceivers for cellular telephones, wireless LANs and similar high-volume applications are implemented almost exclusively in CMOS technology due to the high integration available. MOSFET RF design principles are similar to BJT and JFET designs, and most circuit simulators provide good models for MOSFET devices. These additional techniques are enabled by the excellent device matching available in IC technology and the ability to integrate additional circuitry at low incremental cost.

## PARASITIC ELEMENTS AND NOISE

For accurate RF simulation the effects of additional parasitic elements must be included. The most significant is lead inductance—generally inserted in series with the device’s external connections. Lead-to-package and lead-to-lead capacitances are also included in most high-frequency simulations. Depending

on the simulation package used, the user may be required to install these parasitic elements as separate circuit elements or the simulator or manufacturer may provide special models for high-frequency simulation.

Simulation of device noise is not covered here, but many simulator packages include separate noise models for various active devices. Review the simulator’s documentation for information about how to include noise in your simulation.

## 5.4.3 Amplifier Classes

The class of operation of an amplifier is determined by the fraction of a drive cycle during which conduction occurs in the amplifying device or for switchmode devices. (Switchmode amplifiers use different criteria.) The Class A amplifier conducts for 100% of the cycle. It is characterized by constant flow of supply current, regardless of the strength of the driving signal. Most of the amplifiers we use for RF applications and many audio circuits in receivers operate in Class A.

A Class B amplifier conducts for 50% of the cycle, which is 180 degrees if we examine the circuit with regard to a driving sine wave. A Class B amplifier draws no dc current when no input signal is applied, but current begins to flow with any input, growing with the input strength. A Class B amplifier can display good

envelope linearity, meaning that the output amplitude at the drive frequency changes linearly with the input signal. The total absence of current flow for half of the drive cycle will create harmonics of the signal drive.

A Class C amplifier is one that conducts for less than half of a cycle. No current flows without drive. Application of a small drive produces no output and no current flow. Only after a threshold is reached does the device begin to conduct and provide output. A bipolar transistor with no source of bias for the base typically operates in Class C.

The large-signal models discussed earlier are suitable for the analysis of all amplifier classes. Small-signal models are generally reserved for Class A amplifiers. The most common power amplifier class is a cross between Class A and B — the Class AB amplifier that conducts for more than half of each cycle. A Class AB amplifier at low drive levels is indistinguishable from a Class A design. However, increasing drive produces greater collector (or drain) current and greater output.

Amplifier class letter designators for vacuum tube amplifiers were augmented with a numeric subscript. A Class AB<sub>1</sub> amplifier operates in AB, but with no grid current flowing. A Class AB<sub>2</sub> amplifier's grid is driven positive with respect to the cathode and so some grid current flows. In solid-state amplifiers, which have no grids, no numeric subscripts are used.

While wide-bandwidth Class A and Class B amplifiers are common, most circuits operating in Class C and higher are tuned at the output. The tuning accomplishes two things. First, it allows different terminations to exist for different frequencies. For example, a resistive load could be presented at the drive frequency while presenting a short circuit at some or all harmonics. The second consequence of tuning is that reactive loads can be created and presented to the amplifier collector or drain. This then provides independent control of current and voltage waveforms.

While not as common as A, B, and C, Class D and E amplifiers are of increasing interest. The Class D circuit is a balanced (two transistor) switching format where the input is driven hard enough to produce square wave collector waveforms. Class E amplifiers usually use a single switching device with output tuning that allows high current to flow in the device only when the output voltage is low. Other “switching amplifier” class designators refer to the various techniques of controlling the switched currents and voltages.

Class A and AB amplifiers are capable of good envelope linearity, so they are the most common formats used in the output of SSB amplifiers. Class B and, predominantly, Class C amplifiers are used for CW and FM applications, but lack the envelope linearity

needed for SSB.

Efficiency varies considerably between amplifier class. The Class A amplifier can reach a collector efficiency of 50%, but no higher, with much lower values being typical. Class AB amplifiers are capable of higher efficiency, although the wideband circuits popular in HF transceivers typically offer only 30% at full power. A Class C amplifier is capable of efficiencies approaching 100% as the conduction cycle becomes small, with common values of 50 to 75%. Both Class D and E are capable of 90% and higher efficiency. An engineering text treating power amplifier details is Krauss, Bostian, and Raab's *Solid State Radio Engineering*. A landmark paper by a Cal Tech group led by David Rutledge, KN6EK, targeted to the home experimenter, *High-Efficiency Class-E Power Amplifiers*, was presented in *QST* for May and June, 1997.

### 5.4.4 RF Amplifiers with Feedback

The feedback amplifier appears frequently in amateur RF circuits. This is a circuit with two forms of negative feedback with (usually) a single transistor to obtain wide bandwidth, well-controlled gain and well-controlled, stable input and output resistances. Several of these amplifiers can be cascaded to form a high gain circuit that is both stable and predictable.

The small-signal schematic for the feedback amplifier is shown in Figure 5.38 without bias components or power supply details. The design begins with an NPN transistor biased for a stable dc current. Gain is reduced with emitter degeneration, increasing input resistance while decreasing gain. Additional feedback is then added with a parallel feedback resistor,  $R_f$ , between the collector and base. This is much like the resistor between an op-amp output and the inverting input which reduces gain and decreases input resistance.

Several additional circuits are presented showing practical forms of the feedback amplifier. Figure 5.39 shows a complete circuit. The base is biased with a resistive divider from

Figure 5.38 — Small-signal circuit for a feedback amplifier.

the collector. However, much of the resistor is bypassed, leaving only  $R_f$  active for ac signal feedback. Emitter degeneration is coupled to the emitter. The resistor  $R_E$  denotes the degeneration since  $R_E$  is normally much smaller than the emitter bias resistor. Components that are predominantly used for biasing are marked with “B.” This amplifier would normally be terminated in 50  $\Omega$  at both the input and output. The transformer has the effect of making the 50- $\Omega$  load “look like” a larger load value,  $R_L = 200 \Omega$  to the collector. This is a common and useful value for many HF applications.

Figure 5.40 differs from Figure 5.39 in two places. First, the collector is biased through

Figure 5.39 — A practical feedback amplifier. Components marked with “B” are predominantly for biasing. The 50- $\Omega$  output termination is transformed to 200  $\Omega$  at the collector. A typical RF transformer is 10 bifilar turns of #28 on a FT-37-43 ferrite toroid. The inductance of one of the two windings should have a reactance of around 250  $\Omega$  at the lowest frequency of operation.

Figure 5.40 — A variation of the feedback amplifier with a 50- $\Omega$  output termination at the collector.

RF choke instead of a transformer. The collector circuit then “sees”  $50\ \Omega$  when that load is connected. Second, the emitter degeneration is in series with the bias, instead of the earlier parallel connection. Either scheme works well, although the parallel configuration affords experimental flexibility with isolation between setting degeneration and biasing. Amplifiers without an output transformer are not constrained by degraded transformer performance and often offer constant or “flat” gain to several GHz.

The variation of **Figure 5.41** may well be the most general. It uses an arbitrary transformer to match the collector. Biasing is traditional and does not interact with the feedback.

Feedback is obtained directly from the output tap in the circuit of **Figure 5.42**. While this scheme is common, it is less desirable than the others, for the transformer is part of the feedback loop. This could lead to instabilities. Normally, the parallel feedback tends to stabilize the amplifiers.

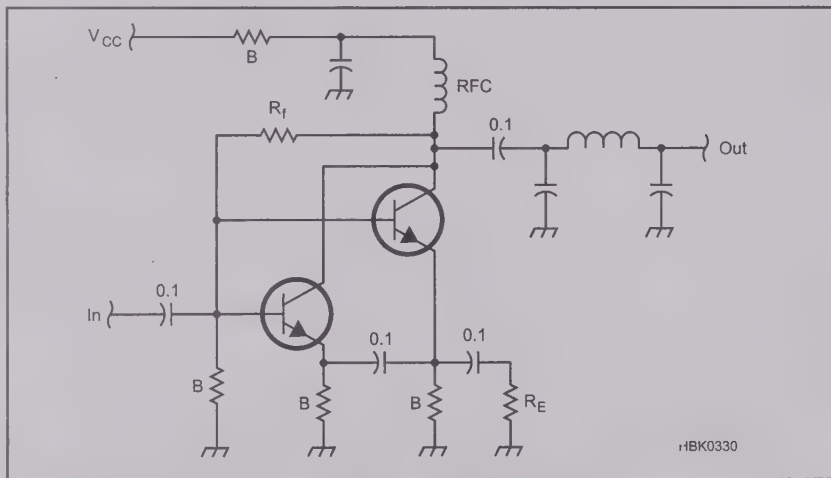

The circuit of **Figure 5.43** has several features. Two transistors are used, each with a separate emitter biasing resistor. However, the coupling causes the pair to operate as a single device with degeneration set by  $R_E$ . The parallel feedback resistor,  $R_f$ , is both a signal feedback element and part of the bias divider. This constrains the values slightly. Finally, an arbitrary output load can be presented to the composite collector through a  $\pi$ -type matching network. This provides some low pass filtering, but constrains the amplifier bandwidth.

**Figure 5.41** — This form of the feedback amplifier uses an arbitrary transformer. Feedback is isolated from bias components.

**Figure 5.42** — A feedback amplifier with feedback from the output transformer tap. This is common, but can produce unstable results.

**Figure 5.43** — Feedback amplifier with two parallel transistors.

## 5.5 Ferrite Materials

Ferrites are ceramics consisting of various metal oxides formulated to have very high permeability. Iron, manganese, manganese zinc (MnZn), and nickel zinc (NiZn) are the most commonly used oxides. Ferrite cores and beads are available in many styles, as shown in **Figure 5.44**. Wires and cables are then passed through them or wound on them.

When ferrite surrounds a conductor, the high permeability of the material provides a much easier path for magnetic flux set up by current flow in the conductor than if the wire were surrounded only by air. The short length of wire passing through the ferrite will thus see its self-inductance “magnified” by the relative permeability of the ferrite. The ferrites used for suppression are soft ferrites — that is, they are not permanent magnets.

Recalling the definition in the **Electrical Fundamentals** chapter, permeability ( $\mu$ ) is the characteristic of a material that quantifies the ease with which it supports a magnetic field. Relative permeability is the ratio of the permeability of the material to the permeability of free space. The relative permeability of nonmagnetic materials like air, copper, and aluminum is 1, while magnetic materials have a relative permeability much greater than 1. Typical values (measured at power frequencies) for stainless steel, steel and mu-metal are on the order of 500, 1000 and 20,000 respectively. Various ferrites have values from the low tens to several thousand. The permeability of these materials changes with frequency and this affects their suitability for use as an inductor’s magnetic core or as a means of providing EMI suppression.

Manufacturers vary the chemical composition (the *mix* or *material “type”*) and the dimensions of ferrites to achieve the desired electrical performance characteristics. It is important to select a mix with permeability and loss characteristics that are appropriate for the intended frequency range and application. (The **Component Data and References** chapter includes tables showing the data for different

**Figure 5.44** — Ferrites are made in many forms. Beads are cylinders with small center holes so that they can be slid over wires or cables. Toroidal cores are more ring-like so that the wire or cable can be passed through the center hole multiple times. Snap-on or split cores are made to be clamped over cables too large to be wound around the core or for a bead to be installed.

**Figure 5.45** — Equivalent circuits for ferrite material. (A) shows the equivalent series circuit specified by the data sheet. (B) shows an over-simplified equivalent circuit for a ferrite choke. (C) shows a better equivalent circuit for a ferrite choke.

types of ferrite and powdered-iron cores and appropriate frequency ranges for each.)

Fair-Rite Products Corp. supplies most of the ferrite materials used by amateurs, and their website ([www.fair-rite.com](http://www.fair-rite.com)) includes extensive technical data on both the materials and the many parts made from those materials. Much can be learned from the study of this data, the most extensive of any manufacturer. The website includes two detailed application notes on the use of ferrite materials, *How to Choose Ferrite Components for EMI Suppression* and *Use of Ferrites in Broadband Transformers*.

### 5.5.1 Ferrite Permeability and Frequency

Product data sheets characterize ferrite materials used as chokes by graphing their series equivalent impedance, and chokes are usually analyzed as if their equivalent circuit had only a series resistance and inductance, as shown in **Figs 5.45A** and **5.45B**. (Figure 5.45 presents small-signal equivalent circuits.

**Figure 5.46** — Permeability of a typical ferrite material, Fair-Rite Type #61 (A) and of Type #43 material (B). (Based on product data published by Fair-Rite Products Corp.)

**Figure 5.47** — Impedance of a bead for EMI suppression at UHF, Fair-Rite Type #61. (Based on product data published by Fair-Rite Products Corp.)

**Figure 5.48 — Impedance of different length beads of Fair-Rite Type #43 material. The longer the bead, the higher the impedance. (Based on product data published by Fair-Rite Products Corp.)**

Issues of temperature and saturation at high power levels are not addressed in this section.) The actual equivalent circuit is closer to Figure 5.45C. The presence of both inductance and capacitance creates resonances visible in the graphs of impedance versus frequency as discussed below. One resonance is created by the pair  $L_D C_D$  and the other by  $L_C C_C$ .

**Figure 5.46A** graphs the permeabilities  $\mu'_S$  and  $\mu''_S$  for Fair-Rite Type #61 ferrite material (Fair-Rite products are identified by a material "Type" and a number), one of the many mix choices available. This material is recommended for use in inductive applications below 25 MHz and for EMI suppression at frequencies above 200 MHz.

For the simple series equivalent circuit of Figure 5.45A and B, the permeability constant for ferrite is actually complex;  $\mu = \mu'_S + j \mu''_S$ . In this equation,  $\mu'_S$  represents the component of permeability defining ordinary inductance, and  $\mu''_S$  describes the component that affects losses in the material. You can see that up to approximately 20 MHz,  $\mu'_S$  is nearly constant, meaning that an inductor wound on a core of this material will have a stable inductance. Below about 15 MHz, the chart shows that  $\mu'_S$  is much smaller than  $\mu''_S$ , so that losses are small, making this material good for high power inductors and transformers in this frequency range.

Above 15 MHz,  $\mu''_S$  increases rapidly and so do the material's associated losses, peaking between 300 and 400 MHz. That makes the inductor very lossy at those frequencies and good for suppressing EMI by absorbing energy in the unwanted signal. **Figure 5.47** shows the manufacturer's impedance data for one "turn" of wire through a cylindrical ferrite bead (a straight wire passing through the bead) made of mix #61 with the expected peak in impedance above 200 MHz. Interestingly,

**Figure 5.49 — Typical one-piece ferrite bead configurations. Component leads or cables can be inserted through beads one or more times to create inductance and loss as described in the text.**

$X_L$  goes below the graph above resonance, but it isn't zero. The negative reactance is created by the capacitors in Figure 5.45C.

The Type #43 mix (see Figure 5.46B) used for the beads of **Figure 5.48** is optimized

**Figure 5.50 — A ferrite choke consisting of multiple turns of cable wound on a 2.4-in. OD x 1.4-in. ID x 0.5-in. toroid core.**

for suppression at VHF (30-300 MHz). Type #43 material's  $\mu'_S$  is much higher than type #61, meaning that fewer turns are required to achieve the needed inductance. But  $\mu''_S$  for #43 remains significant even at low frequencies, limiting its usefulness for inductor and transformer cores that must handle high power. The figure shows the impedance data for several beads of different lengths. The longer the bead, the higher the impedance. The same effect can be obtained by stringing multiple beads together on the same wire or cable.

### 5.5.2 Resonances of Ferrite Cores

Below resonance, the impedance of a wire passing through a ferrite cylinder is propor-

**Figure 5.51 — Impedance of multi-turn choke wound on a Fair-Rite Type #43 core as shown in Figure 5.50. Type #43 material is optimized for use as a choke for the VHF range. (Measured data)**

Figure 5.52 — Impedance of multi-turn choke wound on a Fair-Rite Type #78 core as shown in Figure 5.50. Type #78 material is optimized for use as a choke below 2 MHz. (Measured data)

Figure 5.53 — Series reactive component of the chokes of Figure 5.52. (Measured data)

tional to the length of the cylinder. Figure 5.48 shows the impedance of a family of beads that differ primarily in their length. There are also small differences in their cross section, which is why the resonant frequency shifts slightly as discussed below. Figure 5.49 shows some typical ferrite bead configurations.

Like all inductors, the impedance of a ferrite choke below resonance is approximately proportional to the square of the number of turns passing through the core. Figure 5.50 shows a multi-turn choke wound on a 2.4-inch OD × 1.4-inch ID × 0.5-inch ferrite toroid core. Figure 5.51 is measured data for the

choke in Figure 5.50 made of ferrite optimized for the VHF range (30-300 MHz). The data of Figure 5.52 are for toroids of the same size, but wound on a material optimized for use below 2 MHz.

The measured data for Figures 5.51, 5.52, and 5.53 are for chokes wound with small diameter wire. The choke of Figure 5.50 will exhibit a somewhat lower resonant frequency for the same number of turns because the larger diameter cable has more capacitance between turns. The cable in the photo is a high quality braid-shielded twisted pair with an outside diameter comparable to RG-59.

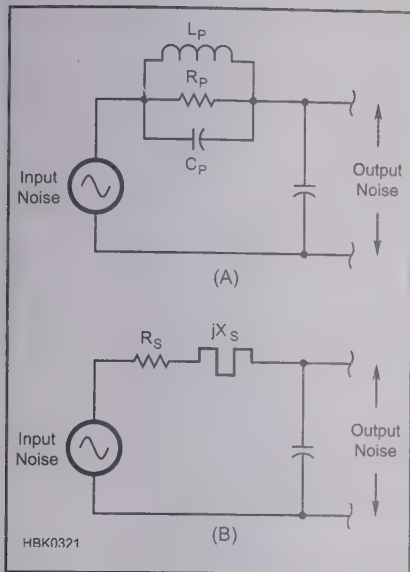

We'll study the  $L_D C_D$  resonance first. A classic text (*Soft Ferrites, Properties and Applications*, by E. C. Snelling, published in 1969), shows that there is a dimensional resonance within the ferrite related to the velocity of propagation ( $V_p$ ) within the ferrite and standing waves that are set up in the cross-sectional dimensions of the core. In general, for any given material, the smaller the core, the higher will be the frequency of this resonance, and to a first approximation, the resonant frequency will double if the core dimension is halved. In Figure 5.45C,  $L_D$  and  $C_D$  account for this dimensional resonance, and  $R_D$  for losses within the ferrite.  $R_D$  is mostly due to eddy currents (and some hysteresis) in the core.

Now it's time to account for  $R_C$ ,  $L_C$  and  $C_C$ . Note that there are two sets of resonances for the chokes wound around the Type #78 material (Figure 5.52), but only one set for the choke of Figure 5.51. For both materials, the upper resonance starts just below 1 GHz for a single turn and moves down in frequency as the number of turns is increased. Figure 5.53, the reactance for the chokes of Figure 5.52, also shows both sets of resonances. That's why the equivalent circuit must include two parallel resonances!

The difference between these materials that accounts for this behavior is their chemical composition (the mix). Type #78 is a MnZn ferrite, while Type #43 is a NiZn ferrite. The velocity of propagation ( $V_p$ ) in NiZn ferrites is roughly two orders of magnitude higher than for MnZn, and, at those higher frequencies, there is too much loss to allow the standing waves that establish dimensional resonance to exist.

To understand what's happening, we'll return to our first order equivalent circuit of a ferrite choke (Figure 5.45C).  $L_C$ , and  $R_C$ , and  $C_C$  are the inductance, resistance, (including the effect of the  $\mu$  of the ferrite), and stray capacitance associated with the wire that passes through the ferrite. This resonance moves down in frequency with more turns because both L and C increase with more turns. The dimensional resonance does not move, since it depends only on the dimensions  $V_p$  of the ferrite.

What is the source of  $C_C$  if there's no "coil," only a single wire passing through a cylinder?

**Figure 5.54** — At A, the series element of the divider is a parallel-resonant circuit. At B, the series element of the divider is the series-equivalent circuit used by ferrite data sheets.

It's the parasitic capacitance from the wire at one end of the cylinder to the wire at the other end, with the ferrite acting as the dielectric. Yes, it's a very small capacitance, but you can see the resonance it causes in the measured data and on the data sheet.

### 5.5.3 Ferrite Series and Parallel Equivalent Circuits

Let's talk briefly about series and parallel equivalent circuits. Many impedance analyzers express the impedance between their terminals as  $Z$  with a phase angle, and the series equivalent  $R_S$  and  $X_S$ . They could just have easily expressed that same impedance using the parallel equivalent  $R_P$  and  $X_P$  but  $R_P$  and  $X_P$  will have values that are numerically different from  $R_S$  and  $X_S$ . (See the section on series-parallel impedance transformation in the **Electrical Fundamentals** chapter.)

It is important to remember that in a series circuit, the larger value of  $R_S$  and  $X_S$  has the greatest influence, while in a parallel circuit, the smaller value of  $R_P$  and  $X_P$  is dominant. In other words, for  $R_P$  to dominate,  $R_P$  must be small.

Both expressions of the impedance (series or parallel) are correct at any given frequency, but whether the series or parallel representation is most useful will depend on the physics of the device being measured and how that

**Figure 5.55** — At A, the impedance of multi-turn chokes on a Type #31 2.4-in. OD toroidal core. At B, the equivalent series resistance of the chokes of (A). (Measured data)

device is used in a circuit. We've just seen, for example, that the parallel equivalent circuit is a more realistic representation of a ferrite choke — the values of  $R_P$ ,  $L_P$ , and  $C_P$  will come much closer to remaining constant as frequency changes than if we use the series equivalent. ( $R_P$ ,  $L_P$  and  $C_P$  won't be precisely constant though, because the physical properties of all ferrites — permeability, resistivity and permittivity — all vary with frequency.)

But virtually all product data for ferrite chokes is presented as the series equivalent

$R_S$  and  $X_S$ . Why? First, because it's easy to measure and understand, second, because we tend to forget there is stray capacitance, and third because ferrite beads are most often used as chokes to reduce current in a series circuit! **Figure 5.54A** and **Figure 5.54B** are both useful representations of the voltage divider formed by a ferrite choke and a small bypass capacitor across the device input. Which we use will depend on what we know about our ferrite.

If we know  $R_P$ ,  $L_P$  and  $C_P$  and they are

**Figure 5.56 — At A, the impedance of multi-turn chokes on a Type #43 2.4-in. OD toroidal core. At B, the equivalent series resistance of the chokes of A. (Measured data).**

constant over the frequency range of interest, Figure 5.54A may be more useful, because we can insert values in a circuit model and perhaps tweak the circuit. But if we have a graph of  $R_S$  and  $X_S$  vs frequency, Figure 5.54B will give us a good answer faster. Because we will most often be dealing with  $R_S$  and  $X_S$  data, the series circuit equivalents are used most often. Another reason for using  $R_S$  and  $X_S$  is that the impedance of two or more ferrite chokes in series can be computed simply by

adding their  $R_S$  and  $X_S$  components, just as with any other series impedances! When you look at the data sheet plots of  $R_S$ ,  $X_L$  and  $Z$  for a standard ferrite part, you are looking at the series equivalent parameters of their dominant resonance. For most MnZn materials, it is dimensional resonance, while, for most NiZn materials, it is the circuit resonance.

Values for  $R_p$ ,  $L_p$  and  $C_p$  for nearly any ferrite choke can be obtained by curve-fitting the data for its parallel-resonance curve. (Self-

resonance is discussed earlier in this chapter.) Because the  $C_p$  of many practical chokes is quite small and their impedance at resonance is often rather high, they are quite difficult to measure accurately, especially with reflection-based measurement systems. See the **Test Equipment and Measurements** chapter for a simple measurement method that can provide good results. More information on the use of ferrite cores and beads for EMI suppression is available in the chapter on **RF Interference** and in *The ARRL RFI Book*. A thorough treatment of the use of these ferrite materials for EMI suppression is continued in the online publication *A Ham's Guide to RFI, Ferrites, Baluns, and Audio Interfacing* at [k9yc.com/publish.htm](http://k9yc.com/publish.htm). The use of ferrite beads and cores for transmitting chokes is presented in the **Transmission Lines** chapter.

### 5.5.4 Type 31 Material

Type #31 material made by Fair-Rite Products is extremely useful as a choke core, especially if some component of your problem occurs below 5 MHz. Measured data for the new material is displayed in **Figs 5.55A and 5.55B**. Compare it with **Figs 5.56A and 5.56B**, which are corresponding plots for the older Type #43 material. By comparison, Type #31 provides nearly 7 dB greater choking impedance at 2 MHz, and at least 3 dB more on 80 meters. At 10 MHz and above, the two materials are nearly equivalent, with Type #43 being about 1 dB better. If your goal is EMI suppression or a feed line choke (a so-called "current balun"), the Type #31 material is the best all round performer to cover all HF bands, and is clearly the material of choice at 5 MHz and below. Between 5 MHz and 20 MHz, Type #43 has a slight edge (about 1 dB), and above 20 MHz they're equivalent. (Baluns are discussed more in the section below on Transmission Line Transformers and in the chapters on **Transmission Lines** and **Antennas**.)

Type #31 material is useful because it exhibits both of the resonances in our equivalent circuit — that is, the dimensional resonance of the core and the resonance of the choke with the lossy permeability of the core material. Below 10 MHz, these two resonances combine (in much the manner of a stagger-tuned IF) to provide significantly greater suppression bandwidth (roughly one octave, or one additional harmonically related ham band). The result is that a single choke on a Type #31 core can be made to provide very good suppression over about 8:1 frequency span, as compared to 4:1 for Type #43. Type #31 also has somewhat better temperature characteristics at HF.

## 5.6 Impedance Matching Networks

An impedance transforming or matching network is one that accepts power from a generator with one characteristic impedance, the source, and delivers virtually all of that power to a load at a different impedance. The simple designs in this section provide matching at only one frequency. More refined methods discussed in the reference texts can encompass a wide band of frequencies.

Both source and load impedances are likely to be complex with both real and imaginary (reactive) parts. The procedures given in this section allow the reader to design the common impedance-matching networks based on the simplification that both the source and load impedance are resistive (with no reactive component). To use these procedures with a complex load or source impedance, the usual method is to place a reactance in series with the impedance that has an equal and opposite reactance to cancel the reactive component of the impedance to be matched. Then treat the

resulting purely-resistive impedance as the resistance to be transformed. For example, if a load impedance to be matched is  $120 + j 40 \Omega$ , add capacitive reactance of  $-j 40 \Omega$  in series with the load, resulting in a load impedance of  $120 + j 0 \Omega$  so that the following procedures can be used. The series reactance-canceling component may then be combined with the matching network's output component in some configurations.

A set of 14 simple resonant networks, and their equations, is presented in **Figure 5.58**. Note that in these diagrams  $R_S$  is the low impedance side and  $R_L$  is the high impedance side and that the X values are calculated in the top-down order given.

The formulas for the various networks use and produce values of reactance. To convert the reactances to L and C values, use the formulas

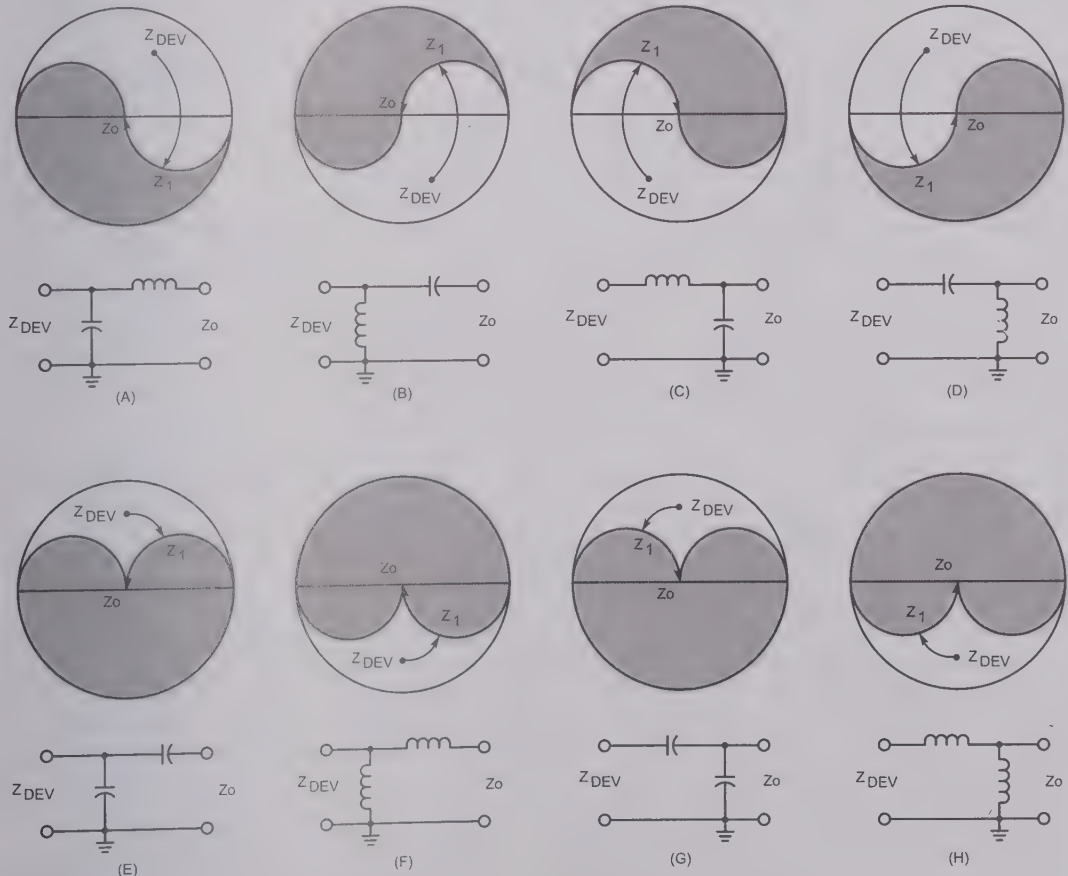

$$C = \frac{1}{2\pi f X_C} \text{ and } L = \frac{X_L}{2\pi f}$$

The program *MATCH.EXE* with the downloadable supplemental material can perform the calculations.

You may wish to review the section on series-parallel impedance transformations in the **Electrical Fundamentals** chapter as those techniques form the basis of impedance-matching network design. There is additional discussion of L networks in the chapters on **Transmission Lines** and of Pi networks in the **RF Power Amplifiers** chapter. These discussions apply to more specific applications of the networks.

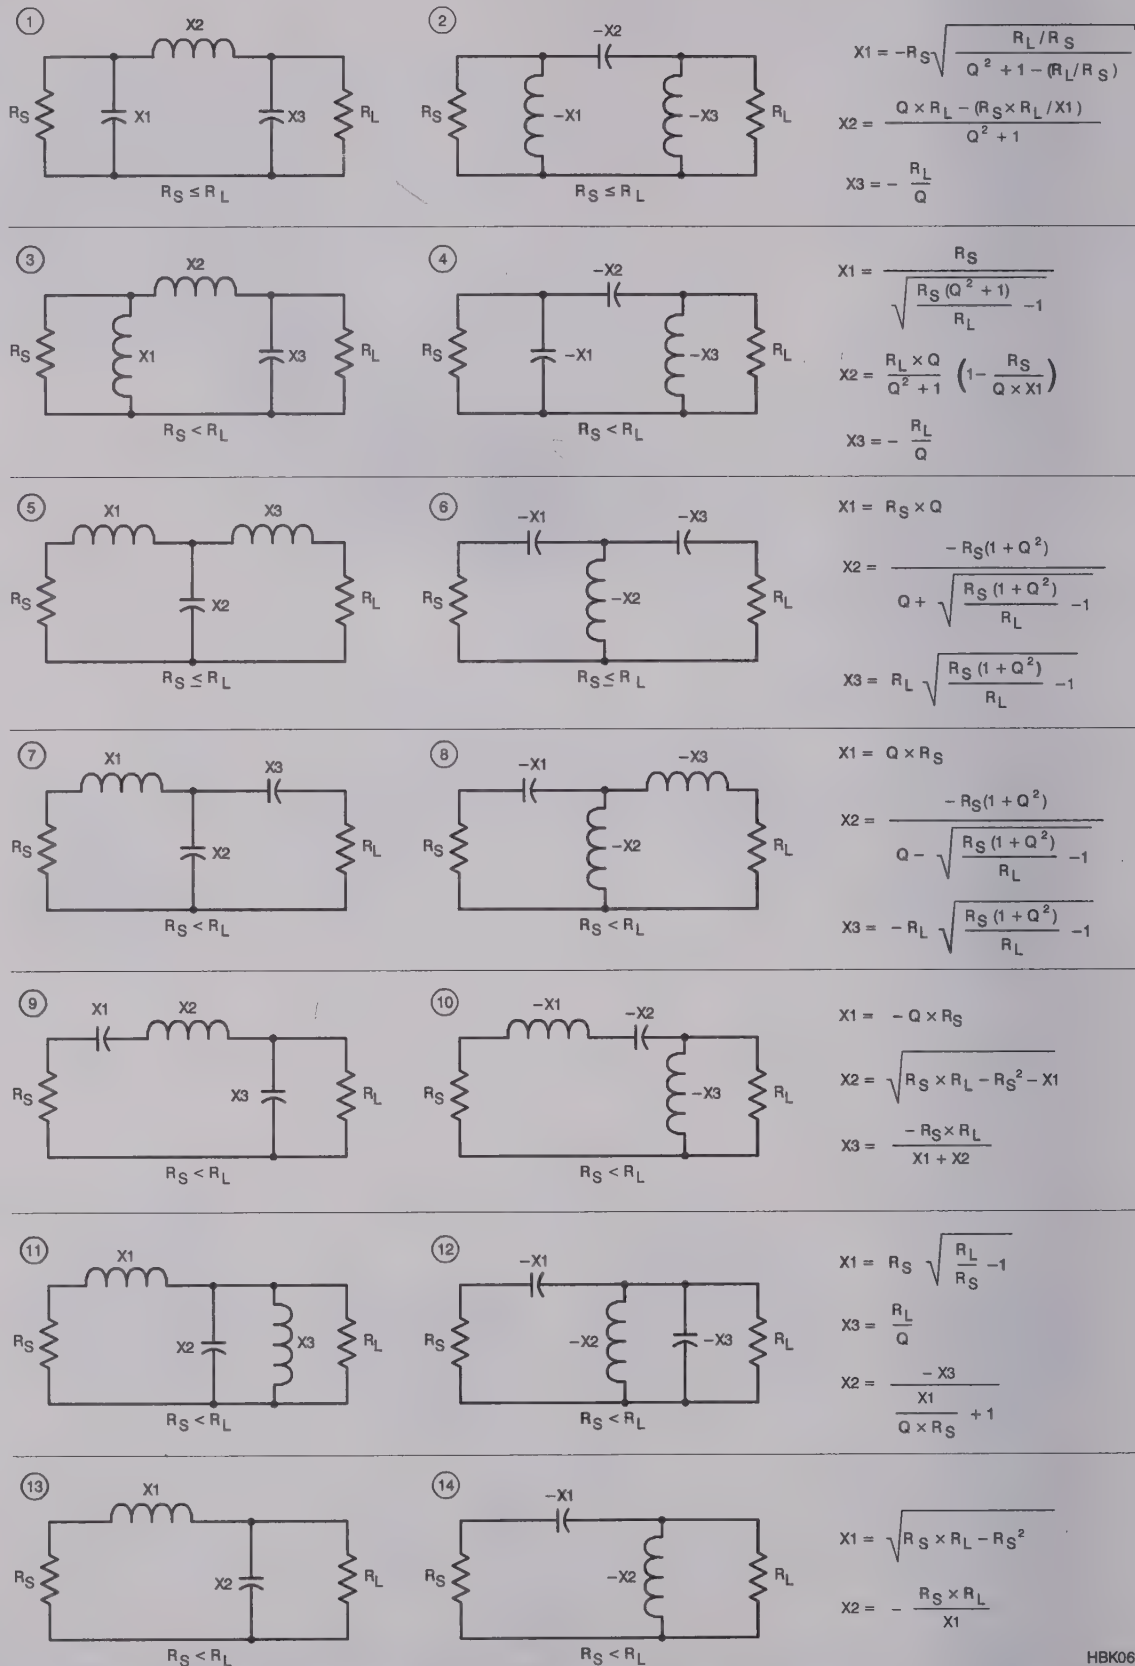

### 5.6.1 L Networks

Perhaps the most common LC impedance transforming network is the L network, so named because it uses two elements — one series element and one parallel — resembling the capital L on its side. There are eight different types of L networks as shown in **Figure**

HBK0331

**Figure 5.57** — L networks which will match a complex impedance (shown here as  $Z_{DEV}$ , the output impedance of a device) to  $Z_0$ , a resistive source or load. Impedances within the shaded portion of the simplified Smith Chart cannot be matched by the network.  $Z_1$  represents the impedance that is transformed from  $Z_{DEV}$  by the series element.

HBK0674

Figure 5.58 — Fourteen impedance transforming networks with their design equations (for lossless components).

5.57. (Types G and H are not as widely used and not covered here.) The simplified Smith Chart sketches show what range of impedance values can be transformed to the required impedance  $Z_0$  and the path on the chart by which the transformation is achieved by the two reactances. (An introductory discussion of the Smith Chart is provided with the downloadable supplemental content, and a detailed treatment is available in *The ARRL Antenna Book*.)  $Z_{DEV}$  represents the output impedance of a device, such as a transistor amplifier or any piece of equipment.

The process of transformation works the same in both “directions.” That is, a network designed to transform  $Z_{DEV}$  to  $Z_0$  will also transform  $Z_0$  to  $Z_{DEV}$  if reversed. The L network (and the Pi and T networks discussed below) is *bilateral*, as are all lossless networks.

Purely from the standpoint of impedance matching, the L network can be constructed with inductive or capacitive reactance in the series arm and the performance will be exactly the same in either case. However, the usual case in amateur circuits is to place the inductive reactance in the series arm to act as a low pass filter. Your particular circumstances may dictate otherwise, however. For example, you may find it useful that the series-C/parallel-L network places a dc short circuit across one side of the network while blocking dc current through it.

The design procedure for L network configurations A through F in Figure 5.57 is as follows:

Given the two resistance values to be matched, connect the series arm of the circuit to the smaller of the two ( $R_S$ ) and the parallel arm to the larger ( $R_P$ ).

Find the ratio  $R_P/R_S$  and the L network’s Q:

$$Q = \sqrt{\frac{R_P}{R_S} - 1}$$

Calculate the series reactance  $X_S = QR_S$

Calculate the parallel reactance  $X_P = R_P/Q$ .

## 5.6.2 Pi Networks

Another popular impedance matching network is the Pi network shown in circuits 1 and 2 of Figure 5.58. The Pi network can be thought of as two L networks “back to back.” For example, the Pi network in circuit 1 can be split into the L network of circuit 13 on the right and its mirror image on the

left. The two inductors in series are combined into the single inductance of the Pi network. There are other forms of the Pi network with different configurations of inductance and capacitance, but the version shown is by far the most common in amateur circuits.

The use of two transformations allows the designer to choose Q for the Pi network, unlike the L network for which Q is determined by the ratio of the impedances to be matched. This is particularly useful for matching amplifier outputs as discussed in the **RF Power Amplifier** chapter because it allows more control of the network’s frequency response and of component values. Q must be high enough that  $(Q^2 + 1) > (R_1/R_2)$ . If these two quantities are equal,  $X_{C2}$  becomes infinite, meaning zero capacitance, and the Pi network reduces to the L network in Figure 5.57A. The design procedure for the Pi network in Figure 5.58 is as follows:

Determine the two resistance values to be matched,  $R_1 > R_2$ , and select a value for Q. Follow the calculation sequence for circuit 1 or 2 in Figure 5.58.

Calculate the value of the parallel reactance  $X_{C1} = R_1/Q$ .

Calculate the value of the parallel reactance  $X_{C2}$

$$X_{C2} = R_2 \sqrt{\frac{R_1/R_2}{Q^2 + 1 - R_1/R_2}}$$

Calculate the value of the series reactance  $X_L$

$$X_L = \frac{QR_1 + R_1R_2/X_{C2}}{Q^2 + 1}$$

## 5.6.3 T Networks

Many amateur transmission line impedance matching units (“antenna tuners”) use the version of the T network in circuit 6 of Figure 5.58. The circuits are constructed using variable capacitors and a tapped inductor. This is easier and less expensive to construct than a fully-adjustable version of circuit 5 in which two variable inductors are required. Circuit 5 is especially useful in matching relatively low input impedances from solid-state amplifier outputs to 50- $\Omega$  loads with low Q and good harmonic suppression due to the series inductances. Circuit 7 is also useful in solid-state amplifier design as described in the reference texts listed at the end of this chapter.

The T network shown in circuit 5 of Figure 5.58 is especially useful for matching to relatively low impedance from 50- $\Omega$  sources with practical components and low Q. Like the Pi network, Q must be high enough that  $(Q^2 + 1) > (R_1/R_2)$ . Designing the component values for this network requires the calculation of a pair of intermediate values, A and B, to make the equations more manageable.

Determine the two resistance values to be matched,  $R_1 > R_2$ , and select a value for Q.

Calculate the intermediate variables A and B

$$A = R_1(Q^2 + 1) \text{ and } B = \sqrt{\frac{A}{R_2} - 1}$$

Calculate the value of the input series reactance  $X_{L1} = R_1 Q$ .

Calculate the value of the output series reactance  $X_{L2} = R_2 B$ .

Calculate the value of the parallel reactance  $X_C = A / (Q + B)$

Convert the reactances to component values:

$$C = \frac{1}{2\pi f X_C} \text{ and } L = \frac{X_L}{2\pi f}$$

## 5.6.4 Impedance Inversion

Symmetrical Pi and T networks have the useful property of *impedance inversion* when the reactances of all elements are the same at the design frequency:  $X_C = X_L = |X|$ , resulting in a Q of 1. For either type of network, the impedance looking into the network,  $Z_{IN}$ , will be the load impedance,  $Z_{OUT}$ , inverted about X:

$$Z_{IN} = \frac{X^2}{Z_{OUT}}$$

This is the same effect as if the network were replaced with a  $1/4$ -wavelength transmission line with  $Z_0 = |X|$ . Since the network is symmetrical, the inversion occurs in either direction through the network. The result is true only at the frequency for which all reactances are equal.

Forexample, to invert all impedances about 50  $\Omega$ , set  $X = 50 \Omega$  at the design frequency. The input impedance will then be  $50^2/Z_{OUT}$ . If  $Z = 10 + j10 \Omega$  is connected to one end of the network, the impedance looking into the other end of the network will be  $2500 / (10 + j10) = 125 - j125 \Omega$ .

# 5.7 RF Transformers

## 5.7.1 Air-Core Nonresonant RF Transformers

Air-core transformers often function as mutually coupled inductors for RF applications. They consist of a primary winding and a secondary winding in close proximity. Leakage reactances are ordinarily high, however, and the coefficient of coupling between the primary and secondary windings is low. Consequently, unlike transformers having a magnetic core, the turns ratio does not have as much significance. Instead, the voltage induced in the secondary depends on the mutual inductance.

In a very basic transformer circuit operating at radio frequencies, such as in **Figure 5.59**, the source voltage is applied to L1.  $R_S$  is the series resistance inherent in the source. By virtue of the mutual inductance,  $M$ , a voltage is induced in L2. A current flows in the secondary circuit through the reactance of L2 and the load resistance, of  $R_L$ . Let  $X_{L2}$  be the reactance of L2 independent of L1, that is, independent of the effects of mutual inductance. The impedance of the secondary circuit is then:

$$Z_S = \sqrt{R_L^2 + X_{L2}^2} \quad (12)$$

where

- $Z_S$  = the impedance of the secondary circuit in ohms,
- $R_L$  = the load resistance in ohms, and
- $X_{L2}$  = the reactance of the secondary inductance in ohms.

The effect of  $Z_S$  upon the primary circuit is the same as a coupled impedance in series with L1. **Figure 5.60** displays the coupled impedance ( $Z_p$ ) in a dashed enclosure to indicate that it is not a new physical component. It has the same absolute value of phase angle as in the secondary impedance, but the sign of the reactance is reversed; it appears as a capacitive reactance. The value of  $Z_p$  is:

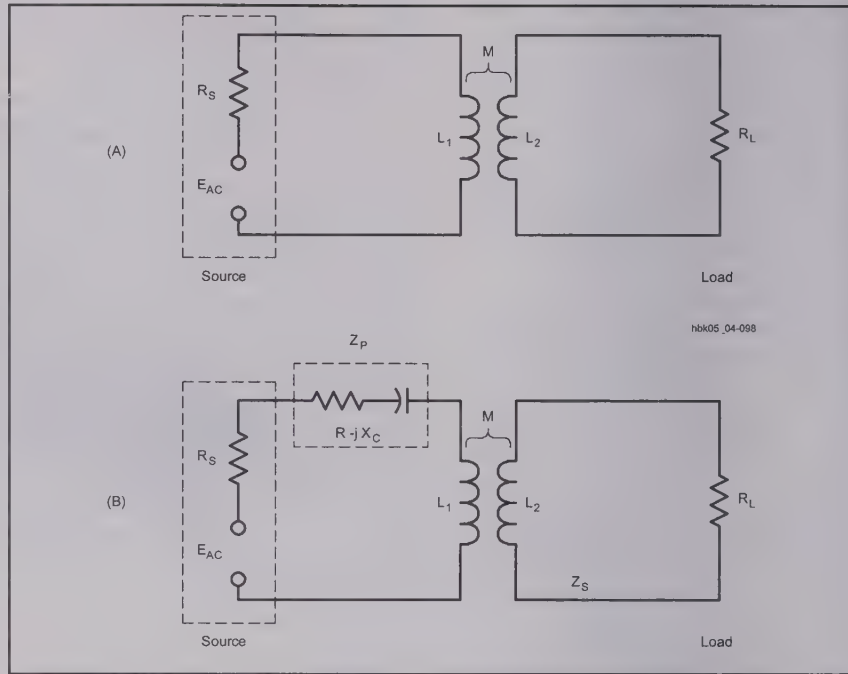

$$Z_p = \frac{(2 \pi f M)^2}{Z_S} \quad (13)$$

where

- $Z_p$  = the impedance introduced into the primary,
- $Z_S$  = the impedance of the secondary circuit in ohms, and
- $2 \pi f M$  = the mutual reactance between the reactances of the primary and secondary coils (also designated as  $X_M$ ).

## 5.7.2 Air-Core Resonant RF Transformers

The use of at least one resonant circuit in place of a pair of simple reactances elimi-

**Figure 5.59** — The coupling of a complex impedance back into the primary circuit of a transformer composed of nonresonant air-core inductors.

**Figure 5.60** — An air-core transformer circuit consisting of a resonant primary circuit and an untuned secondary.  $R_S$  and  $C_S$  are functions of the source, while  $R_L$  and  $C_L$  are functions of the load circuit.

nates the reactance from the transformed impedance in the primary. For loaded or operating Q of at least 10, the resistances of individual components is negligible. **Figure 5.60** represents just one of many configurations in which at least one of the inductors is in a resonant circuit. The reactance coupled into the primary circuit is cancelled if the circuit is tuned to resonance while the load is connected. If the reactance of the load capacitance,  $C_L$  is at least 10 times any stray capacitance in the circuit, as is the case for low impedance loads, the value of resistance coupled to the primary is

$$R1 = \frac{X_M^2 R_L}{X_2^2 + R_L^2} \quad (14)$$

where:

- R1 = series resistance coupled into the primary circuit,
- $X_M$  = mutual reactance,
- $R_L$  = load resistance, and
- $X_2$  = reactance of the secondary inductance.

The parallel impedance of the resonant circuit is just R1 transformed from a series to a parallel value by the usual formula,  $R_p = X_2^2 / R1$ .

The higher the loaded or operating  $Q$  of the circuit, the smaller the mutual inductance required for the same power transfer. If both the primary and secondary circuits consist of resonant circuits, they can be more loosely coupled than with a single tuned circuit for the same power transfer. At the usual loaded  $Q$  of 10 or greater, these circuits are quite selective, and consequently narrowband.

Although coupling networks have to a large measure replaced RF transformer coupling that uses air-core transformers, these circuits are still useful in antenna tuning units and other circuits. For RF work, powdered-iron toroidal cores have generally replaced air-core inductors for almost all applications except where the circuit handles very high power or the coil must be very temperature stable. Slug-tuned solenoid coils for low-power circuits offer the ability to tune the circuit precisely to resonance. For either type of core, reasonably accurate calculation of impedance transformation is possible. It is often easier to experiment to find the correct values for maximum power transfer, however.

### 5.7.3 Broadband Ferrite RF Transformers

The design concepts and general theory of ideal transformers presented in the **Electrical Fundamentals** chapter apply also to transformers wound on ferromagnetic-core materials (ferrite and powdered iron). As is the case with stacked cores made of laminations in the classic I and E shapes, the core material has a specific permeability factor that determines the inductance of the windings versus the number of wire turns used. (See the earlier discussion on Ferrite Materials in this chapter.)

Toroidal cores are useful from a few hundred hertz well into the UHF spectrum. The principal advantage of this type of core is the self-shielding characteristic. Another feature is the compactness of a transformer or inductor. Therefore, toroidal-core transformers are excellent for use not only in dc-to-dc converters, where tape-wound steel cores are employed, but at frequencies up to at least 1000 MHz with the selection of the proper core material for the range of operating frequencies. Toroidal cores are available from micro-miniature sizes up to several inches in diameter that can handle multi-kW military and commercial powers.

One of the most common ferromagnetic transformers used in amateur circuits is the conventional broadband transformer. Broadband transformers with losses of less than 1 dB are employed in circuits that must have a uniform response over a substantial frequency range, such as a 2- to 30-MHz broadband amplifier. In applications of this sort, the reactance of the windings should be at least

four times the impedance that the winding is designed to look into at the lowest design frequency.

Example: What should be the winding reactances of a transformer that has a 300- $\Omega$  primary and a 50- $\Omega$  secondary load? Relative to the 50- $\Omega$  secondary load:

$$X_S = 4 Z_S = 4 \times 50 \Omega = 200 \Omega$$

and the primary winding reactance ( $X_P$ ) is:

$$X_P = 4 Z_P = 4 \times 300 \Omega = 1200 \Omega$$

The core-material permeability plays a vital role in designing a good broadband transformer. The effective permeability of the core must be high enough to provide ample winding reactance at the low end of the operating range. As the operating frequency is increased, the effects of the core tend to disappear until there are scarcely any core effects at the upper limit of the operating range. The limiting factors for high frequency response are distributed capacity and leakage inductance due to uncoupled flux. A high-permeability core minimizes the number of turns needed for a given reactance and therefore also minimizes the distributed capacitance at high frequencies.

Ferrite cores with a permeability of 850 are common choices for transformers used between 2 and 30 MHz. Lower frequency ranges, for example, 1 kHz to 1 MHz, may require cores with permeabilities up to 2000. Permeabilities from 40 to 125 are useful for VHF transformers. Conventional broadband transformers require resistive loads. Loads with reactive components should use appropriate networks to cancel the reactance.

The equivalent circuit in Figure 5.45 applies to any coil wound on a ferrite core, including transformer windings. (See the section on Ferrite Materials.) However, in the series-equivalent circuit,  $\mu'S$  is not constant with frequency as shown in Figure 5.46A and 5.46B. Using the low-frequency value of  $\mu'S$  is a useful approximation, but the effects of the parallel R and C should be included. In high-power transmitting and amplifier applications, the resistance R may dissipate some heat, leading to temperature rise in the core. The parasitic capacitances of each winding are shown as  $C_{PP}$  and  $C_{SP}$  in parallel with the primary and secondary circuits, respectively. These capacitances act to reduce high-frequency response.

Regarding C, there are at least two forms of stray capacitance between windings of a transformer as shown in Figure 5.61A; from wire-to-wire through air and from wire-to-wire through the ferrite, which acts as a dielectric material. These capacitances are combined as  $C_W$  from the primary to secondary circuits. (Ferrites with low iron

content have a relative dielectric constant of approximately 10 to 12.)

Figure 5.61B illustrates one method of transformer construction using a single toroid as the core. The primary of a step-down impedance transformer is wound to occupy the entire core, with the secondary wound over the primary. Conventional broadband transformers provide dc isolation between the primary and secondary circuits.

Winding-to-winding capacitance  $C_W$  reduces isolation between primary and secondary circuits. If isolation is an important characteristic of the transformer, then the windings should *not* be layered but separated on the core as in Figure 5.61C. The effect of  $C_W$  will increase with increasing frequency. This is a likely path for coupling of HF noise onto Ethernet cables if the network interface uses transformers.

A Faraday shield can be used to minimize

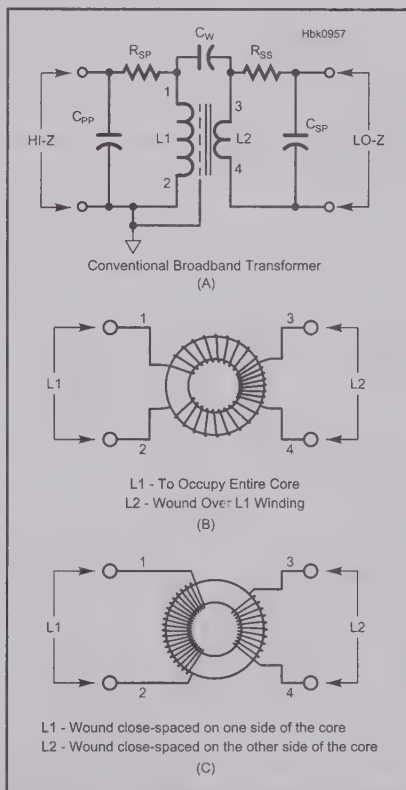

Figure 5.61 — (A) Schematic representation of a conventional broadband transformer wound on a toroid core. A Faraday shield (see text) can also be used to reduce capacitive coupling between the primary and secondary circuits. At (B) a pictorial showing the secondary winding (L2) is wound over the primary winding (L1) which provides very good coupling but low isolation. For designs emphasizing isolation over coupling, wind the transformer as in C with the primary and secondary windings separated on the core.

$C_w$ . It is made of conductive material, such as aluminum foil, that is connected to the circuit reference as in Figure 5.61A. (Faraday shields can also be connected to the secondary circuit reference.) Faraday shields are also used between windings in transformers for use in power, data, and audio circuits to prevent capacitive coupling of noise between windings.

The high voltages encountered in high-impedance-ratio step-up transformers may require that the core be wrapped with glass electrical tape before adding the windings (as an additional protection from arcing and voltage breakdown), especially with ferrite cores that tend to have rougher edges. In addition, high voltage applications should also use wire with high-voltage insulation and a high temperature rating.

The first step in designing the transformer is to select a core of the desired permeability. Convert the required reactances determined earlier into inductance values for the lowest frequency of use. To find the number of turns for each winding, use the  $A_L$  value for the selected core and the equation for determining the number of turns:

$$L = \frac{A_L \times N^2}{1000000} \quad (15)$$

where

$L$  = the inductance in mH

$A_L$  = the inductance index in mH per 1000 turns, and

$N$  = the number of turns.

Be certain the core can handle the power by calculating the maximum flux and comparing the result with the manufacturer's guidelines.

$$B_{\max} = \frac{E_{\text{RMS}} \times 10^8}{4.44 \times A_e \times N \times f} \quad (16)$$

where

$B_{\max}$  = the maximum flux density in gauss

$E_{\text{RMS}}$  = the voltage across the inductor

$A_e$  = the cross-sectional area of the core in square centimeters

$N$  = the number of turns in the inductor, and

$f$  = the operating frequency in Hz.

(Both equations are from the section on ferrite toroidal inductors in the **Electrical Fundamentals** chapter and are repeated here for convenience.)

Example: Design a small broadband transformer having an impedance ratio of 16:1 for a frequency range of 2.0 to 20.0 MHz to match the output of a small-signal stage (impedance  $\approx 500 \Omega$ ) to the input (impedance  $\approx 32 \Omega$ ) of an amplifier.

Since the impedance of the smaller winding should be at least 4 times the lower impedance to be matched at the lowest frequency,

$$X_S = 4 \times 32 \Omega = 128 \Omega$$

**Figure 5.62** — Schematic and pictorial representation of a “binocular” style of conventional broadband transformer. This style is used frequently at the input and output ports of transistor RF amplifiers. It consists of two rows of high-permeability toroidal cores, with the winding passed through the center holes of the resulting stacks.

The inductance of the secondary winding should be

$$L_S = \frac{X_S}{2 \pi f} = \frac{128}{6.2832 \times 2.0 \times 10^6 \text{ Hz}}$$

$$= 0.0101 \text{ mH}$$

Select a suitable core. For this low-power application, a  $\frac{3}{8}$  inch ferrite core with permeability of 850 is suitable. The core has an  $A_L$  value of 420. Calculate the number of turns for the secondary.

$$N_S = 1000 \sqrt{\frac{L}{A_L}} = 1000 \sqrt{\frac{0.010}{420}}$$

$$= 4.88 \text{ turns}$$

A 5-turn secondary winding should suffice. The primary winding derives from the impedance ratio:

$$N_P = N_S \sqrt{\frac{Z_P}{Z_S}} = 5 \sqrt{\frac{16}{1}}$$

$$= 5 \times 4 = 20 \text{ turns}$$

This low-power application will not approach the maximum flux density limits for the core, and #28 AWG enamel wire should both fit the core and handle the currents involved.

A second style of broadband transformer construction appears in **Figure 5.62**. The key elements in this transformer are the stacks of ferrite cores aligned with tubes soldered to pc-board end plates. This style of transformer is suited to high power applications, for example, at the input and output ports of transistor RF power amplifiers. Low-power versions of this transformer can be wound on “binocular” cores having pairs of parallel holes through them.

For further information on conventional transformer matching using ferromagnetic materials, see the **RF Power Amplifiers** chapter. Refer to the **Component Data and References** chapter for more detailed information on available ferrite cores. A standard reference on conventional broadband transformers using ferromagnetic materials is *Ferromagnetic Core Design and Applications Handbook* by Doug DeMaw, W1FB, published by MFJ Enterprises.

## NOTES ON TOROID WINDINGS

For a toroidal (cylindrical) core, the number of turns is the number of times the conductor passes through the core. A wire passing once through a cylindrical core constitutes one turn. Likewise, a split or “clamp-on” core that is simply clamped onto a conductor forms a single-turn choke. A wire passing twice through the core is a two-turn choke, even though there is only one pass external to the core.

The inductance of a toroid can be adjusted. If the turns can be pressed closer together or separated a little, inductance variations of a few percent are possible.

In general, all of the flux associated with ferrite inductors (and chokes) is confined to the core material — for all practical purposes, there is no inductive coupling between inductors (or chokes) that are physically adjacent but wound on different cores. Coupling between adjacent coils can be eliminated by placing a Faraday shield between them as discussed earlier in this section.

Toroidal windings do exhibit a small amount of leakage flux. Toroid coils are wound in the form of a helix (screw thread) around the circular length of the core. This means that there is a small component of the flux from each turn that is perpendicular to the circle of the toroid (parallel to the axis through the hole) and is therefore not adequately linked to all the other turns. This effect is responsible for a small leakage flux and the effect is called the “one-turn” effect.

# 5.8 Noise

The following material was contributed by Paul Wade, W1GHZ. The section on background noise by Joe Taylor, K1JT, is reproduced from his discussion of Earth-Moon-Earth (EME) communications in this book's downloadable supplemental content. Additional discussion of noise measurement is available in the Test Instruments and Measurements chapter and in the Noise Instrumentation document provided with the downloadable supplemental content.

As anyone who has listened to a receiver suspects, everything in the universe generates noise. In communications, the goal is to maximize the desired signal in relation to the undesired noise we hear. In order to accomplish this goal, it would be helpful to understand where noise originates, how much our own receiver adds to the noise we hear, and how to minimize it.

It is difficult to improve something unless we are able to measure it. Measurement of noise in receivers does not seem to be clearly understood by many amateurs, so this section attempts to explain the concepts and clarify the techniques, and to describe the standard "measure of merit" for receiver noise performance: "noise figure." In addition, the Noise Instrumentation document with the downloadable supplemental content describes how to build your own noise generator for noise figure measurements.

A number of equations are included, but only a few need be used to perform noise figure measurements. The rest are included to as an aid to understanding supported by explanatory text.

## 5.8.1. Noise Power

The most pervasive source of noise is thermal noise (also called Johnson or Johnson-Nyquist noise), due to the motion of thermally agitated free electrons in a conductor. Since everything in the universe is at some temperature above absolute zero, every conductor must generate noise.

Every resistor (and all conductors have resistance) generates an RMS noise voltage:

$$e = \sqrt{4kTRB} \tag{17}$$

where R is the resistance, T is the absolute temperature in kelvins (K), B is the bandwidth in hertz, and k is Boltzmann's constant,  $1.38 \times 10^{-23}$  joules /K (or J K<sup>-1</sup>).

Converting to power,  $e^2/R$ , and adjusting for the Gaussian distribution of noise voltage, the noise power generated by the resistor is:

$$P_n = kTB \text{ (watts)} \tag{18}$$

which is independent of the resistance. Thus,

all resistors at the same temperature generate the same noise power.

Thermal noise is white noise, meaning that the power density does not vary with frequency, but always has a power density or spectral density of  $kT$  watts/Hz. (The corresponding noise voltage distribution is a spectral voltage density, measured in volts /  $\sqrt{\text{Hz}}$ , spoken as "volts per root hertz".) More important is that the noise power is directly proportional to absolute temperature T, since k is a constant. At the nominal ambient temperature of 290 K, we can calculate this power; converted to dBm, we get the familiar -174 dBm/Hz. Multiply by the bandwidth in hertz to get the available noise power at ambient temperature. The choice of 290 K for ambient might seem a bit cool, since the equivalent 17° C or 62° F would be a rather cool room temperature, but the value 290 makes for an easier-to-remember numeric calculation of  $P_n = (1.38 \times 10^{-23} \times 290) B = 400 \times 10^{-23} B$ .

The instantaneous noise voltage has a Gaussian distribution around the RMS value. The Gaussian distribution has no limit on the peak amplitude so at any instant the noise voltage may have any value from -infinity to +infinity. For design purposes we can use a value that will not be exceeded more than 0.01% of the time. This voltage is 4 times the RMS value, or 12 dB higher, so our system must be able to handle peak powers 12 dB higher than the average noise power if we are to measure noise without errors. (See Pettai in the Reference section.)

## 5.8.2. Signal to Noise Ratio

Now that we know the noise power in a given bandwidth, we can easily calculate how much signal is required to achieve a desired signal to noise ratio, S/N or SNR. For SSB, perhaps 10 dB SNR is required for good communications; since ambient thermal noise in a 2.5 kHz bandwidth is -140 dBm, calculated as follows:

$$P_n = kTB = 400 \times 10^{-23} \times 2500 = 1.0 \times 10^{-17} \text{ W}$$

$$\text{dBm} = 10 \log (P_n \times 1000) \text{ [multiplying watts by 1000 converts to milliwatts]}$$

The signal power must be 10 dB larger, so minimum signal level of -130 dBm is required for a 10 dB S/N. This represents the noise and signal power levels at the antenna. We are then faced with the task of amplifying the signal without degrading SNR.

## 5.8.3. Noise Temperature

There are many types of noise, but most have similar characteristics to thermal noise

and are often added together, creating a single equivalent noise source whose output power per unit of bandwidth is  $P_{N_e}$ . The noise temperature of the source is defined as the temperature  $T = P_{N_e} / k$  at which a resistor would generate the same noise power per unit of bandwidth as the source. This is a useful way to characterize the various sources of noise in a communications system.

All amplifiers add additional noise to the noise present at their input. The input noise per unit of bandwidth is  $N_i = kT_g$ , where  $T_g$  is the noise temperature at the amplifier's input. Amplified by power gain G, the output noise is  $kT_g G$ . The additional noise contributed by the amplifier can also be represented as a noise temperature,  $T_n$ . The noise power added by the amplifier,  $kT_n$ , is then added to the amplified input noise to produce a total output noise:

$$N_o = kT_g G + kT_n$$

We can treat the amplifier as ideal and noise-free but with an additional noise-generating resistor of temperature  $T_e = T_n / G$  at the input so that all sources of noise can be treated as inputs to the amplifier as illustrated by Figure 5.63. The output noise is then:

$$N_o = kG (T_g + T_e)$$

The noise added by an amplifier can then be represented as  $kGT_e$ , which is amplifier's noise temperature amplified by the amplifier gain.  $T_e$  is sometimes referred to as excess temperature.

Note that while the noise temperature of a resistor is the same as its physical temperature, the noise temperature of a device such as a diode or transistor can be many times the physical temperature.

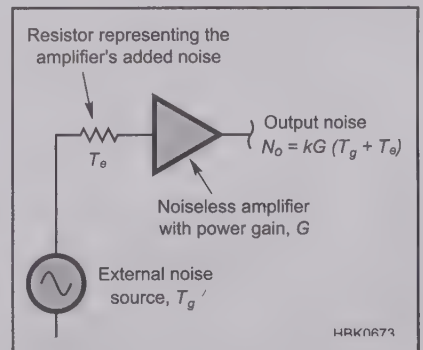

Figure 5.63 — The noise generated by an amplifier can be represented as an external resistor with a noise temperature of  $T_e$  connected at the input of a noiseless amplifier.

## SINAD

Signal-to-noise and distortion ratio (SINAD) is often used to measure of the quality of a demodulated signal.

$$\text{SINAD} = \frac{P_{\text{signal}} + P_{\text{noise}} + P_{\text{distortion}}}{P_{\text{noise}} + P_{\text{distortion}}} \quad (19)$$

where  $P$  is an average power. SINAD is usually expressed in dB and is often used as a condition at which a receiver's RF sensitivity is measured. For example: a sensitivity of  $0.1\mu\text{V}$  for 12 dB SINAD. (A thorough explanation of SINAD and several related terms such as THD is provided by the Analog Devices tutorial MT-003 by Kester listed in the References section of this chapter.)

## 5.8.4. Noise Factor and Noise Figure

The *noise factor*,  $F$ , of an amplifier is the ratio of the total noise output of an amplifier with an input  $T_g$  of 290 K to the noise output of an equivalent noise-free amplifier. A more useful definition is to calculate it from the excess temperature  $T_e$ :

$$F = 1 + T_e / T_g, \text{ where } T_g = 290 \text{ K} \quad (20)$$

It is often more convenient to work with *noise figure*,  $NF$ , the logarithm of noise factor expressed in dB:

$$NF = 10 \log (1 + T_e / T_g) = 10 \log F \quad (21)$$

$$F = \log^{-1} (NF/10)$$

Expressed in terms of signal,  $S$ , and noise power,  $N$ , at the input and output of a device:

$$F = (S_{\text{in}}/N_{\text{in}})/(S_{\text{out}}/N_{\text{out}}) \text{ and}$$

$$F = G_{\text{noise}}/G_{\text{signal}}$$

where  $G_{\text{signal}}$  is the device's power gain and  $G_{\text{noise}}$  is the device's *noise gain*. If SNR in dB is known at the input and output:

$$NF = \text{SNR}_{\text{in}} - \text{SNR}_{\text{out}}$$

If  $NF$  or  $F$  is known, then  $T_e$  may be calculated as:

$$T_e = (F - 1) T_g$$

Typically,  $T_e$  is specified for very low noise amplifiers where the  $NF$  would be fraction of a dB.  $NF$  is used when it seems a more manageable number than thousands of K.

Noise figure is sometimes stated as *input noise figure* to emphasize that all noise sources and noise contributions are converted to an equivalent set of noise sources at the input of a noiseless device. In this way, noise performance can be compared on equal terms across a wide variety of devices.

Noise figure is particularly important at VHF and UHF where atmospheric and other artificial noise is quite low. Typical noise figures of amateur amplifiers range from 1 to 10 dB. Mixers are generally toward the high end of that range. Modern GaAsFET and HEMT preamplifiers are capable of attaining an NF of 0.1 to 0.2 dB at UHF with NF under 1 dB even at 10 GHz.

## 5.8.5. Losses

We know that any loss or attenuation in a system reduces the signal level. If attenuation also reduced the noise level then we could suppress thermal noise by adding attenuation. We know intuitively that this can't be true — the attenuator or any lossy element has a noise temperature,  $T_x$ , which contributes noise to the system while the input noise is being attenuated.

The output noise after a loss  $L$  (expressed as ratio) expressed as an equivalent input noise temperature is:

$$T_g' = T_g / L + [(L - 1)/L] T_x$$

If the original source temperature,  $T_g$ , is higher than the attenuator temperature,  $T_x$ , then the noise contribution is found by adding the loss in dB to the NF. However, for low source temperatures the degradation can be much more dramatic. If we do a calculation for the effect of 1 dB of loss ( $L = 1.26$ ) on a  $T_g$  of 25 K:

$$T_g' = 25/1.26 + (0.26/1.26) \times 290 = 80 \text{ K}$$

The resulting  $T_g'$  is 80 K, a 5 dB increase in noise power (or 5 dB degradation of signal to noise ratio). Since noise power =  $kT$  and  $k$  is a constant, the increase is the ratio of the two temperatures,  $80/25$ , or in dB,  $10 \log (80/25) = 5 \text{ dB}$ .

It is also useful to note that for linear, passive devices, such as resistors or resistive attenuators, noise figure is the same as loss in dB. A resistive attenuator with 6 dB loss has a noise figure of 6 dB which is equal to a noise factor of 4.

## 5.8.6. Cascaded Amplifiers

If several amplifiers are cascaded, the output noise  $N_o$  of each becomes the input noise  $T_g$  to the next stage. We can create a single equation for the total system of amplifiers. After removing the original input noise term, we are left with the added noise:

$$N_{\text{added}} = (k T_{e1} G_1 G_2 \dots G_N) + (k T_{e2} G_2 \dots G_N) + \dots + (k T_{eN} G_N)$$

where  $N$  is the number of stages cascaded. Substituting in the total gain  $G_T = (G_1 G_2 \dots G_N)$  results in the total excess noise:

$$T_{eT} = T_{e1} + \frac{T_{e2}}{G_1} + \frac{T_{e2}}{G_1 G_2} + \dots + \frac{T_{eN}}{G_1 G_2 \dots G_{N-1}}$$

with the relative noise contribution of each succeeding stage reduced by the gain of all preceding stages.

The *Friis formula for noise* (a.k.a. the *Friis equation*) expresses this in terms of noise factor:

$$F = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \dots + \frac{F_N - 1}{G_1 G_2 \dots G_{N-1}} \quad (22)$$

Clearly, if the gain of the first stage,  $G_1$ , is large, then the noise contributions of the succeeding stages become too small to be significant. In addition, the noise temperature of the first stage is the largest contributor to the overall system noise because it is amplified by all remaining stages. The effect on overall noise figure of adding a low-noise preamplifier ahead of a noisy receiver are illustrated in **Figure 5.64**, in which the system's noise figure changes from 20 dB for the receiver alone to 7.1 dB with the preamplifier added.

Any lossy component of an antenna system, such as the feed line, increases the noise figure at its input by an amount equal to the loss. As a result, it is important to concentrate noise-reduction efforts on the first amplifier or preamplifier in a system. Because noise performance is so important in early stages of cascaded systems such as receivers, low-noise VHF+ preamplifiers are usually mounted at the antenna so that their gain occurs ahead

**Figure 5.64** — The effect of adding a low-noise preamplifier in front of a noisy receiver system.

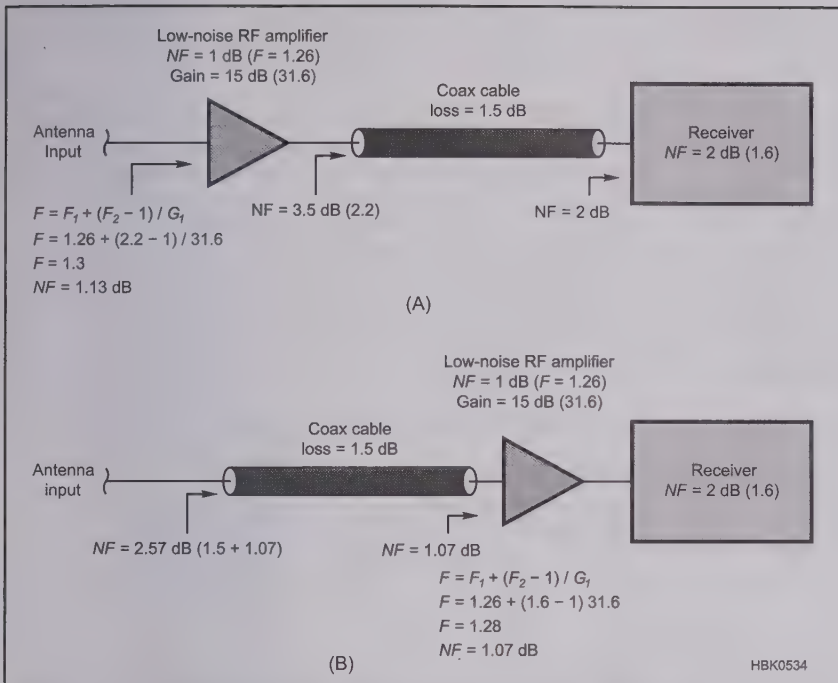

Figure 5.65 — The effect of adding a low-noise preamplifier at the antenna (A) compared to adding it at the receiver input (B).

Figure 5.66 — Top: All-sky contour map of right background temperature at 144 MHz. The dashed curve indicates the plane of our galaxy, the Milky Way; the solid sinusoidal curve is the plane of the ecliptic. The sun follows a path along the ecliptic in one year; the Moon moves approximately along the ecliptic ( $\pm 5^\circ$ ) each month. Map contours are at noise temperatures 200, 500, 1000, 2000 and 5000 K. Bottom: One-dimensional plot of sky background temperature at 144 MHz along the ecliptic, smoothed to an effective beamwidth of 15°.

of the feed line loss. **Figure 5.65** compares the results of adding a preamplifier before and after 1.5 dB of feed line loss. Moving the preamplifier to the antenna improves the system's noise figure from 2.57 to 1.13 dB.

### 5.8.7. Antenna Temperature

*Antenna temperature*,  $T_A$ , is a way of describing how much noise an antenna produces. It is not the physical temperature of the antenna because the antenna gathers noise from the environment according to its radiation pattern. If the antenna is directional and looks at a warm environment,  $T_A$  will be higher than if the antenna is looking at something cooler.

For example, if a lossless dish antenna is receiving signals from space rather than the warm Earth then the background noise is much lower than the warmer ambient temperature of 290 K or so. The background temperature of the universe has been measured as about 3.2 K. An empirical temperature for a 10 GHz antenna pointing into clear sky is about 6 K, since the antenna must always look through attenuation and temperature of the atmosphere. (See Graves in the Reference section.)

If the antenna's radiation pattern has any sidelobes that must be accounted for in the total noise received by the antenna. This raises the noise temperature. If a warm body, such as the Sun, moves into the antenna's view, the additional *sun noise* will raise  $T_A$  as well. If the antenna is looking directly at the Earth,  $T_A$  will be close to ambient temperature. As an example,  $T_A$  will vary with frequency, but a good EME antenna might have a  $T_A$  of around 20 K at UHF and higher frequencies.

### 5.8.8. Image Response

Most receiving systems use at least one frequency converting mixer which has two responses: the desired frequency and an image frequency above and below the frequency of the local oscillator. If the image response is not filtered out, it will add additional noise to the mixer output. Since most preamps are sufficiently broadband to have significant gain (and thus, noise output) at both the desired frequency,  $G_{\text{desired}}$ , and at the image frequency,  $G_{\text{image}}$ , an image filter must be placed between the preamplifier and the mixer. The total NF including image response is:

$$NF = 10 \log \left[ \left( \frac{1 + T_c}{T_0} \right) \left( 1 + \frac{G_{\text{image}}}{G_{\text{desired}}} \right) \right] \quad (23)$$

assuming equal noise bandwidth for the desired and image responses.

Without any filtering,  $G_{\text{image}} = G_{\text{desired}}$  so  $G_{\text{image}}/G_{\text{desired}} = 1$ , doubling the noise figure, which is the same as adding 3 dB. Thus, without any image rejection, the overall

noise figure is at least 3 dB regardless of the NF of the preamplifier. For the image to add less than 0.1 dB to the overall NF, gain at the image frequency must be at least 16 dB lower than at the operating frequency.

As the state of the art improves beyond the typical numbers in this and previous sections, system performance also improves. The very best low-noise preamplifiers today have noise figures as low as 0.2 dB, or a  $T_r$  of about 14 K, at UHF and 1296 MHz. The best EME dishes can have a  $T_a$  in the neighborhood of 20 K at 1296 MHz when pointed at clear sky. Thus the potential  $T_{sys}$  is perhaps 40 K. At these low noise temperatures any small loss or stray noise is significant — a loss of just 0.2 dB will reduce the signal to noise ratio by 1 dB, and low SNR communications such as EME rarely have many dB to spare. The preamp must be right at the antenna for optimum performance, and have sufficient gain so that subsequent stages have little effect.

### 5.8.9. Background Noise

A received signal at VHF and higher frequencies necessarily competes with noise generated in the receiver as well as that picked up by the antenna, including contributions from the warm Earth, the atmosphere, the lunar surface, the diffuse galactic and cosmic background and possibly the Sun and other sources, filling the whole sky. If  $P_n$  is the total noise power collected from all such noise sources expressed in dBW, we can write the expected signal-to-noise ratio of a communications link as

$$SNR = P_r - P_n = P_t + G_t + L + G_r - P_n \quad (24)$$

where  $P_r$  is received power,  $P_n$  is noise power,  $P_t$  is transmitted power,  $G_t$  of the transmitting antennas,  $L$  is *isotropic path loss*, and  $G_r$  is the gain of the receiving antennas. All powers are expressed in dBW and all gains in dBi. (Isotropic path loss is explored further in the material on Earth-Moon-Earth (EME) communications in this book's downloadable supplemental material on **Space Communications**.)

Since isotropic path loss  $L$  is essentially fixed by choice of a frequency band, optimizing the signal-to-noise ratio generally involves trade-offs designed to maximize  $P_r$  and minimize  $P_n$  — subject, of course, to such practical considerations as cost, size, maintainability, and licensing constraints.

It is convenient to express  $P_n$  (in dBW) in terms of an equivalent system noise temperature  $T_s$  in kelvin (K), the receiver bandwidth  $B$  in Hz, and Boltzmann's constant  $k = 1.38 \times 10^{-23} \text{ J K}^{-1}$ :

$$P_n = 10 \log (kT_s B)$$

The system noise temperature may in turn

be written as

$$T_s = T_r + T_a$$

Here  $T_r$  is receiver noise temperature, related to the commonly quoted noise figure (NF) in dB by

$$T_r = 290 (10^{0.1NF} - 1)$$

Antenna temperature  $T_a$  includes contributions from all noise sources in the field of view, weighted by the antenna pattern. Sidelobes are important, even if many dB down from the main beam, because their total

solid angle is large and therefore they are capable of collecting significant unwanted noise power.

At VHF the most important noise source is diffuse background radiation from our galaxy, the Milky Way. An all-sky map of noise temperature at 144 MHz is presented in the top panel of **Figure 5.66**. This noise is strongest along the plane of the galaxy and toward the galactic center. Galactic noise scales as frequency to the  $-2.6$  power, so at 50 MHz the temperatures in Figure 5.66 should be multiplied by about 15, and at 432 divided by 17. At 1296 MHz and above

**Table 5.2**  
Typical Contributions to System Noise Temperature

Freq (MHz)	CMB (K)	Atm (K)	Moon (K)	Gal (K)	Side (K)	$T_r$ (K)	$T_r$ (K)	$T_s$ (K)

**Figure 5.67** — Typical contributions to system noise temperature  $T_s$  as function of frequency. See text for definitions and descriptions of the various sources of noise.

galactic noise is negligible in most directions. (See the previously mentioned downloadable supplemental material on EME for the effects of lunar noise.)

The galactic background (GB) is a factor for HF reception as well. For daytime communications, it is less obvious due to the contributions of daytime band noise. Somewhere above 10 MHz, however, what today's quiet HF receivers hear at night becomes dominated by the GB. The frequency at which GB noise overtakes band noise depends on sunspot activity, the strength of atmospheric noise sources such as storms, geomagnetic conditions, the position of the galaxy in the sky, and the antenna's radiation pattern.

The GB has a negative spectral index, meaning it gets weaker with increasing frequency, but is still strong in the 15, 17, and 20 meter bands. Below 10 MHz the GB continues to increase, peaking around 3 MHz, but ionospheric attenuation increases with decreasing frequency, making it less of a factor than atmospheric noise. (The article "The Galactic Background in the Upper HF Band" by Dave Typinski, AJ4CO discusses the GB at HF and is available with this book's downloadable supplemental content.)

By definition the Sun also appears to an observer on Earth to move along the ecliptic, and during the day solar noise can add significantly to  $P_n$  if the antenna has pronounced sidelobes. At frequencies greater than about 5 GHz the Earth's atmosphere also contributes significantly. An ultimate noise floor of 3 K,

independent of frequency, is set by cosmic background radiation that fills all space. A practical summary of significant contributions

to system noise temperature for the amateur bands 50 MHz through 24 GHz is presented in Table 5.2 and Figures 5.67 and 5.68.

Figure 5.68 — Percentage contributions to system noise temperature as a function of frequency.

## 5.9 Two-Port Networks

A *two-port network* is one with four terminals. The terminals are arranged into pairs, each being called a *port*. The general network schematic is shown in **Figure 5.69**. The input port is characterized by input voltage and current,  $V_1$  and  $I_1$ , and the output is described by  $V_2$  and  $I_2$ . By convention, currents into the network are usually considered positive.

Many devices of interest have three terminals rather than four. Two-port methods are

used with these by choosing one terminal to be common to both input and output ports. The two-port representations of the common emitter, common base and common collector connections of the bipolar transistor are shown in **Figure 5.70**. Similar configurations may

be used with FETs, vacuum tubes, ICs or passive networks.

The general concepts of two-port theory are applicable to devices with a larger number of terminals. The theory is expandable to any number of ports. Alternatively, the

Figure 5.69 — General configuration of a two-port network. Note the voltage polarities and direction of currents.

Figure 5.70 — Two-port representations of the common emitter, common base and common collector amplifiers.

Figure 5.71 — A dual-gate MOSFET treated as a three-terminal device in a two-port network.

bias on some terminals can be established with attention fixed only upon two ports of a multi-element device. An example would be a dual-gate MOSFET in a common-source configuration as shown in Figure 5.71. The input port contain the source and gate 1 while the output port contains the source and drain leads. The fourth device terminal, gate 2, has a fixed bias potential and is treated as an ac ground. Signal currents at this terminal are ignored in the analysis.

### 5.9.1 Two-Port Parameters

There are four variables associated with any two-port network; two voltages and two currents. These are signal components. Any two variables may be picked as independent. The remaining variables are then dependent variables. These are expressed as an algebraic linear combination of the two independent quantities. The following overview are intended for definition purposes. A complete discussion of the use of two-port parameters can be found in the reference texts at the end of this chapter and examples of their use in RF circuit design in Hayward's *Introduction to Radio Frequency Design*.

#### Y AND Z PARAMETERS

Assume that the two voltages are chosen as independent variables. The two currents are then expressed as linear combinations of the voltages,  $I_1 = K_a V_1 + K_b V_2$  and  $I_2 = K_c V_1 + K_d V_2$ . The constants of proportionality,  $K_a$  through  $K_d$ , have the dimensions of admittance. The usual representation is

$$\begin{aligned} I_1 &= y_{11} V_1 + y_{12} V_2 \\ I_2 &= y_{21} V_1 + y_{22} V_2 \end{aligned}$$

The independent and dependent variable sets are column vectors, leading to the equivalent matrix representation

$$\begin{pmatrix} I_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \end{pmatrix} \quad (25)$$

The  $y$  matrix for a two-port network

uniquely describes that network. The set of  $y_{11}$  through  $y_{22}$  are called the two-port network's  $Y$  parameters or admittance parameters. Consider the  $y$  parameters from an experimental viewpoint. The first  $y$  parameter,  $y_{11}$ , is the input admittance of the network with  $V_2$  set to zero. Hence, it is termed the *short-circuit input admittance*.  $y_{21}$  is the *short-circuit forward transadmittance*, the reciprocal of short-circuit conductance. Similarly, if  $V_1$  is set to zero, realized by short-circuiting the input,  $y_{22}$  is the *short-circuit output admittance* and  $y_{12}$  is the *short-circuit reverse transadmittance*.

The matrix subscripts are sometimes replaced by letters. The set of  $y$  parameters can be replaced by  $y_i$ ,  $y_r$ ,  $y_f$ , and  $y_o$  where the subscripts indicate respectively input, reverse, forward, and output. The subscripts are sometimes modified further to indicate the connection of the device. For example, the short circuit forward transfer admittance of a common emitter amplifier would be  $y_{21e}$  or  $y_{fe}$ .

The  $y$  parameters are only one set of two-port parameters. The open-circuited  $Z$  parameters or impedance parameters result if the two currents are treated as independent variables

$$\begin{pmatrix} V_1 \\ V_2 \end{pmatrix} = \begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix} \begin{pmatrix} I_1 \\ I_2 \end{pmatrix} \quad (26)$$

The parameter sets describe the same device; hence, they are related to each other. If the KVL equations are multiplied by  $y_{12}$  and the resulting equations subtracted, the result is the input voltage as a function of the currents

$$V_1 = \frac{I_1 y_{22} - y_{12} I_2}{y_{11} y_{22} - y_{12} y_{21}}$$

A similar procedure is used to find the output voltage as a function of the currents, leading to the general relationships

$$\begin{aligned} z_{11} &= \frac{y_{22}}{\Delta y} & z_{12} &= \frac{-y_{12}}{\Delta y} \\ z_{21} &= \frac{-y_{21}}{\Delta y} & z_{22} &= \frac{y_{11}}{\Delta y} \end{aligned}$$

where  $\Delta y$  is the determinant of the  $y$  matrix,  $y_{11} y_{22} - y_{12} y_{21}$ . The inverse transformations, yielding the  $y$  parameters when  $z$  parameters are known, are exactly the same except that the  $y_{jk}$  and  $z_{jk}$  values are interchanged. The similarity is useful when writing transformation programs for a programmable calculator or computer.

#### H PARAMETERS

The  $H$  parameters or hybrid parameters are defined if the input current and output voltage are selected as independent variables

$$\begin{pmatrix} V_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{pmatrix} \begin{pmatrix} I_1 \\ V_2 \end{pmatrix} \quad (27)$$

The input term,  $h_{11}$ , is an impedance, while  $h_{22}$  represents an output admittance. The forward term,  $h_{21}$ , is the ratio of the output to the input current, beta for a bipolar transistor. The reverse parameter,  $h_{12}$ , is a voltage ratio. The mixture of dimensions accounts for the "hybrid" name of the set.

#### SCATTERING (S) PARAMETERS

The two-port parameters presented above deal with four simple variables; input and output voltage and current at the ports. The variables are interrelated by appropriate matrices. The choice of which matrix is used depends upon which of the four variables are chosen to be independent.

There is no reason to limit the variables to simple ones. Linear combinations of the simple variables are just as valid. The more complicated variables chosen should be linearly independent and, ideally, should have some physical significance.

A transformation to other variables is certainly not new. For example, logarithmic transformations such as the dB or dBm are so common that we used them interchangeably with the fundamental quantities without even mentioning that a transformation has occurred. Such a new viewpoint can be of great utility in working with transmission line when an impedance is replaced by a reflection coefficient,  $\Gamma = (Z - Z_0) / (Z + Z_0)$ .

Scattering parameters or  $S$  parameters are nothing more than a repeat of this viewpoint. Instead of considering voltages and currents to be the fundamental variables, we use four "voltage waves." They are interrelated through an appropriate matrix of  $s$  parameters.

Figure 5.72 shows the traditional two-port network and an alternate one with voltage

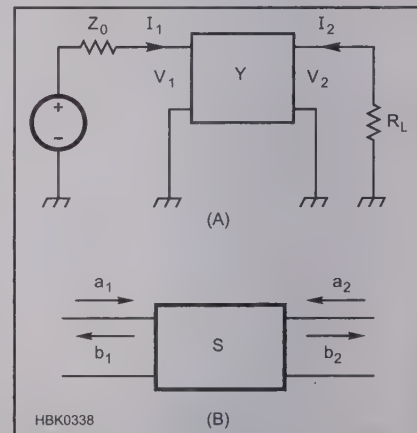

Figure 5.72 — A two-port network viewed as being driven by voltages and currents (A) or voltage waves (B). The voltages and currents are related by  $Y$  parameters while the voltage waves are related by scattering or  $S$  parameters.

waves incident on and reflected from the ports. The voltage waves are defined with the letters  $a_1$ ,  $b_1$ ,  $a_2$ , and  $b_2$ . The  $a$  waves are considered to be incident waves on the parts and are the independent variables. The  $b$  waves are the result of reflection or “scattering” and are the dependent variables. The waves are related to voltages and currents and defined with respect to a characteristic impedance,  $Z_0$ .

The scattered waves are related to the incident ones with a set of linear equations just as the port currents were related to the port voltages with  $y$  parameters. The relating equations are

$$b_1 = S_{11}a_1 + S_{12}a_2$$

$$b_2 = S_{21}a_1 + S_{22}a_2$$

or, in matrix form

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \quad (28)$$

Consider the meaning of  $S_{11}$ . If the incident wave at the output,  $a_2$ , is set to zero, the set of equations 27 reduce to  $b_1 = S_{11}a_1$  and  $b_2 = S_{21}a_1$ .  $S_{11}$  is the ratio of the input port reflected wave to the incident one. This reduces, using the defining equations for  $a_1$  and  $b_1$  to

$$S_{11} = \frac{Z - Z_0}{Z + Z_0} \quad (29)$$

This is the *input port reflection coefficient*. Similarly,  $S_{21}$  is the voltage wave emanating from the output as the result of an incident wave at the network input. In other words,  $S_{21}$  represents a forward gain. The other two

$S$  parameters have similar significance.  $S_{22}$  is the *output reflection coefficient* when looking back into the output port of the network with the input terminated in  $Z_0$ .  $S_{12}$  is the reverse gain if the output is driven and the signal at the input port detected.

The reflection coefficient nature of  $S$  parameters makes them especially convenient for use in design and specification and even more so when displayed on a Smith Chart.

### 5.9.2 Return Loss

Although SWR as described in the **Transmission Lines** chapter is usually used by amateurs to describe the relationship between a transmission line’s characteristic impedance and a terminating impedance, the engineering community generally finds it more convenient to use *return loss*,  $RL$ , instead.

Return loss and SWR measure the same thing — how much of the incident power,  $P_{INC}$ , in the transmission line is transferred to the load and how much is reflected by it,  $P_{REFL}$  — but state the result differently.

$$\text{Return Loss (dB)} = -10 \log \left( \frac{P_{REFL}}{P_{INC}} \right) \quad (30)$$

Because  $P_{REFL}$  is never greater than  $P_{FWD}$ ,  $RL$  is always positive. The more positive  $RL$ , the less the amount of power reflected from the load compared to forward power. If all the power is transferred to the load because  $Z_L = Z_0$ ,  $RL = \infty$  dB. If none of the power is transferred to the load, such as at an open- or short-circuit,  $RL = 0$  dB. (You may encounter negative values for  $RL$  in literature or data sheets. Use the absolute magnitude of these values — the negative value does not indicate power gain.)

$RL$  can also be calculated directly from

power ratios, such as dBm (decibels with respect to 1 mW) or dBW (decibels with respect to 1 watt). In this case,  $RL = P_{INC} - P_{REFL}$  because the logarithm has already been taken in the conversion to dBm or dBW. (Ratios in dB are computed by subtraction, not division.) For example, if  $P_{INC} = 10$  dBm and  $P_{REFL} = 0.5$  dBm,  $RL = 10 - 0.5 = 9.5$  dB. Both power measurements must have the same units (dBm, dBW, and so on) for the subtraction to yield the correct results — for example, dBW can’t be subtracted from dBm directly.

Since SWR and  $RL$  measure the same thing — reflected power as a fraction of forward power — they can be converted from one to the other. Start by converting  $RL$  back to a power ratio:

$$\frac{P_{REFL}}{P_{INC}} = \log^{-1}(-0.1 \times RL) \quad (31)$$

Now use the equation for computing SWR from forward and reflected power (see the **Transmission Lines** chapter):

$$\text{SWR} = \frac{1 + \sqrt{\frac{P_{REFL}}{P_{INC}}}}{1 - \sqrt{\frac{P_{REFL}}{P_{INC}}}} \quad (32)$$

SWR can also be converted to  $RL$  by using the equation for power ratio in terms of SWR:

$$\frac{P_{REFL}}{P_{INC}} = \left[ \frac{\text{SWR} - 1}{\text{SWR} + 1} \right]^2 \quad (33)$$

Then convert to  $RL$  using equation 30.

## 5.10 RF Techniques Glossary

**Arc** — Current flow through an insulator due to breakdown from excessive voltage.

**Balun** — A device that transfers power between *balanced* and *unbalanced* systems, sometimes transforming the impedance level as well (see also **unun**).

**Bead** — Hollow cylinder of magnetic material through which a wire is threaded to form an inductor.

**Bilateral** — A network that operates or responds in the same manner regardless of the direction of current flow in the network.

**Choke balun** — see **current balun**.

**Core** — Magnetic material around which wire is wound or through which it is threaded to form an inductor.

**Current balun** — A balun that transfers power from an unbalanced to a balanced system by forcing current flow in the balanced system to be balanced as well (also called a **choke balun**).

**Dielectric strength** — The rated ability of an insulator to withstand voltage.

**Distributed element** — Electronic component whose effects are spread out over a significant distance, area or volume.

**Dynamic resistance** — The change in

current in response to a small change in voltage.

**Equivalent Series Inductance (ESL)** — A capacitor’s parasitic inductance.

**Ferrite** — A ferromagnetic ceramic.

**Gain-bandwidth product** — The frequency at which a device’s gain drops unity. Below that frequency the product of the device’s gain and frequency tends to be constant.

**Hybrid- $\pi$**  — High-frequency model for a bipolar transistor.

**Impedance inversion** — Dividing a characteristic impedance by the ratio of the impedance to be inverted to the

characteristic impedance. For example, 25  $\Omega$  inverted about 50  $\Omega$  is 100  $\Omega$  and 200  $\Omega$  inverted about 50  $\Omega$  is 12.5  $\Omega$ .

**Insertion loss (IL)** — The loss inherent in a circuit due to parasitic resistance.

**Inter-electrode capacitance** — Capacitance between the internal elements of a semiconductor or vacuum tube.

**Lumped element** — Electronic component that exists at a single point.

**Mix** — The chemical composition of a ferrite or powdered-iron material (also called **type**).

**Noise** — Any unwanted signal, usually refers to signals of natural origins or random effects resulting from interfering signals.

**Noise factor (F)** — The amount by which noise at the output of a device is greater than that at the input multiplied by the gain of the device. A measure of how much noise is generated by a device.

**Noise figure (NF)** —  $10 \log$  (noise factor).

**Noise gain** — Circuit output noise power

divided by the available input noise power. This is not always equal to signal gain, depending on the source of the noise and the location of the noise source in the circuit.

**Nonideal** — Behavior that deviates from that of an ideal component (see also **parasitic**).

**Nonlinear** — A component that acts on a signal differently depending on the signal's amplitude.

**Parasitic** — Unintended characteristic related to the physical structure of a component.

**Permeability** — The ability of a material to support a magnetic field.

**Return loss (RL)** — The difference in dB between forward and reflected power at a network port.

**Self-resonant** — Resonance of a component due to parasitic characteristics.

**Simulate** — Model using numerical methods, usually on a computer.

**Skin effect** — The property of a conductor that restricts high-frequency ac current

flow to a thin layer on its surface.

**Skin depth** — The depth of the layer at the surface of a conductor to which ac current flow is restricted (see **skin effect**).

**Spectral Power Density** — The amount of power per unit of bandwidth, usually "root-Hz" or  $\sqrt{\text{Hz}}$ , the square root of the measurement bandwidth.

**Stray** — see **parasitic**.

**Toroid (toroidal)** — A ring-shaped continuous core.

**Two-port network** — A network with four terminals organized in two pairs, each pair called a port.

**Two-port parameters** — A set of four parameters that describe the relationship between signals at the network's two ports.

**Unun** — A device that transfers power between two unbalanced systems, usually performing an impedance transformation (see also **balun**).

# Computer-Aided Circuit Design

This chapter provides an overview of computer-aided design (CAD) for electronic design and PCB layout. These tools enable the hobbyist to harness some of the circuit simulation power employed by professional electronic and RF engineers in the product and system design cycle.

Material originally contributed by David Newkirk, W9VES, addresses generic circuit simulation tools. Dr Ulrich Rohde, N1UL, surveys issues associated with linear and nonlinear RF simulation and contributes three extensive papers with the downloadable supplemental content. Jim Rautio, AJ3K, presents an overview of electromagnetic (EM) simulation.

The purpose of this chapter is not to provide detailed instructions for using any particular software package, but to explain the basic operations, limitations and vocabulary for circuit and RF design software. Software to aid design and analysis in specialized areas, for example filter design, switchmode power supplies, transmission lines, and RF power amplifiers, is covered in other chapters.

## 6.1 Circuit Simulation Overview

Mathematics can predict and analyze the action of electromagnetic signals and the radio-electronic circuitry we build to produce and process them. Program an electronic computer — which, at base, is a generic math machine — to do the radio/electronics math in practically applicable ways, and you're ready to do computer-aided design (CAD) of radio and electronic circuits. (Program a computer to do radio-electronics math *in real time*, and you're ready to replace radio-electronics hardware with software, as described by this book's coverage of DSP and software-defined radio technology.)

### 6.1.1 Hobby versus Professional Circuit Simulation Tools

Professional grade circuit simulation software exists to facilitate the construction of tightly packaged, highly integrated, no-tweaking-required modern electronics/RF products. These products work predictably well even when reproduced by automated processes in large quantities — quantities that may, with sufficient marketing success and buyer uptake, exceed millions of units.

Manufacturers of specialized *electronic design automation* (EDA) software serve the engineering needs of this industry. Through comprehensive CAD suites, one may proceed from graphical component level circuit and/or IC design (*schematic capture*), through simulation of circuit and IC behavior (often using a variant of the simulator called *SPICE*, but increasingly with non-*SPICE* simulators more fluent in issues of RF and electromagnetic design), through design of PC board and IC masks suitable for driving validation, testing and production. Comprehensive EDA CAD reduces costs and speeds time to market with the help of features that can automatically modify circuits to achieve specific performance goals (*optimization*); predict effects of component tolerances and temperature on circuit behavior across large populations of copies (*Monte Carlo analysis*); and generate bills of materials (BOMs) suitable for driving purchasing and procurement at every step of the way.

Demonstration or student versions are available for some EDA CAD products at no or low cost (see **Table 6.1**), and a subset of these are especially useful for hobby purposes. Although these *demoware* tools come to us with a large-scale-production pedigree, they are greatly (and strategically) feature-limited. Only a relatively few components, often representing only a subset of available component models, may be used per simulation. Monte Carlo analysis, optimization, BOM generation and similar enhancements are usually unavailable. The licenses for these packages often limits the use of the software to noncommercial applications. *Demoware* is intended to drive software purchasing decisions and serve as college level learning aids — learning aids in college study toward becoming electronics/RF professionals who will each day work with the unlimited, full versions of the *demoware*. *Freeware* versions of simulation and layout software with considerable power are also available and may also have some restrictions. In either case, read the licensing agreement to become aware of any obligations on your part.

The radio hobbyist's circuit simulation needs are much simpler than the professional. Most of us will build only one copy of a given design — a copy that may be lovingly tweaked and refined to our hearts' content far beyond "good enough." Many of us may build as much with the intent of learning about and exploring the behavior of circuits as achieving practical results

### 6.1.2 The Design Cycle

The components we use to build real circuits always operate to the full extent of their actual properties, regardless of our relative ignorance of what those properties may be and how and why they operate the way they do. *No real-world component operates ideally.* So it is that we may set out to design, build and publish an amplifier circuit only to discover at power-up that we have instead built a persistent oscillator. Or if the prototype is an oscillator, that for 3 out of every 100 subsequent reader-builders the circuit does not oscillate at all!

The electrical and electronic components available in circuit simulators are only mathematical *models* of real world components — because every modeled behavior of a component is only an approximation relative to the behaviors of its real world counterpart. Simulated component characteristics and behaviors approach those of real world components only as closely as science may allow and only as closely as the model's description of the real world behavior.

Were this chapter a textbook, or part of a textbook, on computer-aided circuit design, we might begin exploring simulation by reviewing the basics of what electronic circuits are and do, following this with a discussion of what computerized circuit simulation is and how it works. An excursion into the arcane world of active device modeling — the construction and workings of mathematical electrical equivalents to the transistors, diodes and integrated circuits that await us at our favorite electronics suppliers and in our junk boxes — might follow. Finally, we might systematically proceed through a series of simulation examples from the basic to the more complex, progressively building our store of understood, trustworthy and applicable-to-future-work concepts as we go.

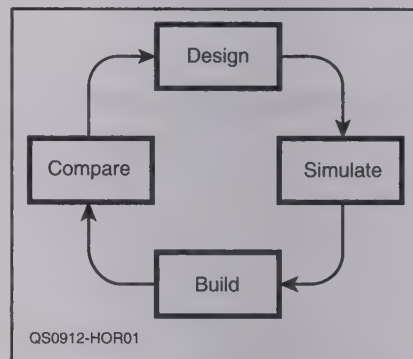

But this is a chapter in a handbook, not a

textbook, and following a sequence of abstract basics to concrete practice very likely does not reflect the process most of us have followed, and follow yet, in learning and using what we know about electronics and radio. More realistically, our approach is more like this: We find ourselves in need of a solution to a problem, identify one, and attempt to apply it. If it works, we move on, likely having learned little if we have not had to troubleshoot. If the solution does *not* work, we may merely abandon it and seek another, or — better, if we are open to learning — we may instead seek to understand why, with the happily revised aim of understanding what we need to understand to make the solution work. Even if we must ultimately abandon the solution as unworkable in favor of another, we do not consider our time wasted because we have further accelerated our deepening intuition by taking the initiative to understand why.

There is no smell of burning resistor or overheated transistor in a simulation. The placement of components on the screen has no effect on the behavior of the circuit, so a high gain stage whose input is too close to its output will never break into oscillation. The dc power sources are free of ripple and noise. These effects and many more can only be experienced (and remedies learned) by building real circuits.

**Figure 6.1** shows the process by which you really learn circuit design from concept to finished project. The first step is to select a type of circuit and describe what it is supposed to do — these are the *performance requirements*. For example, an amplifier will need to achieve some level of gain over some frequency range. You may need a certain input impedance and output impedance. Armed with that information, choose a circuit and come up with a preliminary set of component values by using pencil and paper or a computer design tool. This is your *design*.

Next, *simulate* the circuit's performance. If the result satisfies your performance requirements, you can move to the next step. If not, change the circuit in some way (or change your requirements) until you are satisfied.

**Figure 6.1 — Getting the most out of circuit simulation requires that you compare what the simulator predicts with how the actual circuit behaves.**

Now *build* your design as a real world collection of components and verify that the circuit works. This is where the real fun begins as the effects of construction and actual component variation take effect. Are you done? Not yet!

To soak up every bit of design experience and know-how, go back and *compare* your actual measured performance to what the simulator predicted, particularly near the limits of the circuit's function. Look for *design sensitivities* by substituting different parts or values. If the circuit's behavior diverges from the simulator's predictions, now is the time to take a closer look. You may not be able to say exactly why differences are present, but you'll be aware they exist.

This continual *design cycle* simultaneously builds your knowledge of how real circuits and components behave, how your simulation tools work, and — most importantly — the circumstances for which the two are likely to be different.

The downloadable supplemental content includes a number of design examples developed by the original author of this section, David Newkirk, W9VES. In these examples, he creates real world circuits, simulates their

behavior, compares it to actual performance, and explains why there are differences. Later in this chapter, a section by Ulrich Rohde, N1UL, discusses the differences among the different types of simulation tools used at RF — there are even differences among the different tools!

### 6.1.3 Schematic Capture and Simulation Tools

Almost any circuit-simulation program or electronic design automation (EDA) suite that uses schematic circuit capture can serve as a first rate schematic editor. (See Table 6.1) Although demoware component library limitations usually restrict the types of components you can use — in CAD-speak, *place* — in a design, *part count* limitations usually operate only at simulation time. Restrictions in physical size of the output drawing and layer count will likely apply to whatever layout design facilities may be available. After all, the main purpose of demoware is to let students and potential buyers taste the candy without giving away the store.

Excellent simulation-free schematic capture and layout design products exist, of course. The schematic style long standard in ARRL publications comes from the use of Autodesk *AutoCAD*, a fully professional product with a fully professional price. Long popular with radio amateurs and professionals alike is AutoDesk *EAGLE*, a schematic capture and layout design product available in freeware and affordable full version forms. You can even export *EAGLE* schematics to a *SPICE* simulator and back with Beige Bag Software's *B2 Spice* ([www.beigebag.com](http://www.beigebag.com)). The full function

## CAD Software and Your Computer's Operating System

The *OrCAD 16.0* and *Ansoft Designer SV 2* demoware packages used in this chapter, and most other CAD products you're likely to use, are compiled to run under Microsoft *Windows*. So what if you want to run RF and electronics CAD software under *Linux* or on the Mac?

You're in luck. *EAGLE* schematic and layout software is available in native versions for *Windows*, *Linux*, and the Macintosh. The GPLed EDA application suite, *gEDA*, are primarily developed on *Linux*, but are intended to run under, or at least be portable to, *POSIX*-compliant systems in general. The GPLed schematic and layout editor *Kicad* runs natively under *Windows* and *Linux*, and has been tested under *FreeBSD* and *Solaris*. Further, the great strides made in the *Wine* translation layer ([www.winehq.com](http://www.winehq.com)) allow many applications written for *Windows* to run well under the operating systems supported by *Wine*, including *Linux* and the Macintosh.

*MicroSim DesignLab 8* (a widely distributed precursor to *OrCAD 16* that can run all of the *SPICE* examples described in this chapter) and *Ansoft Serenade SV 8.5* (a precursor to *Ansoft Designer SV 2*) can be run in *Wine* under *Linux* with few artifacts and their expected schematic capture and simulation capabilities intact. Cursor handling in *OrCAD 16* installs under *Wine* readily enough, but cursor handling artifacts in its schematic editor, at least in the computers tried, seems to preclude its use under *Wine* for now. *Ansoft Designer SV 2* installs but does not properly start.

All things considered, however, especially as *Wine* and CAD applications continue to strengthen and mature, running your favorite *Windows* based applications under *Wine* is well worth a try. You may also consider purchasing an inexpensive used computer that runs one of the later versions of *Windows*, such as XP, and dedicating it to running the simulation

freeware schematic and PCB layout application *Kicad* and the EDA suite *gEDA* come to us from the open source community.

The basic drawing utility included with your computer's operating system, such as *Paint* which comes with *Windows*, can also serve as a limited do-it-yourself schematic capture tool. The ARRL also provides a limited set of schematic symbols that can

be used with *PowerPoint* at the Hands-On Radio web page, [www.arrl.org/hands-on-radio](http://www.arrl.org/hands-on-radio). Cutting, copying, moving and pasting components snipped from favorite graphical schematic files and adding new connections as graphical lines is enough to create a picture of the schematic but without any of the underlying tools or facilities of a true schematic capture tool.

## 6.2 Simulation Basics

This section is a collection of notes and illustrations that address various important circuit simulation concepts. In this section, conventional *SPICE* notation and vocabulary are used unless specifically noted differently. Not all simulation tools use exactly the same words and phrases to label and explain their features. When in doubt, refer to the software's user manual or HELP system. There are a number of excellent textbooks about using *SPICE*-based simulators. Widely used simulation tools almost always have online communities of users, all of whom were beginners once, too. Joining one of these groups is highly recommended.

Simulation tool users groups frequently develop and maintain a library of tutorials, Frequently Asked Questions (FAQ), accessory programs and utilities, even models and complex circuit models. Before you ask questions, consult the available resources, such as searchable message archives, to see if your

question has been answered before — it usually has! The other users will appreciate your diligence before asking the entire group.

### 6.2.1 SPICE — History

*SPICE — Simulation Program with Integrated-Circuit Emphasis* — originates from the Electrical Engineering and Computer Sciences Department of the University of California at Berkeley and first appeared under its current name as *SPICE1* in 1972. "SPICE," write the maintainers of the official *SPICE* homepage at <http://bwrcs.eecs.berkeley.edu/Courses/IcBook/SPICE> "is a general-purpose circuit simulation program for nonlinear dc, nonlinear transient, and linear ac analyses. Circuits may contain resistors, capacitors, inductors, mutual inductors, independent voltage and current sources, four types of dependent sources, lossless and lossy transmission lines (two separate implementa-

tions), switches, uniform distributed RC lines, and the five most common semiconductor devices: diodes, BJTs, JFETs, MESFETs, and MOSFETs."

That *SPICE* is "general-purpose" does not mean that its usefulness is unfocused, but rather that it is well established as a circuit simulation mainstay of comprehensive power. A wide, deep *SPICE* community exists as a result of decades of its daily use, maintenance and enhancement by industrial, academic and hobby users. Many excellent commercial versions of *SPICE* exist — versions that may be improved for workhorse use in particular sub-disciplines of electronics, power and RF design.

### 6.2.2 Conventions

#### SCALE FACTORS

*SPICE*'s use of unit suffixes — *scale factors* in *SPICE*-speak — differs from what we

are generally accustomed to seeing in electrical schematics, and that we have multiple options for specifying values numerically using integer and decimal floating point numbers. The scale factors available in *SPICE* include:

- F (femto) — 1E-15
- G (giga) — 1E9
- K (kilo) — 1E3
- M (milli) — 1E-3
- MEG (mega) — 1E6
- MIL (0.001 inch) — 25.4E-6 meter
- N (nano) — 1E-9
- P (pico) — 1E-12
- T (tera) — 1E12
- U (micro) — 1E-6

Specifying the value of a resistor as 1M would cause *SPICE* to assign it the value of 1 milliohm (0.001  $\Omega$ ). This would probably create a wildly different result than expected! Specifying the value of R1 as 1MEG or 1000K would be correct alternatives. *SPICE* scale factors are case insensitive. Until you are thoroughly familiar with using circuit simulation, take the time to double-check component and parameter values. It will save you a lot of time tracking down errors caused by mistaken component values.

Notice that *SPICE* assumes unit *dimensions* — ohms, farads, henrys and so on — from component name context; in specifying resistance, we need not specify ohms. In parsing numbers for scale factors, *SPICE* detects only scale factors it knows and, having found one, ignores any additional letters that follow. This lets us make our schematics more readable by appending additional characters to values — as long as we don't confuse *SPICE* by running afoul of existing scale factors. We may therefore specify “100pF” or “2.2uF” for a capacitance rather than just “100p” or “2.2u” — a plus for schematic readability. (On the reduced readability side, however, *SPICE* requires that there be *no space* between a value and its scale factor — a limitation that stems from programming expediency and is present in many circuit-simulation programs.)

## SOURCES

There are two basic types of sources used in simulation models — voltage sources and current sources — as discussed in the **Electrical Fundamentals** chapter. Sources can be *independent* with an assigned value or characteristic that does not change, or *dependent* with a value or characteristic that depends on some other circuit value. An example of an independent source would be a fixed voltage power supply (dc) or a sinusoidal signal source (ac). An example of a dependent source is a bipolar transistor model's collector current source that has a value of  $\beta I_B$ .

## COMPONENT MODELS

All *real* inductors, capacitors, and resistors — all real components of any type — are non-ideal in many ways. For starters, as **Figure 6.2** models for a capacitor, every real *L* also exhibits some *C* and some *R*; every real *C*, some *L* and *R*; every real *R*, some *L* and *C*. These unwanted qualities may be termed *parasitic*, like the parasitic oscillations that sometimes occur in circuits that we want to act only as amplifiers. The **RF Techniques** chapter discusses parasitics for various components.

For simulating many ham-buildable circuits that operate below 30 MHz, the effects of component parasitic *R*, *L* and *C* can usually be ignored unless guidance or experience suggests otherwise. In oscillator and filter circuits and modeled active devices, however, and as a circuit's frequency of operation generally increases, neglecting to account for parasitic *L*, *C* and *R* can result in surprising performance shortfalls in real world *and* simulated performance. In active device modeling realistic enough to accurately simulate oscillator phase noise and amplifier phase shift and their effects on modern, phase-error-sensitive data communication modes, device-equivalent models must even include *nonlinear* parasitic inductances and capacitances — *L*s and *C*s that vary as their associated voltages and currents change.

Figuring out what the circuit of an appropriate model should be is one thing; measuring and/or realistically calculating real world values for *R<sub>S</sub>*, *L<sub>S</sub>* and *R<sub>P</sub>* for application in a circuit simulator is a significant challenge. How and to what degree these parasitic character-

istics may cause the electrical behavior of a component to differ from the ideal depends on its role in the circuit that includes it and the frequency at which the circuit operates.

Designers aiming for realism in simulating power circuits that include magnetic core inductors face the additional challenge that all real magnetic cores are nonlinear. Their magnetization versus magnetic field strength (*B-H*) characteristics exhibit hysteresis. They can and will saturate (that is, fail to increase their magnetic field strength commensurately with increasing magnetization) when over-driven. Short of saturation, the permeability of magnetic cores varies, hence changing the inductance of coils that include them, with the flow of dc through their windings. These effects can often be considered negligible in modeling ham-buildable low power circuits.

As active device operation moves from small signal — in which the signals handled by a circuit do not significantly shift the dc bias points of its active devices — to large signal — in which applied signals significantly shift active device dc bias and gain — the reality of *device self-heating* must be included in the device model. Examples: When amplitude stabilization occurs in an oscillator or gain reduction occurs in an amplifier as a result of voltage or current limiting or saturation.

While manufacturers often provide detailed models for their devices, avoid the temptation to assume that models will behave in a simulation just as an actual component will behave in a real circuit. *Absolutely every desired behavior exhibited by a simulated device must be explicitly built into the model*, mathematical element by mathematical element. A simulated device can reliably simulate real world behavior only to the extent that it has been programmed and configured to do so. A 1N4148 diode from your junk box “knows” exactly what to do when ac is applied to it, regardless of the polarity and level of the signal. Mathematically *modeling* the forward and reverse biased behavior of the real diode is almost like modeling two different devices. Realistically modeling the smooth transition between those modes, especially with increasing frequency, is yet another challenge.

Mathematical transistor modeling approaches the amazingly complex, especially for devices that must handle significant power at increasingly high frequencies, and especially as such devices are used in digital communication applications where phase relationships among components of the applied signal must be maintained to keep bit error rates low. The effect of nonlinear reactances — for instance, device capacitances that vary with applied signal level — must be taken into account if circuit simulation is to accurately predict oscillator phase noise and

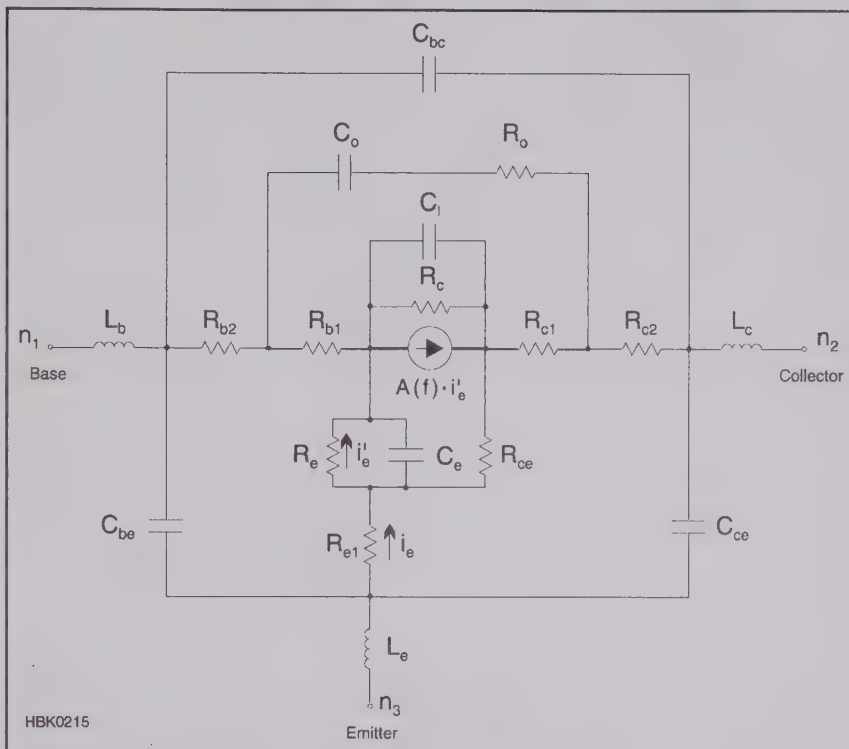

**Figure 6.2 — A capacitor model that aims for improved realism at VHF and above. *R<sub>S</sub>* models the net series resistance of the capacitor package; *L<sub>S</sub>*, the net equivalent inductance of the structure. *R<sub>P</sub>*, in parallel with the capacitance, models the effect of leakage that results in self-discharge.**

effects of the large signal phenomenon known as *AM-to-PM conversion*, in which changes in signal amplitude cause shifts in signal phase. In effect, different aspects of device behavior require greatly different models — for instance, a dc model, a small signal ac model, and a large signal ac model. Of *SPICE*'s bipolar-junction-transistor (BJT) model, we learn from the *SPICE* web pages that “The bipolar junction transistor model in *SPICE* is an adaptation of the integral charge control model of Gummel and Poon introduced in the **RF Techniques** chapter. This modified Gummel-Poon model extends the original model to include several effects at high bias levels. The model automatically simplifies to the simpler Ebers-Moll model when certain parameters are not specified.”

As an illustration of device model complexity, **Figure 6.3** shows as a schematic the BIP linear bipolar junction transistor model from *ARRL Radio Designer*, a linear circuit simulator published by ARRL in the late 1990s. This model worked well at audio and relatively low radio frequencies. The model must be even more complex for accurate results in the upper HF and higher frequency ranges.

Especially in the area of MOSFET and MESFET device modeling, and large signal device modeling in general (of critical importance to designers of RF integrated circuits [RFICs] for use at microwave frequencies), *SPICE* and RF-fluent non-*SPICE* simulators include active device models home experimenters are unlikely to use. Help in deciding on what version of a model is appropriate for your application is another reason to join your simulation tool's users group.

Most of us will go (and need go) no further into the arcanities of device modeling than using *SPICE*'s JFET model for FETs such as the 2N3819, J310, and MPF102, and *SPICE*'s BJT model for bipolar transistors such as the 2N3904. *OrCAD 16* includes preconfig-

**Figure 6.3** — The linear BJT model, BIP, from *ARRL Radio Designer*, a now-discontinued circuit simulation product published by ARRL in the late 1990s.

ured 1N914, 1N4148, 2N2222, 2N2907A, 2N3819, 2N3904 and 2N3906 devices, among many others, and these will be sufficient for many a ham radio simulation session. Getting the hang of the limitations and quirks of these models may well provide challenge enough for years of modeling exploration.

To get parameters for other devices, especially RF devices and specialty components like transformers, we must search the Internet in general and device manufacturer websites

in particular to find the data we need. The manufacturer sites listed in **Table 6.2** will get you started. Because the use of simulation and *SPICE* models is so widespread, manufacturers routinely make those models available at no cost. The usual place to find them is via the device's online data sheet through a hyperlink or in a special model library on the manufacturer's website — enter “models” into the site's search function if you can't find the models.

**Figure 6.4** — A list of parameters specified for the Gummel-Poon model of a 2N2222A transistor and the condensed form usually seen in available model files.

A typical *SPICE* model is shown in **Figure 6.4**. This particular model is for the familiar 2N2222A NPN bipolar transistor. Each parameter in the vertical list (IS, BF, NF and so forth) is one element of the Gummel-Poon model for the generic transistor used by *SPICE* simulation programs. Typically, the model is provided as plain ASCII text in the compressed form at the bottom of the figure with several parameters per line. Every parameter between the opening and closing parentheses defines some element of the underlying model. (See the *SPICE* references listed at the end of this chapter for detailed information about the syntax of *SPICE* models.)

### NETLISTS

A *netlist* is a specialized table that names a circuit's components, specifies their electrical characteristics, and maps in text form the electrical interconnections among them. Uniquely numbered nodes or *nets* — in effect, specifications for each of the connections in the simulated circuit — serve as interconnects between components, with each component defined by a statement comprising one or more netlist lines.

The netlist served as the original means of circuit capture for all simulators known to the

writer, including *SPICE*; *schematic capture* as we imagine it today, using graphic symbols, came later. Further reflecting *SPICE*'s pre-graphical heritage is the fact that, to this day a *SPICE* netlist may be referred to by long-time *SPICE* users as a *SPICE deck*, as in “deck of Hollerith punch cards.” In *SPICE*'s early days, circuit definitions and simulation instructions (netlist statements that begin with a period [.] ) were commonly conveyed to the simulation engine in punched-paper-card form. Netlists are still the means of conveying circuit topology and simulation instructions to most simulators, although they are text files today.

In the models and netlists that you will encounter, statements that must span multiple lines include *continuation characters* (+) to tell the netlist parser to join them at line breaks. Asterisk (\*) or other non-alphanumeric characters denote comments — informational-to-human lines to be ignored by the simulator.

### SUBCIRCUITS

**Figure 6.5** illustrates the level of detail involved in more accurate device modeling typical for devices used at VHF and UHF. The device is a California Eastern Labs NE46134, a surface mount BJT intended to serve as a broadband linear amplifier at collector cur-

rents up to 100 mA and collector voltage up to 12.5 V.

This manufacturer supplied model for the NE46134 embeds an unpackaged device chip (NE46100, shown as Q1 in the figure) within a *subcircuit*. (Note the .SUBCKT label on the first non-comment line of the model which indicates that the following information defines a subcircuit.) The subcircuit includes Q1 plus the parasitic reactances contributed by the transistor package, such as CCBpkg — collector-to-base package capacitance. The chip leads themselves are modeled as transmission lines, TB and TE.

Following the lines that define all of the subcircuit's component values that represent the parasitic reactances, the NE46100 transistor model is provided, beginning with the line .MODEL NE46100 NPN. That information will be used to define Q1 when referenced in the subcircuit model above.

The overall model then appears to the external circuit like a regular three terminal transistor with a base, emitter and collector. In this fashion nested subcircuits can be used to create arbitrarily complex models that can be used as components by the designer.

**Figures 6.6A** and **6.6B** show a schematic of a typical RF circuit — a 7 MHz double-tuned filter. **Figure 6.6A** is the usual depiction you would see in a magazine or book article about the circuit. It has the usual symbols and variable capacitors of a tunable filter. **Figure 6.6B** shows the circuit after schematic capture by the *OrCAD Capture CIS* tool. An ac voltage source, V1, is placed at the input with a 50 Ω series resistor, R1, to create a 50 Ω signal source impedance. The transformers TX1 and TX2 actually contain subcircuits consisting of primary and secondary inductances and coupling element with 0.22 Ω resistors that simulate loss resistance. The paralleled fixed and variable capacitors are combined into single fixed value capacitors. A 50 Ω load, R2, has been attached to the output. Ground symbols now have a 0 nearby to indicate zero voltage.

### TIME STEP

Simulators are *discrete time* devices — calculations are performed throughout the circuit and results obtained, then time is changed by a fixed amount (the *time step*) and the calculations run again. The size of the time step can be automatically chosen by the simulator (a usually reasonable value based on a default setting or some evaluation of the circuit component values) or set to specific values by the user.

While using very small time steps make for a smooth looking output and wide frequency ranges, it makes the simulation run slower (less of an issue as computers get faster) and makes the output data files quite a bit bigger (less of an issue as hard drives get

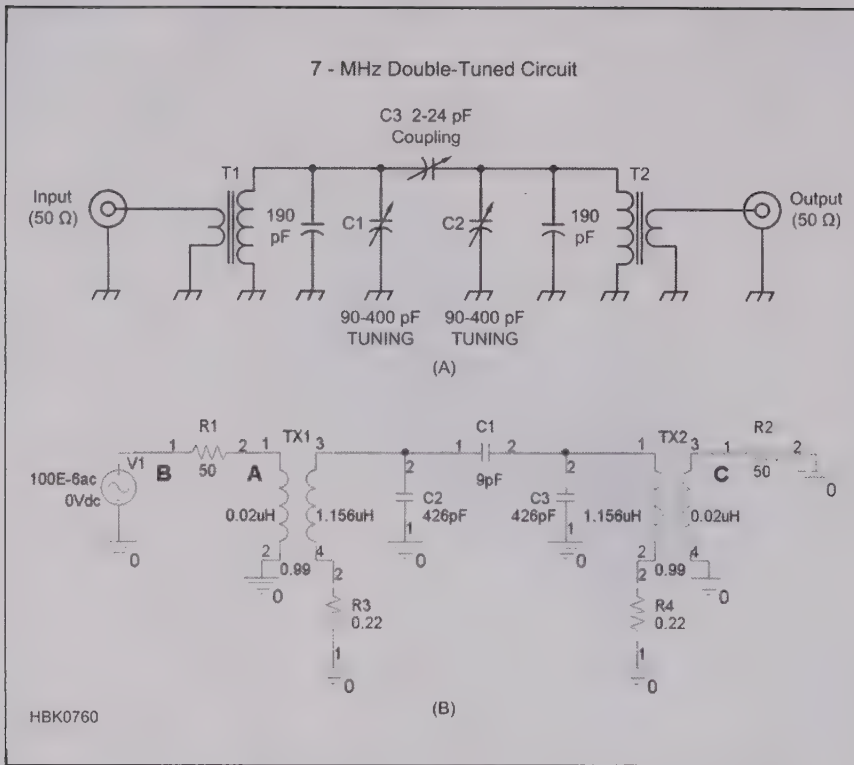

Figure 6.6 — A is a 7 MHz double-tuned filter as drawn for real world builders. B shows the filter schematic as it is typically drawn for construction and service.

Figure 6.7 — A dc operating point simulation allows the designer to verify that the circuit biasing is realistic for all devices and that all voltages and currents are as expected.

run a *DC Operating Point* or *DC Bias Point* analysis. (Remember that terminology usually changes from program to program.) In this analysis, the simulator “applies power” to the circuit and calculates the dc voltages and currents for all circuit components.

Figure 6.7 shows the results of a typical DC Operating Point analysis for an amplifier circuit. The labels obscure the circuit elements a bit in this print image but you can see a transistor (Qbreakn) in the middle, an input voltage source at the lower left (V1), the

power supply voltage source at the upper right (V2), and a variety of components making up the circuit. The darker labels show voltages such as 3.061 V (transistor base voltage) and 46.75 mA (the power supply output current). The information is generally available as a text file, as well. Most simulators also allow you to flag certain points in the circuit for which voltage and current (ac and/or dc) are displayed on screen at all times.

It is good practice, particularly for beginning and occasional modelers, to verify that the dc operating point is as expected for all circuit components before moving ahead to the more interesting ac waveform and spectrum displays. Many hours have been wasted troubleshooting a circuit’s simulated ac performance when the problem is really that the dc operating point isn’t right!

### TIME DOMAIN VS FREQUENCY DOMAIN

Simulators can provide two primary types of ac simulation results. The time domain output displays one or more voltages or currents on an X-Y display as traces with amplitude on the vertical axis and time on the horizontal axis. In other words, it simulates an oscilloscope type display. Figure 6.8 shows an example time domain display of an R-C oscillator starting to oscillate. The single trace is of the oscillator’s ac output voltage, showing that oscillation begins about 30 ms after the simulation begins and quickly stabilizes to a steady sine wave output.

Figure 6.9 shows a frequency domain output that looks very much like a spectrum analyzer display. This particular simulation is of the same amplifier shown in Figure 6.7 with two input signals (the large components at 7 and 10 MHz) and uses a logarithmic vertical scale to show the harmonics and intermodulation products. SPICE-type simulators first perform time domain ac analysis to generate a waveform then use Fast Fourier Transform techniques to calculate a frequency domain output. This technique is often insufficient to obtain highly accurate frequency domain simulations, such as noise and intermodulation performance, leading to alternatives such as harmonic balance simulations that are called *RF-fluent* since they give more accurate results at high frequencies. (See the sections on RF-Fluent Simulators and Limitations of Simulation at RF in this chapter.)

### TRANSIENT

Transient simulation involves putting the circuit in a stable, known state and then applying a controlled disturbance of some sort. The response to the disturbance is then calculated and displayed over some time period in either time domain or frequency domain form. Typical inputs to transient analysis are steps (a parameter changes very quickly from

Figure 6.8 — Time domain display of an R-C oscillator startup showing voltage on the vertical axis and time on the horizontal. The display is very much like that of an oscilloscope.

Figure 6.9 — Frequency domain display of an amplifier undergoing a two-tone test. Amplitude in dB is shown on the vertical axis and frequency on the horizontal axis. This display is very much like that of a spectrum analyzer.

one value to another), delta pulses (infinitely narrow pulses with some finite energy), rectangular pulses, ramps, and various other selectable waveforms.

### DC AND AC SWEEPS

Once a circuit is working, it is useful to characterize its performance over a range of conditions, called a *sweep*: power supply voltage, input voltage, input frequency and

so on. Even temperature can be swept to see how the circuit behaves in different environments. Note that this requires the behavior of components with changing temperature to be accounted for in the component models.

One of the most common swept simulations for ham radio circuits is a frequency sweep to determine the frequency response of an amplifier or filter. **Figure 6.10** shows the insertion loss and return loss (see the

**RF Techniques** chapter) for the 7 MHz filter in **Figure 6.6** across a range of 6.8 to 7.4 MHz. **Figure 6.11** shows the gain of the amplifier in **Figure 6.7** with the input frequency swept across a range of 1 to 100 MHz.

### 6.2.4 RF-Fluent Simulators

*SPICE*-based simulators can do wonders in many classes of circuit simulation. For RF

Figure 6.10 — Insertion loss (A) and return loss (B) of the 7 MHz double-tuned filter in Figure 6.6.

use, however, *SPICE* has significant drawbacks. For starters, *SPICE* is not RF-fluent in that it does not realistically model *physical* distributed circuit elements — microstrip, stripline and other distributed circuit elements based on transmission lines. It cannot directly work with network parameters (*S*, *Y*, *Z* and more — see the **RF Techniques** chapter), stability factor and group delay. It cannot simulate component *Q* attributable to skin effect. It cannot simulate noise in nonlinear circuits, including oscillator phase noise. It

cannot realistically simulate intermodulation and distortion in high-dynamic-range circuits intended to operate linearly. This also means that it cannot simulate RF mixing and intermodulation with critical accuracy.

The feature-unlimited version of *Ansoft Designer* and competing RF-fluent simulation products can do these things and more excellently — but many of these features, especially those related to nonlinear simulation, are unavailable in the student/demoware versions of these packages if such versions exist.

From 2000 to 2005, the free demoware precursor of *Ansoft Designer SV 2*, *Ansoft Serenade SV 8.5*, brought limited use of nonlinear simulation tools to students and experimenters. With *Serenade SV 8.5*, you could simulate mixers, including conversion gain and noise figure of a mixer. Amplifier two-tone IMD could be simulated as in Figure 6.10. Optimization was enabled. Realistic nonlinear libraries were included for several Siemens — now Infineon — parts. You could accurately predict whether or not a circuit you hoped would oscillate would *actually* oscillate, and assuming that it would, you could accurately predict its output power and frequency. **Figures 6.12, 6.13 and 6.14** give some examples of the power of RF-fluent simulation software, in this case, *Ansoft (now ANSYS) Serenade Designer SV 8.5*.

The harmonic balance techniques used by *Ansoft's* nonlinear solver — and by the nonlinear solvers at the core of competing RF-fluent CAD products, such as *Agilent Advanced Design System (ADS)* — allow you to simulate crystal oscillators as rapidly as you can simulate lower-*Q* oscillators based on LC circuits. (In *SPICE*, getting a crystal oscillator to start may be impossible without presetting current and/or voltages in key components to nonzero values.)

Although these features are no longer available as student/demoware/freeware, if you're serious about pushing into RF CAD beyond what *SPICE* can do, see if you can find a used copy of *Serenade SV 8.5* or find a friend working with the professional tool who will let you use it occasionally for hobby applications.

Figure 6.11 — The gain in dB of the amplifier in Figure 6.6 over a range of 1 to 100 MHz.

Figure 6.12 — A two-tone nonlinear simulation of third-order IMD performed by Ansoft *Serenade Designer SV 8.5*.

Figure 6.13 — Professional RF circuit simulators can also simulate mixing and the small signal characteristics of mixers, such as port return loss, conversion gain, and port-to-port isolation. (*Serenade SV 8.5* simulation)

Figure 6.14 — Output spectrum of a diode ring doubly balanced mixer as simulated by *Serenade SV 8.5*. Note the dynamic range implicit in this graph: In a simulation that includes a local oscillator (LO) signal at 7 dBm, accurate values are calculated for IMD products nearly 140 dB weaker without encountering mathematical noise — an achievement unapproachable with *SPICE*-based simulators.

# 6.3 Limitations of Simulation at RF

[Experienced users of circuit simulation software are wary of using any software near or outside the boundaries of circuits and parameters for which it was intended and tested. RF simulation can present just such situations, leading to software failure and unrealistic results. Introduced and summarized in this section, several detailed papers by Dr Ulrich Rohde, NIUL, exploring simulation at RF are provided with the downloadable supplemental content. The papers are:

- “Using Simulation at RF” by Rohde, a survey of the issues of RF simulation and the techniques used in current modeling programs.
- “The Dangers of Simple Usage of Microwave Software” by Rohde and Hartnagel, a discussion of inaccuracies introduced by device parameter measurement and model characteristics.
- “Mathematical Stability Problems in Modern Non-Linear Simulations Programs” by Rohde and Lakhe, presenting various approaches to dealing with nonlinear circuit simulation.

In addition, there are many online resources to help you obtain trustworthy simulation results with a simulator designed for RF. For the interested reader with some technical background, the online paper “Introduction to RF Simulation and its Application” by Ken Kundert ([icslwebs.ee.ucla.edu/dejan/researchwiki/images/3/30/Rf-sim.pdf](http://icslwebs.ee.ucla.edu/dejan/researchwiki/images/3/30/Rf-sim.pdf)) provides an introduction to RF simulation methods and how they account for the characteristics of RF circuits when generating common RF measurements. The website The Designer’s Guide ([www.designers-guide.org](http://www.designers-guide.org)) also provides many tutorials, technical guides, models, and other resources for analog and RF simulation users.

While the precise lower bound of “RF” is ill-defined, RF effects start already at about 100 kHz. This was first noticed as self-resonance of high-Q inductors for receivers. In response, Litz wire was invented in which braided copper wires were covered with cotton and then braided again to reduce self-resonance effects.

As frequencies get higher, passive elements will show the effects of parasitic elements such as lead inductance and stray capacitance. At very high frequencies, the physical dimensions of components and their interconnections reach an appreciable fraction of the signal wavelength and their RF performance can change drastically.

RF simulators fall in the categories of SPICE, harmonic balance (HB) programs

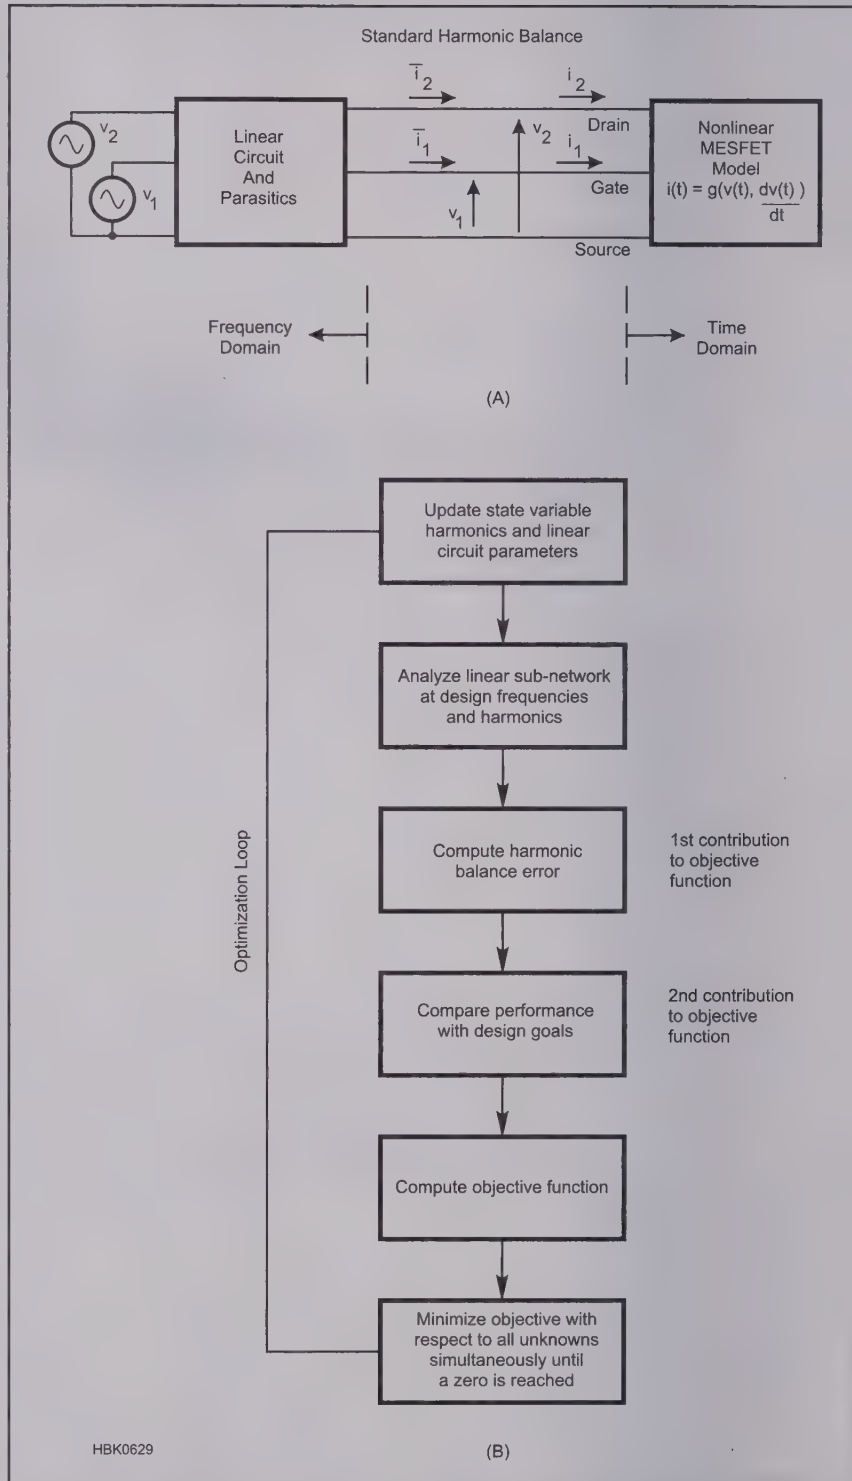

Figure 6.15 — (A) MESFET circuit partitioned into linear and nonlinear sub-circuits for harmonic balance analysis. Applied gate and drain voltages, and relevant terminal voltages and currents, are indicated. (B) Flowchart of a general purpose harmonic balance design algorithm that includes optimization.

and EM (electromagnetic) programs. The EM simulators are more exotic programs. Two types are common, the 2D (2.5) or 2-dimensional and the full 3-dimensional versions. They are used to analyze planar circuits, including vias (connections between layers) and wraparounds (top-to-ground plane connections), and solid-shapes at RF. They go far beyond the *SPICE* concept.

### 6.3.1 *SPICE*-based Simulators

*SPICE* was originally developed for low frequency and dc analysis. (Modern *SPICE* programs are based on *SPICE3* from University of California — Berkeley.) While doing dc, frequency, and time domain simulations very well, *SPICE*-based simulation has some problems. The time domain calculation uses the very complex mathematics of the Newton-Raphson solution to nonlinear equations. These methods are not always stable. All kind of adjustments to the program settings may be necessary for the calculations to converge properly. Knowledge of the specifics of different types of electronic circuits can assist the user in finding an accurate solution by specifying appropriate analysis modes, options, tolerances, and suitable model parameters. For example, oscillators require certain initializations not necessary for amplifiers and bipolar transistors may need different convergence tolerances than do MOS circuits. Generally, *SPICE* finds a solution to most circuit problems. However, because of the nonlinearity of the circuit equations and a few imperfections in the analytical device models, a solution is not always guaranteed when the circuit and its specification are otherwise correct.

The next problem at RF is that the basic *SPICE* simulator uses ideal elements and some transmission line models. As we approach higher frequencies where the lumped elements turn into distributed elements and special connecting elements become necessary, the use of the standard elements ends. To complicate matters, active elements such as diodes and transistors force the designer to more complex simulators. Adding the missing component elements leads to highly complex models and problems of convergence in which the simulator gives an error advising of a numerical problem or more likely by failing to generate a solution.

*SPICE* also has problems with very high-Q circuits and noise analysis. Questions of the noise figure of amplifiers or phase noise of an oscillator cannot be answered by a *SPICE*-based program accurately. Noise analysis, if not based on the noise correlation matrix approach, will not be correct if the feedback capacitance ( $\text{Im}(Y_{12})$ , the imaginary component of Y-parameter  $Y_{12}$ ) is significant at the frequencies involved. Analysis of oscillators

in *SPICE* does not give a reliable output frequency and some of the latest *SPICE* programs resort to some approximation calculations.

### 6.3.2 Harmonic Balance Simulators

Harmonic balance (HB) analysis is performed using a spectrum of harmonically related frequencies, similar to what you would see by measuring signals on a spectrum analyzer. The fundamental frequencies are the

frequencies whose integral combinations form the spectrum of harmonic frequency components used in the analysis. On a spectrum analyzer you may see a large number of signals, even if the input to your circuit is only one or two tones. The harmonic balance analysis must truncate the number of harmonically related signals so it can be analyzed on a computer.

The modern HB programs have found better solutions for handling very large numbers of transistors (>1 million transistors) and their math solutions are much more efficient, leading

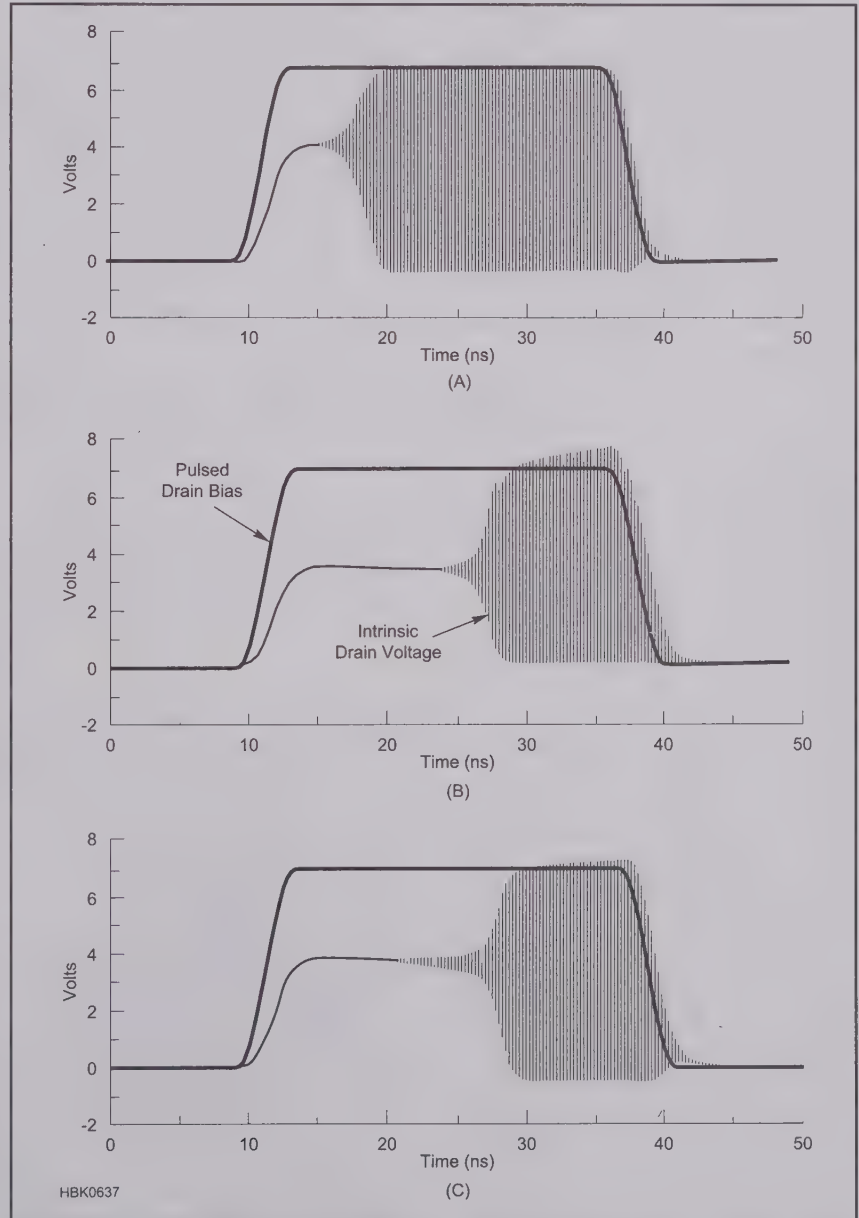

Figure 6.16 — (A) is the initial simulation of a *SPICE*-based simulator. (B) is the correct response of a pulsed microwave oscillator obtained by harmonic balance simulation using the Krylov-subspace solution. (C) is the *SPICE*-based simulation after 80 pulses of the drain voltage.

to major speed improvements. Memory management through the use of matrix formulations reduces the number of internal nodes and solving nonlinear equations for transient analysis are some of the key factors to this success.

HB analysis performs steady-state analysis of periodically excited circuits. The circuit to be analyzed is split into linear and nonlinear sub-circuits. The linear sub-circuit is analyzed in the frequency domain by using distributed models. In particular, this enables straightforward intermodulation calculations and mixer analysis. The nonlinear sub-circuit is calculated in the time domain by using nonlinear models derived directly from device physics. This allows a more intuitive and logical circuit representation.

Figure 6.15A diagrams the harmonic balance approach for a MESFET amplifier. Figure 6.15B charts a general purpose nonlinear design algorithm that includes optimization. Modern analysis tools that must provide accurate phase noise calculation should be based on the principle of harmonic balance.

Analysis parameters such as Number of

Harmonics specify the truncation and the set of fundamental frequencies used in the analysis. The fundamental frequencies are typically not the lowest frequencies (except in the single-tone case) nor must they be the frequencies of the excitation sources. They simply define the base frequencies upon which the complete analysis spectrum is built.

### 6.3.3 Contrasts in Results

The following time domain analysis is a good example of differences between *SPICE* and harmonic balance simulation. A microwave oscillator is keyed on and off and a transient analysis is performed. When using the standard *SPICE* based on *SPICE3*, the initial calculation shows an incorrect response after one iteration as seen in Figure 6.16A. It takes about 80 pulses (80th period of the pulsed drain voltage) until the simulation attains the correct answer (Figure 6.16C) of the Krylov-subspace-based harmonic balance in Figure 6.16B.

The frequencies involved need not be in

the GHz range. Oscillators, in particular, can be very difficult to analyze at any frequency as shown by simulations of a low-MHz phase shift oscillator and a 10 MHz Colpitts oscillator in the referenced papers.

Validating the harmonic balance approach, Figure 6.17 shows a BJT microwave oscillator entered into the schematic capture module of a commercially available HB simulator (Ansoft *Serenade 8.0*); Figure 6.18 compares this oscillator's simulated phase noise to measured data. HB analysis gives similarly accurate results for mixers.

### 6.3.4 RF Simulation Tools

*PSPICE*: OrCAD *PSPICE* is a popular version available from Cadence PCB Solutions ([www.orcad.com](http://www.orcad.com)) and a "Lite" version is available for free download. (The Lite version is limited in the size and complexity of designs that can be created.) AIM-spice ([www.aimspice.com](http://www.aimspice.com)) is a PC version of *SPICE* with a revised user interface, simulation control, and with extra models.

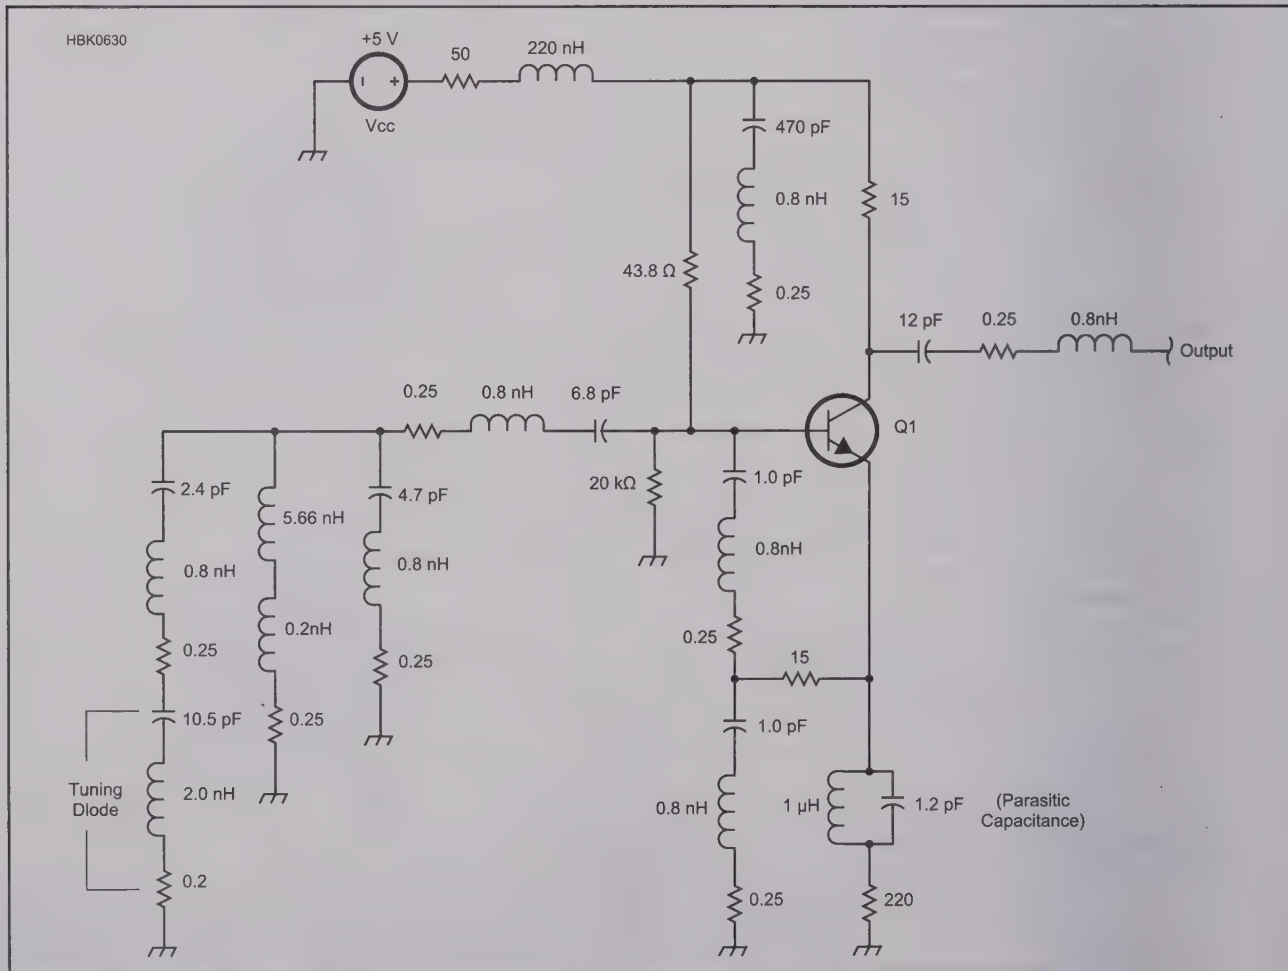

Figure 6.17 — Colpitts oscillator for 800 MHz with lumped elements modeled by their real values.

Figure 6.18 — Comparison between predicted and measured phase noise for the oscillator shown in Figure 6.17.

A student version can be downloaded. Table 6.1 earlier in this chapter shows other free *SPICE* offerings.

There are a number of PC based *SPICE* programs in the \$1000 range but they are designed more for switching power supplies and logic circuits optimization than RF. *ICAP4* ([www.intusoft.com/demos.htm](http://www.intusoft.com/demos.htm)) and *MICROCAP* ([www.spectrum-soft.com/index.shtm](http://www.spectrum-soft.com/index.shtm)) both have demonstration/evaluation versions available for download

Agilent, AWR, Ansys, and Synopsis offer very modern mixed-mode CAD tools and they combine the concept of *SPICE* with the advanced technologies. These are professional quality tools, but if one can arrange to make use of them through a friend or associate, the results are worth investing the time to learn their use.

Linear Technologies also offers a free version, *LTSpice*, in support of its switchmode products but handles all types of circuits and has a large number of users. (For a *QST* tutorial and a set of references and downloadable component libraries, see the Reference entries for Silver and Würth Elektronik.)

## 6.4 Electromagnetic Analysis of RF Circuits

Solving the equations governing electromagnetic (EM) fields first became technically feasible in the late 1970s and is now a well-developed technology. A wide variety of software is available, all developed over decades of intense research. Today, you can take advantage of the fruits of this research without learning the equations and without writing any software. This section provides some historical background, discusses different types of EM analysis techniques, and outline how electromagnetic software is used today. Then we show how you can use some of these tools for your RF designs.

### 6.4.1 Historical Background

In 1865, James Clerk Maxwell, Figure 6.19, published the equations that govern electric and magnetic fields. Maxwell's equations, as they are now called, put in solid mathematical terms the following principles:

- 1) A changing electric field creates a changing magnetic field that is exactly at right angles to the electric field.
- 2) A changing magnetic field creates a changing electric field that is exactly at right angles to the magnetic field.

Maxwell quickly recognized an important implication of his equations. If both an electric and magnetic field could somehow exist at the same time and at the same place and be exactly at right angles to each other with both

changing in just the right way, each one would continually create the other and a propagating wave would result. Using his equations, he calculated the speed of that hypothetical "electromagnetic" wave. Amazingly, he saw that it was virtually identical to the mechanically measured speed of light. His conclusion

was earth-shaking, "...that light is an electromagnetic disturbance propagated through the field according to electromagnetic laws." However, Maxwell felt that the chances of using electricity to actually create such a wave would be difficult if not impossible.

After Maxwell's death, almost by accident while experimenting with a spark-gap, a German professor, Heinrich Hertz, succeeded in creating and detecting electromagnetic waves. He then refined how he created and detected the waves and conducted experiments reflecting, diffracting, focusing, and polarizing electromagnetic waves. This provided definitive proof that Maxwell's equations are correct. However, Hertz felt there was little if any practical use for such waves. As we all know, an Italian entrepreneur, Guglielmo Marconi, thought otherwise and was spectacularly successful.

Science marches on and modern physics has shown us that Maxwell's equations are wrong. You may be familiar with the concept of a "photon," the particle of light. A photon is indivisible. We cannot have half of a photon. The light we see can only be composed of an integer number of photons. A sensitive photomultiplier tube can receive one photon, or two, or three, but never 2.853 photons.

Maxwell's equations form a "field" theory. There are no photons in Maxwell's equations. Mathematically, we can easily write

Figure 6.19 — James Clerk Maxwell (1831 – 1879) gave us the equations which govern the interaction between changing electric and magnetic fields. These equations can be solved on a computer, revealing how our RF and microwave circuits will perform.

## The Basic Elements of Maxwell's Equations

The complete set of Maxwell's equations can be described as, "A set of four simultaneous partial differential equations operating on four vector fields in four dimensions and driven by two scalar fields." The four dimensions are the three spatial dimensions ( $x, y, z$ ) and time. The four vector fields are electric,  $\mathbf{E}$  and  $\mathbf{D}$ , and magnetic,  $\mathbf{H}$  and  $\mathbf{B}$ . The two scalar fields are electric and magnetic charge. (Magnetic charge has yet to be discovered, but that does not stop the mathematics.)

You may also know these equations as laws named for scientists who originally discovered the relationships. It was Maxwell who brought them all together into one set of equations that define electromagnetics. (For an explanation of vectors, scalars, and what the various symbols mean, see the item "Radio Mathematics" in the downloadable supplemental material.)

Gauss' Law for Electric Fields:  $\nabla \cdot \mathbf{D} = \rho$

Gauss' Law for Magnetic Fields:  $\nabla \cdot \mathbf{B} = 0$

Faraday's Law:  $\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}$

Ampere - Maxwell Law:  $\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t}$

Where  $\rho$  represents the density of electric charge and  $\mathbf{J}$  represents a distribution of electric current (moving charge). There are also forms of Maxwell's Laws that are written as integrals; that incorporate relativity; that use mathematical objects known as tensors; and various other ways. The four equations above, though, are the most widely known.

$\mathbf{J}$  is a vector because current has a direction. A distribution of *electric* charge changing with time is exactly what makes electric current. So, for RF, we can use either current or charge (both of which can vary with time) to drive the equations. All sorts of other abstract mathematical quantities are also helpful, including some strange beasts known as vector and scalar potentials. Fortunately, we can often simplify things by assuming that  $\mathbf{D}$  is proportional to  $\mathbf{E}$  ( $\mathbf{D} = \epsilon \mathbf{E}$ ), and  $\mathbf{B}$  is proportional to  $\mathbf{H}$  ( $\mathbf{B} = \mu \mathbf{H}$ ). Then, we have only have two vector fields to deal with, but even that is still a big problem.

By doing this extra math, Maxwell's equations and all their vector and scalar fields are turned into a big pile of discrete numbers that can be stored on and crunched in a computer. It has only taken a couple decades with hundreds if not thousands of researchers all over the world, but it seems like today we are pretty much there.

For a detailed introduction to Maxwell's equations, if you have some calculus background, see *A Student's Guide to Maxwell's Equations* by Daniel Fleisch from Cambridge Press. It is an excellent tutorial on this important topic.

the equations for an electromagnetic wave with the energy of 2.853 photons. But we know that such a wave cannot exist. It is here that something called quantum electrodynamics (QED) takes over. Fortunately, for virtually everything we do, QED is not needed. The number of photons is so incredibly huge, we can just pretend that we are dealing with electric and magnetic fields. So, we use Maxwell's equations. Just as Newton's laws of motion are still useful when figuring how long it will take to get to the grocery store, Maxwell's equations are useful for our work with radio waves.

We are especially fortunate to have Maxwell's equations. In nearly all other fields of science and engineering, exact solutions to practical problems are often impossible. In contrast, given a precisely known passive RF circuit, we can use Maxwell's equations to get precise results for how it will operate. (Active circuits, typically with transistors, are with elsewhere in this book.) Appropriate circuits include filters, matching networks, couplers, power dividers, connectors, transformers, and

any passive structure involved in handling RF.

All this gradually started to become possible in the 1970s. Computers were just starting to come into wide use. Large corporate time-share computers saw some of the first EM software ever developed. The first IBM-PC put serious computing power (for the day) in front of a lot of eager, bright-eyed experimenters and amateurs. We were off to the races! As with many things, there is more than one way to slice that loaf of bread. Let's see what toys we now have in our electromagnetic tool box.

### 6.4.2 Types of Electromagnetic Analysis

Maxwell liked to think "analogically," reasoning that completely different areas of physics and nature somehow use similar equations. For example, he suspected that incompressible fluid flow (think of a submarine powering through the ocean depths) and electrostatics (think about rubbing a balloon on your hair) use the same equations. So

he derived the equations for incompressible fluid flow and found that they magically work just fine for electrostatics...absolutely mind-boggling when we think about it. That was his first step in coming up with the full set of Maxwell's equations.

We can use analogical thinking in solving Maxwell's equations on a computer, too. The problem is that we have continuous electric and magnetic fields everywhere. In contrast, a computer can only store numbers, and we must be careful that we do not overrun the computer's memory capacity. The same is true for images. To get an image into a computer, we take a picture with a camera. The camera converts the continuous image into discrete pixels. There are three numbers (red, green, and blue, colors which Maxwell was the first to figure out) for each pixel. In this form, our picture is just a bunch of numbers. We can now store the picture on any computer and use software to process the picture as we like. So, if analogical thinking works for this case, maybe we can convert our electromagnetic problem into "pixels."

And indeed we can. First, the fields and currents are *discretized*, just like an image being converted to pixels. However, an image is usually two-dimensional while EM fields are three-dimensional in space, and they vary with time. Thus, we actually have to deal with pixels in four dimensions. To make the problem worse, we have to discretize the electric field, the magnetic field, the charge (or, equivalently, the current), and even the circuit itself. That is a lot of numbers!

Fortunately, today's computers have gotten really good at storing lots of numbers. Once we have the numbers stored, then, just like when we do image processing, we can use software to do what we want with the numbers. This is where the last few decades of EM research has concentrated. There are two ways to do this: *Volume meshing* and *surface meshing*. (Meshing means to divide a volume or surface into many smaller volumes or surfaces with boundaries that are connected to each other, forming a mesh filling or covering the entire volume or surface.) We discuss each below.

#### VOLUME MESHING — FDTD

The easiest to understand is *finite difference time domain* (FDTD) analysis. In its simplest form, we mesh the entire volume of the RF structure into tiny rectangular hexahedral cells (six sides, for example cubes, rectangular cuboids, and similar shapes). Note that we must also mesh all of space that might have any EM fields. This includes any air (e.g., free space) surrounding the structure. You can imagine this structure as an enormous spreadsheet in which the value in each cell depends on the values of each neighboring cell.

Next we assume an initial condition. This

s like an RF input into the structure. Let's say we have 1 volt of electric field at the input right at the start (time:  $t = 0$ ). This input is a single impulse, we put it there for only a single instant (i.e., time step). This is like hitting a bell to start it ringing.

And indeed it does ring. Changing the input voltage, which we placed on an edge of one of the hexahedrals (one face of a cube), from 0 volts to 1 volt right at the start gives us a changing electric field. In addition to meshing the structure, we also have to discretize time. So we pick a tiny time-step. Then the software uses Maxwell's equations to calculate exactly how much changing magnetic field is created by the changing electric field at the input. In addition, the software knows, because of Maxwell's equations, that this changing magnetic field must be at right angles to the changing electric field. This changing magnetic field is now created on the edges of every hexahedral surrounding the hexahedral edge that has the changing electric field input.

In the next time-step, we have both changing magnetic fields and changing electric fields near the original input. Each hexahedral edge with a changing magnetic field creates a changing electric field in all surrounding hexahedral edges. Each changing electric field creates a changing magnetic field in all surrounding edges. Using Maxwell's equations, the software calculates how much electric and magnetic field is created. And so it repeats. Imagine each cell of the spreadsheet constantly updating its value based on the value of its neighbors.

Soon (at the speed of light) electric and magnetic fields propagate throughout the entire structure. For every hexahedral in the structure, the computer now stores a list of numbers that tell us how the electric and magnetic fields change as a function of time. If there is a little bit of loss (and in real life, there is always at least a little bit of either conductor or radiation loss), the ringing electric and magnetic fields gradually die out to zero, and the solution is complete.

Often, we are not interested in the electric and magnetic fields in the entire circuit. For example, we might be interested only in an input and an output. We still need to calculate all the field information everywhere to get to the final desired result. But at any given time-step during analysis, only the last several time-steps of complete field information are needed. In this case, we discard all internal field information after it is no longer needed for calculating the next time-step. In other cases, we actually want to see the complete internal fields as they develop during the analysis and we keep that information available, usually by storing it conveniently on the computer's hard drive.

**Figure 6.20** shows a typical FDTD result. Red (or bright) color indicates high electric fields as a continuous RF wave at a single

**Figure 6.20** — A complex rectangular waveguide mode converter as analyzed by FDTD. Electric field is shown with red (or bright) indicating high field strength. Input is on the right. [Courtesy Remcom, used with permission]

**Figure 6.21** — The FDTD calculated time-domain response to a brief RF pulse on the input of the mode converter of Figure 6.20 resembles the ringing of a bell. This is called the “impulse response”. [Courtesy Remcom, used with permission]

frequency propagates along a complex rectangular waveguide circuit. The field strength is shown across the entire cross-section of the guide at the ports, and on a horizontal plane in the middle of the waveguide along its length. The hexahedral meshing is so fine that it is not visible in this image. The set of full-color figures is available as a PDF file in the online supplemental information for this book.

A little more detail is important. Due to problems calculating rate-of-change with time (known in calculus as a “time derivative”) and rate-of-change across space (a “gradient”), there are actually two full and nearly identical discretizations of the structure being analyzed. Both discretizations cover the same volume. The only difference is one discretization is offset from the other by one-half of a hexahedral. The changing electric field is calculated on one discretization, and the changing magnetic field is calculated on the other. This means that every sample of mag-

netic field is midway between all adjacent samples of the electric field. Likewise, the electric field calculation is always for points that are midway between all adjacent samples of the magnetic field. Without this special modification, there can be stability problems.

In practice, the input is typically not a simple impulse. A pure impulse can cause numerical instability. So, we typically use a “gentler” input, like a Gaussian pulse. This kind of pulse is the well-known “bell curve” used to curve test grades or to represent the probability of many random processes. If we are especially interested in results over a specific band of frequencies, we can use the Gaussian pulse to modulate an RF carrier centered on the band of interest.

For most circuits, the electric and magnetic fields at a given point plotted as a function of time look just like what we would expect for a ringing bell, or a ringing resonant LC circuit, **Figure 6.21**. For this case, the input

**Figure 6.22** — Performing a Fourier transform on the circuit response is equivalent to using a spectrum analyzer to see the frequency domain response of the mode converter given the broad band impulse used to excite the filter. [Courtesy Remcom, used with permission]

is a modulated Gaussian pulse modulating an RF carrier. The rapid oscillation is from the RF carrier, and the envelope is the result of the “bell” ringing. This is closely related to what professionals call the “impulse response,” the impulse being a single instant of electric field that started all the fields going. While impressive, this is not of much use in designing our circuit. We typically need a frequency response.

The input pulse that started everything ringing actually has a wide band of frequencies present in it. Think about the spark gaps that Hertz and Marconi, as well as early hams, used to generate electromagnetic waves. They were very broad band. If we think of our circuit as being a filter, the output is just a filtered version of that broad band impulse we put on the input. The spectrum of that output is the filter response that we want to see. The computer can take the numbers that were calculated for the impulse response and simulate a spectrum analyzer by using a mathematical algorithm, i.e., a mathematical recipe, called a *Fourier transform*. The fastest way of doing a Fourier transform on a computer is creatively called the *fast Fourier Transform (FFT)*. (The FFT is also discussed in the chapter **DSP and SDR Fundamentals**.)

So the software simply performs an FFT on the impulse response, and we have the current and voltage output of our circuit. This output is then converted to S-parameters and plotted, **Figure 6.22**. The indicated “S21” is the ratio of the amplitude of the output voltage wave (i.e., coming out of port 2) to the amplitude of the input voltage wave (i.e., going into port 1). “S11” is the reflection coefficient, i.e., the ratio of the reflected wave to the input wave.

There are a number of time domain approaches similar to FDTD. Another approach

is called the *transmission line method* or TLM in which Maxwell’s equations are modeled as a fine mesh of short transmission lines. However, the basic idea of all time domain volume meshing EM tools is similar to what we describe above. The entire volume is meshed, an input pulse is applied, the time-domain response is calculated one time-step at a time, and then the output is (usually) converted from time-domain to frequency-domain.

## VOLUME MESHING — FINITE ELEMENT METHOD

Mechanical engineers use the *Finite Element Method (FEM)* extensively. Materials can only take so much stress and strain before they fail. FEM allows designers to rapidly try out many different structure designs on the computer. Then they build the best one, where “best” might be based on the most strength for the least weight, or size, or cost or other factor.

Stresses and strains are vector fields, just like electromagnetic fields. A “vector” has a magnitude and a direction. For example, an electric vector field at a given point might be “5 V/m in the *x* direction”. A “field” means that the vector is defined over a region, like inside a waveguide, or even everywhere in all of space. So, by analogical thinking, it seems we might be able to apply FEM to our RF and microwave problems too. And indeed we can. But the devil is in the details. Like all numerical EM techniques, it has taken world class researchers several decades to reach today’s high level of maturity.

FDTD is a time domain analysis. In other words, the EM analysis evaluates the EM fields as they evolve in time. We get the full frequency response by performing an FFT on the calculated impulse response.

For RF work, FEM tools typically provide frequency domain results. In this case, we specify a frequency of interest and the FEM

**Figure 6.23** — Extremely arbitrary structures can be analyzed with FEM. Here we see the meshing for a PCB multi-pin connector. High accuracy analysis at high frequency is critical when high performance is needed. The entire volume is meshed with tetrahedra. For clarity, the tetrahedra used for meshing are outlined only where they intersect with a surface of the connector. [Courtesy Keysight, used with permission]

software analyzes the response at that frequency. Then we specify a second frequency, and repeat the analysis for the new frequency. This repeats until we have results at all frequencies of interest.

The advantage of frequency domain analysis is that we analyze only the frequencies that we want. In addition, we now need to solve only for the three spatial dimensions. We already know that the fields all vary in time with a sine wave at a given frequency. We are however, restricted to working with linear circuits. Given input at a single frequency, linear circuits have only that exactly same frequency present everywhere in the circuit. An amplifier or a mixer would have several frequencies bouncing around even if only one frequency is input. Given only one frequency is present everywhere, our EM analysis now needs to solve only for the magnitude and phase of that sine wave. The advantage of time domain analysis is that we get all the frequencies (by using the FFT on the impulse response) with a single analysis.

FEM starts just like FDTD, by discretizing the structure we are analyzing. For RF work, FEM tools mesh our structure into tetrahedral (a three-sided pyramid with a triangular base). **Figure 6.23** shows an example of a multi-pin connector meshing. The rectangular hexahedral mesh used for structures in FDTD often leaves a “staircase” appearance. The staircase can be reduced by making the mesh very fine, but this increases memory requirements and analysis time. With pictures, the pixels also give a staircase appearance too. But with today’s cameras, the pixels are so tiny (and there are so many of them) that they are hard to see without magnification.

FEM can use tetrahedra of any size. Thus curving surfaces appear to be meshed into triangles (the exposed surface of each tetrahedra). This is often a better representation of the surface than is possible with the hexahedral cells of FDTD. In addition, since different size tetrahedra can be used as desired, the accuracy of the mesh can be varied. Very tiny tetrahedra can be used where the highest accuracy is needed, and large tetrahedra can be used elsewhere. In fact, an initial solution can be performed and the error estimated everywhere. Adaptive meshing then refines the mesh (makes more and smaller tetrahedra) where ever the error is too high. Thus the fine mesh, which can consume a lot of analysis time and computer memory, is only used where it is needed. Care should be taken because the region of fine mesh might require modification depending on the frequency of analysis and on how the structure is excited.

The mathematics of FEM can get very involved, and there are many different ways to implement it. High level, we must cast the

problem into what is called a “variational form.” For example, an equation for the energy in, say, a microwave filter, given some boundary conditions (like an RF voltage source on the input) is a variational form. FEM then finds the EM fields consistent with Maxwell’s equations and the given boundary conditions that give the minimum total energy. That field is the solution.

We can intuitively see why the minimum energy solution is the correct solution. Imagine a length of a thin, moderately wide conductor on a printed circuit board. Next, we place static electric charge on the conductor. Electrons are all negative and repel each other, pushing themselves to opposite edges of the conductor as best they can. We now have the highest charge on the edges of the conductor and lower charge towards the center of the conductor. This configuration of charge gives the minimum potential energy for the charge. This is the solution that FEM finds. It makes sense, highest charge on the edges means we have the highest voltage there too. If we add too much charge, the sharp edges are where the arcs and sparks will come from (do not try this at home!).

Mathematically, the situation for RF is nearly identical. It is just that instead of charge, we have RF current flowing. The RF current flows most strongly on the edges of a planar (for example, printed circuit board, PCB) conductor. In fact, if we run too much RF current, the edges literally start evaporating. This can actually happen even with low power if the conductor dimensions are very small, for example, on a silicon RF integrated circuit (SiRFIC) as is widely used in cell phones. In this case, the evaporation

process is called “electromigration.” SiRFIC designers add a layer of insulator on top of the RF conductors because of this problem. Otherwise, our cell phone would quickly fail. **Figure 6.24** shows a drawing of a typical RFIC made using GaAs (instead of silicon) mounted on a carrier. This was prepared using CAD (computer aided design) software and is ready for FEM meshing.

Thus, FEM is similar to an optimization problem. As such it is often iterative. It will try an initial (usually fast, coarse mesh, high error) analysis and evaluate the error (i.e., non-minimum energy) everywhere in that solution. Then the FEM software refines the meshing and refines the solution. This process repeats until the error is below a user-specified threshold. If you feel you need a better solution, just make the error threshold smaller. For high-accuracy work, it is best to refine the solution until all FEM calculated fields and currents appear smooth (error appears as noise in the fields). Sharp edges (as in PCB and SiRFIC) should have smooth high current. However, results can be useful even if error is still apparent in the field display. **Figure 6.25** shows a high quality result for a complex coaxial connector-to-PCB transition.

As we can see above, a major strength of the volume meshing techniques, like FEM and FDTD, is that they can easily analyze just about anything no matter what shape it is. These techniques excel by being able to handle extremely arbitrary structures, provided (as with all EM analyses) the problem does not get too big for our computer memory or our willingness to wait for an answer.

Next, we consider a technique that can

**Figure 6.24** — This RF integrated circuit is mounted on a carrier with wire bonds making connections to the outside world. This is a view of the circuit prior to meshing. FEM can analyze the entire structure including all electromagnetic interactions. [Courtesy Keysight, used with permission]

**Figure 6.25** — FEM has meshed a circuit with two coaxial connectors transitioning to two PCB conductors. The PCB conductors then come close to each other to form the start of a coupled line. The color coding shows current density on the conductors with red (or bright) indicating high current. This includes a ground plane on the underside, which we can see through the narrow slots between the PCB conductors and the ground plane that surrounds them on the top side of the substrate. This is known as CPW, or coplanar waveguide. Note that the current is smooth with high current on the edges, indicating a high quality result. [Courtesy Keysight, used with permission]

handle much larger problems, but only if the problem is appropriate for the technique.

### SURFACE MESHING — METHOD OF MOMENTS

Like FEM and FDTD, *Method of Moments* (MoM) was developed in the 1960s. MoM was fully formalized and popularized in the West by Prof. Roger Harrington of Syracuse University. He named it after similar work that had previously been performed in Russia. The equations needed to understand Method of Moments can be difficult. Fortunately, the concept is easy to understand:

Imagine we have a planar circuit, say a filter on a printed circuit board (PCB). In the first step, we discretize (divide into small subsections) only the metal of the circuit. In contrast with volume meshing techniques, we do not mesh the substrate and we do not mesh the air around the substrate. We mesh only the metal of the circuit. Next, we put current (at a given RF frequency) on one subsection of that circuit. We calculate how much voltage that bit of RF current induces on all other subsections. We can view this as one tiny transmitting antenna (the subsection with current) and all the other subsections are tiny receiving antennas. Typically high voltage is induced on nearby subsections, and lower voltage on more distant subsections. The effect of the PCB dielectric material is included in this calculation. (This is the step

where the math can get really complicated. But all that has already been done. You don't have to worry about it!)

This calculation (i.e., current on one subsection induces voltage on all other subsections) is repeated for all subsections in the circuit, one at a time. All this information is stored on the computer in the form of a matrix. Next, the computer puts current on all subsections at the same time. This, as previously calculated, induces voltage in all the subsections in the circuit. Every subsection has voltage induced in it from all the other subsections in the circuit. In fact, each subsection also has voltage induced in it due to itself. All these voltages in all of these subsections add together.

But a perfect conductor (which is our assumption for this description) cannot have any voltage at all across it! (Measure the voltage across any piece of copper. It is really close to short circuit, zero voltage. A perfect conductor would be exactly zero voltage.) So, the computer adjusts all the currents in all the subsections so that there is zero voltage in all the subsections. (In practice, this is actually done by a process called “matrix inversion.”) Of course, the subsection that we are using for the input to the circuit must have some voltage across it. Otherwise, we will have zero current (and zero voltage) everywhere... no fun in that!

The currents in all the subsections that

give us zero voltage everywhere that there is conductor (given an input voltage in the input subsection) is the current distribution in the conductor. That is our solution. Next, we take the now-known current on the input subsection and, given the voltage we assumed on that subsection, we can calculate the input impedance. Repeat this process for each frequency of interest and we have a plot of the input impedance as a function of frequency. We now have all this information without ever having built anything.

This implementation of the method of moments is restricted to planar circuits only. Arbitrary 3D structures, including those illustrated in the previous section, are not appropriate for this approach. The reason planar method of moments has seen widespread use is that it can handle much larger planar circuits at high levels of accuracy, provided the circuits are planar. Appropriate planar circuits can include a large number of layers. PCBs in a computer might contain as many as 28 layers. This is no problem for the method of moments. Sometimes planar problems are referred to as having 2.5 dimensions, rather than full 3D. However, full 3D fields and full 3D current are calculated (conducting vias allow current to flow vertically between layers), so describing this kind of problem as 3D planar is more accurate. Fields and currents are 3D, while the circuit is formed on layered (i.e., planar) dielectric.

RF and microwave designers usually work with S-parameters, or “Scattering-Parameters.” (See the chapter on **RF Techniques** for a discussion of S-parameters.) For example, we could take the input impedance calculated above and convert it to SWR (standing wave ratio) or VSWR (voltage standing wave ratio). We can also mathematically convert either the VSWR or input impedance into a *reflection coefficient*. This gives us the voltage amplitude of the reflected wave given a 1 volt incident wave. When we include the phase of the reflected wave in the calculation, it becomes an S-parameter.

If we are dealing with a 2-port filter (an input port and an output port), we also need to know how much of that the 1 volt wave incident on the input makes it to the output. (2-port circuits are discussed in the RF Techniques chapter.) This is a *transmission coefficient*. Now, let's say, our antenna is not perfectly matched and reflects RF back to the output of our filter. In response, the filter output now generates a reflected wave that goes right back to the antenna. This is called an *output reflection coefficient*. Finally, a portion of that wave that was reflected from the antenna and is hitting the output of our filter finds its way through the filter and actually comes out of the input of the filter. This is called the *reverse transmission coefficient*. So, we have four numbers now to describe our 2-port filter.

These are all scattering parameters and for the benefit of our computer, we put them all in a  $2 \times 2$  matrix.

The Method of Moments has been developed for a wide variety of problems. For example, there are a few ways to implement the Method of Moments that make it amazingly efficient for doing extremely large problems such as a radar signal illuminating an aircraft, or even an entire aircraft carrier. However, this type of implementation tends not to be as useful for, say, circuits on PCBs or other planar circuits where they can suffer reduction in speed and accuracy.

There are two widely used approaches that are preferred for MoM analysis of planar circuits. Both approaches can handle large planar circuits, even when they have multiple layers. One approach performs the required current-induced-voltage calculation assuming the planar circuit is unshielded. The other assumes the circuit is shielded. Both approaches have useful accuracy. The unshielded approach is a natural for unshielded circuits, such as antennas. The shielded approach is a natural for shielded circuits, such as a filter inside a shielding box. However, each approach can flex into the other's domain. The shielded approach benefits from a more accurate induced voltage calculation but it requires an underlying, fine pixel-like grid for meshing. The unshielded approach benefits from allowing arbitrary subsection size, which can be handy provided the required less accurate induced-voltage calculation is not of concern.

**Figure 6.26** shows a typical circuit analyzed using shielded 3D planar method of moments. This is a spiral inductor on silicon, a critical component used in many places in all cell phone RF chip sets. For example, when you make a call, the cell phone computer must move the transmitter and receiver to the channel assigned by the cell site for your call. To do this, it programs a VCO (voltage controlled oscillator) that is inside a PLL (phase locked loop) to move to the required frequency. The VCO has an inductor as part of its tuned circuit. From the view point of silicon chips, inductors are gigantic. They take up a lot of space and space (or "real estate" as the RFIC designers call it) is expensive. The solution is to make the spiral turns even smaller and use more of them. However, that increases the loss. If there is too much loss, the VCO noise goes up and tuning range goes down. In the worst case, loss might be so high that the VCO does not even start oscillating.

A typical wafer fabrication ("wafer fab" for short) in which a circuit is actually etched into semiconductor material such as silicon can easily cost \$1 million. We cannot build and tweak a circuit. It is critical that the VCO, and everything else on that wafer, work the first time. This is where EM analysis saves the day. The engineer does all the trial and

**Figure 6.26** — Method of Moments can be used to analyze planar 3D circuits like this spiral inductor over silicon. Many such inductors are present in the RF chip set for every cell phone. Silicon dioxide insulator (not shown) gives some separation between the bottom of the inductor and the top of the semi-conducting silicon. To reduce inductor losses, a grid-like ground shield is placed directly on the silicon to try to keep the inductor fields out of the silicon. [Courtesy Sonnet, used with permission]

**Figure 6.27** — The spiral inductor, here without the ground shield, induces current in the silicon. This current increases loss and must be minimized. [Courtesy Sonnet, used with permission]

## A Sonnet Tutorial using Port Tuning

Up to this point, we have described how EM software solves what is called the “analysis” problem. In other words, we have a planar RF circuit layout and we need to analyze the RF circuit response. This was a huge advantage when it first became available because without it, we would be forced to build a circuit and then measure it. Of course, it would never work quite the way we wanted it to work. Now what do we do?

Before EM software, we would get out the razor knife and little bits of copper and start tuning the circuit. Maybe this open-circuited stub needs to be a little shorter. But if shorter makes it worse, now we realize we need to make it longer. Get out the soldering iron. High-level designers could dab on some silver epoxy. Those days are gone, thank goodness.

With EM analysis, we just make the open stub (or whatever part of the circuit you think might improve the response) a little shorter or a little longer and then repeat the analysis. This is so much better than the old days!

As you might imagine, we are never satisfied. Each time we repeat the EM analysis, it can be a long wait, especially for the larger and more complicated circuits. We want something faster.

Over the last decade, a much faster methodology has developed called *port tuning*. We can do things with EM analysis that we could never do with a circuit that we actually built. For example, a typical filter has a few resonators in it. These are often just half-wave long lengths of line, just like a dipole antenna, but often with nothing connected. If our filter has its passband a little bit low in frequency, we make the resonator shorter. If the passband is a little too high, we make it longer. It turns out that port tuning lets us do this without having to repeat the entire EM analysis each time.

The following section uses a port-tuning exercise to illustrate this using *Sonnet*. If you would like to follow along, download the free *SonnetLite* at [www.sonnetsoftware.com](http://www.sonnetsoftware.com). The following description is for *Sonnet Version 16*. If you have a later version, the user interface will probably be somewhat different.

After you install the software, go through the *Sonnet* tutorial by selecting HELP->GETTING STARTED from the menus at the top. Concentrate on Chapter 4, “Tutorial: A Quick Tour”. It will take around one hour to do this.

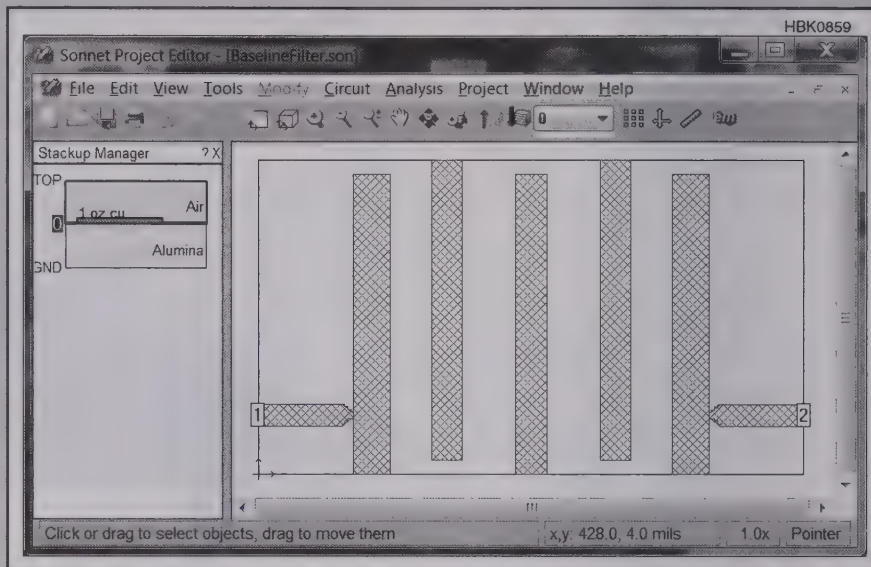

Figure A — The baseline filter that we use to illustrate port tuning is made of quarter wavelength resonators, each grounded at one end to a perfectly conducting sidewall that is present at the edge of the substrate. [Courtesy Sonnet, used with permission]

Figure B — Following instructions in the text, a gap is placed halfway along the length of the first (left) resonator. This is a zoomed detail of the inductor component that was inserted in that gap. The value of the inductance, “Ind”, is a variable parameter that will be tuned. [Courtesy Sonnet, used with permission]

When you are finished, you can start your first port tuning project.

Upon completing Chapter 4 of the tutorial, you will have the layout of **Figure A** on your *Sonnet* screen. The *Sonnet* file for this filter is *BaselineFilter.son* with the downloadable supplemental content. This is an interdigital filter. The resonators are one-quarter wavelength long with one end of each resonator shorted to ground. The antenna equivalent is a quarter-wave-

length vertical antenna, which also has one end shorted to ground.

Select one of the resonators to tune. For this example, we select the first (left) resonator, but any resonator can be tuned with this method. Lengthening a resonator lowers the resonant frequency and shortening a resonator increases the resonant frequency. To tune the length of the resonator you selected, we need to remove a very small portion of the resonator creating

**Figure C** — Results of running a parameter sweep for the value of “Ind” from 0 to 0.08 nH shows that 0.04 nH gives almost the same response as the original (untuned) filter. A value of 0.08 nH gives an improved reflection coefficient (“S11”) and indicates the first resonator should be made 0.002 inch longer (see text for details). [Courtesy Sonnet, used with permission]

a narrow gap. Then we replace the piece we removed with a small, ideal inductor. Repeating an EM analysis for every little change in a layout takes time. But we can change the small inductor and get nearly instantaneous analysis results.

Before proceeding, it is worth your time to read Chapter 7, about Components, of the *Sonnet Version 16* User’s Manual (HELP->MANUALS). We are inserting an “Ideal Component”, an inductor. Here is step-by-step description for *SonnetLite Version 16*:

- 1) Select EDIT->DIVIDE POLYGONS.
- 2) Cut across the width of the desired resonator about half way along the length (the exact position is not critical).
- 3) Select EDIT->DIVIDE POLYGONS again.
- 4) Cut across the width of the resonator again, one cell away from your first cut. A “cell” is the smallest bit of metal allowed for a given analysis. The cell size is indicated by a grid of dots. For this project, the cell size was set to 0.002 inches square.
- 5) Select the one cell long piece of resonator and press DELETE. This leaves a narrow gap across the width of the resonator.
- 6) Select MODIFY->ADD COMPONENT->IDEAL. We are going to add a small

inductor across the narrow gap we just cut. In the window that appears, select Inductor, and set the Terminal Width to Feedline Width. For the value of the inductor, we will use a Sonnet variable. Type in “Ind” for the name of the inductor value variable. “Ind” is variable that we will sweep, i.e., *Sonnet* will automatically change the value of the variable and repeat the analysis. Next, click OK, and you are asked for more information about the variable. Nothing more is needed, so just click OK.

7) When the information windows you were just using disappear, click in the center of one side of the gap and click a second time in the center of the other side of the gap. This places the inductor across the gap.

Your layout, zoomed to the region around the gap, should be similar to **Figure B** (*Port Tuning Example.son* with the downloadable supplemental content). As you have likely guessed, we are going to use the inductor that we added to this layout to replace the metal that we took out to make the gap in the resonator. If it turns out a little more inductance gives us a more desirable filter, then we make the resonator a little longer. A little less inductance means we should make the resonator a little shorter. Here, even negative inductors are allowed.

First, we must find out how much inductance corresponds to how much change in resonator length by using a parameter sweep. To do a parameter sweep, read Chapters 9 and 10 of the *Sonnet Version 16* User’s Manual.

**Figure B** shows the results of the parameter sweep, sweeping the value of the port tuning inductor from 0.0 to 0.08 nH with a step of 0.01 nH. Also plotted is the original filter, the one that we started with before adding the tuning ports. The original filter reflection coefficient is highlighted. Reflection (S11) is about -10 dB. It turns out that the curve for Ind = 0.04 nH gives a very close match to the original filter. Thus we conclude that the 0.002 inch gap in the resonator is equal to about 0.04 nH.

Next notice that the curve for Ind = 0.08 nH gives a reflection that is 5 dB better, or -15 dB. This tells us that we can improve the filter return loss by 5 dB if we make the input resonator another 0.002 inch (i.e., another 0.04 nH) longer.

If we take the original filter and increase the length of that resonator by 0.002 inch, a confirming EM analysis, *FinalFilter.son* with the downloadable supplemental content, gives us almost exactly the same response as the port tuning filter with Ind = 0.08 nH. That is the filter we will build.

There are some other practical considerations when port tuning real filters. For example, in this filter the distance from the open end of the resonator to the sidewall is 0.010 inch. Making that resonator longer by 0.002 inch reduces that distance. That increases the open end capacitance, which lowers the resonant frequency a small amount. This would become critical if the resonator must be lengthened by, say, 0.008 inch. The gap to the wall would only be 0.002 inch. Lengthening the resonator by even more would require that we move the wall.

Also, in practice, we would lengthen the resonators symmetrically. In other words, if we lengthen the input resonator, we would lengthen the output resonator by the same amount. This can be done by adding an identical inductor in an identical gap in the output resonator. The inductance of the first inductor is a variable name (“Ind”) so we can just use that same variable name for the output resonator tuning inductor. Then, both resonators are automatically equal.

error on the computer, and then builds the circuit once.

Silicon is a lossy conductor — a semiconductor. Any RF designer knows that when we put an inductor close to a lossy conductor, the inductor loss increases. To reduce the loss, we try to get the inductor as far as possible from the silicon. A given process might have a few microns of silicon dioxide, or other insulators, deposited on top of the silicon. So, the designer puts the inductor on top of all available silicon dioxide. In Figure 6.26, these insulating layers are not shown, so it looks like the inductor is floating in air.

Another trick to reduce loss is to add a ground shield. This is the grid-like conductor pattern under the inductor. It is important that the ground shield conductors are, more or less, at right angles to the spiral inductor turns above them. If the ground shield conductors are parallel, they start to act like a shorted turn in the secondary winding of a transformer, not good!

Figure 6.27 shows the current in the surface of the silicon directly under the spiral inductor when there is no ground shield. Red (or bright) is high current. At first it is a surprise that the direction of the current (not shown) is radial, flowing toward or away from the inductor. This means the current is driven by the electric field around the inductor, not by the magnetic field. The designer wants this current to be as low as possible in order to reduce loss.

Figure 6.28 shows the substrate current in the silicon under a small portion of the inductor with a ground shield. This was analyzed

Figure 6.28 — A small section of the current in the silicon under the inductor with ground shield in place shows a strongly modified current in the silicon. Whether or not inductor loss is actually decreased, or increased, strongly

using *Sonnet*, a shielded 3D planar EM tool. As mentioned above, the induced voltage calculation is very accurate for shielded tools, but a fine, underlying rectangular mesh is required. If you look closely at this zoomed image, you can see the “pixelation” caused by the fine mesh.

Normally, we view only the current in the conductors of our circuit with planar EM tools. A description of how to view tangential electric fields using something called “sense metal” in planar method of moments is given in Chapter 4 of *Sonnet Version 16* user’s manual ([www.sonnetsoftware.com](http://www.sonnetsoftware.com)). By Ohm’s law, the tangential electric field on the surface of the silicon substrate is proportional the current flowing in the silicon.

Professionals often use an EM analyzer, such as *Sonnet*, in conjunction with a so-called “framework.” A microwave design framework includes many different interconnected microwave-related software tools including, for example, circuit theory analysis. For port-tuning, a designer using both the Keysight Technologies *ADS* framework and *Sonnet* can use any *ADS* component as a tuning element in *Sonnet*. In this case, using a transmission line model (instead of a small inductor) makes life especially easy as the designer can simply read off the required resonator change of length right from the optimized transmission line element. Figuring out how much inductance corresponds to how much resonator length is not needed. This can even be done in *Sonnet* by using a “Project” component for tuning and making a *Sonnet* netlist project with the tuning transmission line in the project.

Finally, designers also often need to tune the length of every resonator, not just one or two of them. In addition, they also need to tune the coupling between resonators (adjust the gap between resonators). Figure 6.29 shows an example of a filter tuned in this way. All of this can be done with port tuning, but it exceeds the capability of *SonnetLite*. For those with access to a full copy of *Sonnet* and a full microwave framework (Keysight Technologies *ADS*, National Instruments’ *Microwave Office*, or Cadence *Virtuoso*), detailed tutorials can be found at [www.sonnetsoftware.com](http://www.sonnetsoftware.com).

## COMMERCIAL ELECTROMAGNETIC ANALYSIS TOOLS

Below we describe most of the current RF and microwave EM software vendors that concentrate on the microwave market. These vendors have all exhibited at IMS, the International Microwave Symposium which is the premier microwave conference in the world. (See [www.ims2018.org](http://www.ims2018.org), for example, and search for “General Exhibition Content” to see all of the EM software vendors. Our apologies to any vendors that we missed.)

All product names are trademarks of the associated vendors.

**Ansoft** (a division of Ansys): Widely used finite element code specialized for microwave work, *HFSS* (High Frequency Structure Simulator). Ansoft provides a variety of other EM tools, including planar unshielded method of moments. All tools are integrated into a comprehensive microwave design framework with a wide variety of circuit theory and systems simulation tools. [www.ansys.com](http://www.ansys.com)

**AWR** (a division of National Instruments): Their tool, *Axiem*, uses unshielded planar method of moments integrated into a comprehensive widely used microwave design framework (*Microwave Office*) incorporating a wide variety of circuit theory and systems simulation tools. [www.awrcorp.com](http://www.awrcorp.com)

**CST** (a division of Dassault Systèmes): A wide range of nearly every kind of EM solver available today. Their primary tool is based on a technique closely related to FDTD providing time-domain full 3D volume meshing EM analysis. Their wide range of tools are organized into various suites. For example, *CST Microwave Studio* includes transient, frequency domain, eigenmode, resonant, integral equation, asymptotic, and TLM solvers. [www.cst.com](http://www.cst.com)

**EM Software and Systems** (a division of Altair): Primary product is *FEKO*, based on a fast implementation of method of moments intended for very large problems. It is hybridized with several other EM techniques including finite elements, physical optics, geometric optics, and uniform theory of diffraction. Suitable for EMC, cable harnesses, antenna placement, bio-medical, microwave circuits, and other applications. [www.feko.info](http://www.feko.info)

**IMST**: Their main software product, *Empire XPU*, provides time domain 3D volume meshing FDTD analysis of microwave structures. They also offer a tool, *MultiLib*, that provides models for planar multi-layer microwave circuits that can be used directly in the Keysight Technologies microwave design framework *ADS*. [www.imst.com](http://www.imst.com)

**Integrand Software**: Used widely for Si RFIC design, *EMX* is a 3D unshielded method of moments analysis that is tailored specifically for RF design work on silicon, including a high degree of automation. It is fully integrated into Cadence *Virtuoso*, a widely used Si RFIC design framework. [www.integrandsoftware.com](http://www.integrandsoftware.com)

**Keysight Technologies**: Two main EM tools, unshielded 3D planar method of moments EM analysis *Momentum*, and 3D volume meshing finite elements *EMPro*. Formerly Agilent Technologies Electronic Measurement Group, they offer the largest and most widely used range of integrated microwave tools including their microwave design framework, *ADS* (*Advanced Design System*). [www.keysight.com/find/eesof](http://www.keysight.com/find/eesof)

Figure 6.29 — For professional use, port tuning can be used to tune all resonator lengths and couplings between resonators in order to obtain the desired response. This illustrates a filter tuned using Keysight ADS and Sonnet EM analysis. The lower right detail illustrates a circuit theory coupled line used to fine tune the coupling between two resonators. [Courtesy Sonnet, used with permission]

**Mician:** Mode matching tool *μWave Wizard*, uses the fact that every finite volume structure has a finite set of characteristic modes, sometimes also called resonances. Any structure that can be decomposed into a set of simpler building blocks that have known modes solved for by any of the many different EM tools included can be analyzed by adding all modes together weighted so that all fields match at the boundaries between the blocks. Very fast and accurate analysis of waveguide filters, for example, is possible. A free version is available. [www.mician.com](http://www.mician.com)

**Microwave Innovation Group:** Mode matching tool *WASP-NET*, uses the fact that every finite volume structure has a finite set of characteristic modes, sometimes also called resonances. Any structure which can

be de-composed into a set of simpler building blocks that have known modes solved for by any of the many different EM tools included can be analyzed by adding all modes together weighted so that all fields match at the boundaries between the blocks. Very fast and accurate analysis of waveguide filters, for example, is possible. [www.wasp-net.com](http://www.wasp-net.com)

**Remcom:** Provider of *XFtd*, a full wave 3D EM solver for antenna design and placement, mobile device design, biomedical, microwave, automotive radar, and so on. Other products include *Wireless InSite*, site-specific radio propagation software for analysis of wireless communication systems, and *XGtd*, a ray-based EM analysis tool for antenna placement on large structures such as ships and

aircraft. [www.remcom.com](http://www.remcom.com)

**Sonnet Software:** Main tool, *Sonnet Suites*, integrates a shielded 3D planar method of moments EM analysis with plotting, modeling, and other tools. Sonnet also integrates well with Keysight Technologies *ADS*, AWR *Microwave Office*, and Cadence *Virtuoso* microwave design frameworks. A free version is available. [www.sonnetsoftware.com](http://www.sonnetsoftware.com)

**WIPL-D:** A range of products all based on unshielded method of moments. Emphasis is on fast solution of very large problems. Primary applications include large antennas, including dish antennas, antenna placement, EM compatibility analysis (EMC), and microwave circuits. A free version is available. [www.wipl-d.com](http://www.wipl-d.com)

# Power Sources

Our transceivers, amplifiers, accessories, computers and test equipment all require power to operate. This chapter illustrates the various techniques, components and systems used to provide power at the voltage and current levels our equipment needs. Topics range from basic transformers, rectifiers and filters to linear voltage regulation, switch-mode power conversion, high voltage techniques and batteries. Material on switchmode conversion was contributed by Rudy Severns, N6LF and Chuck Mullett, KR6R. The section on batteries was contributed by Isidor Buchmann from his book *Batteries in a Portable World*. Alan Applegate, KØBG contributed the section on selecting batteries for mobile use.

The title of this chapter reflects the broad assortment of methods for powering amateur equipment. More mobile and portable operation relies on power from batteries, for example. Hybrids of ac and dc power sources are becoming more common, blurring what has traditionally been known as a “power supply.” (Generators are covered in the Portable Installations section of the chapter on *Assembling a Station*.)

## 7.1 Power Processing

Figure 7.1 illustrates the concept of a power processing unit inserted between the energy source and the electronic equipment or load. The *power processor* is often referred to as the *power supply*. That’s a bit misleading in that the energy “supply” actually comes from some external source (battery, utility power and so forth), which is then converted to useful forms by the power processor. Be that as it may, in practice the terms “power supply” and “power processor” are used interchangeably.

The real world is even more arbitrary. Power processors are frequently referred to as *power converters* or simply as *converters*, and we will see other terms used later in this chapter. It is usually obvious from the context of the discussion what is meant and the glossary at the end of this chapter gives some additional information.

Power conversion schemes can take the form of: ac-to-ac (usually written

Figure 7.1 — Basic concept of power processing.

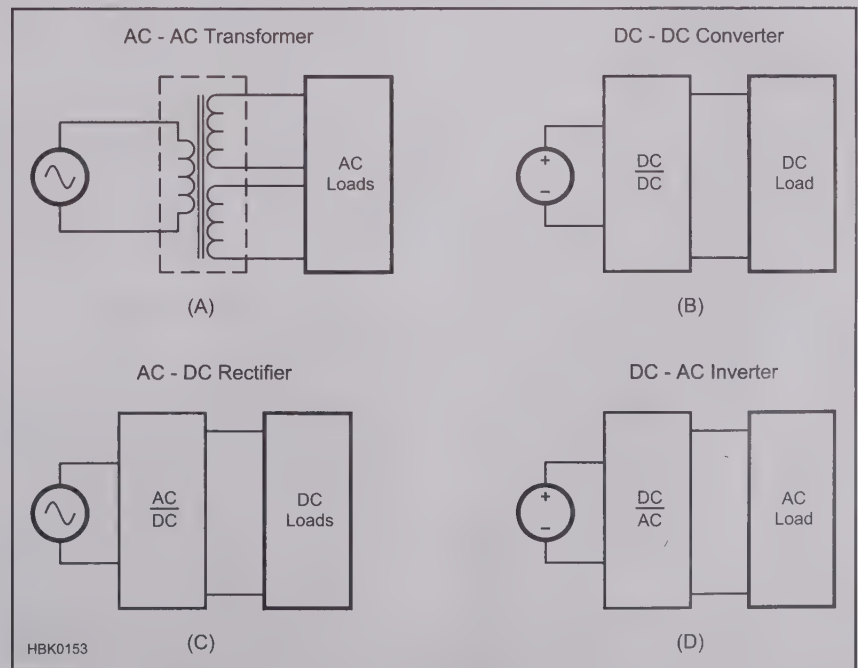

Figure 7.2 — Four power processing schemes: ac-ac, dc-dc, ac-dc and dc-ac.

ac-ac), ac-dc, dc-ac and dc-dc. Examples of these schemes are given in **Figure 7.2**. Specific names may be given to each scheme: ac-dc => rectifier, dc-dc => converter and dc-ac => inverter. These are the generally recognized terms but you will see exceptions.

Power conversion normally includes

voltage and current regulation functions. For example, the voltage of a vehicle battery may vary from more than 14 V when being charged down to 10 V or less when discharged. A converter and regulator are required to maintain adequate voltage to mobile

equipment at both over- and under-voltage conditions. Commercial utility power may vary from 90 to 270 V ac depending on where you are in the world. AC power converters are frequently required to handle that entire voltage range while still providing tightly regulated dc power.

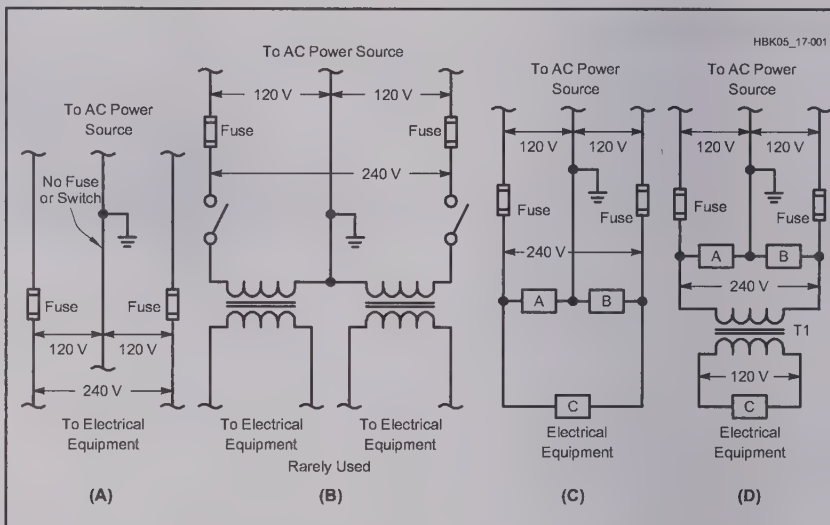

## 7.2 AC-AC Power Conversion

In most US residences, three wires are brought in from the outside electrical-service mains to the house distribution panel. In this three-wire system, one wire is neutral and should be connected to a ground electrode. (See the **Safety** chapter for information on electrical safety.) The neutral connection to a ground rod or electrode is usually made at the distribution panel. The voltage between the other two wires is 60-Hz ac with a potential difference of approximately 240 V RMS. Half of this voltage appears between each of these wires and the neutral, as indicated in **Figure 7.3A**. In systems of this type, the 120 V household loads are divided at the breaker panel as evenly as possible between the two sides of the power mains. Heavy appliances such as electric stoves, water heaters, central air conditioners and so forth, are designed for 240 V operation and are connected across the two ungrounded wires.

Both hot wires for 240 V circuits and the single hot wire for 120 V circuits should be protected by either a fuse or breaker. A fuse or breaker or any kind of switch should *never* be used in the neutral wire. Opening the neutral wire does not disconnect the equipment from an active or “hot” line, possibly creating a potential shock hazard between that line and earth ground.

Another word of caution should be given at this point. Since one side of the ac line is grounded (through the green or bare wire — the standard household wiring color code) to earth, all communications equipment should be reliably connected to the ac-line ground through a heavy ground conductor made of strap, heavy flat-weave braid or #14 AWG or heavier wire. This safety conductor must be separate from the power wiring neutral conductor. (A properly-wired 120 V outlet with a ground terminal uses one wire for the ac hot connection, one wire for the ac neutral connection and a third wire for the safety ground connection.) This provides a measure of safety for the operator in the event of accidental short or leakage of one side of the ac line to the chassis.

Remember that the antenna system is frequently bypassed to the chassis via an RF choke or tuned circuit, which could make the antenna electrically “live” with respect

**Figure 7.3 — Three-wire power-line circuits. At A, normal three-wire-line termination. No fuse should be used in the grounded (neutral) line. The ground symbol is the power company’s ground, not yours! Do not connect anything other than power return wiring, including the equipment chassis, to the power neutral wire. At B, the “hot” lines each have a switch, but a switch in the neutral line would not remove voltage from either side of the line and should never be used. At C, connections for both 120 and 240 V transformers. At D, operating a 120 V plate transformer from the 240 V line to avoid light blinking. T1 is a 2:1 step-down transformer.**

to the earth ground and create a potentially lethal shock hazard. A *ground fault circuit interrupter* (GFCI or GFI) is also desirable for safety reasons, and should be a part of the shack’s electrical power wiring. (See the reference item for Silver for more information on grounding and bonding.)

### 7.2.1 Fuses and Circuit Breakers

All transformer primary circuits should be fused properly and multiple secondary outputs should also be individually fused. To determine the approximate current rating of the fuse or circuit breaker on the line side of a power supply it is necessary to determine the total load power. This can be done by multiplying each current (in amperes) being drawn by the load or appliance, by the voltage at which the current is being drawn. In the case of linear regulated power supplies, this voltage has to be the voltage appearing at the output of the rectifiers before being applied to the regulator

stage. Include the current drawn by bleeder resistors and voltage dividers. Also include filament power if the transformer is supplying vacuum tube filaments. The National Electrical Code (NEC) also specifies maximum fuse ratings based on the wire sizes used in the transformer and connections.

After multiplying the various voltages and currents, add the individual products. This is the total power drawn from the line by the supply. Then divide this power by the line voltage and add 10 to 30% to account for the inefficiency of the power supply itself. Use a fuse or circuit breaker with the nearest larger current rating. Remember that the charging of filter capacitors can create large surges of current when the supply is turned on. If fuse blowing or breaker tripping at turn on is a problem, use slow-blow fuses, which allow for high initial surge currents.

For low-power semiconductor circuits, use fast-blow fuses. As the name implies, such fuses open very quickly once the current exceeds the fuse rating by more than 10%.

# 7.3 Power Transformers

Numerous factors are considered to match a transformer to its intended use. Some of these parameters are:

1. Output voltage and current (volt-ampere rating).
2. Power source voltage and frequency.
3. Ambient temperature.
4. Duty cycle and temperature rise of the transformer at rated load.
5. Mechanical considerations like weight, shape and mounting.

## 7.3.1 Volt-Ampere Rating

In alternating-current equipment, the term *volt-ampere* (VA) is often used rather than the term watt. This is because ac components must handle reactive power as well as real power. If this is confusing, consider a capacitor connected directly across the secondary of a transformer. The capacitor appears as a reactance that permits current to flow, just as if the load were a resistor. The current is at a 90° phase angle, however. If we assume a perfect capacitor, there will be no heating of the capacitor, so no real power (watts) will be delivered by the transformer. The transformer must still be capable of supplying the voltage, and be able to handle the current required by the reactive load. The current in the transformer windings will heat the windings as a result of the  $I^2R$  losses in the winding resistances. The product of the voltage and current in the winding is referred to as “volt-amperes,” since “watts” is reserved for the real, or dissipated, power in the load. The volt-ampere rating will always be equal to, or greater than, the power actually being drawn by the load.

The number of volt-amperes delivered by a transformer depends not only upon the dc load requirements, but also upon the type of dc output filter used (capacitor or choke input), and the type of rectifier used (full-wave center tap or full-wave bridge). With a capacitive-input filter, the heating effect in the secondary is higher because of the high peak-to-average current ratio. The volt-amperes handled by the transformer may be several times the power delivered to the load. The primary winding volt-amperes will be somewhat higher because of transformer losses. This point is treated in more detail in the section on ac-dc conversion. (See the **Electrical Fundamentals** chapter for more information on transformers and reactive power.)

## 7.3.2 Source Voltage and Frequency

A transformer operates by producing a magnetic field in its core and windings. The intensity of this field varies directly with the instantaneous voltage applied to the

transformer primary winding. These variations, coupled to the secondary windings, produce the desired output voltage. Since the transformer appears to the source as an inductance in parallel with the (equivalent) load, the primary will appear as a short circuit if dc is applied to it. The unloaded inductance of the primary (also known as the *magnetizing inductance*) must be high enough so as not to draw an excess amount of input current at the design line frequency (normally 60 Hz in the US). This is achieved by providing a combination of sufficient turns on the primary and enough magnetic core material so that the core does not saturate during each half-cycle.

The voltage across a winding is directly related to the time rate of change of magnetic flux in the core. This relationship is expressed mathematically by  $V = N d\Phi/dt$  as described in the section on Inductance in the **Electrical Fundamentals** chapter. The total flux in turn is expressed by  $\Phi = A_e B$ , where  $A_e$  is the cross-sectional area of the core and B is the flux density.

The maximum value for *flux density* (the magnetic field strength produced in the core) is limited to some percentage (< 80% for example) of the maximum flux density that the core material can stand without saturating, since in saturation the core becomes ineffective and causes the inductance of the primary to plummet to a very low level and input current to rise rapidly. Saturation causes high primary currents and extreme heating in the primary windings.

At a given voltage, 50 Hz ac creates more flux in an inductor or transformer core because the longer time period per half-cycle results in more flux and higher magnetizing current than the same transformer when excited by same 60-Hz voltage. For this reason, transformers and other electromagnetic equipment designed for 60-Hz systems must not be used on 50-Hz power systems unless specifically designed to handle the lower line frequency.

## 7.3.3 How to Evaluate an Unmarked Power Transformer

Hams who regularly visit hamfests frequently develop a junk box filled with used and unmarked transformers. Over time, transformer labels or markings on the coil wrappings may come off or be obscured. There is a good possibility that the transformer is still useable, but the problem is to determine what voltages and currents the transformer can supply. First consider the possibility that you may have an audio transformer or other impedance-matching device rather than a power transformer. If you aren't sure, don't connect it to ac power!

If the transformer has color-coded leads, you are in luck. There is a standard for transformer lead color-coding, as is given in the **Component Data and References** chapter. Where two colors are listed, the first one is the main color of the insulation; the second is the color of the stripe.

Figure 7.4 — Use a test fixture like this to test unknown transformers. Don't omit the isolation transformer, and be sure to insulate all connections before you plug into the ac mains.

Check the transformer windings with an ohmmeter to determine that there are no shorted (or open) windings. In particular, check for continuity between any winding and the core. If you find that a winding has been shorted to the core, do not use the transformer! The primary winding usually has a resistance higher than a filament winding and lower than a high-voltage winding.

**Figure 7.4** shows that a convenient way to test the transformer is to rig a pair of test leads to an electrical plug with a 25 W household light bulb in series to limit current to safe (for the transformer) levels. For safety reasons use an isolation transformer and be sure to insulate all connections before you plug into the ac mains. Switch off the power while making or changing any connections. You can be electrocuted if the voltmeter leads or meter insulation are not rated for the transformer output voltage! If in doubt, connect the meter with the circuit turned off, then apply power while you are not in contact with the circuit. *Be careful! You are dealing with hazardous voltages!*

Connect the test leads to each winding separately. The filament/heater windings will cause the bulb to light to full brilliance because a filament winding has a very low

impedance and almost all the input voltage will be across the series bulb. The high-voltage winding will cause the bulb to be extremely dim or to show no light at all because it will have a very high impedance, and the primary winding will probably cause a small glow. The bulb glows even with the secondary windings open-circuited because of the small magnetizing current in the transformer primary.

When the isolation transformer output is connected to what you think is the primary winding, measure the voltages at the low-voltage windings with an ac voltmeter. If you find voltages close to 6 V ac or 5 V ac, you know that you have identified the primary and the filament windings. Label the primary and low voltage windings.

Even with the light bulb, a transformer can be damaged by connecting ac mains power to a low-voltage or filament winding. In such a case the insulation could break down in a primary or high-voltage winding because of the high turns ratio stepping up the voltage well beyond the transformer ratings.

Connect the voltmeter to the high-voltage windings. Remember that transformers from vacuum tube equipment may supply as much as 800 V<sub>pk</sub> or so across the winding, so make sure that your meter can withstand these

potentials without damage and that you use the voltmeter safely.

Divide 6.3 (or 5) by the voltage you measured across the 6.3 V (or 5 V) winding in the test setup. This gives a multiplier that you can use to determine the actual no-load voltage rating of the high-voltage secondary. Simply multiply the ac voltage measured across the high-voltage winding by the multiplier.

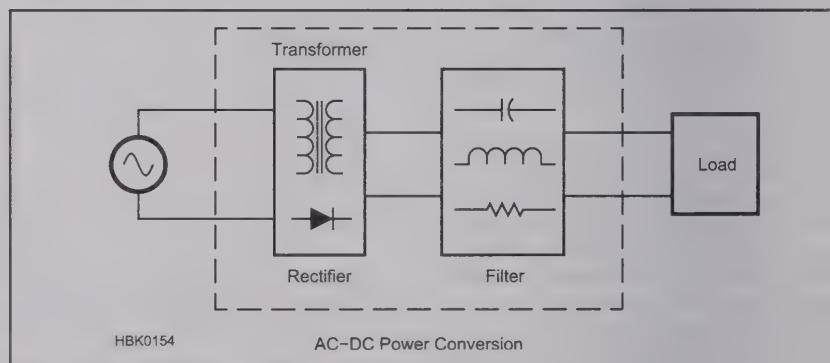

You may find that with vintage equipment the power transformers were designed for an ac line voltage of 110 V ac. The higher secondary voltages from today's 120 V ac line can damage older equipment, particularly the tube filaments. Primary voltage can be reduced without a variable input transformer as described in the Repair and Restoration of Vintage Equipment section of the book's **Troubleshooting and Maintenance** chapter.

The current rating of the windings can be determined by loading each winding with the primary connected directly (no bulb) to the line. Using power resistors, increase load on each winding until its voltage drops about 10% from the no-load figure. The current drawn by the resistors is the approximate winding load-current rating.

## 7.4 AC-DC Power Conversion

One of the most common power supply functions is the conversion of ac power to dc, or *rectification*. The output from the rectifier will be a combination of dc, which is the desired component, and ac *ripple* superimposed on the dc. This is an undesired but inescapable component. Since most loads cannot tolerate more than a small amount of ripple on the dc voltage, some form of filter is required. The result is that ac-dc power conversion is performed with a rectifier-filter combination as shown in **Figure 7.5**.

As we will see in the rectifier circuit examples given in the next sections, sometimes the rectifier and filter functions will be separated into two distinct parts but very often the two will be integrated. This is particularly true for voltage and current multipliers as described in the sections on multipliers later in the chapter. Even when it appears that the rectifier and filter are separate elements, there will still be a strong interaction where the design and behavior of each part depends heavily on the other. For example the current waveforms in the rectifiers and the input source are functions of the load and filter characteristics. In turn the voltage waveform applied to the filter depends on the rectifier circuit and the input source voltages. To simplify the discussion we will treat the rectifier connections and the

**Figure 7.5 — Ac-dc power conversion with a rectifier and a filter.**

filters separately but always keeping in mind their interdependence.

The following rectifier-filter examples assume a conventional 60 Hz ac sine wave source, but these circuits are frequently used in switching converters at much higher frequencies and with square wave or quasi-square wave voltage and current waveforms. The component values may be different but the basic behavior will be very similar.

There are many different rectifier circuits or “connections” that may be used depending on the application. The following discussion

provides an overview of some of the most common ones. The circuit diagrams use the symbol for a semiconductor diode, but the same circuits can be used with the older type of rectifiers that may be encountered in older equipment.

For each circuit we will show the voltage and current waveforms in the circuit for resistive, capacitive and inductive loads. The inductive and capacitive loads represent commonly used filters. We will be interested in the peak and average voltages as well as the RMS currents.

## 7.4.1 Half-Wave Rectifier

Figure 7.6 shows several examples of the half-wave rectifier circuit. It begins with a simple transformer with a resistive load (Figure 7.6A) and goes on to show how the output voltage and transformer current varies when a diode and filter elements are added.

Without the diode (Figure 7.6A) the output voltage ( $V_R$ ) and current are just sine waves, and the RMS current in the transformer windings will be the same as the load (R) current.

Next, add a rectifier diode in series with the load (Figure 7.6B). During one half of

the ac cycle, the rectifier conducts and there is current through the rectifier to the load. During the other half cycle, the rectifier is reverse-biased and there is no current (indicated by the broken line in Figure 7.6B) in R. The output voltage is pulsating dc, which is a combination of two components: an average dc value of  $0.45 E_{RMS}$  (the voltage read by a dc voltmeter) and line-frequency ac ripple. The transformer secondary winding current is also pulsating dc. The power delivered to R is now  $\frac{1}{2}$  that for Figure 7.6A but the secondary RMS winding current in Figure 7.6B is still 0.707 times what it was in Figure 7.6A.

For the same winding resistance, the winding loss, in proportion to the output power, is twice what it was in Figure 7.6A. This is an intrinsic limitation of the half-wave rectifier circuit — the RMS winding current is larger in proportion to the load power. In addition, the dc component of the secondary winding current may bias the transformer core toward saturation and increased core loss.

A filter can be used to smooth out these variations and provide a higher average dc voltage from the circuit. Because the frequency of the pulses (the ripple frequency) is low (one pulse per cycle), considerable filtering is required to provide adequately smooth dc output. For this reason the circuit is usually limited to applications where the required current is small. Parts C, D and E in Figure 7.6 show some possible capacitive and inductive filters.

As shown in Figure 7.6C and D, when a capacitor is used for filtering the output dc voltage will approach

$$V_{pk} = \sqrt{2} \times E_{RMS} = 1.4 \times E_{RMS} \quad (1)$$

and the larger we make the filter capacitance, the smaller the ripple will be.

Unfortunately, as we make the filter capacitance larger, the diode, capacitor and transformer winding currents all become high-amplitude narrow pulses which will have a very high RMS value in proportion to the power level. These current pulses are also transmitted to the input line and inject currents at harmonics of the line frequency into the power source, which may result in interference to other equipment. Narrow high-amplitude current pulses are characteristic of capacitive-input filters in all rectifier connections when driven from voltage sources.

As shown in Figure 7.6E, it is possible to use an inductive filter instead, but a second diode (D2, sometimes called a *free-wheeling diode*) should be used. Without D2 the output voltage will get smaller as we increase the size of L to get better filtering, and the output voltage will vary greatly with load. By adding D2 we are free to make L large for small output ripple but still have reasonable voltage regulation. Currents in D1 and the winding will be approximately square waves, as indicated. This will reduce the line harmonic currents injected into the source but there will still be some.

Peak inverse voltage (PIV) is the maximum voltage the rectifier must withstand when it isn't conducting. This varies with the load and rectifier connection. In the half-wave rectifier, with a resistive load the PIV is the peak ac voltage ( $1.4 \times E_{RMS}$ ). With a capacitor-input filter (Figure 7.6C and 7.6D), the capacitor is assumed to stay charged between the charging half-cycles. This means the rectifier output

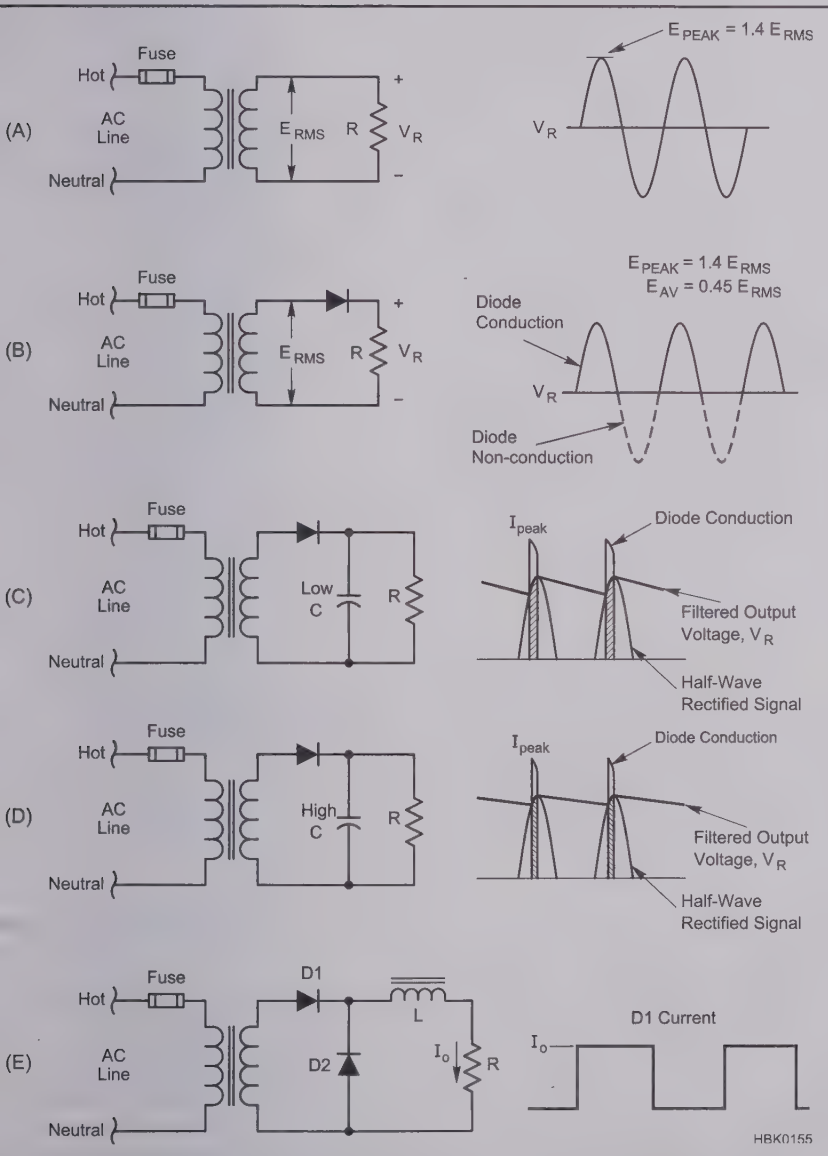

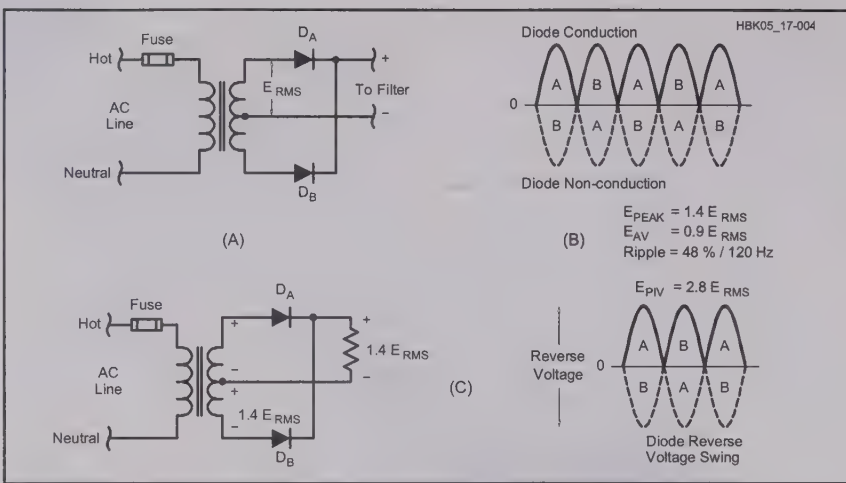

Figure 7.6 — Half-wave rectifier circuits. A illustrates the voltage waveform at the output without a rectifier. B represents the basic half-wave rectifier and the output waveform. C and D illustrate the impact of small and large filter capacitors on the output voltage and input current waveforms. E shows the effect of using an inductor filter with the half-wave rectifier. Note the addition of the shunt diode (D2) when using inductive filters with this rectifier connection.

**Figure 7.7 — Full-wave center-tap rectifier circuits. A illustrates the basic circuit. Diode conduction is shown at B with diodes A and B alternately conducting. The peak inverse voltage for each diode is  $2.8 E_{RMS}$  as depicted at C.**

stays near  $1.4 \times E_{RMS}$  while its input reaches the full opposing peak voltage. Thus, the rectifier experiences a PIV of  $2 (1.4 \times E_{RMS}) = 2.8 \times E_{RMS}$ .

### 7.4.2 Full-Wave Center-Tapped Rectifier

The full-wave center-tapped rectifier circuit is shown in Figure 7.7. The operation of this circuit can be imagined as the secondary of the transformer producing two waveforms (A and B) that are  $180^\circ$  out of phase that are each connected to a half-wave rectifier. The half-wave rectifier outputs are then combined so that both halves of the ac cycle are used to deliver power to the output. A transformer with a center-tapped secondary is required.

The average output voltage of this circuit is  $0.9 \times E_{RMS}$  of half the transformer secondary (the center-tap to one side); this is the maximum that can be obtained with a suitable choke-input filter. The peak output voltage is  $1.4 \times E_{RMS}$  of half the transformer secondary; this is the maximum voltage that can be obtained from a capacitor-input filter.

As can be seen in Figure 7.7C, the PIV impressed on each diode is independent of the type of load at the output. This is because the peak inverse voltage condition occurs when diode  $D_A$  conducts and diode  $D_B$  is not conducting. The positive and negative voltage peaks occur at precisely the same time, a condition different from that in the half-wave circuit. As the cathodes of diodes  $D_A$  and  $D_B$  reach a positive peak ( $1.4 E_{RMS}$ ), the anode of diode  $D_B$  is at a negative peak, also  $1.4 E_{RMS}$ , but in the opposite direction. The total peak inverse voltage is therefore  $2.8 E_{RMS}$ . If a capacitor-input filter is used, the capacitor stays charged to nearly  $1.4 \times E_{RMS}$  during each diode's non-conducting

half cycles and so the PIV is  $2.8 \times E_{RMS}$ .

Figure 7.7C shows that the ripple frequency is twice that of the half-wave rectifier (two times the line frequency). Substantially less filtering is required because of the higher ripple frequency. Since the rectifiers work alternately, each handles half of the load current. The current rating of each rectifier need be only half the total current drawn from the supply.

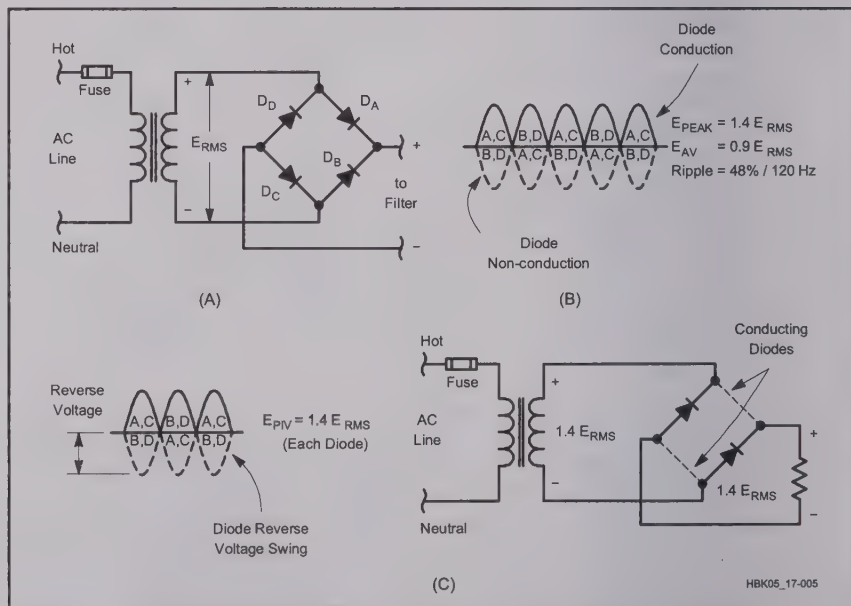

The problem with dc bias in the transformer core associated with the half-wave connection is largely eliminated with this circuit and the RMS current in the primary winding will also be reduced.

### 7.4.3 Full-Wave Bridge Rectifier

Another commonly used rectifier circuit that does not require a center-tapped transformer is illustrated in Figure 7.8. In this arrangement, two rectifiers operate in series on each half of the cycle, one rectifier being in the lead supplying current to the load, the other being the current return lead. As shown in Figures 7.8A and B, when the top lead of the transformer secondary is positive with respect to the bottom lead, diodes  $D_A$  and  $D_C$  will conduct while diodes  $D_B$  and  $D_D$  are reverse-biased. On the next half cycle, when the top lead of the transformer is negative with respect to the bottom, diodes  $D_B$  and  $D_D$  will conduct while diodes  $D_A$  and  $D_C$  are reverse-biased.

The output voltage wave shape and ripple frequency are the same as for the full-wave center-tapped circuit. The average dc output voltage into a resistive load or choke-input filter is  $0.9$  times  $E_{RMS}$  delivered by the transformer secondary; with a capacitor filter and a light load, the maximum output voltage is  $1.4$  times the secondary  $E_{RMS}$  voltage.

Figure 7.8C shows the PIV to be  $1.4 E_{RMS}$  for each diode which is half that of the full-wave center-tapped circuit for the same output voltage. When an alternate pair of diodes (such as  $D_A$  and  $D_C$ ) is conducting, the other diodes are essentially connected in parallel (the conducting diodes are essentially short circuits) in a reverse-biased direction. This limits the diode PIV to  $1.4 \times E_{RMS}$  even if a capacitor-input filter is used. Each pair of

**Figure 7.8 — Full-wave bridge rectifier circuits. The basic circuit is illustrated at A. Diode conduction and nonconduction times are shown at B. Diodes A and C conduct on one half of the input cycle, while diodes B and D conduct on the other. C displays the peak inverse voltage for one half cycle. Since this circuit reverse-biases two diodes essentially in parallel,  $1.4 E_{RMS}$  is applied across each diode.**

diodes conducts on alternate half cycles, with the full load current through each diode during its conducting half cycle. Since each diode is not conducting during the other half cycle the average diode current is one-half the total load current drawn from the supply.

Compared to the half-wave and full-wave center-tapped circuit, the full-wave bridge circuit further reduces the transformer RMS winding currents. In the case of a resistive load the winding currents are the same as when the resistive load is connected directly across the secondary. The RMS winding currents will still be higher when inductive and especially capacitive filters are used because of the pulsating nature of the diode and winding currents.

## 7.4.4 Comparison of Rectifier Circuits

Comparing the full-wave center-tapped and the full-wave bridge circuits, we can see that the center-tapped circuit has half the number of rectifiers as the bridge but these rectifiers have twice the PIV rating requirement of the bridge diodes. The diode current ratings are identical for the two circuits. The bridge makes better use of the transformer's secondary than the center-tapped rectifier, since the transformer's full winding supplies power during both half cycles, while each half of the center-tapped circuit's secondary provides power only during its positive half-cycle.

The full-wave center-tapped rectifier is typically used in high-current, low-voltage applications because only one diode conducts

at a time. This reduces the loss associated with diode conduction. In the full-wave bridge circuit there are two diodes in series in conduction simultaneously, which leads to higher loss. The full-wave bridge circuit is typically used for higher output voltages where this is not a serious concern. The lower diode PIV and better utilization of the transformer windings makes this circuit very attractive for higher output voltages and higher powers typical of high voltage amplifier supplies.

Because of the disadvantages pointed out earlier, the half-wave circuit is rarely used in 60-Hz rectification except for bias supplies or other small loads. It does see considerable use, however, in high-frequency switchmode power supplies.

## 7.5 Voltage Multipliers

Other rectification circuits are sometimes useful, including *voltage multipliers*. These circuits function by the process of charging one or more capacitors in parallel on one half cycle of the ac waveform, and then connecting that capacitor or capacitors in series with the opposite polarity of the ac waveform on the alternate half cycle. In full-wave multipliers, this charging occurs during both half-cycles.

Voltage multipliers, particularly *voltage doublers*, find considerable use in high-voltage supplies. When a doubler is employed, the secondary winding of the power transformer need have only half the voltage that would be required for a bridge rectifier. This reduces voltage stress in the windings and decreases the transformer insulation requirements. This is not without cost, however, because the transformer-secondary *current* rating has to be correspondingly doubled for a given load current and charging of the capacitors leads to narrow high-RMS current waveforms in the transformer windings and the capacitors.

### 7.5.1 Half-Wave Voltage Doubler

Figure 7.9 shows the circuit of a half-wave voltage doubler and illustrates the circuit operation. For clarity, assume the transformer voltage polarity at the moment the circuit is activated is that shown at Figure 7.9B. During the first negative half cycle,  $D_A$  conducts ( $D_B$  is in a nonconductive state), charging  $C_1$  to the peak rectified voltage ( $1.4 E_{RMS}$ ).  $C_1$  is charged with the polarity shown in Figure 7.9B. During the positive half cycle of the secondary voltage,  $D_A$  is cut off and  $D_B$  conducts, charging capacitor  $C_2$ . The amount

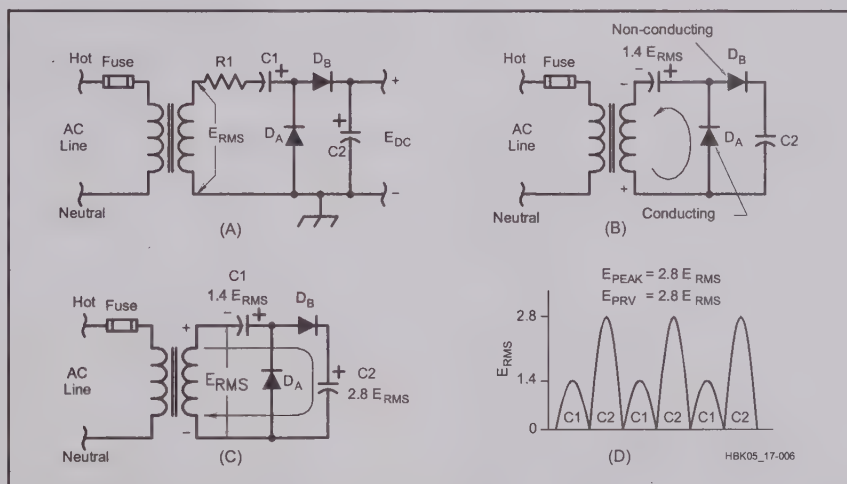

Figure 7.9 — Part A shows a half-wave voltage-doubler circuit. B displays how the first half cycle of input voltage charges  $C_1$ . During the next half cycle (shown at C), capacitor  $C_2$  charges with the transformer secondary voltage plus that voltage stored in  $C_1$  from the previous half cycle. The arrows in parts B and C indicate the conventional current. D illustrates the levels to which each capacitor charges over several cycles.

of voltage delivered to  $C_2$  is the sum of the transformer peak secondary voltage plus the voltage stored in  $C_1$  ( $1.4 E_{RMS}$ ). On the next negative half cycle,  $D_B$  is non-conducting and  $C_2$  will discharge into the load. If no load is connected across  $C_2$ , the capacitors will remain charged —  $C_1$  to  $1.4 E_{RMS}$  and  $C_2$  to  $2.8 E_{RMS}$ . When a load is connected to the circuit output, the voltage across  $C_2$  drops during the negative half cycle and is recharged up to  $2.8 E_{RMS}$  during the positive half cycle.

The output waveform across  $C_2$  resembles that of a half-wave rectifier circuit because  $C_2$  is pulsed once every cycle. Figure 7.9D illustrates the levels to which the two capacitors

are charged throughout the cycle. In actual operation the capacitors will usually be large enough that they will discharge only partially, not all the way to zero as shown.

### 7.5.2 Full-Wave Voltage Doubler

Figure 7.10 shows the circuit of a full-wave voltage doubler and illustrates the circuit operation. During the positive half cycle of the transformer secondary voltage, as shown in Figure 7.10B,  $D_A$  conducts charging capacitor  $C_1$  to  $1.4 E_{RMS}$ .  $D_B$  is not conducting at this time.

During the negative half cycle, as shown in Figure 7.10C,  $D_B$  conducts, charging capacitor  $C_2$  to  $1.4 E_{RMS}$ , while  $D_A$  is non-conducting. The output voltage is the sum of the two capacitor voltages, which will be  $2.8 E_{RMS}$  under no-load conditions. Figure 7.10D illustrates that each capacitor alternately receives a charge once per cycle. The effective filter capacitance is that of  $C_1$  and  $C_2$  in series, which is less than the capacitance of either  $C_1$  or  $C_2$  alone.

Resistors  $R_1$  and  $R_2$  in Figure 7.10A are used to limit the surge current through the rectifiers. Their values are based on the transformer voltage and the rectifier surge-current rating, since at the instant the power supply is turned on, the filter capacitors look like a short-circuited load. Provided the limiting resistors can withstand the surge current, their current-handling capacity is based on the maximum load current from the supply. Output voltages approaching twice the peak voltage of the transformer can be obtained with the voltage doubling circuit shown in Figure 7.10.

Figure 7.11 shows how the voltage depends upon the ratio of the series resistance to the load resistance, and the load resistance times the filter capacitance. The peak inverse voltage across each diode is  $2.8 E_{RMS}$ . As indicated by the curves in Figure 7.11, the output voltage regulation of this doubler connection is not very good and it is not attractive for providing high voltages at high power levels.

There are better doubler connections for higher power applications, and two possibilities are shown in Figure 7.12. The connection in Figure 7.12A uses two bridge rectifiers in series with capacitive coupling between the ac terminals of the bridges. At the expense of more diodes, this connection will have much better output voltage regulation at higher power levels. Even better regulation can be achieved by using the connection shown in Figure 7.12B. In this example, two windings on the transformer are used. It is not essential that both windings have the same voltage, but both must be capable of providing the desired output current. In addition, the insulation of the upper winding must be adequate to accommodate the additional dc bias applied to it from the lower winding.

### 7.5.3 Voltage Tripler and Quadrupler

Figure 7.13A shows a voltage-tripling circuit. On one half of the ac cycle,  $C_1$  and  $C_3$  are charged to the source voltage through  $D_1$ ,  $D_2$  and  $D_3$ .  $R_1$  represents the resistance of the transformer secondary winding, which limits the amount of current available for charging the capacitors. On the opposite half of the cycle,  $D_2$  conducts and  $C_2$  is charged

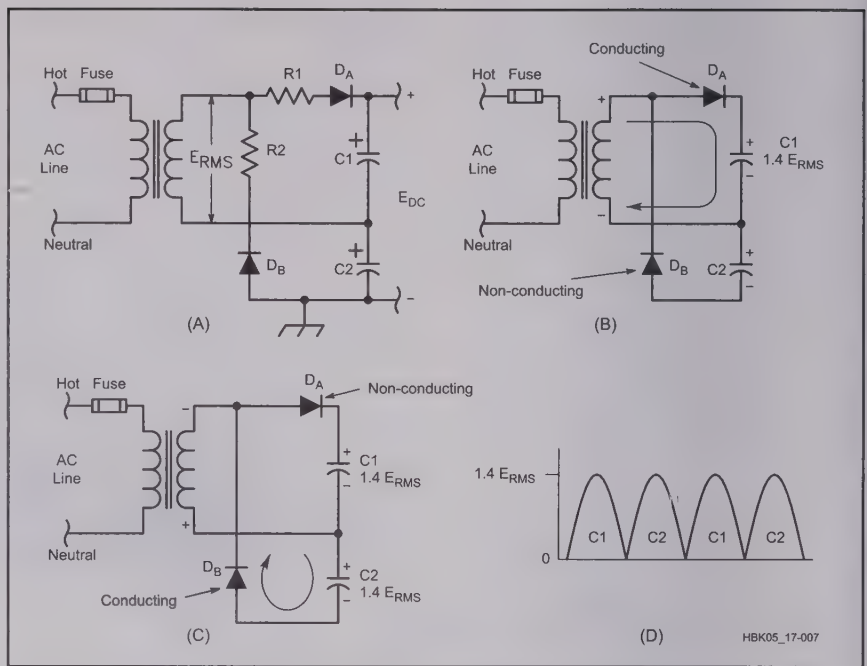

Figure 7.10 — Part A shows a full-wave voltage-doubler circuit. One-half cycle is shown at B and the next half cycle is shown at C. Each capacitor receives a charge during every input-voltage cycle. D illustrates how each capacitor is charged alternately.

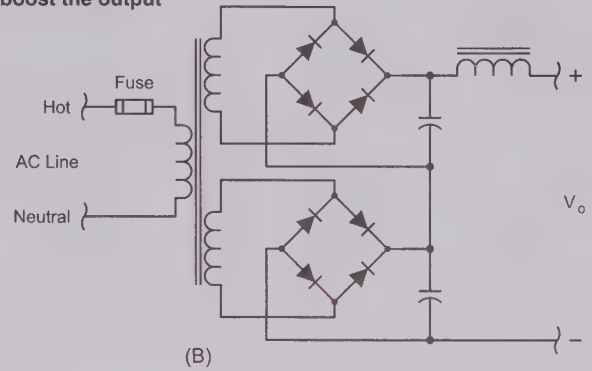

Figure 7.11 — DC output voltages from a full-wave voltage-doubler circuit as a function of the filter capacitances and load resistance. For the ratio  $R_1 / R_3$  and for the  $R_3 \times C_1$  product, resistance is in ohms and capacitance is in microfarads. Equal resistance values for  $R_1$  and  $R_2$ , and equal capacitance values for  $C_1$  and  $C_2$  are assumed. (From Schade, see References)

**Figure 7.12 — Voltage-doubler rectifier connections for higher power levels. A is a capacitor-coupled doubler that can be extended to more sections for a higher multiplying factor. The circuit in B uses multiple transformer windings to boost the output voltage.**

HBK0156

**Figure 7.13 — Voltage-multiplying circuits with one side of the transformer secondary used as a common connection. A shows a voltage tripler and B shows a voltage quadrupler. Capacitances are typically 20 to 50  $\mu\text{F}$ , depending on the output current demand. Capacitor dc ratings are related to  $E_{\text{PEAK}}$  ( $1.4 E_{\text{RMS}}$ ):**

- C1 — Greater than  $E_{\text{PEAK}}$**
- C2 — Greater than  $2 E_{\text{PEAK}}$**
- C3 — Greater than  $3 E_{\text{PEAK}}$**
- C4 — Greater than  $2 E_{\text{PEAK}}$**
- R1 — Resistance of the transformer secondary winding**

to twice the source voltage, because it sees the transformer plus the charge in C1 as its source (D1 is cut off during this half cycle). At the same time, D3 conducts, and with the transformer and the charge in C2 as the source, C3 is charged to three times the transformer voltage.

The voltage-quadrupling circuit of Figure 7.13B works in similar fashion. In either of the circuits of Figure 7.13, the output voltage will approach an exact multiple of the peak ac voltage when the output current drain is low and the capacitance values are large.

The secondary resistance, R1, limits the charging current for the capacitors, and thus the maximum output voltage. This is illustrated in a complementary way by the flattening of the output voltage curve in Figure 7.11 as filter capacitance increases. Increasing R1 has the same effect. For high-voltage supplies, a low-resistance secondary is often required to reach a full multiple of the available ac voltage.

## 7.6 Current Multipliers

Just as there are voltage multiplier connections for high-voltage, low-current loads, there are current multiplier connections for low-voltage, high-current loads. An example of a current-doubler is given in **Figure 7.14A**.

To make the circuit operation easier to visualize, we can represent L1 and L2 as current sources (Figure 7.14B) which is a good approximation for steady-state operation. When terminal 1 of the secondary winding is positive with respect to terminal 2, diode  $D_A$  will be reverse-biased and therefore non-conducting. The current flows within the circuit are shown in Figure 7.14B. Note that all of the output current ( $I_o$ ) flows through  $D_B$  but only half of  $I_o$  flows through the winding. At the cathode of  $D_B$  the current divides with half going to L2 and the other half to the transformer secondary. The output voltage will be one-half the voltage of the average winding voltage ( $0.45 E_{RMS}$ ). This rectifier connection divides the voltage and multiplies the current! Because of the need for two inductors, this circuit is seldom used in line-frequency applications but it is very useful in high-frequency switchmode regulators with very low output voltages ( $<10$  V) because it makes the secondary winding design easier and can improve circuit efficiency. At high frequencies, the inductors can be quite small.

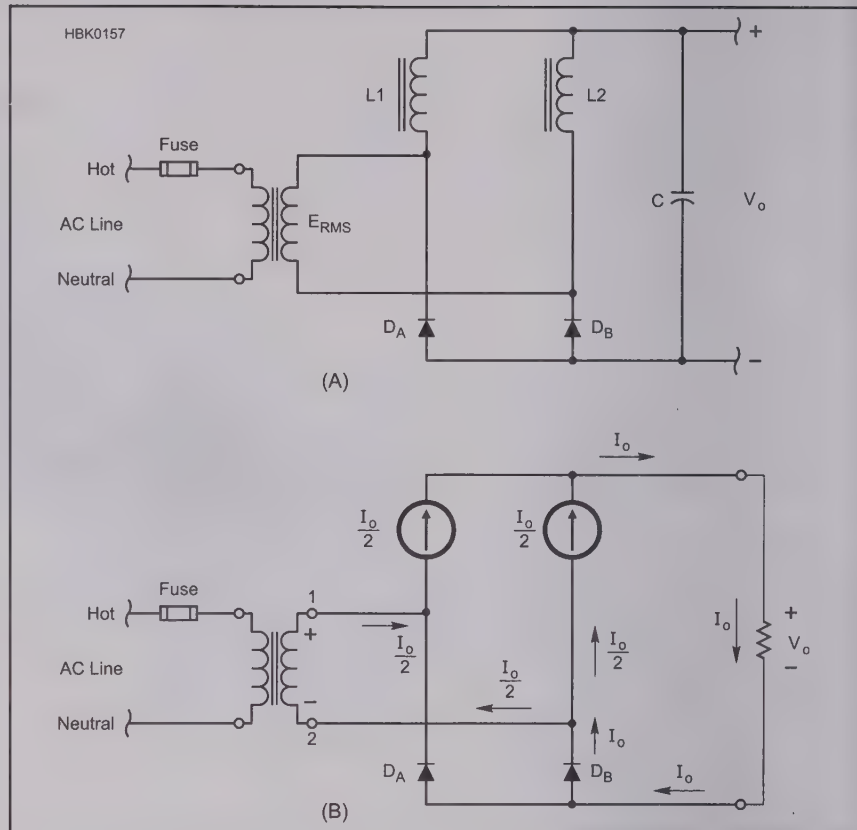

Figure 7.14 — A current doubler rectifier connection. A is the basic circuit. B illustrates current flow within the circuit.

## 7.7 Rectifier Types

Rectifiers have a long history beginning with mechanical rectifiers in the 1800s to today's abundant variety of semiconductor devices. While many different devices have been created for this purpose, they all have the characteristic that they block current flow in the reverse direction, withstanding substantial reverse voltage and allowing current flow in the forward direction with minimum voltage drop. The simplest rectifiers are diodes, but it is also possible to have three-terminal devices (such as a thyristor) that can be controlled to regulate the output dc in addition to providing rectification. It is also possible to use devices like MOSFETs as synchronous rectifiers with very low forward drop during conduction. This is typically done to improve efficiency for very low voltage outputs. The following is a brief description of several of the more common examples. The sections on vacuum tube and other obsolete types of rectifiers from previous editions are available as a PDF article with this book's downloadable supplemental content.

### 7.7.1 Semiconductor Diodes

Rectifier diodes can be made from a number of different semiconductor materials such as germanium, silicon, silicon-carbide or gallium-arsenide, and no doubt other materials will appear in the future. The choice will depend on the application and as always cost is a factor.

Germanium diodes were the first of the solid-state semiconductor rectifiers. They have an extremely low forward voltage drop but are relatively temperature sensitive, having high reverse leakage currents at higher temperatures. They can be easily destroyed by overheating during soldering as well. Germanium diodes are no longer used as power rectifiers.

Today, silicon diodes are the primary choice for virtually all power rectifier applications. They are characterized by extremely high reverse resistance (low reverse leakage), forward drops of a volt or less and operation at junction temperatures up to 125 °C. Some

multi-junction HV diodes will have forward drops of several volts, but that is still low compared to the voltage at which they are being used.

Many different types of silicon diodes are available for different applications. Silicon rectifiers fall into two general categories: PN-junction diodes and Schottky barrier diodes (see the **Circuits and Components** chapter). Schottky diodes are the usual choice for low output voltages ( $<20$  V) where their low forward conduction drop is critical for efficiency. For higher voltages however, the high reverse leakage of Schottky diodes is not acceptable and PN-junction diodes are normally chosen.

For 50/60 Hz applications, diodes with reverse recovery times of a microsecond or even more are suitable and very economical. For switchmode converters and inverters that regularly operate at 25 kHz and higher frequencies, fast-recovery diodes are needed. These converters typically have waveform

transitions of less than 1  $\mu\text{s}$  within the circuit. MOSFET power transistors often have transitions of less than 100 ns.

During the switching transitions, previously conducting diodes see a reversal of current direction. This change tends to reverse-bias those diodes, and thereby put them into an open-circuit condition. Unfortunately, as explained in the **Circuits and Components** chapter, solid-state rectifiers cannot be made to cease conduction instantaneously. As a result, when the opposing diodes in a bridge rectifier or full-wave rectifier become conductive at the time the converter switches states, the diodes being turned off will actually conduct in the reverse direction for a brief time. That effectively short circuits the converter for a period of time depending on the reverse recovery characteristics of the rectifiers. This characteristic can create high current transients that stress the switching transistors and lead to increased loss and electromagnetic interference. As the switching frequency increases, more of these transitions happen each second, and more power is lost because of diode cross-conduction.

These current transients and associated losses are reduced by using *fast recovery* diodes, which are specially doped diodes designed to minimize storage time. Diodes with recovery times of 50 ns or less are available.

## 7.7.2 Rectifier Strings or Stacks

### DIODES IN SERIES

When the PIV rating of a single diode is not sufficient for the application, similar diodes may be used in series. (Two 500 PIV diodes in series will withstand 1000 PIV and so on.) There used to be a general recommendation to place a resistor across each diode in the string to equalize the PIV drops. With modern diodes, this practice is no longer necessary.

Modern silicon rectifier diodes are constructed to have an avalanche characteristic. Simply put, this means that the diffusion process is controlled so the diode will exhibit a Zener characteristic in the reverse-biased direction before destructive breakdown of the junction can occur. This provides a measure of safety for diodes in series. A diode will go into Zener conduction before it self-destructs. If other diodes in the chain have not reached their avalanche voltages, the current through the avalanched diode will be limited to the leakage current in the other diodes. This should normally be very low. For this reason, shunting resistors are generally not needed across diodes in series rectifier strings. In fact, shunt resistors can actually create problems because they can produce a low-impedance source of damaging current

to any diode that may have reached avalanche potential.

### DIODES IN PARALLEL

Diodes can be placed in parallel to increase current-handling capability. Equalizing resistors should be added as shown in **Figure 7.15**. Without the resistors, one diode may take most of the current. The resistors should be selected to have a drop of several tenths of a volt at the expected peak current. A disadvantage of this form of forced current sharing will be the increase in power loss because of the added resistors.

### 7.7.3 Rectifier Ratings versus Operating Stress

Power supplies designed for amateur equipment use silicon rectifiers almost exclusively. These rectifiers are available in a wide range of voltage and current ratings: PIV ratings of 600 V or more and current ratings as high as 400 A are available. At 1000 PIV, the current ratings may be several amperes. It is possible to stack several units in series for higher voltages. Stacks are available commercially that will handle peak inverse voltages up to 10 kV at a load current of 1 A or more.

### 7.7.4 Rectifier Protection

The discussion of rectifier circuits included the peak reverse voltage seen by the rectifiers in each circuit. You will need this information to select the voltage rating of the diodes in given application. It is normal good practice to not expose the diodes to more than 75% of their rated voltage for the worst case reverse voltage. This will probably be when operating at the highest input voltage but should also take into account transients that may occur.

The important specifications of a silicon diode are:

1. PIV — the peak inverse voltage.
2.  $I_0$  — the average dc current rating.
3.  $I_{\text{REP}}$  — the peak repetitive forward current.
4.  $I_{\text{SURGE}}$  — a non-repetitive peak half-sine wave of 8.3 ms duration (one-half cycle of 60-Hz line frequency).
5. Switching speed or reverse recovery time.
6. Power dissipation and thermal resistance.

The first two specifications appear in most catalogs.  $I_{\text{REP}}$  and  $I_{\text{SURGE}}$  are not often specified in catalogs, but they are very important. Except in some switching regulator and capacitive filter circuits, rectifier current typically flows half the time — when it does conduct, the rectifier has to pass at least twice the average direct current. With a capacitor-input filter, the rectifier conducts much less than half the time. In this case, when it does conduct, it may pass as much as 10 to 20

**Figure 7.15** — Diodes can be connected in parallel to increase the current-handling capability of the circuit. Each diode should have a series current-equalizing resistor, with a value selected to have a drop of several tenths of a volt at the expected current.

times the average dc current, under certain conditions.

### CURRENT INRUSH

When the supply is first turned on, the filter capacitors are discharged and act like a dead short. The result can be a very heavy current surge through the diode for at least one half-cycle and sometimes more. This current transient is called  $I_{\text{SURGE}}$ . The maximum surge current rating for a diode is usually specified for a duration of one-half cycle (at 60 Hz), or about 8.3 ms. Some form of surge protection is usually necessary to protect the diodes until the filter capacitors are nearly charged, unless the diodes used have a very high surge-current rating (several hundred amperes). If a manufacturer's data sheet is not available, an educated guess about a diode's capability can be made by using these rules of thumb for silicon diodes commonly used in Amateur Radio power supplies:

**Rule 1.** The maximum  $I_{\text{REP}}$  rating can be assumed to be approximately four times the maximum  $I_0$  rating, where  $I_0$  is the average dc current rating.

**Rule 2.** The maximum  $I_{\text{SURGE}}$  rating can be assumed to be approximately 12 times the maximum  $I_0$  rating. This figure should provide a reasonable safety factor. Silicon rectifiers with 750 mA dc ratings, for example, seldom have 1-cycle surge ratings of less than 15 A; some are rated up to 35 A or more. From this you can see that the rectifier should be selected on the basis of  $I_{\text{SURGE}}$  and not on  $I_0$  ratings.

Although you can sometimes rely on the resistance of the transformer windings to provide surge-current limiting, this is seldom adequate in high-voltage power supplies. Series resistors are often installed between the secondary and the rectifier strings or in the transformer's primary circuit, but these can be a deterrent to good voltage regulation.

One way to have good surge current limiting at turn-on without affecting voltage regulation during normal operation is to have a resistor in series with the input, along with

a relay across the resistor that shorts it out after 50 ms or so. This kind of arrangement is particularly important in HV supplies.

## VOLTAGE TRANSIENTS

Vacuum-tube rectifiers had little problem with voltage transients on the incoming power lines. The possibility of an internal arc was of little consequence, since the heat produced was of very short duration and had little effect on the massive plate and cathode structures.

Unfortunately, such is not the case with silicon diodes. Because of their low forward voltage drop, silicon diodes create very little heat with high forward current and therefore have tiny junction areas. However, conduction in the reverse direction beyond the normal reverse recovery time (reverse avalanching) can cause junction temperatures to rise extremely rapidly with the resulting destruction of the semiconductor junction.

To protect semiconductor rectifiers from voltage transients, special surge-absorption devices are available for connection across the incoming ac bus or transformer secondary. These devices operate in a fashion similar to a Zener diode; they conduct heavily when a specific voltage level is reached. Unlike Zener diodes, however, they have the ability to absorb very high transient energy levels without damage. With the clamping level set well above the normal operating voltage range for the rectifiers, these devices normally appear as open circuits and have no effect on the power-supply circuits. When a voltage transient occurs, however, these protection devices clamp the transient and thereby prevent destruction of the rectifiers.

Transient protectors are available in three basic varieties:

1. *Silicon Zener diodes* — large junction Zeners specifically made for this purpose and available as single junction for dc (unipolar)

and back-to-back junctions for ac (bipolar). These silicon protectors are available under the trade name of TransZorb from General Semiconductor Corporation and are also made by other manufacturers. They have the best transient-suppressing characteristics of the three varieties mentioned here, but are expensive and have the least energy absorbing capability per dollar of the group.

2. *Varistors* — made of a composition metal-oxide material that breaks down at a certain voltage. Metal-oxide varistors, also known as MOVs, are cheap and easily obtained, but have a higher internal resistance, which allows a greater increase in clamped voltage than the Zener variety. Varistors can also degrade with successive transients within their rated power handling limits (this is not usually a problem in the ham shack where transients are few and replacement of the varistor is easily accomplished).

Varistors usually become short-circuited when they fail. Large energy dissipation can result in device explosion. Therefore, it is a good idea to include a fuse that limits the short-circuit current through the varistor, and to protect people and circuitry from debris.

3. *Gas tube* — similar in construction to the familiar neon bulb, but designed to limit conducting voltage rise under high transient currents. Gas tubes can usually withstand the highest transient energy levels of the group. Gas tubes suffer from an ionization time problem, however. A high voltage across the tube will not immediately cause conduction. The time required for the gas to ionize and clamp the transient is inversely proportional to the level of applied voltage in excess of the device ionization voltage. As a result, the gas tube will let a little of the transient through to the equipment before it activates.

In installations where reliable equipment operation is critical, the local power is poor and transients are a major problem, the usual

practice is to use a combination of protectors. Such systems consist of a varistor-Zener protector, combined with a gas-tube device. Often there is an indicator light to warn when a surge has blown out the varistor. Operationally, the solid-state device clamps the surge immediately, with the beefy gas tube firing shortly thereafter to take most of the surge from the solid-state device.

## HEAT

The junction of a diode is quite small, so it must operate at a high current density. Thermal heat-handling capability is, therefore, quite small. Normally, this is not a prime consideration in high-voltage, low-current supplies. Use of high-current rectifiers at or near their maximum ratings (usually 2 A or larger, stud-mount rectifiers) requires some form of heat sinking. Frequently, mounting the rectifier on the main chassis — directly or with thermal insulating washers — will suffice.

When a rectifier is directly mounted on the heatsink it is good practice to use a thin layer of thermal grease between the diode and the heat sink to assure good heat conduction. Most modern insulating thermal washers do not require the use of grease, but the old mica and other washers may benefit from a *very thin layer* of grease. Thermal grease and heat conducting insulating washers and pads are standard products available from mail-order component sellers.

Large, high-current rectifiers often require special heat sinks to maintain a safe operating temperature. Forced-air cooling from a fan is sometimes used as a further aid. Safe case temperatures are usually given in the manufacturer's data sheets and should be observed if the maximum capabilities of the diode are to be realized. See the thermal design section in the chapter on **Electric Fundamentals** for more information.

## 7.8 Power Filtering

Most loads will not tolerate the ripple (an ac component) of the pulsating dc from the rectifiers. Filters are required between the rectifier and the load to reduce the ripple to a low level. As pointed out earlier, some capacitances or inductances may be inherent in the rectifier connection, reducing the ripple amplitude. In most cases, however, additional filtering is required. The design of the filter depends to a large extent on the dc voltage output, the desired voltage regulation of the power supply and the maximum load current. Power-supply filters are low-pass devices using series inductors and/or shunt capacitors.

### 7.8.1 Load Resistance

In discussing the performance of power-supply filters, it is sometimes convenient to characterize the load connected to the output as a resistance. This *load resistance* is equal to the output voltage divided by the total load current, including the current drawn by the bleeder resistor.

### 7.8.2 Voltage Regulation

In an unregulated supply, the output voltage usually decreases as more current is drawn. This happens not only because of increased voltage drops in the transformer and filter

chokes, but also because the output voltage of light loads tends to soar to the peak value of the transformer voltage as a result of charging the first capacitor. Proper filter design can reduce this effect. The change in output voltage with load is called the *voltage regulation* and is expressed as a percentage.

$$\text{Percent Regulation} = \frac{(E_1 - E_2)}{E_2} \times 100 \quad (7.8)$$

where

$E_1$  = the no-load voltage  
 $E_2$  = the full-load voltage.

A steady load, such as that represent

a receiver, speech amplifier or unkeyed  
ages of a transmitter, does not require good  
(w) regulation as long as the proper voltage  
obtained under load conditions. The filter  
capacitors must have a voltage rating safe for  
highest value to which the voltage will rise  
when the external load is removed.

Typically the output voltage will display  
larger change with long-duration changes  
load resistance than with short transient  
changes. The reason for this is that transient  
currents are supplied from energy stored in  
the output capacitance. The regulation with  
long-term changes is often called the *static*  
*regulation*, to distinguish it from the *dynamic*  
*regulation* (transient load changes). A load  
that varies at a syllabic or keyed rate, as rep-  
resented by some audio and RF amplifiers,  
usually requires good dynamic regulation  
(5%) if distortion products are to be held  
at a low level. The dynamic regulation of a  
power supply can be improved by increasing  
the output capacitance.

When essentially constant voltage is re-  
quired, regardless of current variation (for  
stabilizing an oscillator, for example), special  
voltage regulating circuits described later in  
this chapter are used.

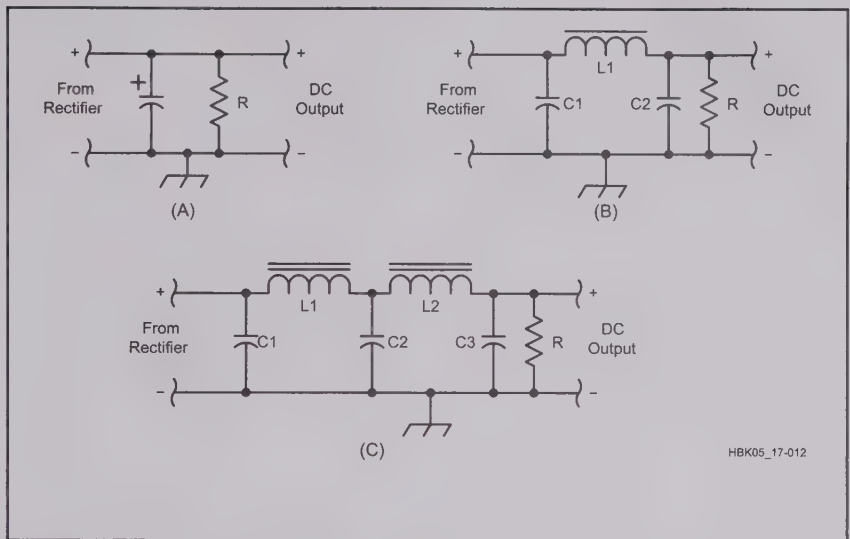

### 3.3 Bleeder Resistors

A *bleeder resistor* is a resistance (R) con-  
nected across the output terminals of the  
power supply as shown in **Figure 7.16A**. Its  
functions are to discharge the filter capacitors  
as a safety measure when the power is turned  
off and to improve voltage regulation by  
providing a minimum load resistance. When  
voltage regulation is not of importance, the  
resistance may be as high as 100 Ω per volt of  
output voltage. The resistance value to be used  
for voltage-regulating purposes is discussed  
in later sections. From the consideration of  
safety, the power rating of bleeder resistors  
should be as conservative as possible — hav-  
ing a burned-out bleeder resistor is dangerous!

### 3.4 Ripple Frequency and Voltage

The ripple at the output of the rectifier is an  
alternating current superimposed on a steady  
direct current. From this viewpoint, the filter  
may be considered to consist of: 1) shunt  
capacitors that short circuit the ac component  
while not interfering with the flow of the dc  
component; and/or 2) series chokes that read-  
pass dc but will impede the ac component.  
The effectiveness of the filter can be ex-  
pressed in terms of percent ripple, which is  
the ratio of the RMS value of the ripple to the  
average value in terms of percentage.

$$\text{Percent Ripple (RMS)} = \frac{E_1}{E_2} \times 100\% \quad (3)$$

**Figure 7.16** — Capacitor-input filter circuits. At A is a simple capacitor filter. B and C are single- and double-section filters, respectively.

where

- E1 = the RMS value of ripple voltage
- E2 = the steady dc voltage.

Any frequency multiplier or amplifier  
supply in a CW transmitter should have less  
than 5% ripple. A linear amplifier can toler-  
ate about 3% ripple on the plate voltage. Bias  
supplies for linear amplifiers should have less  
than 1% ripple. VFOs, speech amplifiers and  
receivers may require no greater than 0.01%  
ripple.

Ripple frequency refers to the frequency of  
the pulsations in the rectifier output waveform  
— the number of pulsations per second. The  
ripple frequency of half-wave rectifiers is the  
same as the line-supply frequency — 60 Hz  
with a 60-Hz supply. Since the output pulses  
are doubled with a full-wave rectifier, the  
ripple frequency is doubled — to 120 Hz with  
a 60-Hz supply.

The amount of filtering (values of in-  
ductance and capacitance) required to give  
adequate smoothing depends on the ripple  
frequency. More filtering is required as the  
ripple frequency is reduced. This is why the  
filters used for line-frequency rectification are  
much larger than those used in switchmode  
converters where the ripple frequency is often  
in the hundreds of kHz.

### 7.8.5 Capacitor-Input Filters

Typical capacitor-input filter systems are  
shown in Figure 7.16. The ripple can be re-  
duced by making C1 larger, but that can lead  
to very large capacitances and high inrush  
currents at turn-on. Better ripple reduction  
will be obtained when moderate values for

C1 are employed and LC sections are added  
as shown in Figure 7.16B and C.

### INPUT VERSUS OUTPUT VOLTAGE

The average output voltage of a capaci-  
tor-input filter is generally poorly regulated  
with load-current variations. As shown earlier  
(Figure 7.6) the rectifier diodes conduct for  
only a small portion of the ac cycle to charge  
the filter capacitor to the peak value of the ac  
waveform. When the instantaneous voltage  
of the ac passes its peak, the diode ceases to  
conduct. This forces the capacitor to support  
the load current until the ac voltage on the  
opposing diode in the bridge or full wave  
rectifier is high enough to pick up the load  
and recharge the capacitor. For this reason,  
the peak diode currents are usually quite high.

Since the cyclic peak voltage of the capaci-  
tor-filter output is determined by the peak of  
the input ac waveform, the minimum voltage  
and, therefore, the ripple amplitude, is deter-  
mined by the amount of voltage discharge,  
or “droop,” occurring in the capacitor while  
it is discharging and supporting the load.  
Obviously, the higher the load current, the  
proportionately greater the discharge, and  
therefore the lower the average output.

There is an easy way to approximate the  
peak-to-peak ripple for a certain capacitor  
and load by assuming a constant load current.  
We can calculate the droop in the capacitor  
by using the relationship;

$$C \times E = I \times t \quad (4)$$

where

C = the capacitance in microfarads

$E$  = the voltage droop, or peak-to-peak ripple voltage  
 $I$  = the load current in milliamperes  
 $t$  = the length of time in ms per cycle during which the rectifiers are not conducting, during which the filter capacitor must support the load current. For 60-Hz, full-wave rectifiers,  $t$  is about 7.5 ms.

As an example, let's assume that we need to determine the peak-to-peak ripple voltage at the dc output of a full-wave rectifier/ filter combination that produces 13.8 V dc and supplies a transceiver drawing 2.0 A. The filter capacitor in the power supply is 5000  $\mu\text{F}$ . Using the above relationship:

$$C \times E = I \times t \quad (5)$$

$$5000 \mu\text{F} \times E = 2000 \text{ mA} \times 7.5 \text{ ms}$$

$$E = \frac{2000 \text{ mA} \times 7.5 \text{ ms}}{5000 \mu\text{F}} = 3 \text{ V P-P}$$

Obviously, this is too much ripple. A capacitor value of about 20,000  $\mu\text{F}$  would be better suited for this application. If a linear regulator is used after this rectifier/filter combination, then it is possible to trade off higher ripple voltage against high power dissipation in the regulator. A properly designed linear regulator can reduce the ripple amplitude to a very small value.

### 7.8.6 Choke-Input Filters

Choke-input filters provide the benefits of greatly improved output voltage stability over varying loads and low peak-current surges in the rectifiers. On the negative side, the output voltage will be lower than that for a capacitor-input filter.

In line-frequency power supplies, choke-input filters are less popular than they once were. This change came about in part because

**Figure 7.17** — Inductive filter output voltage regulation as a function of load current. The transition from capacitive peak charging to inductive averaging occurs at the critical load current,  $I_C$ .

**Figure 7.18** — The choke inductor constant,  $A$ , is used to solve equation 6.

of the high surge current capability of silicon rectifiers, but more importantly because size, weight and cost are reduced when large filter chokes are eliminated. However, choke input filters are frequently used in high-frequency switchmode converters where the chokes will be much smaller.

As long as the inductance of the choke is

large enough to maintain a continuous current over the complete cycle of the input waveform, the filter output voltage will be the average value of the rectified output. The average dc value of a full-wave rectified sine wave is 0.637 times its peak voltage. Since the RMS value is 0.707 times the peak, the output of the choke input filter will be  $(0.637 / 0.707)$ , or 0.9 times the RMS ac voltage.

As shown in **Figure 7.17**, there is a minimum or "critical" load current below which the choke does not provide the necessary filtering. For light loads, there may not be enough energy stored in the choke during the input waveform crest to allow continuous current over the full cycle. When this happens, the filter output voltage will rise as the filter assumes more and more of the characteristics of a capacitor-input filter. One purpose of the bleeder resistor is to keep the minimum load current above the critical value.

The value for the critical (or minimum) inductance for a given maximum value of load resistance in a single phase, full-wave rectifier with a sine wave source voltage can be approximated from:

$$L_C = R/A \quad (6)$$

where

$R$  = the maximum load resistance

$A$  = a constant obtained from **Figure**

7.18, derived from the frequency of the input current (see Reference 1).

Low values for minimum load current (high minimum load  $R$ ) can lead to large values for  $L_C$  which may not be practical. Standard filter inductors typically have a relatively constant value for  $L$  as the dc current is varied but it is possible to use a swinging choke instead. This is an inductor which has a high inductance at low currents and much lower inductance at high currents. Using a swinging choke will usually result in a much smaller filter choke and/or better output regulation.

# 7.9 Power Supply Regulation

The output of a rectifier/filter system may be usable for some electronic equipment, but for today's transceivers and accessories, further measures may be necessary to provide power sufficiently clean and stable for their needs. Voltage regulators are often used to provide this additional level of conditioning.

Rectifier/filter circuits by themselves are unable to protect the equipment from the problems associated with input-power-line fluctuations, load-current variations and residual ripple voltages. Regulators can eliminate these problems, but not without costs in circuit complexity and power-conversion efficiency.

## 7.9.1 Zener Diodes

A Zener diode (developed by Dr Clarence Zener) can be used to maintain the voltage applied to a circuit at a practically constant value, regardless of the voltage regulation of the power supply or variations in load current. The typical circuit is shown in **Figure 7.19**. Note that the cathode side of the diode is connected to the positive side of the supply.

Zener diodes are available in a wide variety of voltages and power ratings. The voltages range from less than 2 V to a few hundred volts, while the power ratings (power the diode can dissipate) run from less than 0.25 W to 50 W. The ability of the Zener diode to stabilize a voltage depends on the diode's conducting impedance. This can be as low as 1  $\Omega$  or less in a low-voltage, high-power diode or as high as 1000  $\Omega$  in a high-voltage, low-power diode.

The circuit in Figure 7.19 is a *shunt* regulator in that it "shunts" current through a controlling device (the Zener diode) to maintain a constant output voltage. To design a Zener shunt regulator, you must know the minimum and maximum input voltage ( $E_{DC}$ ); the

**Figure 7.19** — Zener-diode voltage regulation. The voltage from a negative supply may be regulated by reversing the power-supply connections and the diode polarity.

**Figure 7.20** — Linear electronic voltage regulator circuits. In these diagrams, batteries represent the unregulated input-voltage source. A transformer, rectifier and filter would serve this function in most applications. Part A shows a series regulator and Part B shows a shunt regulator. Part C shows how remote sensing overcomes poor load regulation caused by the IR drop in the connecting wires by bringing them inside the feedback loop. The use of extra connections to sense voltage is called a "four wire Kelvin connection."

output voltage, which is equal to the Zener diode voltage ( $E_Z$ ); and the minimum and maximum load current ( $I_L$ ) through  $R_L$ . If the input voltage is variable, you must specify the maximum and minimum values for  $E_{DC}$ . As a rule of thumb, the current through the Zener should be 10% of the maximum load current for good regulation and must be greater than the  $I_{Z(\min)}$  at which the Zener diode maintains its constant voltage drop. Once these quantities are known the series resistance,  $R_S$ , can be determined:

$$R_S = \frac{E_{DC(\min)} - E_Z}{1.1 I_{L(\max)}} \quad (7)$$

The power dissipation of the Zener diode,  $P_{DZ}$ , is

$$P_{DZ} = \left[ \frac{E_{DC(\max)} - E_Z}{R_S} - I_{L(\min)} \right] E_Z \quad (8)$$

and of the series resistor,  $R_S$ ,

$$P_{DR} = \frac{(E_{DC(\max)} - E_Z)^2}{R_S} \quad (9)$$

It is good practice to provide a five times rated power dissipation safety margin for both the series resistor and the Zener diode. This avoids heating in the Zener and the resulting drift in voltage. High-power Zener diodes (10 W dissipation or more) will require heat-sinking as discussed in the section on Heat Management in the **Circuits and Components** chapter.

## 7.9.2 Linear Regulators

Linear regulators come in two varieties, *series* and *shunt*, as shown in **Figure 7.20**. The shunt regulator is simply an electronic (also called “active”) version of the Zener diode. For the most part, the active shunt regulator (**Figure 7.20B**) is rarely used since the series regulator is a superior choice for most applications.

The series regulator (**Figure 7.20A**) consists of a stable voltage reference, which is usually established by a Zener diode, a transistor in series between the power source and the load (called a *series pass transistor*), and an error amplifier. In critical applications a temperature-compensated reference diode would be used instead of the Zener diode.

The output voltage is sampled by the error amplifier, which compares the output (usually scaled down by a voltage divider) to the reference. If the scaled-down output voltage becomes higher than the reference voltage, the error amplifier reduces the drive current to the pass transistor, thereby allowing the output voltage to drop slightly. Conversely, if the load pulls the output voltage below the desired value, the amplifier drives the pass transistor into increased conduction.

The “stiffness” or tightness of regulation

**Figure 7.21** — At A, a Darlington-connected transistor pair for use as the pass element in a series-regulating circuit. At B, the method of connecting two or more transistors in parallel for high-current output. Resistances are in ohms. The circuit at A may be used for load currents from 100 mA to 5 A, and the one at B may be used for currents from 6 A to 10 A.

**Q1** — NPN transistor, MJE340 or equivalent

**Q2-Q4** — Power transistor such as 2N3055 or 2N3772

of a linear regulator depends on the gain of the error amplifier and the ratio of the output scaling resistors. In any regulator, the output is cleanest and regulation stiffest at the point where the sampling network or error amplifier is connected. If heavy load current is drawn through long leads, the voltage drop can degrade the regulation at the load. To combat this effect, the feedback connection to the error amplifier can be made directly to the load. This technique, called *remote sensing*, or a *four wire Kelvin connection*, moves the point of best regulation to the load by bringing the connecting loads inside the feedback loop. This is shown in **Figure 7.20C**.

### INPUT VERSUS OUTPUT VOLTAGE

In a series regulator, the pass-transistor power dissipation is directly proportional to the load current and input/output voltage differential. The series pass element can be located in either leg of the supply. Either NPN or PNP devices can be used, depending on the ground polarity of the unregulated input.

The differential between the input and output voltages is a design tradeoff. If the input voltage from the rectifiers and filter is only slightly higher than the required output voltage, there will be minimal voltage drop across the series pass transistor. A small drop results in minimal thermal dissipation and high power-supply efficiency. The supply will have less capability to provide regulated power in the event of power line brownout and other reduced line voltage conditions, however. Conversely, a higher input voltage will provide operation over a wider range of input voltage, but at the expense of increased heat dissipation.

## 7.9.3 Linear Regulator Pass Transistors

### DARLINGTON PAIRS

A simple Zener-diode reference or IC op-amp error amplifier may not be able to source enough current to a pass transistor that must conduct heavy load current. The Darlington configuration of **Figure 7.21A** multiplies the pass transistor beta, thereby extending the control range of the error amplifier. If the Darlington arrangement is implemented with discrete transistors, resistors across the base-emitter junctions may be necessary to prevent collector-to-base leakage currents in Q1 from being amplified and turning on the transistor pair. These resistors are contained in the envelope of a monolithic Darlington device.

When a single pass transistor is not available to handle the current required from a regulator, the current-handling capability may be increased by connecting two or more pass transistors in parallel. The circuit of **Figure 7.21B** shows the method of connecting these pass transistors. The resistances in the emitter leads of each transistor are necessary to equalize the currents.

### TRANSISTOR RATINGS

When bipolar (NPN, PNP) power transistors are used in applications in which they are called upon to handle power on a continuous basis, rather than switching, there are four parameters that must be examined to see if any maximum limits are being exceeded. Operation of the transistor outside these limits can easily result in device failure, and these parameters must be considered during the design process.

**Figure 7.22** — Typical graph of the safe operating area (SOA) of a transistor. See text for details. Safe operating conditions for specific devices may be quite different from those shown here.

The four limits are maximum collector current ( $I_C$ ), maximum collector-emitter voltage ( $V_{CE0}$ ), maximum power and *second breakdown* ( $I_{SB}$ ). All four of these parameters are graphically shown on the transistor's data sheet on what is known as a *safe operating area (SOA)* graph. (see **Figure 7.22**) The first three of these limits are usually also listed prominently with the other device information, but it is often the fourth parameter — secondary breakdown — that is responsible for the “sudden death” of the power transistor after an extended operating period.

The maximum current limit of the transistor ( $I_{C\ MAX}$ ) is usually the current limit for fusing of the bond wire connected to the emitter, rather than anything pertaining to the transistor chip itself. When this limit is exceeded, the bond wire can melt and open circuit the emitter. On the operating curve, this limit is shown as a horizontal line extending out from the Y-axis and ending at the voltage point where the constant power limit begins.

The maximum collector-emitter voltage limit of the transistor ( $V_{CE\ MAX}$ ) is the point at which the transistor junctions can no longer withstand the voltage between collector and emitter.

With increasing collector-emitter voltage drop at maximum collector current, a point is reached where the power in the transistor will cause the junction temperature to rise to a level where the device leakage current rapidly increases and begins to dominate. In this region, the product of the voltage drop and the current would be constant and represent the maximum power ( $P_f$ ) rating for the transistor; that is, as the voltage drop continues to increase, the collector current must decrease to maintain the power dissipation at a constant value.

With most transistors rated for higher voltages, a point is reached on the constant power portion of the curve whereby, with further increased voltage drop, the maximum power rating is *not* constant, but decreases as the collector to emitter voltage increases. This decrease in power handling capability continues until the maximum voltage limit is reached.

This special region is known as the *forward bias second breakdown (FBSB)* area. Reduction in the transistor's power handling capability is caused by localized heating in certain small areas of the transistor junction (“hot spots”), rather than a uniform distribution of power dissipation over the entire surface of the device.

The region of operating conditions contained within these curves is called the safe operating area, or SOA. If the transistor is always operated within these limits, it should provide reliable and continuous service for a long time.

**MOSFET TRANSISTORS**

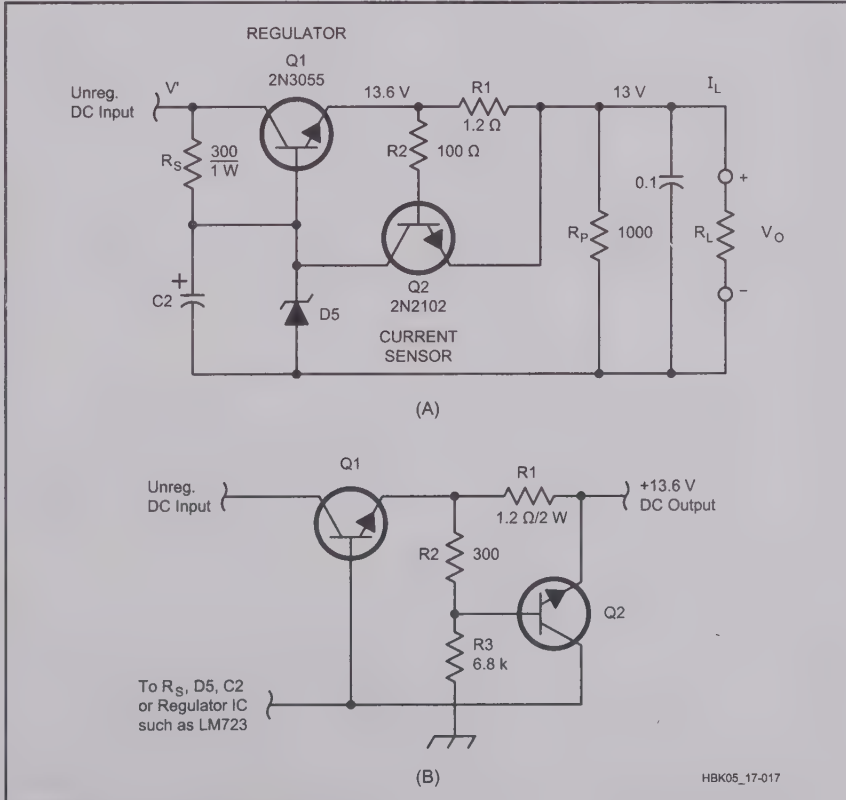

The bipolar junction transistor (BJT) is rapidly being replaced by the MOSFET in new power supply designs because MOSFETs are easier to drive. The N-channel MOSFET (equivalent to the NPN bipolar) is more

popular than the P-channel for pass transistor applications.

There are some considerations that should be observed when using a MOSFET as a linear regulator series pass transistor. Several volts of gate drive are needed to start conduction of the device, as opposed to less than 1 V for the BJT. MOSFETs are inherently very-high-frequency devices and will readily oscillate with stray-circuit capacitances. To prevent oscillation in the transistor and surrounding circuits, it is common practice to insert a small resistor of about 100  $\Omega$  directly in series with the gate of the series-pass transistor to reduce the gate circuit Q.

**OVERCURRENT PROTECTION**

Damage to a pass transistor can occur when the load current exceeds the safe amount. **Figure 7.23A** illustrates a simple current-limiter circuit that will protect Q1. All of the load current is routed through R1. A voltage difference will exist across R1; the value will depend on the exact load current at a given time. When the load current exceeds a predetermined safe value, the voltage drop across R1 will forward-bias Q2 and cause it to conduct. Because Q2 is a silicon transistor, the voltage drop across R1 must exceed

**Figure 7.23** — Overload protection for a regulated supply can be implemented by addition of a current-overload-protective circuit, as shown at A. At B, the circuit has been modified to employ current-foldback limiting.

0.6 V to turn Q2 on. This being the case, R1 is chosen for a value that provides a drop of 0.6 V when the maximum safe load current is drawn. In this instance, the drop will be 0.6 V when  $I_L$  reaches 0.5 A. R2 protects the base-emitter junction of Q2 from current transients, or from destruction in the event Q1 fails under short-circuit conditions.

When Q2 turns on, some of the current through  $R_S$  flows through Q2, thereby depriving Q1 of some of its base current. This action, depending upon the amount of Q1 base current at a precise moment, cuts off Q1 conduction to some degree, thus limiting the current through it.

### FOLDBACK CURRENT LIMITING

Under short-circuit conditions, a constant-current type current limiter must still withstand the full source voltage and limited short-circuit current simultaneously, which can impose a very high power dissipation or second breakdown stress on the series pass transistor. For example, a 12 V regulator with current limiting set for 10 A and having a source of 16 V will have a dissipation of 40 W [(16 V - 12 V) × 10 A] at the point of current limiting (knee). But its dissipation will rise to 160 W under short-circuit conditions (16 V × 10 A).

A modification of the limiter circuit can cause the regulated output current to decrease with decreasing load resistance beyond the over-current knee. With the output shorted, the output current is only a fraction of the knee current value, which protects the series-pass transistor from excessive dissipation and possible failure. Using the previous example of the 12 V, 10 A regulator, if the short-circuit current is designed to be 3 A (the knee is still 10 A), the transistor dissipation with a short circuit will be only 16 V × 3 A = 48 W.

Figure 7.23B shows how the current-limiter

Figure 7.24 — The 1 A regulator shown in Figure 7.23B will fold back to 0.5 A under short-circuit conditions. See text.

example given in the previous section would be modified to incorporate foldback limiting. The divider string formed by R2 and R3 provides a negative bias to the base of Q2, which prevents Q2 from turning on until this bias is overcome by the drop in R1 caused by load current. Since this hold-off bias decreases as the output voltage drops, Q2 becomes more sensitive to current through R1 with decreasing output voltage. See **Figure 7.24**.

The circuit is designed by first calculating the value of R1 for short-circuit current. For example, if 0.5 A is chosen, the value for R1 is simply 0.6 V / 0.5 A = 1.2 Ω (with the output shorted, the amount of hold-off bias supplied by R2 and R3 is very small and can be neglected). The knee current is then chosen. For this example, the selected value will be 1.0 A. The divider string is then proportioned to provide a base voltage at the knee that is just sufficient to turn on Q2 (a value of 13.6 V for 13.0 V output). With 1.0 A flowing through R1, the voltage across the divider will be 14.2 V. The voltage dropped by R2 must then be 14.2 V - 13.6 V, or 0.6 V. Choosing a divider current of 2 mA, the value of R2 is then 0.6 V / 0.002 A = 300 Ω. R3 is calculated to be 13.6 V / 0.002 A = 6800 Ω.

### 7.9.4 Three-Terminal Voltage Regulators

The modern trend in regulators is toward the use of three-terminal devices commonly referred to as *three-terminal regulators*. Inside each regulator is a voltage reference, a high-gain error amplifier, temperature-compensated voltage sensing resistors and a pass element. Many currently available units have thermal shut-down, overvoltage protection and current foldback, making them virtually destruction-proof. It is easy to see why

regulators of this sort are so popular when you consider the low price and the number of individual components they can replace.

Three-terminal regulators have connections for unregulated dc input, regulated dc output and ground, and they are available in a wide range of voltage and current ratings. Fixed-voltage regulators are available with output ratings in most common values between 5 and 28 V. Other families include devices that can be adjusted from 1.25 to 50 V.

The regulators are available in several different package styles, depending on current ratings. Low-current (100 mA) devices frequently use the plastic TO-92 and DIP-style cases. TO-220 packages are popular in the 1.5 A range, and TO-3 cases house the larger 3 A and 5 A devices. They are available in surface mount packages too.

Three-terminal regulators are available as positive or negative types. In most cases, a positive regulator is used to regulate a positive voltage and a negative regulator a negative voltage. Depending on the system ground requirements, however, each regulator type may be used to regulate the “opposite” voltage.

**Figure 7.25A** and **B** illustrate how the regulators are used in the conventional mode. Several regulators can be used with a common-input supply to deliver several voltages with a common ground. Negative regulators may be used in the same manner. If no other common supplies operate from the input supply to the regulator, the circuits of **Figure 7.25C** and **D** may be used to regulate positive voltages with a negative regulator and vice versa. In these configurations the input supply is floated; neither side of the input is tied to the system ground.

Manufacturers have adopted a system of

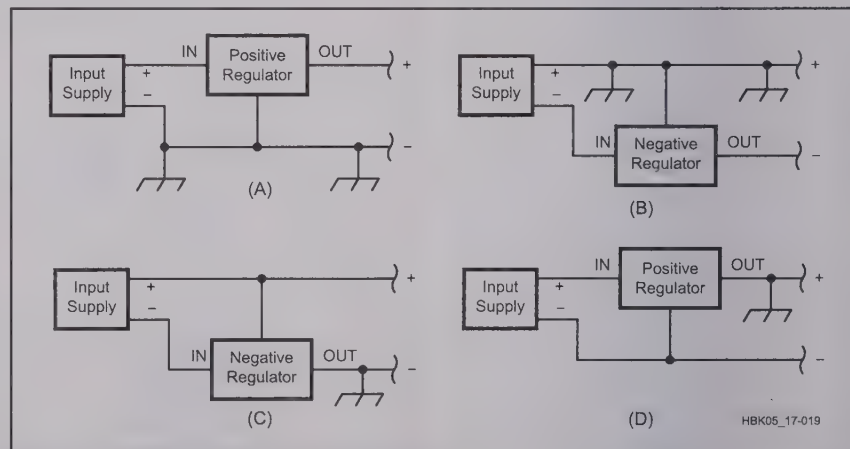

Figure 7.25 — Parts A and B illustrate the conventional manner in which three-terminal regulators are used. Parts C and D show how one polarity regulator can be used to regulate the opposite-polarity voltage.

family numbers to classify three-terminal regulators in terms of supply polarity, output current and regulated voltage. For example, 7805 describes a positive 5 V, 1.5 A regulator and 7905 a negative 5 V, 1.5 A unit. Depending on the manufacturer, the full part number might have a prefix such as LM, UA or MC, along with various suffixes (for example, LM7805CT or MC7805CTG). There are many such families with widely varied ratings available from manufacturers. More information may be found in the **Component Data and References** chapter.

## SPECIFYING A REGULATOR

When choosing a three-terminal regulator for a given application, the most important specifications to consider are device output voltage, output current, minimum and maximum input-to-output differential voltages, line regulation, load regulation and power dissipation. Output voltage and current requirements are determined by the load with which the supply will ultimately be used.

Input-to-output differential voltage is one of the most important three-terminal regulator specifications to consider when designing a supply. The differential value (the difference between the voltage applied to the input terminal and the voltage on the output terminal) must be within a specified range. The minimum differential value, usually about 2.5 V, is called the *dropout voltage*. If the differential value is less than the dropout voltage, no regulation will take place. Special *low dropout regulators* with lower minimum differential values are available as well. At the other end of the scale, maximum input-output differential voltage is generally about 40 V. If this differential value is exceeded, device failure may occur.

Increases in either output current or differential voltage produce proportional increases in device power consumption. By employing current foldback, as described above, some manufacturers ensure that maximum dissipation will never be exceeded in normal operation. **Figure 7.26** shows the relationship between output current, input-output differential and current limiting for a three-terminal regulator nominally rated for 1.5 A output current. Maximum output current is available with differential voltages ranging from about 2.5 V (dropout voltage) to 12 V. Above 12 V, the output current decreases, limiting the device dissipation to a safe value. If the output terminals are accidentally short circuited, the input-output differential will rise, causing current foldback, and thus preventing the power-supply components from being over stressed. This protective feature makes three-terminal regulators particularly attractive in simple power supplies.

When designing a power supply around

**Figure 7.26** — Effects of input-output differential voltage on three-terminal regulator current.

**Figure 7.27** — By varying the ratio of R2 to R1 in this simple LM317 schematic diagram, a wide range of output voltages is possible. See text for details.

**Figure 7.28** — The basic LM317 voltage regulator is converted into a constant-current source by adding only one resistor.

a particular three-terminal regulator, input-output voltage characteristics of the regulator should play a major role in selecting the transformer-secondary and filter-capacitor component values. The unregulated voltage applied to the input of the three-terminal device should be higher than the dropout voltage, yet low enough that the regulator does not go into current limiting caused by an excessive differential voltage. If, for

example, the regulated output voltage of the device shown in Figure 7.26 were 12 V, then unregulated input voltages of between 14.5 and 24 V would be acceptable if maximum output current is desired.

In use, all but the lowest-current regulators generally require an adequate external heat sink because they may be called on to dissipate a fair amount of power. Also, because the regulator chip contains a high-gain error amplifier, bypassing of the input and output leads is essential for stable operation.

Most manufacturers recommend bypassing the input and output directly at the leads where they protrude through the heat sink. Solid tantalum capacitors are usually recommended because of their good high-frequency capabilities.

External capacitors used with IC regulators may discharge through the IC junctions under certain circuit conditions, and high-current discharges can harm ICs. Look at the regulator data sheet to see whether protection diodes are needed, what diodes to use and how to place them in any particular application.

## Adjustable Regulators

In addition to fixed-output-voltage ICs, high-current, adjustable voltage regulators are available. These ICs require little more than an external potentiometer for an adjustable output range from 5 to 24 V at up to 5 A. The unit price on these items is only a few dollars, making them ideal for test-bench power supplies. A very popular low current, adjustable output voltage three terminal regulator, the LM317, is shown in **Figure 7.27**. It develops a steady 1.25 V reference,  $V_{REF}$ , between the output and adjustment terminals. By installing R1 between these terminals, a constant current,  $I_1$ , is developed, governed by the equation:

$$I_1 = \frac{V_{REF}}{R_1} \quad (10)$$

Both  $I_1$  and a 100  $\mu$ A error current,  $I_2$ , flow through R2, resulting in output voltage  $V_O$ .  $V_O$  can be calculated using the equation:

$$V_O = V_{REF} \left( 1 + \frac{R_2}{R_1} \right) + I_2 \times R_2 \quad (11)$$

Any voltage between 1.2 and 37 V may be obtained with a 40 V input by changing the ratio of R2 to R1. At lower output voltages, however, the available current will be limited by the power dissipation of the regulator.

**Figure 7.28** shows one of many flexible applications for the LM317. By adding only one resistor with the regulator, the voltage regulator can be changed into a constant-current source capable of charging NiCd batteries, for example. Design equations are given in the figure. The same precautions

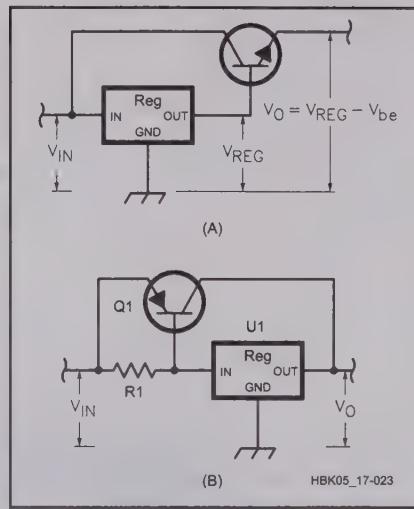

should be taken with adjustable regulators as with the fixed-voltage units. Proper heat sinking and lead bypassing are essential for proper circuit operation.

### INCREASING REGULATOR OUTPUT CURRENT

When the maximum output current from an IC voltage regulator is insufficient to operate the load, discrete power transistors may be connected to increase the current capability. **Figure 7.29** shows two methods for boosting the output current of a positive regulator, although the same techniques can be applied to negative regulators.

In A, an NPN transistor is connected as an emitter follower, multiplying the output current capacity by the transistor beta. The shortcoming of this approach is that the base-emitter junction is not inside the feedback loop. The result is that the output voltage is reduced by the base-emitter drop, and the load regulation is degraded by variations in this drop.

The circuit at B has a PNP transistor

“wrapped around” the regulator. The regulator draws current through the base-emitter junction, causing the transistor to conduct. R1 provides bias voltage for turning on Q1

**Figure 7.29** — Two methods for boosting the output-current capacity of an IC voltage regulator. Part A shows an NPN emitter follower and B shows a PNP “wraparound” configuration. Operation of these circuits is explained in the text.

so that U1 doesn't see the excess current. For example, a 6 Ω resistor will limit the current U1 sees to 100 mA. The IC output voltage is unchanged by the transistor because the collector is connected directly to the IC output (sense point). Any increase in output voltage is detected by the IC regulator, which shuts off its internal-pass transistor, and this stops the boost-transistor base current.

## 7.10 “Crowbar” Protective Circuits

Electronic components *do* fail from time to time. In a regulated power supply, the only component standing between an elevated dc source voltage and your transceiver is one transistor, or a group of transistors wired in parallel. If the transistor, or one of the transistors in the group, happens to short internally, your equipment could suffer lots of damage.

To safeguard the load equipment against possible overvoltage, some power-supply manufacturers include a circuit known as a *crowbar*. This circuit usually consists of a

silicon-controlled rectifier (SCR) or thyristor connected directly across the output of the power supply, with an over-voltage-sensing trigger circuit tied to its gate. The SCR is large enough to take the full short-circuit output current of the supply, as if a crowbar were placed across the output terminals, thus the name.

In the event the output voltage exceeds the trigger set point, the SCR will fire, and the output is short circuited. The resulting high current in the power supply (shorted

output in series with a series pass transistor failed short) will blow the power supply's line fuses. This is a protection for the supply as well as an indicator that something has malfunctioned internally. For these reasons, never replace blown fuses with ones that have a higher current rating.

An example of a crowbar overvoltage protection circuit can be found as a project at the end of this chapter. It provides basic design equations that can be adapted to a wide range of power supply applications.

# 7.11 DC-DC Switchmode Power Conversion

Very often the power source is dc, such as a battery or solar cell, or the output of an unregulated rectifier connected to an ac source. In most applications high conversion efficiency is desired, both to conserve energy from the source and to reduce heat dissipation in the converter. When high efficiency is needed, some form of switching circuit will be employed for dc-dc power conversion. Besides being more efficient, switching circuits are usually much smaller and lighter than conventional 60 Hz, transformer-rectifier circuits because they operate at much higher frequencies — from 25 to 400 kHz or even higher. Switching circuits go by many names; *switching regulators* and *switchmode converters* are just two of the more common names.

The possibility of achieving high conversion efficiency stems directly from the use of switches for the power conversion process, along with low-loss inductive and capacitive elements. An active switch is a device that is either ON or OFF and the state of the switch (ON or OFF) can be controlled with an external signal. The loss in the switch is always the product of the voltage across the switch and the current flowing through it ( $P = E \times I$ ).

In the ON (conducting) state the voltage drop across the switch is small, and in the OFF state the current through the switch is small. In both cases the losses can be small relative to the power level of the converter. During transitions between ON and OFF states, however, there will simultaneously be both substantial voltage across the switch and significant current flowing through it. This results in power dissipation in the switch, called *switching loss*. This loss is minimized by making the switching transitions as short as possible. In this way even though the instantaneous power dissipation may be high, the average loss is low because of the small duty cycle of the transitions. Of course the more frequently the switch operates (higher switching frequency), the higher the average loss will be and this eventually limits the maximum operating frequency. A limitation on the lower end of the switching frequency range is that it needs to be above audible frequencies (>25 kHz).

This is quite different from the linear regulators discussed earlier in which there is always some voltage drop across the pass transistor (which is acting as a controlled variable resistor) while current is flowing through it. As a result the efficiency of a linear regulator can be very low, often 65% or less. Switchmode converters on the other hand will typically have efficiencies in the range of 85 to 95%.

Switchmode circuits can also generate radio-frequency interference (RFI) through VHF because of switching frequency

harmonics and ringing induced by the rapid rise and fall times of voltage and current. In attempting to minimize the ON-OFF transition time, significant amounts of RF energy can be generated. To prevent RFI to sensitive receivers, careful bypassing, shielding and filtering of both input and output circuits is required. (RFI from switchmode or “switching” supplies is also discussed in the chapter on **RF Interference**.)

There are literally hundreds of different switchmode circuits or “topologies” (see Reference 2) but we will only look at a few of those most commonly used by amateurs. Fortunately, the characteristics of the simpler circuits are to a large extent replicated in more complex circuits so that an understanding of the basic circuits provides an entry point to many other circuits.

The following discussion is only an introduction to the basics of switchmode converters. To really get a handle on designing these circuits the reader will have to do some additional reading. Fortunately a very large amount of useful information is freely available on-line. Many useful application notes are available from semiconductor manufacturers, and additional information can be found on the websites of filter capacitor and ferrite core manufacturers (see References 3 and 4). There are also numerous books on

the subject, often available in libraries and used book stores.

Switchmode circuits can and have been implemented with many different kinds of switches, from mechanical vibrators to vacuum and gas tubes to semiconductors. Today however, semiconductors are the universal choice. For converters in the power range typical of amateur applications (a few watts through 2-3 kW) the most common choices of semiconductor switches would be either bipolar junction transistors (BJTs) or power MOSFETs. BJTs have a long history of use in switchmode applications, but to employ BJTs in a reliable and trouble-free circuit requires a relatively sophisticated understanding of them. While the MOSFET must also be used carefully, it is generally easier for a newcomer. The following circuit diagrams will show MOSFETs or generic switch symbols for the switches but keep in mind that all of the circuits can be implemented with other types of switches.

## 7.11.1 The Buck Converter

A schematic for a *buck converter* is shown in **Figure 7.30A**. This circuit is called a “buck” converter because the output voltage is always less than or equal to the input voltage. Power is supplied from the dc source ( $V_s$ )

Figure 7.30 — Typical buck converter.

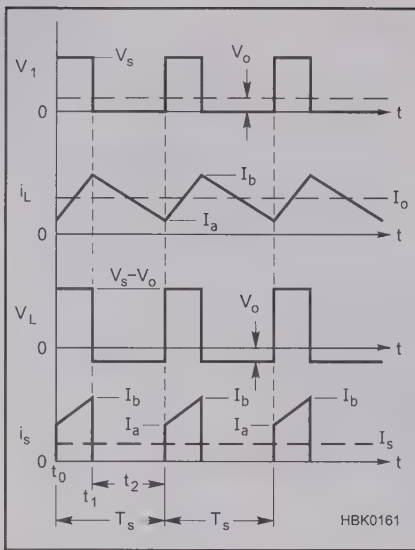

Figure 7.31 — Waveforms in a buck converter.

through the input filter (L1, C1) to the drain of the switch (Q1). The load (R) is connected across the output filter (L, C2).

The equivalent circuit when Q1 is ON is shown in Figure 7.30B (where the input filter components are assumed to be part of  $V_S$ ).  $V_S$  is connected to one end of the output inductor (L) and, because  $V_O < V_S$ , current flows from the source to the output delivering energy from the source to the output and also storing energy in L. At some point Q1 is turned OFF and the current flowing in L commutates (switches) to D1, as shown in Figure 7.30C. (The current in an inductor cannot change instantaneously, so when Q1 turns OFF, the collapsing magnetic field in L pulls current through shunt diode D1, called a *free-wheeling diode*.) The energy in L is now being discharged into the output. This cycle is repeated at the switching frequency ( $f_s$ ). The ratio of the switch ON-time to the total switching period ( $T_s = t_{on} + t_{off} = 1/f_s$ ) is called the *duty cycle* (D).

Typical voltage and current waveforms for a buck converter are shown in **Figure 7.31** where  $V_1$  is the voltage at the junction of Q1, D1 and L (see Figure 7.30A).

The interval  $0-t_1$  corresponds to the ON time of Q1 and  $T_s - t_1$  corresponds to the OFF time ( $T_s = t_1 + t_2$ ). From the waveforms it can be seen that the current in the inductor rises while Q1 is ON and falls while Q1 is OFF. The energy in the inductor is proportional to  $LI^2/2$ .

The input current ( $I_s$ ) is pulsating at the switching frequency. This pulsation in the input current is the reason for the input filter (L1 and C1). We need to keep this high frequency noise (the ac component of the pulsation) out of the source. All switchmode converters require some form of filter on the input to

Figure 7.32 — Change in output voltage to input voltage ratio ( $M = V_O/V_S$ ) as a function of switch duty cycle (D).

keep switching noise out of the source. Some form of filter is also required on the output to keep the switching noise out of the load. In Figure 7.30, L and C2 form the output filter. For applications requiring low ripple it would not be unusual to see an additional stage of L-C filtering added to the output.

The voltage waveform ( $V_1$ ) at the input to the output filter (L and C2) is pulse-width modulated (PWM) and  $V_O$  (the dotted line in the waveform for  $V_1$  in Figure 7.31A) is the time average of  $V_1$ .  $V_O$  is controlled or regulated by adjusting the duty cycle of Q1 in response to input voltage or output load changes. If we increase D we increase  $V_O$  up to the point where  $D = 1$  (the switch is ON all the time) and  $V_O \approx V_S$ . If we never turn Q1 on ( $D = 0$ ) then  $V_O = 0$ . Normal operation will be somewhere between these extremes.

The inductor current waveform in Figure 7.31 does not go to zero while Q1 is OFF. In other words, not all of the energy stored in L is discharged into the output by the end of each switching cycle. This is a common mode of operation for heavier loads. It is referred to as the *continuous conduction mode* or CCM, where the conduction referred to is the current in L. There is another possibility: during the time Q1 is off all of the energy in L may be discharged and for some period of time the inductor current is zero until Q1 is turned ON again. This is referred to as the *discontinuous conduction mode* or DCM. A typical converter will operate in CCM for heavy loads but as the load is reduced, at some point the circuit operation will change to DCM. CCM is often referred to as the “heavy load” condition and DCM as the “light load” condition.

This distinction turns out to be very important because the behavior of the circuit, for

both small signal and large signal, is radically different between the two modes. **Figure 7.32** shows the relationship between the duty cycle (D) of Q1 and the ratio of the output voltage to the input voltage ( $M = V_O/V_S$ ) as a function of  $\tau_L$  in Figure 7.32:

$$\tau_L = \left( \frac{L}{R} \right) f_s \quad (12)$$

$\tau_L$  is just a convenient way to make Figure 7.32 more general by tying together the variables L, R and  $f_s$ . Smaller values for  $\tau_L$  correspond to lighter loads (larger values for R). As can be seen in Figure 7.32, for very light loads the higher values for D have little effect on the output/input voltage ratio. This is basically charging of the output capacitor (C2) to the peak value of  $V_1 \approx V_S$ .

For CCM operation, M is a linear function of D. As we vary the load,  $V_O$  will remain relatively constant. But when we go into DCM, the relation between D and M is no longer linear and in addition is heavily dependent on the load:  $V_O$  will vary as the load is changed unless the duty cycle is varied to compensate. This kind of behavior is typical of all switching regulators, even those not directly related to the buck converter. In fact, we have seen this behavior already in the section on choke input filters in Figure 7.17 where the output voltage is close to the peak input voltage for light loads and decreases as the load increases until a point is reached ( $I_C$ ) where  $V_O$  stabilizes.

In a buck converter the value for the critical inductance ( $L_C$ ) can be found from:

$$L_c = R \left( \frac{1 - M}{2 f_s} \right) \quad (13)$$

This looks just like equation 6 (in the

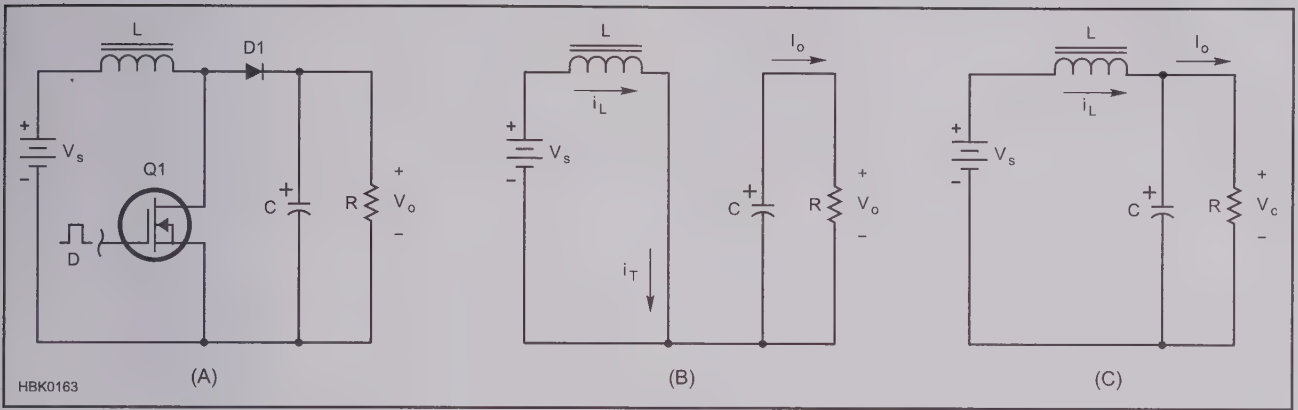

Figure 7.33 — Typical boost converter.

earlier section on choke-input filters) with  $A = 2fs / (1 - M)$ ! The two phenomena are the same: peak charging versus averaging of  $V_1$ .

### 7.11.2 The Boost Converter

A *boost converter* circuit is shown in **Figure 7.33A**. This circuit is called a “boost” converter because the output voltage is always greater than or equal to the input voltage.

When Q1 is ON (**Figure 7.33B**), L is connected in parallel with the source ( $V_S$ ) and energy is stored in it. During this time interval load energy is supplied from C. When Q1 turns OFF (**Figure 7.33C**), L is connected via D1 to the output and the energy in L, plus additional energy from the source, is discharged into the output. The value for L,  $V_S$  and length of time it is charged determines the energy stored in L. Again we have the possibilities that either some (CCM) or all (DCM) the energy in L is discharged during the OFF-time of Q1. The variation in the ratio of the output-to-input voltage ( $M$ ) with duty cycle is shown in **Figure 7.34**.

As we saw in the buck converter, the conduction mode of L is important. In an ideal converter operating in CCM, the output voltage is substantially independent of load and  $M \approx 1 / (1 - D)$ . In realistic boost converters there is an important limit on the CCM value for  $M$ . In an ideal boost converter you could make the boost ratio ( $M$ ) as large as you wish but in real converters the parasitic resistances associated with the components will limit the maximum value of  $M$  as indicated by the dashed line for CCM operation. The exact shape of this part of the control function will depend on the ratio of the parasitic resistance within the converter to the load resistance (see Reference 2).

There is also another very important practical effect of this limitation on the peak value for  $M$ . When the duty cycle is increased beyond the point of maximum  $M$  (this occurs at  $D = 0.9$  in **Figure 7.34**), the sign of the slope of the control function changes so that

Figure 7.34 — DC control characteristic for a boost converter.  $M = V_o/V_s$ ,  $D =$  duty cycle of Q1 and  $\tau_L = f_s (L/R)$ .

the control loop will change from negative feedback to positive feedback. This can cause the converter to latch up under some load conditions if the control circuit allows  $D$  to exceed the value at maximum  $M$ . In boost converters the design of the control circuit must limit the maximum value for  $D$  so that latch-up is not possible although this may be difficult for overload conditions.

As in the case of the buck converter, in DCM the control function for  $M$  is very different from what it is in CCM and is strongly dependent on the load  $R$ . One advantage of the DCM operation is that the limitation on the maximum value for  $M$  because of parasitic circuit resistances is not nearly so pronounced. By operating in DCM it is possible to have  $M > 5$ .

An important limitation of the boost converter is that with Q1 turned OFF, you have no control over  $V_o$ .  $V_o$  will simply equal  $V_S$ . In addition, when  $V_S$  is turned on there will

be an inrush current through D1, into C which cannot be controlled by Q1. In the case of the buck converter, if Q1 is kept OFF when  $V_S$  is turned on, there will be no inrush current charging the output filter capacitor ( $C_2$ ). In the buck converter  $C_2$  can be charged slowly by ramping up the duty cycle of Q1 during turn-on but this is not possible in the boost converter.

### 7.11.3 Buck-Boost and Flyback Converters

**Figure 7.35** shows an example of a *buck-boost converter*. The name “buck-boost” comes from the fact that the magnitude of the output voltage can be either greater or less than the input voltage.

When S1 is ON,  $V_S$  is applied across L and energy is stored in it. During the ON time of Q1, D1 is reverse-biased and non-conducting. The output voltage ( $V_o$ ) across

Figure 7.35 — An example of a buck-boost converter.

the load ( $R$ ) is supported solely from the energy stored in  $C$ . When  $S1$  is OFF, the energy in  $L$  is discharged into  $C$  through  $D1$ . Note that the polarity of  $V_o$  is inverted from  $V_s$ : positive  $V_s$  means negative  $V_o$ . The relationship between  $V_o$  and  $V_s$  as a function of duty cycle is shown in Figure 7.36.

This graph closely resembles that for the boost converter (Figure 7.34) with one important exception:  $|M|$  begins at zero. This allows the magnitude of the output voltage to be either below or above the source voltage, hence the name “buck-boost.”

### FLYBACK CONVERTERS

Simple buck-boost converters are occasionally used, but much more often it is the transformer-coupled version of this converter, referred to as a *flyback converter*, that is employed. The relationship between the flyback

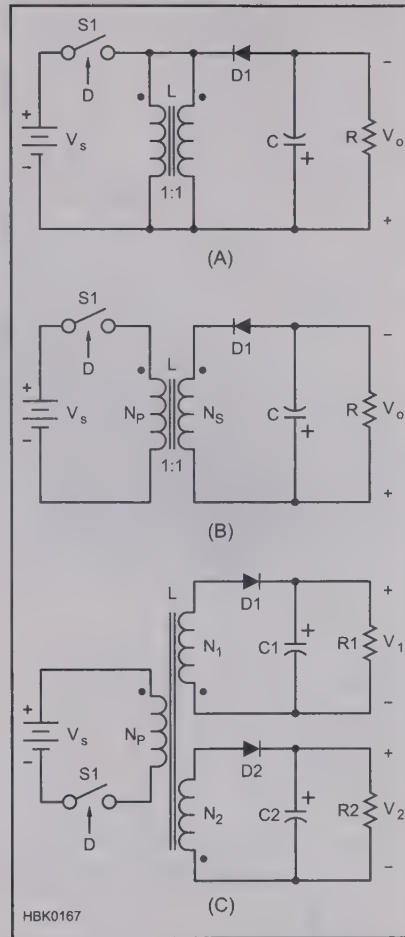

Figure 7.37 — The relationship between buck-boost and flyback converters.

and buck-boost converters is illustrated in Figure 7.37. In Figure 7.37A we have a standard buck-boost converter, the only change from Figure 7.35 being two parallel and equal windings on the inductor. In Figure 7.37B we remove the links at the top and bottom of the two parallel windings, converting the inductor into a transformer with primary and secondary windings. The only change is that when  $S1$  is ON, current flows in the primary of the transformer and when  $S1$  is OFF, the current flows in the secondary winding delivering the stored energy to the output. At this point the circuit operation is the same except that we have introduced primary-to-secondary galvanic isolation.

We are now free to change the turns ratio from 1:1 to anything we wish. We can also change the polarity of the output voltages and/or add more windings with other voltages and additional loads as shown in Figure 7.37C, a typical example of a flyback converter. These are most often used in the power range of a few watts to perhaps 200 W. For higher power levels other circuits are generally more useful.

The advantages of the flyback converter lie in its simplicity. It requires only one power switch and one diode on each of the output windings. The inductor is also the isolation transformer so you have only one magnetic component. The disadvantage of this circuit is that both in the input and output current waveforms are pulsating. The result is that more filtering is required and the filter capacitors are exposed to high RMS currents relative to the power level.

Figure 7.36 — DC control function for an ideal buck-boost converter.  $M = V_o/V_s$ ,  $D$  = duty cycle of  $Q1$  and  $\tau_L = f_s(L/R)$ .

### 7.11.4 The Forward Converter

The buck converter has many useful properties but it lacks input-to-output galvanic isolation, the ability to produce output voltages higher than the input voltage, and/or multiple isolated output voltages for multiple loads. We can overcome these drawbacks by inserting a transformer between the switch ( $S1$ ) and the shunt diode ( $D1$ ). To make this simple idea work however, we also have to add a diode in series with the output of the transformer ( $D2$ ), and a third winding ( $N_R$ ) with another diode ( $D3$ ) to the transformer. This is done to provide a means for resetting the core (returning the magnetic flux to zero) by the end of each switching cycle. The result is the *forward converter* shown in Figure 7.38.

The circuit in A is the one just described. The variation in B uses two switches ( $S1$  and  $S2$ ), which switch ON and OFF *simultaneously* instead of one but eliminates the need for a reset winding on the transformer. For the circuit in A and a given input voltage, the voltage across the switch (in the OFF state) will be equal to  $V_s$  plus the reset voltage during the OFF-time. Typically the peak switch voltage

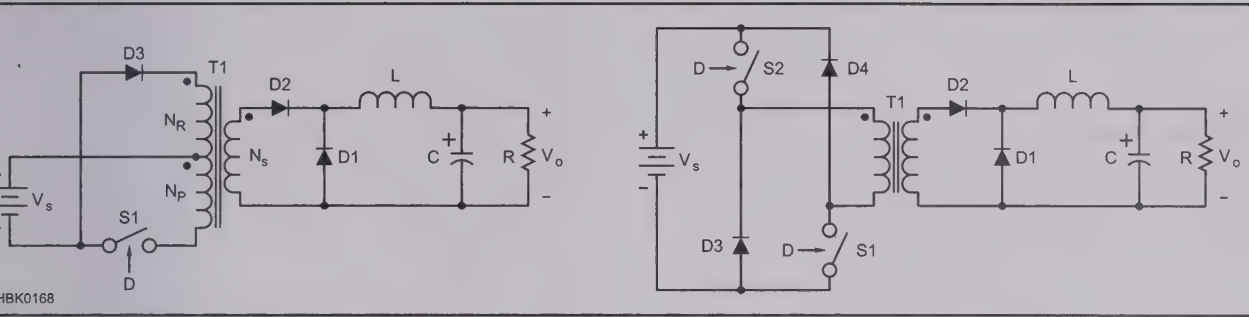

Figure 7.38 — Example of a forward converter.

Figure 7.39 — Example of a parallel quasi-square wave dc-dc

will be about  $2V_s$ . In the circuit shown in B the switch voltage is limited to  $V_s$  which is very helpful at higher line voltages. These circuits behave just like a buck converter except you can now have multiple isolated outputs with arbitrary voltages and polarities. These circuits are typically used in converters with power levels of 100 to 500 W.

### 11.5 Parallel, Half and Full-Bridge Converters

As the power level increases it becomes advantageous to use more switches in a

somewhat more complex circuit. For applications where the input voltage is low ( $<100V$ ) and the current high, the push-pull *quasi-square wave* circuit shown in **Figure 7.39** is often used.

S1 and S2 are switched on alternately with duty cycles  $<0.5$ . The output voltages are controlled by the duty cycle,  $D$ . The peak switch currents are equal to the input current but the peak switch voltages will be  $2V_s$ .

This circuit is still just a buck converter, but with an isolation transformer added that allows multiple outputs with different voltages above or below the input voltage. It would

be very common to have a 5 V, high-current output and  $\pm 12$  V, lower-current outputs, for example. This converter is typically used for operation from vehicular power with loads up to several hundred watts.

Operating directly from rectified ac utility power usually means that  $V_s$  will be 200 V or more. For these applications, **Figure 7.40** shows how the switches are configured in either a half- (Figure 7.40A) or full-bridge (Figure 7.40B) circuit.

In A, S1 and S2 switch alternately and are pulse-width modulated (PWM) to control the output. CA and CB are large capacitors that form a voltage divider with  $V_s/2$  across each capacitor. The peak switch voltages will be equal to  $V_s$  but the switch currents will be  $2I_s$ . The peak voltage across the primary winding will be  $V_s/2$ . This circuit would typically be used for off-line applications with output powers of 500 W or so.

In B, S1 and S4 switch simultaneously alternating with S2 and S3 which also switch simultaneously. The output is controlled by PWM. The peak switch voltage will be equal to  $V_s$  and the peak switch current close to  $I_s$  (the peak value is a little higher due to ripple on the inductor current which is reflected back into the primary winding). The full-bridge circuit is typically used for power levels of 500 W to several kW.  $C_s$  is present in the full-bridge circuit to prevent core saturation due to any asymmetry in the primary PWM voltage waveforms. Cs should be a non-polarized capacitor since differences in duty cycle

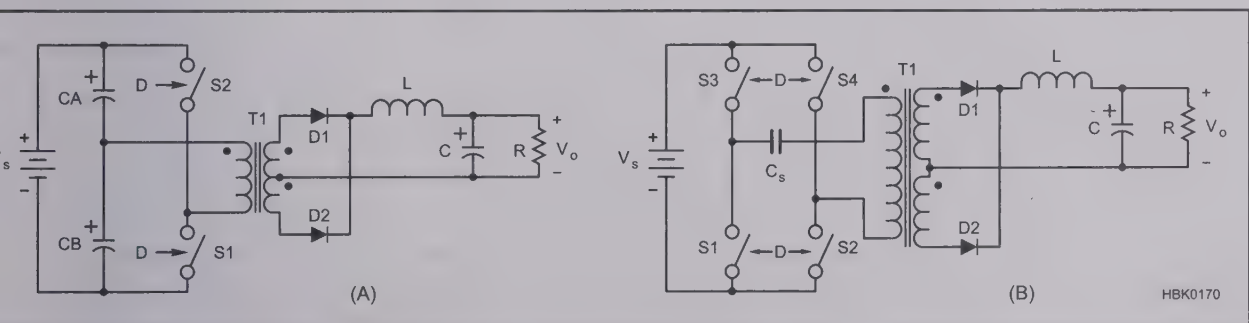

Figure 7.40 — Examples of half and full-bridge quasi-square wave dc-dc converters.

between S1-4 can create dc voltages of either polarity across it.

### 7.11.6 Building Switchmode Power Supplies

Selecting a switching circuit or topology is just the first step in building a practical switchmode power supply. In the actual circuit you will have to sample the output voltage, provide a voltage reference against which to compare the output, include a modulator that will convert the error voltages to a variable-duty cycle signal and finally provide correct drive to the power switches. Fortunately, all of these functions can be provided with readily available integrated

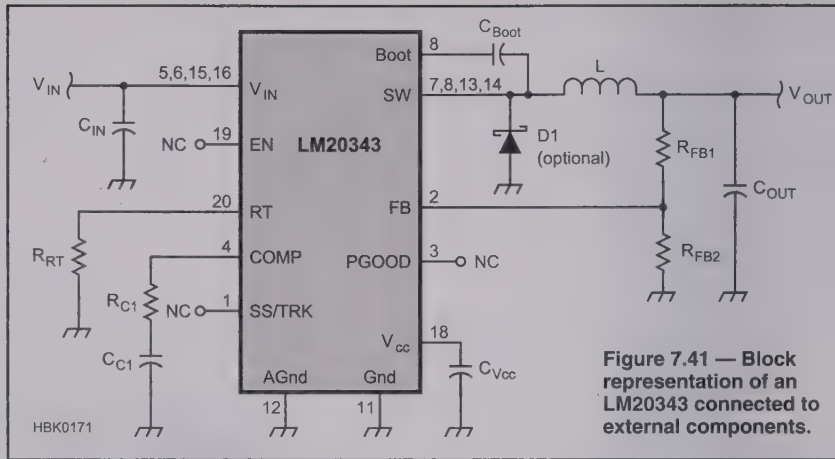

Figure 7.41 — Block representation of an LM20343 connected to external components.

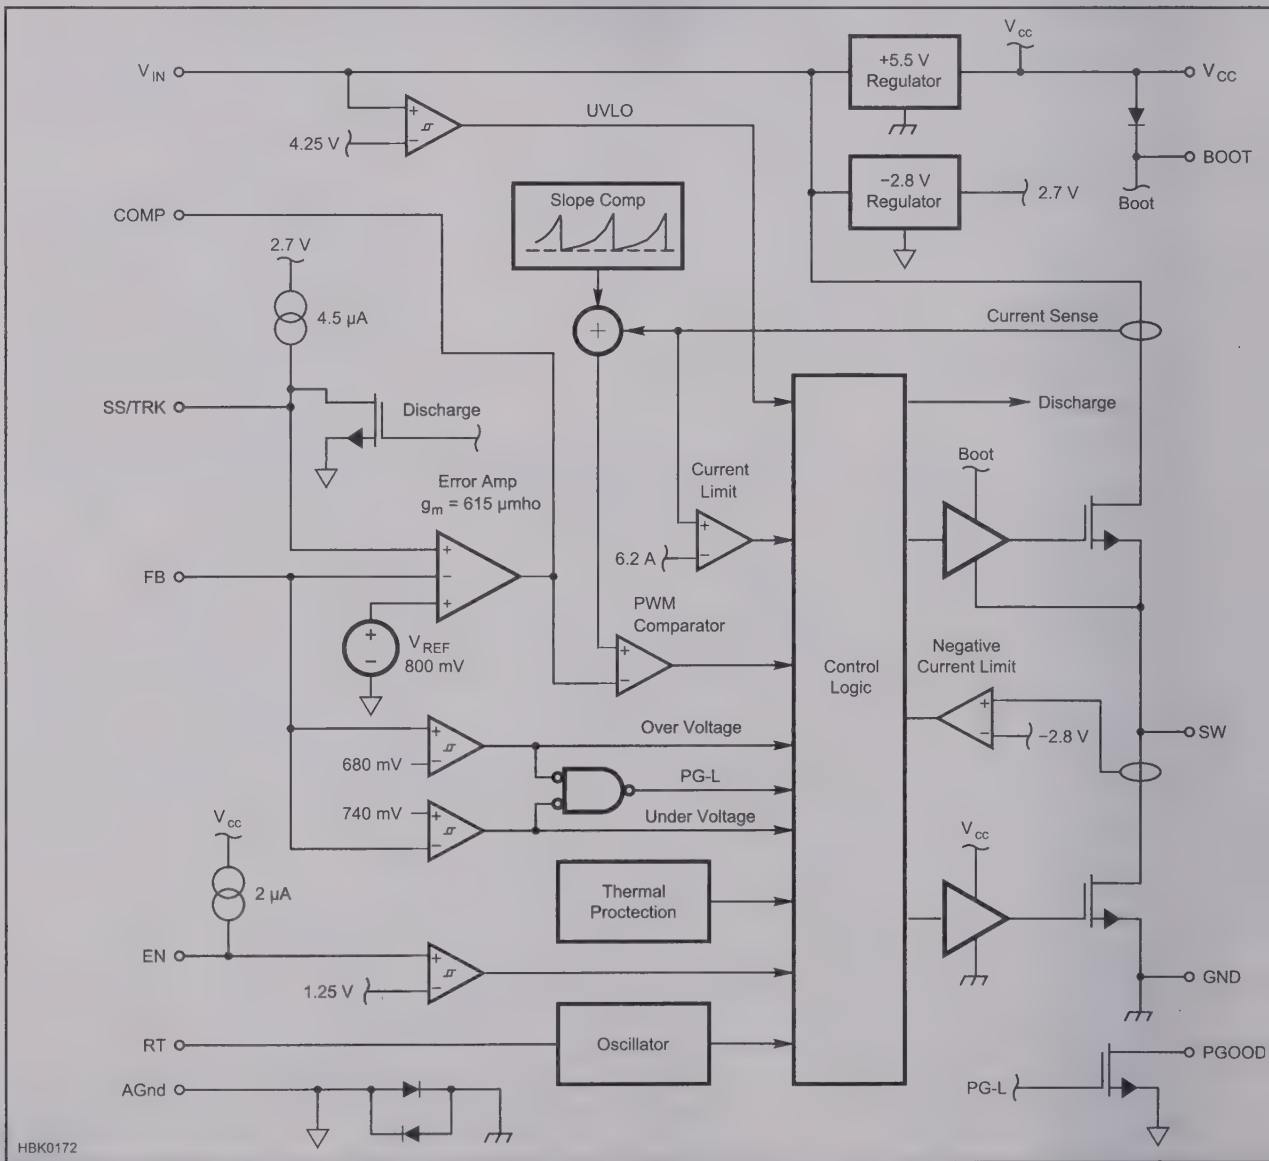

Figure 7.42 — Internal block diagram for the LM20343.

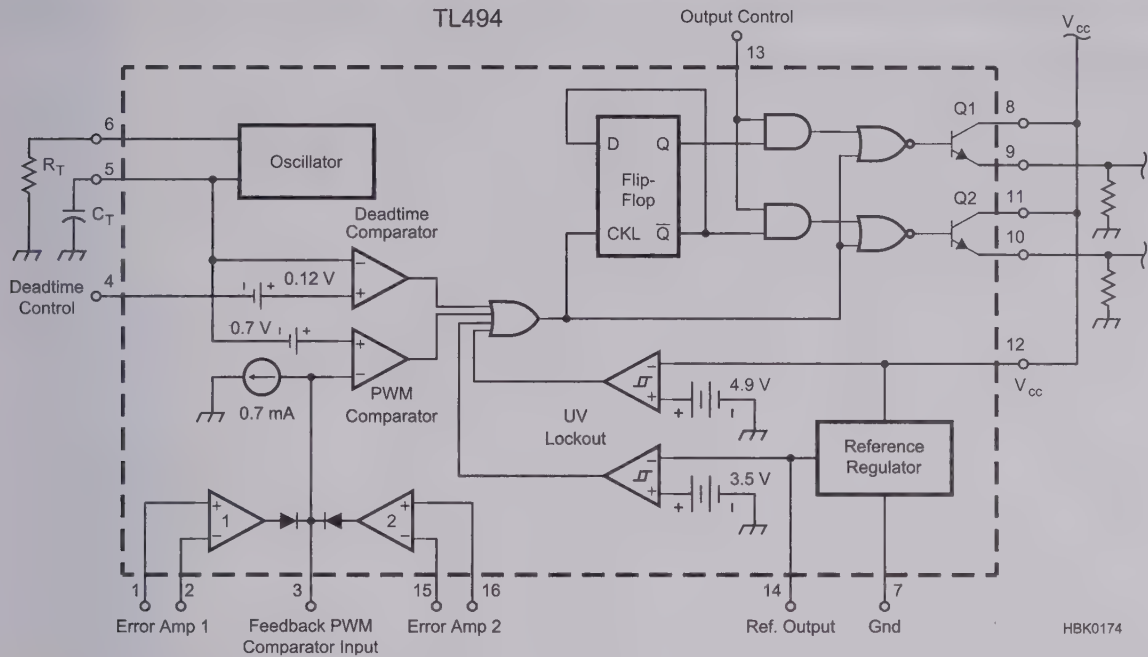

Figure 7.43 — Internal block diagram representation for the TL494.

circuits and a few external components. These ICs typically come with extensive applications information.

Particularly for low power applications (<100 W) there are ICs that provide all the control functions *and* the power switch. In some cases a power diode is also included. Figure 7.41 gives an example of one of these ICs. Similar ICs are made by many different manufacturers.

The IC provides most of the components for a buck converter but some external components are still needed: filter capacitors ( $C_{IN}$ ,  $C_{OUT}$ ,  $C_{VCC}$ ), the output inductor (L), output voltage sensing ( $R_{FB1}$  and  $R_{FB2}$ ) and components to set the switching frequency ( $R_{C1}$  and  $C_{C1}$ ). The shunt diode (D1) is marked as optional because there is an internal switch that can perform this function for lower powers.

Figure 7.42 and Figure 7.43 show the internal block-diagram of typical voltage regulator control ICs. (See the manufacturer data sheets for application information and reference designs.) In addition to the control functions there are also some protective functions such as input under- and overvoltage protection, over-temperature (thermal) protection, over-current limiting and slow-starting

(slowly ramping up D) to limit inrush current at turn-on. ICs similar to this one are available for boost, buck-boost and flyback converters, as well as many other topologies. There are also ICs available that implement more complex control schemes such as current mode control and feed-forward compensation.

### 7.11.7 Switchmode Control Loop Issues

We do not have the space in this book to explain all the control issues associated with switchmode converters, but it is important to recognize that designing stable, high performance control loops for switchmode converters is a much more complex task than it would be for a series pass-regulator or an audio amplifier. All we can do here is to alert the reader to some of the issues and suggest consulting Reference 2 with detailed explanations and examples. In addition, there are numerous books and applications notes on switchmode converter design that go into the necessary detail.

The complexities arise from the inherent behavior of switchmode circuits. This

behavior is often non-intuitive and sometimes even bizarre. As we've seen already, the dc behavior differs dramatically between CCM and DCM modes of operation. This difference is even more pronounced in the small-signal control-to-output characteristics. It is very common to see poles and zeros in the control system's response (see the **Circuits and Components** chapter) that move with input voltage, duty cycle and/or load. Fixed double-poles can change to moving single-poles. Moving right-half-plane zeros (this is a zero with decreasing phase-shift instead of increasing phase-shift with frequency) are inherent in CCM operation of boost and buck-boost circuits and their derivatives. There can also be large signal instabilities such as oscillations at sub-harmonics of the switching frequency and occasionally chaotic response to large load current or line voltage changes.

This is not intended to discourage readers from working with switchmode converters, but to simply alert them in advance to some of the difficulties. Once a basic understanding is achieved, the design of switchmode converters can be very interesting and rewarding.

## Switchmode Converter Design Aids

Today, there are hundreds of ICs on the market, from dozens of manufacturers, aimed at controlling the power conversion process. These devices have grown from their simplest forms when introduced over 20 years ago to include a long list of ancillary functions aimed at reducing the supporting circuitry and enhancing the quality and efficiency of the power conversion process. As a result, the task of designing these ICs into the final power conversion circuit has actually become more complex. To the circuit designer who is below the expert level, the task can seem daunting, indeed.

In answer to this problem, many IC manufacturers provide computer-aided design tools that greatly simplify the task of using their products. These tools take several forms, from the most rudimentary cookbook-style guides, to full-fledged circuit simulation tools like *SPICE*. The purpose of these tools is to help the designer pick appropriate

resistors, capacitors and magnetic components for the design, and also to estimate the stresses on the power-handling components.

These design tools fall generally into two types: equation-based design tools and iterative circuit simulators. The differences are that the equation-based tools simply automate the basic design equations of the circuit, providing recommended choices for the components and then solving equations to compute the voltage, current and power stresses on the components. In some cases, thermal analysis is also included.

The simulators, on the other hand, use detailed mathematical models for the components and provide both dc and ac simulation of the circuits. This allows the user to see the dynamic behavior of the circuit. The simulation includes details during the switching intervals and shows rise times, parasitic effects caused by component

capacitance, internal resistance and other characteristics.

In modern power converter design, the magnetic components — transformers, power inductors and filter inductors — can be a challenge to the designer not versed in magnetic design. As a result, the vendors of these parts usually furnish design tools created specifically to the design of these components and/or the proper choice of off-the-shelf versions.

The reader is encouraged to explore design aids available from the websites of manufacturers (**Table 7.A1**). The following is far from complete, but should give the reader valuable insight into the vast array of available tools. Remember also that manufacturers of passive components such as capacitors, resistors, heat sinks and thermal hardware may also have helpful and informative design aids on their websites. — *Chuck Mullett, KR6R*

## 7.12 High-Voltage Techniques

The construction of high-voltage supplies requires special considerations in addition to the normal design and construction practices used for lower-voltage supplies. In general, the builder needs to remember that physical spacing between leads, connections, parts and the chassis must be sufficient to prevent arcing. Also, the series connection of components such as capacitor and resistor strings needs to be done with consideration for the distribution of voltage stresses across the components. High-voltages can constitute a safety hazard and great care must be taken to limit physical access to components and wiring while high potentials are present.

### 7.12.1 High-Voltage Capacitors

For reasons of economy and availability, electrolytic capacitors are frequently used for output filter capacitors. Because these capacitors have relatively low voltage ratings (<600 V), in HV applications it will usually be necessary to connect them in series strings to form an equivalent capacitor with the capability to withstand the higher applied voltage. Electrolytic capacitors have relatively high leakage currents (low leakage resistance) especially at higher temperatures.

To keep the voltages across the capacitors in the series string relatively constant, equal-value bypassing resistors are connected across each capacitor. These *equalizing resistors* should have a value low enough to equalize differences in capacitor leakage resistance between the capacitors, while high enough not to dissipate excessive power. Also, capacitor bodies need to be insulated from the chassis and from each other by mounting them on insulating panels, thereby preventing arcing to the chassis or other capacitors in the string. The insulated mounting for the capacitors is often plastic or other insulating material in board form. A typical example from a commercial amplifier that implements some of the guidelines given in this section is shown in Figure 7.44.

Equalizing resistors are needed because of differences in dc leakage current between different capacitors in the series string. The data sheet for an electrolytic capacitor will usually give the dc leakage current at 20 °C in the form of an equation. For example:

$$I_{\text{leakage}} = 3\sqrt{CV} \quad (14)$$

where

C = the value in  $\mu\text{F}$

V = the working voltage

$I_{\text{leakage}}$  = leakage current in  $\mu\text{A}$ .

Keep in mind that the leakage current will

### High Voltage Safety Considerations

We are all so besieged these days with verbose safety warnings on mostly harmless consumer goods that it is easy to forget that some things really are dangerous. High voltage power supplies definitely fall into this category, especially since many amateurs are accustomed to solid-state circuits and seldom encounter any dc voltage higher than 12 V. **This power supply produces voltages that are highly lethal.** So please take to heart the following 10 precautions. Furthermore, don't expect to learn from your mistakes, because if you don't exercise proper precautions the first time, you're unlikely ever to have a second chance.

1. Don't let your reach exceed your grasp. High voltage power supplies are not a project for beginners. You should not attempt to build this type of power supply unless you're a seasoned builder who has experience with high voltage circuitry.
2. Young amateurs should not attempt this type of project alone. Working with high voltages requires the maturity and patience that comes with age and experience.
3. Never work around high voltage when you are tired, stressed, or in a hurry.
4. Never work around high voltage after drinking alcohol. Even one beer or glass of wine can impair your judgment and make you careless.
5. Before working on a high voltage power supply, always follow these three steps: Unplug (the ac power cord), discharge (the filter capacitors) and verify (that the output voltage is truly zero). Time-honored practice is to use a "chicken stick" (a wooden dowel or PVC tube, with one end attached to a grounded wire) to make sure filter capacitors are completely discharged. See Figure 7.46 for an example.
6. When working on a high voltage power supply, remember that a dangerous time is after the power supply has just been turned off, but before the filter capacitors have fully discharged. A 50  $\mu\text{F}$  capacitor charged to 4000 V holds a potentially deadly 400 joules of energy. Even with bleeder resistors, it can take a minute or more to discharge fully.
7. When removing a recently discharged filter capacitor from a power supply, tie the two terminals together with wire. Large high voltage capacitors can self-charge to dangerous levels if the terminals are left floating.
8. Don't stake your life on the expectation that bleeder resistors, fuses, circuit breakers, relays, and switches are always going to do their job. Even though modern components are very reliable, it is safe practice always to assume the worst.
9. Don't build a high voltage power supply if you don't understand how the circuit works. High power amplifiers and power supplies are not "plug-and-play" projects with step-by-step instructions. Builders must be knowledgeable enough to improvise, make component substitutions, and implement design changes.
10. With high voltage projects, it doesn't pay to be "penny wise and pound foolish." Use high quality components throughout and save your forty-year-old junk box parts for projects where safety and reliability are not paramount requirements.

(The preceding guidelines are taken from the QEX article "A Deluxe High Voltage Supply" by Jim Garland, W8ZR, which is included with this book's downloadable supplemental content.)

Figure 7.44 — Example of the filter capacitor/bleeder resistor installation in a high voltage power supply.

increase as the capacitor temperature rises above 20 °C. A value of 3 to 4 times the 20 °C value would not be unusual because of normal heating.

We can use an approximation which includes allowance for heating to determine the maximum value of the divider resistors:

$$R \leq \frac{V_r - V_m}{I_{\text{leakage}}} \quad (15)$$

where

$V_r$  = the voltage rating of the capacitor  
 $V_m$  = the voltage across the capacitor during normal operation.

A typical 3000 V power supply might use eight 330  $\mu\text{F}$ , 450 V capacitors in series. In that case,  $V_r = 450$  V,  $V_m = 375$  V and  $I_{\text{leakage}} = 1.06$  mA. This would make  $R = 68$  k $\Omega$  (standard value) or a total of 544 k $\Omega$  for the resistor string. With 3000 V across the resistor string, the total power dissipation would be 16.5 W or about 2.06 W per resistor. To be conservative you should use resistors rated for at least 4 W each.

The equalizing resistors may dissipate significant power and become quite warm. It is important that these resistors do not heat the capacitors they are associated with, as this will increase the capacitor leakage current. You also have to be careful that the heat from the resistors is not trapped under the plastic support panels. The best practice is to place the resistors above the capacitors and their mounting structure allowing the heat to rise unobstructed as shown in Figure 7.44.

### OIL-FILLED CAPACITORS

For high voltages, oil-filled paper-dielectric capacitors are superior to electrolytics because they have lower internal impedance at high frequencies, higher leakage resistance and are available with much higher working voltages. These capacitors are available with values of several microfarads and have working voltage ratings of thousands of volts. On the other hand, they can be expensive, heavy and bulky.

Oil-filled capacitors are frequently offered for sale at flea markets at attractive prices. One caution: It is best to avoid older oil-filled capacitors because they may contain polychlorinated biphenyls (PCBs), a known cancer-causing agent. Newer capacitors have eliminated PCBs and have a notice on the case to that effect. Older oil-filled capacitors should be examined carefully for any signs of leakage. Contact with leaking oil should be avoided, with careful washing of the hands after handling. Do not dispose of any oil-filled capacitors with household trash, particularly older units. Contact your local recycling agency for information about how to dispose of them properly.

### 7.12.2 High-Voltage Bleeder Resistors

Bleeder resistors across the output are used to discharge the stored energy in the filter capacitors when the power supply is turned off and should be given careful consideration. These resistors provide protection against shock when the power supply is turned off and dangerous wiring is exposed. A general rule is that the bleeder should be designed to reduce the output voltage to 30 V or less within 30 seconds of turning off the power supply.

Take care to ensure that the maximum voltage rating of the resistor is not exceeded. In a typical divider string, the resistor values are high enough that the voltage across the resistor is not dissipation limited. The voltage limit is typically related to the insulation intrinsic to the resistor. Resistor maximum voltage ratings are usually given in the manufacturer's data sheet and can be found online. Two major resistor manufacturers are Ohmite Electronics ([www.ohmite.com](http://www.ohmite.com)) and Stackpole Electronics ([www.seiect.com](http://www.seiect.com)).

A 2 W carbon composition resistor will have a maximum voltage rating of 500 V. As a rough estimate, larger wire-wound power resistors are typically rated at 500  $V_{\text{RMS}}$  per inch of length — but check with the manufacturer to be sure.

The bleeder will consist of several resistors in series. Typically wire-wound power resistors are used for this application. One additional recommendation is that two separate (redundant) bleeder strings be used, to provide safety in the event one of the strings fails. When electrolytic capacitors are used, the equalizing resistors can also serve as the bleeder resistor but they should be redundant. Again, give careful attention to keeping the heat from the resistors away from the capacitors as shown in Figure 7.44.

In the example given above for calculating the equalizing resistor value, eight 330  $\mu\text{F}$  capacitors in series created the equivalent of a 41  $\mu\text{F}$  capacitor with a 3000 V rating. The total resistance across the capacitors was  $8 \times 63$  k $\Omega = 504$  k $\Omega$ . This gives us a time constant ( $R \times C$ ) of about  $R \times C \approx 21$  seconds. To discharge the capacitors to 30 V from 3000 V would take about four time constants (about 84 seconds) which is well over a minute. To get the discharge time down to 30 seconds would require reducing the equalizing resistors to 25 k $\Omega$  each. The bleeder power dissipation would then be:

$$P = \frac{V^2}{R} = \frac{3000^2}{200,000} = 45 \text{ W} \quad (16)$$

For a 2 or 3 kV power supply, this is a reasonable value but it is still a significant amount of power and you need to make sure the resulting heat is properly managed.

### 7.12.3 High-Voltage Metering Techniques

Special considerations should be observed for metering of high-voltage supplies, such as the plate supplies for linear amplifiers. This is to provide safety to both personnel and to the meters themselves.

To monitor the current, it is customary to place the ammeter in the supply return (ground) line. This ensures that both meter terminals are close to ground potential. Placing the meter in the positive output line creates a hazard because the voltage on each meter terminal would be near the full high-voltage potential. Also, there is the strong possibility that an arc could occur between the wiring and coils inside the meter and the chassis of the amplifier or power supply itself. This hazardous potential cannot exist with the meter in the negative leg.

Another good safety practice is to place a low-voltage Zener diode across the terminals of the ammeter. This will bypass the meter in the event of an internal open circuit in the meter. A 1 W Zener diode will suffice since the current in the metering circuit is low.

The chapter on **RF Power Amplifiers** contains examples of how to perform current and voltage metering in high voltage supplies and amplifiers. In the past, amplifier articles have shown the meters mounted on plastic boards with stand-off insulators behind a plastic window in the amplifier or power supply front panel. While this can work it is not considered good practice today. It is usually possible to arrange the metering so that the meters are close to ground potential and may be safely mounted on the front panel of either the amplifier or the power supply.

For metering of high voltage, the builder should remember that resistors to be used in multiplier strings will often have voltage-breakdown ratings well below the total voltage being sampled. Usually, several identical series resistors will be used to reduce voltage stress across individual resistors. A basic rule of thumb is that these resistors should be limited to a maximum of 200 V, unless rated otherwise. For example, in a 2000 V power supply, the voltmeter multiplier should have a string of 10 resistors connected in series to distribute the voltage equally. The comments on resistor voltage rating in the sections on capacitor equalization and bleeder resistors apply to this case, as well.

### 7.12.4 High-Voltage Transformers and Inductors

Usable transformers and filter inductors can often be found at amateur flea markets but frequently these are very old units, often dating from WWII. The hermetically-sealed military components are likely to still be

**Figure 7.45** — Example of a high voltage board with a protruding lead and the use of a cap nut to terminate the end of a screw thread.

good, especially if they have not been used. Open-frame units, with insulation that has been directly exposed to the atmosphere and moisture for long periods of time, should be considered suspect. These units can be checked by running what is called a “hipot test” (high potential test). This involves a low current, variable output voltage power supply with a high-value resistor in series with the output. Unfortunately this equipment is seldom available to amateurs. Some motor repair shops will have an insulation tester called a “Megger” and may be willing to perform an insulation test on a transformer or inductor for you. This is not a completely definitive test but will certainly detect any gross problems with the insulation.

An alternative would be to perform the transformer tests discussed earlier with a variable autotransformer on the ac input. Slowly increase the input voltage until full line voltage is reached and let the transformer run for an hour or two while watching to see if there are any signs of failure. Doing this test in a dark room makes it easier to see any visible corona discharge, another sign of insulation problems. Because the transformer terminals will be at full voltage great care should be taken to avoid contact with the HV terminals. Some form of transparent insulating shield for the test setup is necessary.

### 7.12.5 Construction Techniques for High-Voltage Supplies

Layout and component arrangement in HV supplies requires some additional care beyond those for lower voltage projects. The photographs in the **RF Power Amplifiers** chapter are a good start, but there are some points which may not be obvious from the pictures.

#### SHARP EDGES

Sharp points, board edges and/or hardware with ragged edges can lead to localized intensification of the electric field’s strength, resulting in a possible breakdown. One common offender is the component leads on the soldered side of a printed-circuit board. These

are usually soldered and then cut off leaving a small but often very sharp point. The best way to handle this is to cut the lead as close to the board as practical and form a small solder ball or mound around the cutoff lead end. An example of these suggestions is given in **Figure 7.45**. The protruding component wire near the top would have a high field gradient. Below that we see a wire cut short with a rounded mound of solder covering the end of the wire.

The ends of bolts with sharp threads often protrude beyond the associated nut. One way to eliminate this is to use the dome-style nuts (cap nuts) that capture the end of the bolt or screw, forming a nicely rounded surface. An example of a cap nut is shown in **Figure 7.45**.

Sheet metal screws, with their needle-sharp ends, should be avoided if possible. Sheet metal screws used to close metal housings at high potential should have the screw tips inside the enclosure, which would be normal in most cases. You must also be careful of the tips of sheet metal screws that protrude on the inside of an outer enclosure. If these are in proximity to circuits at high potential, they can also lead to arcing. Keeping sheet metal screw tips well away from high voltage circuitry is the best defense.

Small pieces of sheet metal that may be part of a structure at high potential should have their edges rounded off with a file. Copper traces near the edges of circuit boards do not benefit from rounding, however. In fact, filing may make the edge sharper, ragged and more prone to breakdown. In critical areas, a small solid round wire can be soldered to the edges of a copper trace to form a rounded edge as illustrated at the right side of **Figure 7.45**.

#### INSULATORS

Some portions of the circuit may be mounted on insulators or plastic sheets. A new, clean insulator should easily withstand 10 kV per inch without creepage or breakdown across the insulating surface, but over time that surface will accumulate dirt and dust. Reducing the high-voltage stress across insulators to 5 kV per inch would be more conservative.

In theory the spacing between two smooth surfaces across an air gap can be much smaller, perhaps 20 to 30 kV per inch or even higher. But given the uncertainties of layout and voltage gradients around hardware, wiring, components and board edges, sticking with 5 kV per inch is good idea even for air gaps. This separation will seldom cause construction layout problems unless you are trying to build a very compact unit.

#### WIRE

Be sure to use wire that is rated for high voltage and for high temperatures. Pomona Electronics type 6733 test lead wire is stranded #18 AWG, rated for 10 kV and 150° C with

silicone insulation, available in both red and black. Flexible and durable, it is easy to route around a chassis or to fit inside sleeving with other wires. The outer diameter (0.144 inch) is thinner and more flexible than spark plug wire or most HV cable.

#### FUSES

Sometimes a fuse will be placed in series with a high voltage output to provide protection in case of load arcing. These fuses pose special problems. When a fuse blows, the fuse element will at least melt and perhaps even vaporize. There may be an interval when most, if not all, the output voltage appears across the fuse but the fuse has not stopped conducting. That is, there can be a sustained arc in the fuse.

Fuses have voltage ratings that are the maximum voltages across the fuse for which the arc can be expected to quench quickly. The standard 0.25 × 1.25 inch fuses used in the input ac line are typically rated for 250 V. While no doubt these ratings are conservative, this type of fuse cannot be expected to reliably clear an arc with 2 to 3 kV across the fuse and should not be used in series with a high-voltage output.

Your first choice for HV fuses should be the recommended part specified by the power supply manufacturer. If those are unavailable or you are building the supply yourself, fuses for microwave oven transformer secondary use are often suitable. Do not substitute lower-voltage fuses or fuse holders not rated for HV service. When working on a HV power supply with the fuse visible and uncovered, be sure to wear safety glasses as the fuse may explode during a high-current overload, scattering shards of glass or ceramic at high speed.

### 7.12.6 Construction Practices for High-Voltage Safety

The voltages present in HV power supplies are lethal. Every effort must be made to restrict physical access to any high voltages. A number of steps can be taken:

- 1) Build the power supply within a closed box, preferably a metal one.
- 2) Install interlocks on removable panels used for access to the interior. An interlock is usually a normally-open microswitch in series with the input power line. The microswitch is positioned so that it can be closed only when the overlying panel has been secured in place. When the panel is removed the switch moves to the open position, removing power from the supply.
- 3) As noted previously, the use of a bleeder resistor to rapidly discharge the capacitors is mandatory.
- 4) To further protect the operator when accessing the inside of a high-voltage power

supply, a grounding hook like that shown in **Figure 7.46A** should be used to positively discharge each capacitor by touching the hook to each capacitor terminal. The hook is connected to the chassis via the wire shown and held by the insulated handle. It is normal practice to leave the hook in place across the capacitors while the supply is being worked on, just in case primary power is inadvertently applied. When the work is finished, remove the hook and replace the covers on the power supply.

Figure 7.46B shows how to construct a grounding stick of your own. A large screw eye or hook is substituted for the hook. It is important that the grounding wire be left *outside* the handle so that any hazardous voltages or currents will not be present near your hand or body.

**Figure 7.46** — Example of a grounding stick or hook to discharge capacitor energy safely. The end of the wire is connected to ground and the hook is touched to the capacitor terminals to discharge them. A diagram showing how to construct a grounding stick is shown at B.

# 7.13 Batteries

A battery is a group of individual *cells*, usually series-connected to give some desired multiple of the *cell voltage*. The cell voltage is usually in the range of 1 to 4 V. Each chemical system used in the cell gives a particular nominal voltage that will vary with temperature and state of charge. This must be taken into account to make up a particular battery voltage. For example, four 1.5 V carbon-zinc cells make a 6 V battery and six 2 V lead-acid cells make a 12 V battery. **Table 7.1** lists the dimensions of commonly used batteries.

The following sections on battery types and usage consist primarily of excerpts from *Batteries in a Portable World* by Isidor Buchmann, CEO of Cadex Electronics ([www.cadex.com](http://www.cadex.com)), a leading manufacturer of battery charging and related equipment. The ARRL appreciates having been given permission to use this material. The book discusses the issues summarized here (and many others) in detail. The reader is directed to the original text for more complete information. This summary is intended to present and compare the various options commonly used by amateurs. Additional information and an extensive battery glossary is provided online at [www.batteryuniversity.com](http://www.batteryuniversity.com).

Batteries are divided into two categories: *primary* (non-rechargeable) and *secondary* (rechargeable). Secondary batteries are expected to account for more than 80% of global battery use by 2015. The most common types of battery chemistry are lithium, lead and nickel-based systems.

Batteries store energy well and for a considerable length of time. Primary batteries hold more energy than secondary, and their *self-discharge* is lower. Alkaline cells are good for 10 years with minimal losses. Lead, nickel and lithium-based batteries need periodic recharges to compensate for lost power. **Figure 7.47** illustrates the energy and power densities of lead acid, nickel-cadmium (NiCd), nickel-metal-hydride (NiMH), and the lithium-ion family (Li-ion).

Rather than giving batteries unique names by type, they are broadly distinguished by the following characteristics:

**Chemistry** — the families of chemicals used to make the battery. The most common chemistries are lead, nickel and lithium.

**Voltage** — the nominal open circuit voltage (OCV), which varies with chemistry and the number of cells connected in series.

**Size** — standard sizes of batteries or cells, such as AAA, AA, C and D.

**Capacity (C)** — the specific energy in ampere-hours (Ah).

**Cold Cranking Amps (CCA)** — a starter battery's ability to supply high load current

at  $-18^{\circ}\text{C}$  ( $0^{\circ}\text{F}$ ) as specified by the vehicle standard SAE J357.

**Specific energy** — battery capacity in watt-hours per kilogram (Wh/kg)

**Specific power** — indicates the loading capability or the amount of current the battery can provide in watts/kilogram (W/kg)

**C-rate** — charge and discharge rate

specified in units of C (capacity). At 1 C, the battery charges or discharges at a current numerically equal to its Ah rating. For example, a 2000 mAh battery discharging at 1 C is supplying a current of 2 A. At 0.5 C, the current would be 1 A, and so forth.

**Load** — whatever draws energy from the battery. Internal battery resistance and

## Battery Safety

In addition to the precautions given for each type of battery, the following precautions apply to all battery types. Always follow the manufacturer's advice! Extensive application information can be found on manufacturer's websites.

Hydrogen gas escaping from storage batteries can be explosive. Keep flames or any kind of burning material away, including cigarettes, cigars, pipes and so on. Use and charge batteries in well-ventilated areas to prevent hydrogen gas from building up.

No battery should be subjected to unnecessary heat, vibration or physical shock. The battery should be kept clean. Frequent inspection for leaks is a good idea. Electrolyte that has leaked or sprayed from the battery should be cleaned from all surfaces. The electrolyte is chemically active and electrically conductive, and may ruin electrical equipment. Acid may be neutralized with sodium bicarbonate (baking soda), and alkalis (found in NiCd batteries) may be neutralized with a weak acid such as vinegar. Both neutralizers will dissolve in water and should be quickly washed off. Do not let any of the neutralizer enter the battery.

Keep a record of the battery use, and include the last output voltage and, for lead-acid storage batteries, the hydrometer reading. This allows prediction of useful charge remaining, and the recharging or procuring of extra batteries, thus minimizing failure of battery power during an excursion or emergency.

Batteries can contain a number of hazardous materials such as lead, cadmium, mercury or acid, and some thought is needed for their disposal at the end of useful life. Municipal and county waste disposal sites and recycling centers will usually accept lead acid batteries because they can readily be recycled. Other types of batteries are typically not recycled and should be treated as hazardous waste. Most disposal sites and recycling centers will have occasional special programs for accepting household hazardous waste. Hardware and electronic stores may have battery recycling programs, as well. Take advantage of them.

**Table 7.1**  
**Dimensions of Common Standard Cells**

Size	Dimensions	Notes
D	34 × 61 mm	
C	25.5 × 50 mm	
A	17 × 50 mm	Only available for NiCd; also available in half-length size
AA	14.5 × 50 mm	
AAA	10.5 × 44.5 mm	
AAAA	8.3 × 42.5 mm	Typical size of cell making up 9 V batteries
N	12 × 32 mm	
9 V	48.5 × 26.5 × 17.5 mm	Contains six AAAA cells in series, snap terminals
18650	18 × 65 mm	Commonly used in lithium-ion battery packs
Lantern	115 × 68.2 × 68.2	Spring terminals
CR2016	20 × 1.6 mm	Coin cell
CR2025	20 × 2.5 mm	Coin cell
CR2032	20 × 3.2 mm	Coin cell

D	1.5	17,000	0.8	39	0.0022

(Table courtesy of Cadex)

depleting the battery’s state of charge cause the voltage to drop.

Primary batteries have one of the highest energy densities. One of the most common primary batteries is the *alkaline-manganese*, or alkaline battery. The *carbon-zinc* or *Leclanché battery* is less expensive but holds less energy than the alkaline battery. Although secondary batteries have improved, a regular household alkaline cell provides 50% more energy than lithium-ion.

Primary batteries tend to have high internal resistance, which limits the discharge to light loads. This reduces the battery’s specific power, even though its specific energy may be quite high. Non-rechargeable lithium metal and alkaline batteries are commonly used in low power applications such as clocks, meter LCDs, keyers and so forth.

Manufacturers of primary batteries specify specific energy at a small fraction of C and the batteries are allowed to discharge to a very low voltage of 0.8 volts per cell. **Figure 7.48** compares primary and secondary batteries discharged at a rate of 1 C. The primary (alkaline and lithium) batteries are unable to deliver their rated specific energy at heavy loads. **Table 7.2** gives typical specifications for alkaline batteries at light loads, such as operating a handheld radio during receive.

If recharging is available, using primary batteries can be expensive — about thirty-fold higher than for secondary batteries. Amateurs using batteries in the field, particularly for emergency communications, may want to maintain the ability to use primary batteries for times when recharging for secondary batteries is not available.

7.13.1 Choices of Secondary Batteries

The following discussion examines today’s most popular secondary battery systems according to specific energy, years of service life, load characteristics, safety, price, self-discharge, environmental issues, maintenance and disposal. **Table 7.3** compares the characteristics of four commonly used rechargeable battery systems showing average performance rating at the time of publication in 2013.

The lithium-ion family is divided into three major battery types, so named by their cathode oxides, which are cobalt, manganese and phosphate. The characteristics of these Li-ion systems are as follows:

**Lithium-ion-cobalt or lithium-cobalt** ( $\text{LiCoO}_2$ ) — Has high specific energy with moderate load capabilities and modest service life.

**Lithium-ion-manganese or lithium-manganese** ( $\text{LiMn}_2\text{O}_4$ ) — Is capable of high charge and discharge currents but has low specific energy and modest service life.

**Lithium-ion-phosphate or lithium-**

**phosphate** (LiFePO<sub>4</sub>) — often abbreviated LiPo, is similar to lithium-manganese; nominal voltage is 3.3 V/cell; offers long cycle life, has a good safety record but exhibits higher self-discharge than other Li-ion systems.

Another type of lithium-ion cell is the popular *lithium-ion-polymer* or *Li-polymer*. While Li-ion systems get their name from their unique cathode materials, Li-polymer differs by having a distinct architecture in

which a gelled electrolyte replaces the usual porous separator between the anode and cathode. The gelled electrolyte acts as a catalyst to enhance the electrical activity of the other battery materials.

### 7.13.2 Lead Acid Batteries

Most lead acid batteries used today are *maintenance-free* types in which the liquid

electrolyte is sealed inside the battery in liquid or gel form. Two similar types are used: the *sealed lead acid* (SLA) and the *valve-regulated lead acid* (VRLA). SLA batteries have capacities up to about 30 Ah. VRLA batteries are larger and have capacities from 30 Ah to several thousand Ah. **Table 7.4** summarizes the advantages and limitations of lead acid battery systems.

Applying the right voltage limit when

**Table 7.3**  
**Characteristics of Commonly Used Rechargeable Batteries**

Specification	Lead Acid	NiCd	NiMH	Li-ion Cobalt	Li-ion Manganese	Li-ion Phosphate
Specific energy (Wh/kg)	30-50	45-80	60-120	150-190	100-135	90-120
Internal resistance <sup>1</sup> (mΩ)	<100 12 V pack	100-200 6 V pack	200-300 6 V pack	150-300 7.2 V	25-75 <sup>2</sup> per cell	25-50 <sup>2</sup> per cell

Toxicity	Very high	Very high	Low	Low	Low	Low

**Table Notes:**

<sup>1</sup> Internal resistance of a battery pack varies with milliampere-hour (mAh) rating, wiring and number of cells. Protection circuit of lithium-ion adds about 100 mΩ.

<sup>2</sup> Based on 18650 cell size. Cell size and design determines internal resistance.

<sup>3</sup> Cycle life is based on battery receiving regular maintenance.

<sup>4</sup> Cycle life is based on the depth of discharge (DoD). Shallow DoD improves cycle life.

<sup>5</sup> Self-discharge is highest immediately after charge. NiCd loses 10% in the first 24 hours, then declines to 10% every 30 days. High temperature increases self-discharge.

<sup>6</sup> Internal protection circuits typically consume 3% of the stored energy per month

<sup>7</sup> The traditional voltage is 1.25 V; 1.2 V is more commonly used.

<sup>8</sup> Low internal resistance reduces the voltage drop under load and Li-ion is often rated higher than 3.6 V/cell. Cells marked 3.7 V and 3.8 V are fully compatible with 3.6 V.

<sup>9</sup> Capable of high current pulses; needs time to recuperate.

<sup>10</sup> Applies to discharge only; charge temperature is more confined.

<sup>11</sup> Maintenance may be in the form of equalizing or topping charge to prevent sulfation (Table courtesy of Cadex)

charging lead acid systems is critical and will be a compromise between capacity when recharged and maintaining the battery's internal materials. A low charge limit voltage may shelter the battery but this causes poor performance and a buildup of *sulfation* on the negative plate. A high voltage limit improves performance but it promotes irreversible grid corrosion on the positive plate. Temperature also changes the voltage threshold.

Lead acid does not lend itself to fast charging and a fully saturated charge requires 14 to 16 hours. The battery must always be stored at full state-of-charge to avoid sulfation. Lead acid is not subject to memory, but correct charge and float voltages are important to get a long life (see the section on charging below). While NiCd loses approximately 40% of its stored energy in three months, lead acid self-discharges the same amount in one year.

Lead acid batteries are inexpensive on cost-per-watt basis but are less suitable for repeated deep cycling. A full discharge causes strain and each discharge/charge cycle permanently robs the battery of a small amount of capacity. The fading becomes more acute as the battery falls below 80% of its nominal capacity. Depending on the depth of discharge and operating temperature, lead acid for deep-cycle applications provides 200 to 300 discharge/charge cycles.

High temperature reduces the number of available cycles. As a guideline, every 8° C (13° F) rise above the optimum temperature of 25° C (77° F) cuts battery life in half.

Lead acid batteries are rated at a 5-hour (0.2 C) and 20-hour (0.05 C) discharge, and the battery performs best when discharged slowly. Lead acid can deliver high pulse currents of several C if done for only a few seconds, making lead acid well suited as a *starter battery*.

### STARTER AND DEEP-CYCLE BATTERIES

The *starter* battery is designed to crank an engine with a momentary high power burst; the *deep-cycle* battery, on the other hand, is built to provide continuous power. The starter battery is made for high peak power and does not tolerate deep cycling well. The deep-cycle battery has a moderate power output but permits cycling.

Starter batteries have a CCA rating in amperes and a very low internal resistance. Deep-cycle batteries are rated in Ah or minutes of runtime. A starter battery cannot be swapped with a deep-cycle battery and vice versa because of their different internal construction. **Table 7.5** compares the typical life of starter and deep-cycle batteries when deep-cycled.

### ABSORBENT GLASS MAT (AGM)

AGM is an improved lead acid battery in which the electrolyte is absorbed in a mat of fine glass fibers. This makes the battery spill-proof. AGM has very low internal resistance, is capable of delivering high currents and offers long service even if *occasionally* deep-cycled. It also stands up well to high and low

temperatures and has a low self-discharge. AGM has a higher specific power rating for high load currents and allows faster charge times (up to five times faster) than conventional lead acid. AGM has a slightly lower specific energy and higher manufacturing cost.

AGM batteries are sensitive to overcharging. They can be charged to 2.40 V/cell without problems but the float charge should be reduced to 2.25 to 2.30 V/cell and summer temperatures may require lower voltages. Automotive charging systems designed for flooded lead acid often have a fixed float voltage setting of 14.40 V (2.40 V/cell) and a direct replacement with an AGM battery could result in overcharge on a long drive.

Heat can be a problem for AGM and other gelled electrolyte batteries. Manufacturers recommend halting charge if the battery core reaches 49° C (120° F). However, AGM batteries can sit in storage for long periods before a recharge to prevent sulfation becomes necessary.

### 7.13.3 Nickel-based Batteries NICKEL-CADMIUM (NiCd)

The standard NiCd remains one of the most rugged and forgiving batteries but needs proper care to attain longevity. Nickel-based batteries also have a flat discharge curve that ranges from 1.25 to 1.0 V/cell. **Table 7.6** summarizes the advantages and limitations of NiCd battery systems.

### NICKEL-METAL-HYDRIDE (NiMH)

NiMH provides 40% higher specific energy than standard NiCd, but the decisive advantage is the absence of toxic metals. NiMH also has two major advantages over Li-ion: price and safety. NiMH is offered in AA and AAA sizes.

NiMH is not without drawbacks. It has a lower specific energy than Li-ion and also has high self-discharge, losing about 20% of its capacity within the first 24 hours, and 10% per month thereafter. New types of NiMH such as the Enloop from Sanyo, ReCyko by GP and others have reduced the self-discharge by a factor of six, increasing storage life by the same amount at the sacrifice of some capacity. **Table 7.7** summarizes the advantages and limitations of NiMH battery systems.

### 7.13.4 Lithium-based Batteries

The specific energy of Li-ion is twice that of NiCd and the high nominal cell voltage of 3.60 V as compared to 1.20 V for nickel systems contributes to this gain. The load characteristics are good, and the flat discharge curve offers effective utilization of the stored energy in a desirable voltage spectrum of 3.70 to 2.80 V/cell. Li-ion batteries vary in performance

**Table 7.4**  
**Advantages and Limitations of Lead Acid Batteries**

#### Advantages

Inexpensive and simple to manufacture; lowest cost per watt-hour  
Mature and well-understood technology; provides dependable service  
Low self-discharge; lowest among rechargeable batteries  
High specific power, capable of high discharge currents

#### Limitations

Low specific energy; poor weight-to-energy ratio  
Slow charge; fully saturated charge takes 14 hours  
Must always be stored in charged condition  
Limited cycle life; repeated deep-cycling reduces battery life  
Flooded version requires watering  
Not environmentally friendly  
Transportation restrictions on the flooded type  
(Table courtesy of Cadex)

**Table 7.5**  
**Cycle Performance of Starter and Deep-Cycle Batteries**

Depth of Discharge	Starter Battery	Deep-cycle Battery
100%	12-15 cycles	150-200 cycles
50%	100-120 cycles	400-500 cycles
30%	130-150 cycles	1000 and more cycles

(Table courtesy of Cadex)

**Table 7.6****Advantages and Limitations of NiCd Batteries**

Advantages	Fast and simple charging even after prolonged storage High number of charge/discharge cycles; provides over 1000 charge/discharge cycles with proper maintenance Good load performance; rugged and forgiving if abused Long shelf life; can be stored in a discharged state Simple storage and transportation; not subject to regulatory control Good low-temperature performance Economically priced; NiCd is the lowest in terms of cost per cycle Available in a wide range of sizes and performance options
Limitations	Relatively low specific energy compared with newer systems Memory effect; needs periodic full discharges Environmentally unfriendly; cadmium is a toxic metal and cannot be disposed of in landfills High self-discharge; needs recharging after storage

(Table courtesy of Cadex)

**Table 7.7****Advantages and Limitation of NiMH Batteries**

Advantages	30-40% higher capacity than a standard NiCd Less prone to memory than NiCd Simple storage and transportation; not subject to regulatory control Environmentally friendly; contains only mild toxins Nickel content makes recycling profitable
Limitations	Limited service life; deep discharge reduces service life Requires complex charge algorithm Does not absorb overcharge well; trickle charge must be kept low Generates heat during fast-charge and high-load discharge High self-discharge; chemical additives reduce self-discharge at the expense of capacity Performance degrades if stored at elevated temperatures; should be stored in a cool place at about 40% state-of-charge

(Table courtesy of Cadex)

**Table 7.8****Characteristics of the Four Most Commonly Used Lithium-ion Batteries**

<i>Specifications</i>	<i>Li-cobalt</i> <i>LiCoO<sub>2</sub> (LCO)</i>	<i>Li-manganese</i> <i>LiMn<sub>2</sub>O<sub>4</sub> (LMO)</i>	<i>Li-phosphate</i> <i>LiFePO<sub>4</sub> (LFP)</i>	<i>NMC<sup>1</sup></i> <i>LiNiMnCoO<sub>2</sub></i>
Voltage (V)	3.60	3.80	3.30	3.60/3.70
Charge limit (V)	4.20	4.20	4.20	4.20
Cycle life <sup>2</sup>	500-1000	500-1000	1000-2000	1000-2000
Operating temperature	Average	Average	Good	Good
Specific energy (Wh/kg)	150-190	100-135	90-120	140-180
Specific Power (C)	1	10, 40 pulse	35 continuous	10
Safety	Average <sup>3</sup>	Average <sup>3</sup>	Very safe <sup>4</sup>	Safer than Li-cobalt <sup>4</sup>
Thermal runaway <sup>5</sup> (°C/°F)	150/302	250/482	270/518	210/410
Cost	Raw material high	30% less than cobalt	High	High
In use since	1994	1996	1999	2003

**Table Notes**<sup>1</sup> NMC (nickel-manganese-cobalt), NCM, CMN, CNM, MNC and MCN are basically the same. The order of Ni, Mn and Co does not matter much<sup>2</sup> Application and environment govern cycle life; the numbers do not always apply correctly<sup>3</sup> Requires protection circuit and cell balancing of multi cell pack. Requirements for small formats with 1 or 2 cells can be relaxed<sup>4</sup> Needs cell balancing and voltage protection<sup>5</sup> A fully charged battery raises the thermal runaway temperature, a partial charge lowers it

(Table courtesy of Cadex)

according to the choice of cathode materials. **Table 7.8** presents the characteristics of common Li-ion battery chemistries and **Table 7.9** summarizes the advantages and limitations of lithium-ion battery systems.

Lithium-polymer employs a gelled electrolyte in a micro-porous separator between the anode and cathode. Li-polymer is a construction technique and not a type of battery chemistry, so it can be applied to any of the lithium battery chemistries. Most Li-polymer battery packs are based on Li-cobalt. Charge and discharge characteristics of Li-polymer are identical to other Li-ion systems and this chemistry does not require a special charger.

**Figure 7.49** compares the specific energy of lead, nickel and lithium-based systems. While Li-cobalt is the clear winner in terms of higher capacity than other systems, this only applies to specific energy. In terms of specific power and thermal stability, Li-manganese and Li-phosphate are superior.

**7.13.5 Charging Methods**

The performance and longevity of rechargeable batteries are to a large extent governed by the quality of the charger. Choosing a quality charger is important considering the costs of battery replacement and poor performance.

**CHARGERS**

This discussion focuses on third-party chargers designed to charge and maintain individual cells or batteries. *Fleet chargers* designed for maintaining many batteries of a common type in a company or agency environment are often provided by the equipment OEM and usually have special features for battery conditioning.

**Table 7.9**

**Advantages and Limitations of Li-ion Batteries**

Advantages	High specific energy Relatively low self-discharge; less than half that of NiCd and NiMH Low maintenance. No periodic discharge is needed; no memory
Limitations	Requires protection circuit to limit voltage and current Subject to aging, even if not in use (life span is similar to other chemistries) Transportation regulations apply when shipping in larger quantities

(Table courtesy of Cadex)

**Figure 7.49 — Typical energy densities of lead, nickel- and lithium-based batteries.**

“Smart” chargers include valuable additional features beyond simply applying current to a battery. Temperature protection is particularly important to slow or prevent charging below freezing or above recommended thresholds when the battery is hot. Advanced lead acid chargers adjust the float and trickle charge thresholds based on temperature and battery age. **Table 7.10** summarizes the types of third-party chargers.

There are two common charge methods: voltage limiting (VL) and current limited (CL). Lead and lithium-based chargers cap the voltage at a fixed threshold. When reaching the cutoff voltage, the battery begins to saturate and the current drops while receiving the remaining charge on its own timetable.

Full charge detection occurs when the current drops to a designated level.

Nickel-based batteries charge with a controlled current and the voltage is allowed to fluctuate freely. A slight voltage drop after a steady rise indicates a fully charged battery. The voltage drop method works well in terminating a fast charge, but the charger should detect and protect against shorted or mismatched cells. Most chargers include temperature sensors to end the charge if the temperature exceeds a safe level. (Some batteries also have internal temperature sensors.)

A temperature rise is normal as nickel-based batteries approach full charge. When in “ready” mode, the battery must cool down to room temperature. Heat causes stress and

prolonged exposure to elevated temperature shortens battery life. Extended trickle charge also inflicts damage on nickel-based batteries, which should not be left in the charger continuously or beyond a few days.

A lithium-based battery should not get warm in a charger, and if this happens either the battery or charger may be faulty. Li-ion chargers do not apply a trickle charge and disconnect the battery electrically when fully charged. If the battery is left in the charger, a recharge may occur when its open circuit voltage drops below a set threshold. It is not necessary to remove Li-ion batteries from a charger.

**SIMPLE GUIDELINES WHEN BUYING A CHARGER**

- Use the correct charger for battery chemistry. Most chargers service one chemistry only.
- The battery voltage must agree with the charger. Do not charge if different.
- The Ah rating of a battery can be somewhat higher or lower than specified on the charger. A larger battery will take longer to charge than a smaller one and vice versa.
- The higher the amperage of the charger, the shorter the charge time will be, subject to limits on how fast the battery can be charged.
- Accurate charge termination and correct trickle charge prolong battery life.
- When fully saturated, a lead acid charger should switch to a lower voltage; a nickel-based charger should have a trickle charge; a Li-ion charger provides no trickle charge.
- Chargers should have a temperature override to end charge on a malfunctioning battery.
- Observe the temperature of the charger and battery. Lead acid batteries stay cool during charge; nickel-based batteries elevate the temperature toward the end of charge and should cool down after charge; Li-ion batteries should stay cool throughout charge.

**SLOW CHARGERS**

This type of charger applies a fixed current of about 0.1 C (one-tenth of the rated capacity) as long as the battery is connected. Slow chargers have no full-charge detection, charge current is always applied, and the charge time for a fully discharged battery is 14 to 16 hours.

**Table 7.10**

**Charger Characteristics**

Type	Chemistry	C-rate (C)	Time	Charge Termination
Slow	NiCd, Lead acid	0.1	14 h	Continuous low charge or fixed timer. Subject to overcharge. Remove battery when charged.
Rapid	NiCd, NiMH, Li-ion	0.3-0.5	3-6 h	Senses battery by voltage, current, temperature, and time-out timer
Fast	NiCd, NiMH, Li-ion	1	1+ h	Same as rapid charger with faster service
Ultra-Fast	Li-ion, NiCd, NiMH	1-10	10-60 min	Applies ultra-fast charge to 70% SoC; limited to specialty batteries

All values specified over 0°C to 45°F (32°F to 113°F) range

(Table courtesy of Cadex)

Most slow chargers have no “ready” indicator.

When fully charged, a slow charger keeps NiCd batteries lukewarm to the touch. Some overcharge is acceptable and the battery does not need to be removed immediately when ready. Leaving the battery in the charger can cause internal crystal growth that leads to “memory effects” in NiCd batteries.

Charging a battery with a lower Ah rating than specified for the charger will cause the battery to heat up as it approaches full charge due to the higher charging rate. Because slow chargers have no provision to lower the current or terminate the charge, the excessive heat will shorten the life of the battery.

The opposite can occur when a slow charger is charging a larger battery than it is rated for. In this case, the battery may never reach full charge and remains cold. Battery performance will be poor because of insufficient charge. Repeated partial charging can also cause crystal growth and memory effects.

### RAPID CHARGERS

Falling between a slow and fast charger, the rapid charger is designed for nickel and lithium-based batteries. Unless specially designed, the rapid charger cannot service both types of batteries.

Rapid chargers are designed to charge fully discharged batteries and battery packs in 3 to 6 hours. When full charge is reached, the charger switches to a “ready” state. Most rapid chargers include temperature protection.

### FAST CHARGERS

The fast charger typically applies charge at a 1 C rate so that a fully discharged battery is recharged in a little over 1 hour. As the battery approaches full charge, the charger may reduce the charge current (particularly for NiCd), and when the battery is fully charged, the charger switches to a trickle or maintenance charge mode.

Most nickel-based fast chargers accommodate NiCd and NiMH batteries and apply the same charging algorithm, but cannot charge Li-ion batteries. To service a Li-ion pack, specialty dual-mode chargers can read a security code on the battery to switch to the right charger setting.

Lead acid batteries cannot be fast-charged and the term “fast charge” is a misnomer for lead acid chargers. Most lead acid chargers charge the battery in 14 hours; anything slower may be a compromise. Lead acid can be charged relatively quickly to 70% of full charge with the important saturation charge consuming the remaining time. A partial charge at high rate is acceptable provided the battery receives a fully saturated charge once every few weeks to prevent sulfation.

### ULTRA-FAST CHARGERS

Large NiCd and Li-ion batteries can be

charged at a very high rate (10 C is typical) up to 70% of full charge. Ultra-fast charging stresses batteries. If possible, charge the battery at a more moderate current. An ultra-fast charger should offer user-selectable rates to optimize the charging requirements.

At a rate of 10 C, a battery can be charged in a few minutes but several conditions must be observed:

- The battery must be designed to accept an ultra-fast charge.
- Ultra-fast charging only applies during the first charge phase and charge current must be lowered once the 70% state-of-charge (SoC) threshold is reached.
- All cells in a pack must be balanced and in good condition. Older batteries with high internal resistance will heat up and are no longer suitable for ultra-fast charging.
- Ultra-fast charging can only be done at moderate temperatures. Low temperatures slow the chemical reaction and the unabsorbed energy results in gassing and heat buildup.
- The charge must include temperature compensation and other safety provisions to end the charge if the battery is overly stressed.

### CHARGING FROM A USB PORT

The universal serial bus (USB) interface has become ubiquitous on computers and consumer electronics. It is increasingly used on radio equipment. A drawing and pin connections for the USB interface are available in the **Component Data and References** chapter.

USB hubs are specified to provide 5 V and 500 mA of current. (High-current charging ports can supply up to 2.0 A.) While this would be enough to charge a small Li-ion battery, it could overload the hub if other devices are attached. Many hubs limit the current and will shut down if overloaded, so charging capacity is quite limited.

The most common USB chargers are designed for single-cell Li-ion batteries. The charge begins with a constant current charge to 4.20 V/cell, at which point the voltage levels off and current begins to decrease. Due to voltage drops in the USB cable and charger circuit, the hub may not be able to fully charge the battery. This will not damage a Li-ion battery but it will deliver shorter than expected runtimes.

### CHARGING LEAD ACID

Lead acid batteries should be charged in three stages as shown in **Figure 7.50**:

- 1 — constant-current charge
- 2 — topping charge
- 3 — float charge

The constant-current charge applies the bulk of the charge and takes up roughly half of the required charge time. The topping charge continues at a lower charge current and provides saturation. The float

charge compensates for the loss caused by self-discharge.

During the constant-current charge the battery charges to 70% SoC in 5 to 8 hours and the remaining 30% is supplied by the slower topping charge that lasts another 7 to 10 hours. The topping charge is essential for the well-being of the battery. If topping charge is not performed, the battery will eventually lose the ability to accept a full charge and performance will decrease because of sulfation. The float charge maintains the battery at full charge.

The switch to topping charge happens when the battery reaches the set voltage limit. Current begins to drop as the battery starts to saturate and full charge is reached when the current decreases to 3% of the rated current. A battery with high leakage may never reach this level and a timer is required to start charging termination.

The correct setting of the charge voltage is critical, ranging from 2.3 to 2.45 V per cell. The threshold is selected as a compromise between charging to maximum capacity and creating internal corrosion and gassing. The battery voltage also shifts with temperature, with warmer temperatures requiring slightly lower voltage thresholds. If variable voltage thresholds are not available in the charger, it is better to use a lower voltage threshold for safety.

Once fully charged through saturation, the battery should not dwell at the *topping voltage* for more than 48 hours and must be reduced to the *float voltage* level. This is especially critical for sealed systems because they are less able to tolerate overcharge than the flooded type due to heating and gas (hydrogen) generation. The recommended float voltage of most lead acid batteries is 2.25 to 2.27 V/cell. Manufacturers recommend lowering the float charge at ambient temperatures above 29° C (85° F). Not all chargers feature float charge. If the charger remains at the topping voltage and does not drop below 2.30 V/cell, remove the charger after a maximum of 48 hours of charge.

Aging batteries develop imbalances between cells that can result in overcharge and gassing from weak cells. This can also cause a strong cell to be undercharged and develop sulfation. Some battery manufacturers have developed cell-balancing devices that compensate for cell imbalance.

Lead acid batteries must always be stored in a charged state. A topping charge should be applied every six months to prevent the voltage from dropping below 2.10 V/cell. With AGM, these requirements can be somewhat relaxed.

Measuring the open circuit voltage (OCV) while in storage provides a reliable indication of the battery’s state-of-charge (SoC). A voltage of 2.10 V at room temperature indicates a charge of about 90%. (That is equivalent to

**Figure 7.50 — Charge stages of a lead acid battery. The battery is fully charged when the current drops to a pre-determined level or levels out in stage 2. The float voltage must be reduced at full charge. (Courtesy of Cadex)**

12.6 V for a typical six-cell “12 V” lead acid battery.) Such a battery is in good condition and needs only a brief full charge prior to use. If the OCV is lower, the battery must be charged to prevent sulfation. Cool temperatures increase OCV slightly and warm temperatures lower it. Use OCV as an SoC indicator after the battery has rested for a few hours to allow the effects of charging to dissipate.

### SIMPLE GUIDELINES FOR CHARGING LEAD ACID BATTERIES

- Charge in a well-ventilated area. Hydrogen gas generated during charging is explosive.
- Choose the appropriate charge program for flooded, gel and AGM batteries. Follow the manufacturer’s specifications of voltage thresholds.
- Charge lead acid batteries after each use to prevent sulfation. Do not store in a low-charge condition.
- The plates of flooded batteries must always be fully submerged in electrolyte. Fill battery with distilled or de-ionized water to cover the plates if low. Never add electrolyte.
- Fill water level to designed level after charging. Overfilling a discharged battery can result in overflow and acid spillage.
- Formation of gas bubbles in a flooded lead acid battery is an indication of approaching

full charge.

- Reduce float charge if the ambient temperature is higher than 29° C (85° F).
- Do not allow a lead acid battery to freeze and never charge a frozen battery.
- Do not charge at temperatures above 49° C (120° F).

### CHARGING NICKEL-CADMIUM

Battery manufacturers recommend that new NiCd batteries be slow-charged for 16 to 24 hours before use. A slow charge brings all cells in a battery pack to an equal charge level. This is important because each cell within the NiCd battery may have self-discharged at its own rate. Furthermore, during long storage the electrolyte tends to gravitate to the bottom of the cell and the initial trickle charge helps redistribute the electrolyte to eliminate dry spots on the separator. The cells will reach optimal performance after several charge/discharge cycles.

### Full-charge Detection by Temperature

Full-charge detection of sealed nickel-based batteries is more complex than for lead acid and lithium-ion systems. Low-cost chargers often use temperature sensing to end the fast-charge, but this can be inaccurate

due to internal and external temperature differences. Charger manufacturers use 50° C (122° F) as the temperature cutoff. Although any prolonged temperature above 45° C (113° F) is harmful, brief overshoot is acceptable if temperature will drop quickly when the charger changes to the “ready” state.

Some microprocessor-controlled chargers sense the rate of temperature increase with time, using the rapid temperature rise toward the end of charge to trigger the “ready” state. This is referred to as *delta temperature over delta time* or  $dV/dt$ . A rate of 1° C (1.8° F) per minute terminates charging. This keeps the battery cooler, but the cells need to charge reasonably fast for temperature to rise at the required rate. An absolute temperature of 60° C (140° F) terminates charging under any circumstances.

Chargers relying on temperature inflict harmful overcharges when fully charged batteries are inserted into the charger, such as if a hand-held radio is left in the charger between each use. This is not the case with Li-ion batteries where the charger uses voltage as the SoC indicator.

### Full-charge Detection by Voltage Signature

Advanced chargers terminate charging when a defined voltage signature or profile with time occurs, referred to as *negative delta V* or NDV. This provides more precise full-charge detection for nickel-based batteries than temperature-based methods. Charging is terminated when the battery voltage drops as full charge is reached. NDV is the recommended method for NiCd cells that do not include an internal thermistor for temperature control and avoids overcharging of fully-charged batteries. NDV requires a charge rate of at least 0.5 C to generate a reliably measurable change in voltage and works best with fast charging. At a charge rate of 1 C, a fully discharged battery is recharged in about an hour.

**Figure 7.51** illustrates the relationship of cell voltage, pressure, and temperature of a charging NiCd battery. Up to about 70% SoC, the battery accepts almost all of the energy supplied (called *charge efficiency*). Above 70%, the battery loses ability to accept charge, begins to generate gases so that pressure rises, and temperature increases rapidly.

Ultra-high-capacity NiCd batteries tend to heat up more than standard batteries when charging at 1 C and higher rates due to their higher internal resistance. Applying a high current during initial charge and tapering to a lower rate achieves good results with all nickel-based batteries and moderates temperature rise.

Some chargers can “burp” a charging battery by applying a load to generate a discharge pulse to cause gases to recombine and lower

**Figure 7.51 — Charge characteristics of a NiCd cell. Above 70% state-of-charge, temperature and cell pressure rise quickly. NiMH has similar charge characteristics. (Courtesy of Cadex)**

internal pressure. The result is a cooler and more effective charge than with conventional dc charging. Pulse charging does not apply to lead and lithium-based systems.

After full charge, the NiCd battery receives a trickle charge of between 0.05 C and 0.1 C to compensate for self-discharge. To avoid possible overcharge, trickle charging should be done at the lowest possible rate and the batteries should be removed from the charger after more than a few days.

### CHARGING NICKEL-METAL-HYDRIDE

The charging algorithm for NiMH is similar to NiCd with the exception that NiMH is more complex. The NDV method of measuring full charge has difficulty because the voltage drop at full charge is very small — about 5 mV/cell. As a result, modern chargers combine the various methods of measuring voltage and temperature into a composite algorithm that reacts depending on battery condition.

Some advanced chargers apply an initial fast charge at 1 C. After reaching a certain voltage threshold, a few minutes rest is taken to allow the battery to cool. Charging then resumes at lower currents as the charge progresses to full charge. This is known as the “step-differential charge” and works well for all nickel-based batteries, achieving an extra capacity of about 6% above basic chargers. A drawback of this method is that the fast-charge stress on the battery will shorten overall battery life by 10 to 20%.

NiMH cannot absorb overcharge well and the trickle charge current must be limited to around 0.05 C. In comparison, a basic NiCd charger trickle charges at 0.1 C. This higher trickle charge and the need for sensitive full-charge detection render the basic NiCd chargers unsuitable for NiMH batteries. On the other hand, NiCd cells can be charged in a NiMH charger at the lower trickle charge rate.

Slow charging should not be used for NiMH batteries. At the charging rate of 0.1 to 0.3 C, the voltage and temperature profiles make it very difficult to measure full charge accurately so the charger must depend on a timer. Harmful overcharge will occur if a fixed timer is used, particularly when charging partially or fully charged batteries. The same is true for charging old batteries with reduced capacity.

Inexpensive chargers are prone to incorrect charging because of the difficulty in correctly sensing full charge. Remove the batteries from the charger when you think they are fully charged. For high charge rates, remove the batteries when they are warm to the touch. It is better to remove the batteries and recharge them before use than to leave them in the charger where they might be overcharged and damaged.

### SIMPLE GUIDELINES ON CHARGING NICKEL-BASED BATTERIES

- Do not charge at high or freezing temperatures; room temperature is best.

- Do not use chargers that allow the batteries to heat; remove the batteries when warm to the touch.
- Nickel-based batteries are best fast charged.
- NiMH chargers can charge NiCd batteries but not vice versa.
- High charge current or overcharging on an aging battery may cause heat build-up.
- Do not leave a nickel-based battery in the charger for long periods, even with correct trickle charge. Remove and apply a brief charge before use.
- Nickel- and lithium-based batteries require different charge algorithms and cannot share the same charger unless it can switch between the different chemistries.

### CHARGING LITHIUM-ION

The Li-ion charger is a voltage-limiting device that is similar to the lead acid system. The difference lies in a higher voltage per cell, tighter voltage tolerance and the absence of trickle or float charge at full charge. Li-ion cannot accept overcharge — any extra charging causes stress.

Most Li-ion cells charge to 4.20 V/cell with a tolerance of  $\pm 50$  mV/cell. **Figure 7.52** shows the voltage and current signature as lithium-ion passes through the stages for constant current and topping charge. The charge rate of a typical consumer Li-ion battery is between 0.5 and 1 C in Stage 1 and the charge time is about three hours. Manufacturers recommend charging the 18650 cell at 0.8 C or less. The cell should remain cool during the charging process although there may be a slight temperature rise of a few degrees when reaching full charge. Full charge occurs when the battery reaches the voltage threshold and the current drops to 3% of the rated current, or if the charging current reaches a constant value and does not decrease further. The latter may be due to elevated self-discharge.

Li-ion does not need to be fully charged, as is the case with lead acid, nor is it desirable to do so. In fact, it is better not to fully charge so as not to stress the battery. Choosing a lower voltage threshold or eliminating saturation charge prolongs battery life at the cost of reduced runtime. Without a saturation stage, the battery is usually charged to around 85% of capacity.

Once charging is terminated, the battery voltage begins to drop and this eases the voltage stress. Over time, the open circuit voltage (OCV) will settle to between 3.60 and 3.90 V/cell. A battery receiving a fully saturated charge will keep the higher voltage longer than a battery that was fast charged and terminated without a saturation charge.

If a lithium-ion battery must be left in the charger for operational readiness, some chargers apply a brief topping charge to

**Figure 7.52** — Charge stages of lithium ion. Li-ion is fully charged when the current drops to a predetermined level or levels out at the end of Stage 2. In lieu of trickle charge, some chargers apply a topping charge when the voltage drops to 4.05 V/cell (Stage 4). (Courtesy of Cadex)

compensate for the small self-discharge of the battery and its protective circuit. It is common to let the battery voltage drop to 4.00 V/cell and then recharge to 4.05 V/cell to reduce voltage-related stress and prolong battery life. Battery-powered devices should be turned off when charging their battery. Otherwise, the *parasitic load* of the device can confuse the charger, distorting the charge cycle and stressing the battery.

### Overcharging Lithium-ion

Lithium-ion systems operate safely within the designated operating voltages; however, the battery becomes unstable if inadvertently charged to a voltage higher than specified. Prolonged charging above 4.30 V/cell forms plating of metallic lithium on the anode, while the cathode material becomes an oxidizing agent, loses stability and produces CO<sub>2</sub>. Cell pressure rises until the internal *current interrupt device* (CID) disconnects the current at 1380 kPa (200 psi).

Should the pressure rise further, a safety membrane bursts open at 3450 kPa (500 psi) and the cell might eventually vent with flame. The thermal runaway moves lower when the battery is fully charged; for Li-cobalt this threshold is between 130-150° C (266-302° F), for nickel-manganese-cobalt (NMC) between 170-180° C (338-356° F), and manganese is 250° C (482° F). Li-phosphate enjoys similar and better temperature stabilities

than manganese.

Lithium-ion is not the only battery that is a safety hazard if overcharged. Lead and nickel-based batteries are also known to melt down and cause fires if improperly handled. Properly designed charging equipment is paramount for all battery systems.

### SIMPLE GUIDELINES FOR CHARGING LITHIUM-BASED BATTERIES

- A battery-powered device should be turned off while charging.
- Charge at a moderate temperature. Do not charge below freezing.
- Lithium-ion does not need to be fully charged; a partial charge is better.
- Chargers use different methods for “ready” indication and may not always indicate a full charge.
- Discontinue using a charger and/or battery if the battery gets excessively warm.
- Before prolonged storage, apply some charge to bring a pack to about half charge.

### SUMMARY OF CHARGING

Batteries have unique needs and **Table 7.11** explains how to satisfy these needs with correct handling. Because of similarities within the battery families, only lead, nickel and lithium systems are covered. Along with these guidelines, you can prolong battery life by following three simple rules: keep the battery

at moderate temperatures, control the level and rate of discharge, and avoid abusing the battery.

### 7.13.6 Discharge Methods

#### C-RATE

According to the definition of *coulomb*, a current of 1 ampere is a flow of 1 coulomb (C) of charge per second. Today, the battery industry uses *C-rate* to scale the charge and discharge current of a battery.

Most portable batteries are rated at 1 C, meaning that a 1000 mAh battery that is discharged at 1 C should under ideal conditions provide a current of 1000 mA for 1 hr. The same battery discharging at 0.5 C would provide 500 mA for 2 hours, and at 2 C, the 1000 mAh battery would deliver 2000 mA for 30 minutes. 1 C is also known as a one-hour discharge; a 0.5 C is a two-hour discharge, a 2 C is a half-hour discharge, and so on.

A battery’s capacity — the amount of energy a battery can hold — can be measured with a *battery analyzer*. The analyzer discharges the battery at a calibrated current while measuring the time it takes to reach its specified end-of-discharge voltage. If a 1000 mAh battery could provide 1000 mA for 1 hour, 100% of the battery’s nominal energy rating would be reached. If the discharge only lasted 30 minutes before reaching the specified voltage, the battery has a capacity of 50% of its nominal rating.

When discharging a battery at different rates a higher C-rate will produce a lower capacity reading due to the internal resistance turning some of the energy into heat instead of delivering it as current to a load. Lower C-rate discharges will produce a higher capacity.

For example, to obtain a reasonably good capacity rating, manufacturers commonly rate lead acid batteries at 0.05 C, or a 20-hour discharge. **Figure 7.53** illustrates the discharge times of a lead acid battery at various loads expressed in C-rate.

**Figure 7.53** — Typical discharge curves of lead acid as a function of C-rate. Smaller batteries are rated at a 1 C discharge rate. Due to sluggish behavior, lead acid is rated at 0.2 C (5 hours) and 0.05 C (20 hours). (Courtesy of Cadex)

**Table 7.11**  
**Best Charging Methods**

<i>Frequently Asked Question</i>	<i>Lead Acid (Sealed, flooded)</i>	<i>Nickel-Based (NiCd and NiMH)</i>	<i>Lithium-ion (Li-ion, Polymer)</i>
How should I prepare a new battery?	Battery comes fully charged. Apply topping charge	Charge 14-16 h. Priming may be needed.	Apply a topping charge before use. No priming needed
Can I damage a battery with incorrect use?	Yes, do not store partially charged, keep fully charged	Battery is robust and the performance will improve with use.	Keep some charge. Low charge can turn off protection circuit.
Do I need to apply a full charge?	Yes, partial charge causes sulfation.	Partial charge is fine.	Partial charge better than a full charge.
Can I disrupt a charge cycle?	Yes, partial charge causes no harm.	Interruptions can cause heat buildup.	Yes, partial charge causes no harm.
Should I use up all battery energy before charging?	No, deep discharge wears the battery down. Charge more often.	Apply scheduled discharges only to prevent memory.	No, deep discharge wears the battery down.
Do I have to worry about "memory"?	No memory	Discharge NiCd every 1-3 months.	No memory
How do I calibrate a "smart" battery?	Not applicable	Apply discharge/charge when the fuel gauge gets inaccurate. Repeat every 1-3 months.	Apply discharge/charge when the fuel gauge gets inaccurate. Repeat every 1-3 months.
Must I remove the battery when fully charged?	Depends on charger; needs correct float voltage	Remove after a few days in charger.	Not necessary; charger turns off
How do I store my battery?	Keep cells above 2.10 V, charge every 6 months	Store in cool place; a total discharge causes no harm.	Store in cool place partially charged, do not fully drain
Is the battery allowed to heat up during charge?	Battery may get lukewarm toward the end of charge.	Battery gets warm but must cool down on ready.	Battery may get lukewarm toward the end of charge.
How do I charge when cold?	Slow charge (0.1C): 0°-45° C (32°-113° F) Fast charge (0.5-1C): 5°-45° C (41°-113° F)	Slow charge (0.1C): 0°-45° C (32°-113° F) Fast charge (0.5-1C): 5°-45° C (41°-113° F)	Do not charge above 50° C (122° F) Do not charge above 50° C (122° F)
Can I charge at hot temperatures?	Above 25° C, lower threshold by 3 mV/°C.	Battery will not fully charge when hot	Do not charge above 50° C (122° F)
What should I know about chargers?	Charger should float at 2.25-2.30 V/cell when ready.	Battery should not get too hot; should include temp sensor.	Battery must stay cool; no trickle charge when ready.

(Table courtesy of Cadex)

## DEPTH OF DISCHARGE

The end-of-discharge voltage for lead acid is 1.75 V/cell; for nickel-based systems it is 1.00 V/cell; and for most Li-ion it is 3.00 V/cell. At this level, roughly 95% of the battery's stored energy has been spent and voltage would drop rapidly if discharge were to continue. Most devices prevent operation beyond the specified end-of-discharge voltage. When removing the load after discharge, the voltage of a healthy battery gradually recovers toward the nominal voltage.

Because of internal resistance, wiring, protection circuits and contact resistance, a high load current lowers the battery voltage and the end-of-discharge voltage threshold should be lowered accordingly. The cutoff voltage should also be lowered when discharging at

**Table 7.12**  
**Recommended End-of-Discharge Voltages in V/Cell**

<i>End-of-discharge</i>	<i>Li-manganese</i>	<i>Li-phosphate</i>	<i>Lead-acid</i>	<i>NiCd/NiMH</i>
Normal load	3.00	2.70	1.75	1.00
Heavy load	2.70	2.45	1.40	0.90

(Table courtesy of Cadex)

very cold temperatures. **Table 7.12** shows typical end-of-discharge voltages of various battery chemistries. The lower end-of-discharge voltage for higher loads compensates for the losses from internal battery resistance.

Since the cells in a battery pack can never be perfectly matched, a negative voltage potential can occur across a weaker cell on a

multi-cell pack if the discharge is allowed to continue beyond a safe cutoff point. Known as *cell reversal*, the weak cell suffers damage to the point of developing a permanent electrical short circuit. The larger the number of cells in the pack, the greater the likelihood that a cell might reverse under heavy load. Over-discharge, particularly at low temperatures, is

a large contributor to battery failure of cordless power tools, especially for nickel-based packs. Li-ion packs have protection circuits and the failure rate is lower.

### DISCHARGING AT HIGH AND LOW TEMPERATURES

Batteries achieve optimum service life if used at 20° C (68° F) or slightly below, and nickel-based chemistries degrade rapidly when cycled at high ambient temperatures. Higher temperature operation lowers internal resistance and speeds up the chemical reactions but shortens service life if prolonged.

The performance of all battery chemistries drops drastically at low temperatures. At -20° C (-4° F) most nickel, lead, and lithium-based batteries stop functioning. Although NiCd can be used down to -40° C (-40° F), the permissible discharge is only 0.2 C (5-hour rate). Lead acid also has the problem of the electrolyte freezing which can crack the enclosure. Lead acid electrolyte also freezes more easily at a low charge.

### SIMPLE GUIDELINES FOR DISCHARGING BATTERIES

- Battery performance decreases with cold temperature and increases with heat.
- Heat increases battery performance but shortens cycle life by a factor of two for every 10° C (18° F) above 25-30° C (18° F above 77-86° F).
- Only charge at moderate temperatures. Check the manufacturer's specifications for charging below freezing.
- Use heating blankets if batteries need rapid charging at cold temperatures.
- Prevent over-discharging. Cell reversal can cause an electrical short circuit.
- Use a larger battery if repetitive deep discharge cycles cause stress.
- A moderate dc discharge is better for a battery than pulsed loads.
- Lead acid systems are sluggish and require a few seconds of recovery between heavy loads.

### 7.13.7 Battery Handling

This section touches on the most important aspects of handling batteries when they are new, during their service life, and how to store and dispose of them.

### FORMATTING AND PRIMING BATTERIES

Rechargeable batteries may not deliver their full rated capacity when new and will require *formatting* — a process that essentially completes the manufacturing process. Li-ion systems require less care in this regard, but cycling these batteries after long storage has been reported to improve performance. *Priming* is a conditioning cycle that is applied

to improve battery performance during usage or after prolonged storage. Priming applies mainly to nickel-based batteries.

Formatting of lead acid batteries occurs by applying a charge, followed by a discharge and recharge as part of regular use. Gradually increase the load on a new battery, allowing it to reach full capacity after 50 to 100 cycles.

Manufacturers advise to trickle charge a nickel-based battery pack for 16 to 24 hours when new and after a long storage. This allows the individual cells to reach an equal charge level. A slow charge also helps to redistribute the electrolyte to eliminate dry spots on the separator that may have formed due to gravity. Applying several charge/discharge cycles through normal use or with a battery analyzer completes the formatting process. This can require from five to seven cycles or as many as 50 cycles depending on battery quality.

Cycling also restores lost capacity when a nickel-based battery has been stored for six months or longer. Storage time, state-of-charge, and storage temperature all affect battery recovery. The longer the storage and the higher the temperature, the more cycles are required to regain full capacity.

Lithium-ion does not need formatting when new, nor does it require the level of maintenance that nickel-based batteries do. Maximum capacity is available immediately. A discharge/charge cycle may be beneficial for calibrating a "smart" battery but this does not improve the internal chemistry.

### STORING BATTERIES

The recommended storage temperature

### Testing and Monitoring Batteries

Several sections of the "Testing and Monitoring" chapter from *Batteries in a Portable World* are provided with this book's downloadable supplemental content. The information covers measuring internal resistance and state-of-charge, measuring capacity, and special techniques for measuring nickel- and lithium-based batteries.

for most batteries is 15° C (59° F) and the extreme allowable temperature is -40° C to 50° C (-40° F to 122° F) for most chemistries. While lead acid must be kept at full charge during storage, nickel and lithium-based chemistries should be stored at around 40% state-of-charge.

Storage will always cause batteries to age. **Table 7.13** illustrates the *recoverable capacity* of lithium and nickel-based batteries over various temperatures and charge levels over one year. Recoverable capacity is the available battery capacity after storage with a full charge.

A sealed lead acid battery can be stored up to two years. It is important to apply a charge when the battery falls to 70% SoC, typically 2.07 V/cell or 12.42 V for a 12 V pack.

Nickel-metal-hydride can be stored for about three years. The capacity drop that occurs during storage can partially be reversed with priming.

Primary alkaline and lithium batteries can be stored for up to 10 years with minimum capacity loss.

### SIMPLE GUIDELINES FOR STORING BATTERIES

- Remove batteries from equipment and store in a dry and cool place.
- Avoid freezing. Batteries freeze more easily if in a discharged state.
- Charge lead acid before storing and monitor the voltage frequently; apply a charge if below 2.10 V/cell.
- Nickel-based batteries can be stored for five years and longer, prime before use.
- Lithium-ion must be stored in a charged state, ideally 40%.
- Discard Li-ion if the voltage has stayed below 2.00 V/cell for more than a week.

### RECYCLING BATTERIES

The main objective for recycling batteries is to prevent hazardous materials from entering landfills. Lead acid and NiCd batteries are of special concern.

Under no circumstances should batteries be incinerated, as fire can cause an explosion. Wear approved gloves when touching electrolyte. On exposure to skin, flush with water immediately. If eye exposure occurs,

**Table 7.13**  
Estimated Recoverable Capacity After Storage For 1 Year

Temp (°C)	Lead acid at full charge	Nickel-based at any charge	Lithium-ion (Li-cobalt)	
			40% charge	100% charge
0	97%	99%	98%	94%
25	90%	97%	96%	80%
40	62%	95%	85%	65%
60	38% (after 6 months)	70%	75%	60% (after 3 months)

(Table courtesy of Cadex)

flush with water for 15 minutes and consult a physician immediately.

Automotive and larger lead acid batteries can be recycled through auto parts stores and battery dealers. A recycling fee is usually charged when the battery is purchased.

Smaller batteries, including smaller SLA, can be recycled at many electronics and hardware stores, or your local municipal recycling center. Perform an Internet search for battery recyclers in your area.

It is helpful to create a specific location or designate a container for spent batteries at your home, office or workbench. This makes it easy to recycle the batteries by keeping them together in one spot.

### 7.13.8 DC-AC Inverters

For battery-powered operation of ac-powered equipment, dc-ac inverters are used. An inverter is a dc-to-ac converter that provides 120 V ac. Inverters come with varying degrees of sophistication. The simplest type of inverter switches directly at 60 Hz to produce a square-wave output. This is no problem for lighting and other loads that don't care about the input waveform. However, some equipment will work poorly or not at all when supplied with square wave power because of the high harmonic content of the waveform.

The harmonic content of the inverter output waveform can be reduced by the simple expedient of reducing the waveform duty cycle from 50% (for the square wave) to about 40%. For many loads, such as computers and other electronic devices, this may still not be adequate, and so many inverters use waveform shaping to approximate a sine-wave output. The simplest of these methods is a resonant inductor-capacitor filter. This adds significant weight and size to the inverter. Most modern inverters use high-frequency pulse-width modulation (PWM) techniques to synthesize the 60 Hz sinusoidal output waveform, much like a switching power supply. See **Figure 7.54**.

Inverters are usually rated in terms of their VA or "volt-ampere product" capability although sometimes they will be rated in watts. Care is required in interpreting inverter ratings. A purely resistive load operating from a sinusoidal voltage source will have a sinusoidal current flowing in phase with the voltage. In this case, VA, the product of the voltage (V) and the current (A), will equal the actual power in watts delivered to the load so that the VA and the watt ratings are the same. Some loads, such as motors and many rectifier power supplies, will shift the phase of load current away from the source voltage; or the load current will flow in short pulses as shown earlier for capacitor input filters. In these cases (which are very common), the VA product for that type of load can be

**Figure 7.54** — Output waveforms of typical dc-ac inverters. At A, the output of a modified sine wave inverter. Note the stepped square waves. At B, the output of a "pure sine wave" inverter. Note the close approximation of a commercial ac sine wave.

much larger than the delivered power in watts. In the absence of detailed knowledge of the load characteristics it is prudent to select an inverter with a VA or wattage capability of 25% or more above the expected load.

### 7.13.9 Selecting a Battery for Mobile Operation

There are two basic modes of mobile operation: *in-motion*, and *stationary*. Each mode has unique power requirements and thus different battery requirements. To satisfy these needs, there are three basic battery types. It is important to understand the differences between the types and to apply them properly.

Standard vehicle batteries are referred to as *SLI* (starting, lights, ignition) or just *starter* batteries. Their primary function is to start the engine and then act as a power filter for the alternator which is the actual long-term power source. The most important rating of an SLI battery is the *cold cranking amps* (CCA) rating — the number of amps that the battery can produce at 32 °F (0 °C) for 30 seconds.

Batteries designed for repeated cycles of charging and discharging use are often called *deep-cycle* although the term is widely overused. A true deep-cycle battery is designed to

be repeatedly discharged to 20% remaining capacity. The term "deep cycle" is a misnomer, as all lead-acid batteries are considered discharged when their output voltage drops below 10.5 V at some specified current draw as outlined by the Battery Council Institute (BCI—[www.batterycouncil.org](http://www.batterycouncil.org)). At 10.5 V, a six-cell lead-acid battery is considered discharged.

*Marine* batteries are designed to be stored without charging for up to two years, yet still maintain enough power to start a marine engine. Contrary to common practice, they're not really designed for extended low-current power delivery. Marine batteries often have hybrid characteristics between SLI and deep-cycle batteries.

To differentiate true deep-cycle batteries from SLI and marine batteries, examine a battery's *reserve capacity* (RC). A battery's RC rating is the number of minutes that the battery can deliver 25 A while maintaining an output voltage above 10.5 V. Deep cycle batteries typically have RC ratings 20% or more higher than SLI batteries and perhaps 50% higher under ICAS (intermittent, commercial, and amateur service) conditions. A deep-cycle battery has a lower CCA rating than an SLI battery due to its internal construction that favors long-term power delivery over high-current starting loads.

With these facts in mind, we can now select the correct battery for our style of mobile operating. For in-motion operation with power outputs up to 200 W, a second trunk-mounted battery is seldom needed if the power cabling wire size is chosen correctly. (See the **Assembling a Station** chapter for information on wire sizes in mobile applications.)

When an amplifier is added for higher output power levels, it is often less expensive to add a second trunk-mounted battery than to install larger cables to the main battery. In these cases, the second battery can be of almost any type, as long as it is lead-acid. The second battery should be connected in parallel to the vehicle's main SLI battery. The battery's ampere-hour rating should be close to that of the vehicle's main SLI battery.

All secondary wiring should be properly fused, as outlined in the **Assembling a Station** chapter's section on mobile installations. The use of relays and circuit breakers should be avoided. Remember, should a short circuit occur, good-quality lead-acid batteries can deliver upwards of 3000 A which exceeds the break circuit ratings of most relays and circuit breakers. A better solution is a FET switch such as those made by Perfect Switch ([www.perfectswitch.com](http://www.perfectswitch.com)).

Assuming the second battery is mounted inside the vehicle's passenger compartment or in the trunk, it should be an AGM type. AGM (Absorption Glass Mat) batteries do not outgas explosive hydrogen gas under normal

operating conditions. Flooded (liquid electrolyte) batteries should *never* be used in an enclosed environment.

For stationary operation, select a battery with a large RC rating because it will not be continuously charged. There are two main considerations; the ampere-hour rating (Ah) and the reserve capacity rating, typically listed as C/8, C/10, or C/20, with units of hours. (C is the battery's capacity in Ah.) Dividing the Ah rating by the load amperage (8, 10 or 20 A) will give you the reserve capacity in hours, but the actual ampere-hours any given battery can deliver before the voltage reaches 10.5 V (nominal discharge level) will vary with the load, both average and peak. Heavier loads will reduce the actual ampere-hours available.

Automotive batteries are arranged in BCI group sizes ([www.batterystuff.com/kb/tools/bci-battery-group-sizes.html](http://www.batterystuff.com/kb/tools/bci-battery-group-sizes.html)), from 21 through 98. Generally speaking, the larger the group size the larger the battery and the higher the Ah rating. For example, size 24 (small car) has an average rating of 40 Ah, and size 34 (large car) has an average rating of 55 Ah. Exact ratings, including their reserve

capacity, are available from the manufacturers' websites listed below. A good rule of thumb is to select a battery as physically large as you have room for, consistent with the highest RC rating for any given Ah rating.

Batteries are heavy, and need to be properly secured inside a battery box or by using factory-supplied brackets. For example, a BIC group 34 (average SLI size) battery weighs about 55 pounds. Some battery models (such as the Optima) come supplied with mounting brackets and terminal protection covers. Even though battery boxes aren't always needed, they should be used as a safety precaution to prevent accidental contact with the terminals and can protect the battery from external items. Battery restraints should be adequate to provide 6 Gs of lateral and 4 Gs of vertical retention, ruling out sheet metal screws and most webbing material. Use the proper brackets!

There are three other considerations: isolating the battery electrically, recharging the battery, and output voltage regulation. Diode-based battery isolators are not all equal. Models with FET bypass switches are the preferred type because of the low

voltage-drop across the FET.

If you have wired the battery in parallel with the vehicle's main SLI battery, recharging is taken care of whenever the vehicle is running. If you plan on operating in stationary mode, you'll need a separate recharging system. Most vehicle factory-installed trailer wiring systems also include a circuit for charging RV or boat "house" batteries. Check with your dealer's service personnel about these options.

Voltage regulators, commonly called "battery boosters," are almost a necessity for stationary operation. A model with a low-voltage cutoff should be used to avoid discharging the battery below 10.5 V, as discharging a lead-acid battery beyond this point drastically reduces its charge-cycle life — the number of full-charge/full-discharge cycles. (See the November 2008 *QST* Product Review column.)

## 7.14 Glossary of Power Source Terms

**Bleeder** — A resistive load across the output or filter of a power supply, intended to quickly discharge stored energy once the supply is turned off.

**Boost converter** — A switchmode converter in which the output voltage is always greater than or equal to the input voltage.

**Buck converter** — A switchmode converter in which the output voltage is always less than or equal to the input voltage.

**Buck-boost converter** — A switchmode converter in which the magnitude of the output voltage can be either greater or less than the input voltage.

**C-rate** — The charging rate for a battery, expressed as a ratio of the battery's ampere-hour rating.

**CCA (cold cranking amps)** — A measure of a battery's ability to deliver high current to a starter motor.

**Circular mils** — A convenient way of expressing the cross-sectional area of a

round conductor. The area of the conductor in circular mils is found by squaring its diameter in mils (thousandths of an inch), rather than squaring its radius and multiplying by pi. For example, the diameter of 10-gauge wire is 101.9 mils (0.1019 inch). Its cross-sectional area is 10380 CM, or 0.008155 square inches.

**Core saturation (magnetic)** — That condition whereby the magnetic flux in a transformer or inductor core is more than the core can handle. If the flux is forced beyond this point, the permeability of the core will decrease, and it will approach the permeability of air.

**Crowbar** — A last-ditch protection circuit included in many power supplies to protect the load equipment against failure of the regulator in the supply. The crowbar senses an overvoltage condition on the supply's output and fires a shorting device (usually an SCR) to directly short-circuit the supply's output and protect

the load. This causes very high currents in the power supply, which blow the supply's input-line fuse.

**Darlington transistor** — A package of two transistors in one case, with the collectors tied together, and the emitter of one transistor connected to the base of the other. The effective current gain of the pair is approximately the product of the individual gains of the two devices.

**DC-DC converter** — A circuit for changing the voltage of a dc source to ac, transforming it to another level, and then rectifying the output to produce direct current.

**Deep-cycle** — A battery designed for repeated charge-discharge cycles to 20% of remaining capacity.

**Equalizing resistors** — Equal-value bypassing resistors placed across capacitors connected in series for use in a high-voltage power supply to keep the voltages across the capacitors in the string relatively constant.

- Fast recovery rectifier** — A specially doped rectifier diode designed to minimize the time necessary to halt conduction when the diode is switched from a forward-biased state to a reverse-biased state.
- Flyback converter** — A transformer-coupled version of the **buck-boost converter**.
- Forward converter** — A **buck converter** with multiple isolated outputs at different voltage levels and polarities.
- Foldback current limiting** — A special type of current limiting used in linear power supplies, which reduces the current through the supply's regulator to a low value under short circuited load conditions in order to protect the series pass transistor from excessive power dissipation and possible destruction.
- Ground fault (circuit) interrupter (GFI or GFCI)** — A safety device installed between the household power mains and equipment where there is a danger of personnel touching an earth ground while operating the equipment. The GFI senses any current flowing directly to ground and immediately switches off all power to the equipment to minimize electrical shock. GFCIs are now standard equipment in bathroom and outdoor receptacles.
- Input-output differential** — The voltage drop appearing across the series pass transistor in a linear voltage regulator. This term is usually stated as a minimum value, which is that voltage necessary to allow the regulator to function and conduct current. A typical figure for this drop in most three-terminal regulator ICs is about 2.5 V. In other words, a regulator that is to provide 12.5 V dc will need a source voltage of at least 15.0 V at all times to maintain regulation.
- Inverter** — A circuit for producing ac power from a dc source.
- Li-ion** — Lithium-ion, a type of rechargeable battery that is about 1/3 the weight and 1/2 the volume of a **NiCd** battery of the same capacity.
- Low dropout regulator** — A three-terminal regulator designed to work with a low minimum input-output differential value.
- Marine** — A battery designed to retain significant energy over long periods of time without being continuously charged.
- NiCd** — Nickel cadmium, a type of rechargeable battery.
- NiMH** — Nickel metal hydride, a type of rechargeable battery that does not contain toxic substances.
- Peak inverse voltage (PIV)** — The maximum reverse-biased voltage that a semiconductor is rated to handle safely. Exceeding the peak inverse rating can result in junction breakdown and device destruction.
- Power converter** — Another term for a power supply.
- Power processor** — Another term for a power supply.
- Primary battery** — A battery intended for one-time use and then discarded.
- RC (reserve capacity)** — A measure of a battery's ability to deliver current over long periods.
- Regulator** — A device (such as a Zener diode) or circuitry in a power supply for maintaining a constant output voltage over a range of load currents and input voltages.
- Resonant converter** — A form of dc-dc converter characterized by the series pass switch turning on into an effective series-resonant load. This allows a zero current condition at turn-on and turn-off. The resonant converter normally operates at frequencies between 100 kHz and 500 kHz and is very compact in size for its power handling ability.
- Ripple** — The residual ac left after rectification, filtration and regulation of the input power.
- RMS** — Root Mean Square. Refers to the effective value of an alternating voltage or current, corresponding to the dc voltage or current that would cause the same heating effect.
- Secondary battery** — A battery that may be recharged many times. Also called a *storage battery*.
- Secondary breakdown** — A runaway failure condition in a transistor, occurring at higher collector-emitter voltages, where hot spots occur due to (and promoting) localization of the collector current at that region of the chip.
- Series pass transistor, or pass transistor** — The transistor(s) that control(s) the passage of power between the unregulated dc source and the load in a regulator. In a linear regulator, the series pass transistor acts as a controlled resistor to drop the voltage to that needed by the load. In a switch-mode regulator, the series pass transistor switches between its ON and OFF states.
- SLI (starter, lights, ignition)** — An automotive battery designed to start the vehicle and provide power to the lighting and ignition systems.
- SOA (Safe Operating Area)** — The range of permissible collector current and collector-emitter voltage combinations where a transistor may be safely operated without danger of device failure.
- Surge** — A moderate-duration perturbation on a power line, usually lasting for hundreds of milliseconds to several seconds.
- Switching regulator** — Another name for a switchmode converter.
- Switchmode converter** — A high-efficiency switching circuit used for dc-dc power conversion. Switching circuits are usually much smaller and lighter than conventional 60 Hz, transformer-rectifier circuits because they operate at much higher frequencies — from 25 to 400 kHz or even higher.
- Three-terminal regulator** — A device used for voltage regulation that has three leads (terminals) and includes a voltage reference, a high-gain error amplifier, temperature-compensated voltage sensing resistors and a pass element.
- Transient** — A short perturbation or "spike" on a power line, usually lasting for microseconds to tens of milliseconds.
- Varistor** — A surge suppression device used to absorb transients and spikes occurring on the power lines, thereby protecting electronic equipment plugged into that line. Frequently, the term MOV (*Metal Oxide Varistor*) is used instead.
- Volt-Amperes (VA)** — The product obtained by multiplying the current times the voltage in an ac circuit without regard for the phase angle between the two. This is also known as the apparent power delivered to the load as opposed to the actual or real power absorbed by the load, expressed in watts.
- Voltage multiplier** — A type of rectifier circuit that is arranged so as to charge a capacitor or capacitors on one half-cycle of the ac input voltage waveform, and then to connect these capacitors in series with the rectified line or other charged capacitors on the alternate half-cycle. The voltage doubler and tripler are commonly used forms of the voltage multiplier.
- Voltage regulation** — The change in power supply output voltage with load, expressed as a percentage.

# 7.16 Power Source Projects

Construction of a power supply or accessory — basic to all of the radio equipment we operate and enjoy — can be one of the most rewarding projects undertaken by a radio amateur. Final testing and adjustment of most power-supply projects requires only a voltmeter, and perhaps an oscilloscope — tools commonly available to most amateurs.

General construction techniques that may be helpful in building the projects in this chapter are outlined in the **Construction Techniques** chapter. Other chapters in the *Handbook* contain basic information about the components that make up power supplies.

Safety must always be carefully considered during design and construction of any power supply. Power supplies contain potentially lethal voltages, and care must be taken to guard against accidental exposure. For example, electrical tape, insulated tubing ("spaghetti") or heat-shrink tubing is recommended for covering exposed wires, components leads, component solder terminals and tie-down points. Whenever possible, connectors used to mate the power supply to the outside world should be of an insulated type designed to prevent accidental contact.

Connectors and wire should be checked for voltage and current ratings. Always use wire with an insulation rating higher than the working voltages in the power supply. For supply

voltages above 300 V, use wire with insulation rated accordingly. The **Component Data and References** chapter contains a table showing the current-carrying capability of various wire sizes. Scrimping on wire and connectors to save money could result in flashover, meltdown or fire.

All fuses and switches should be placed in the hot circuit(s) only. The neutral circuit should not be interrupted. Use of a three-wire (grounded) power connection will greatly reduce the chance of accidental shock. The proper wiring color code for 120 V circuits is: black — hot; white — neutral; and green — ground. For 240 V circuits, the second hot circuit generally uses a red wire.

## POWER SUPPLY PRIMARY-CIRCUIT CONNECTOR STANDARD

The International Commission on Rules for the Approval of Electrical Equipment (CEE) standard for power-supply primary-circuit connectors for use with detachable cable assemblies is the CEE-22. The CEE-22 has been recognized by the ARRL and standards agencies of many countries. Rated for up to 250 V, 6 A at 65 °C, the CEE-22 is the most commonly used three-wire (grounded), chassis-mount primary circuit connector for electronic equipment in North America and Europe. It is often used in Japan and Australia as well.

When building a power supply requiring 6 A or less for the primary supply, a builder would do well to consider using a CEE-22 connector and an appropriate cable assembly, rather than a permanently installed line cord. Use of a detachable line cord makes replacement easy in case of damage. CEE-22 compatible cable assemblies are available with a wide variety of power plugs including most types used overseas.

Some manufacturers even supply the CEE-22 connector with a built-in line filter. These connector/filter combinations are especially useful in supplies that are operated in RF

fields. They are also useful in digital equipment to minimize conducted interference to the power lines.

CEE-22 connectors are available in many styles for chassis or PC-board mounting. Some have screw terminals; others have solder terminals. Some styles even contain built-in fuse holders.

## 7.16.1 Four-Output Switching Bench Supply

This project by Larry Cicchinelli, K3PTO, describes the four-output bench power supply shown in **Figure 7.55** with three positive outputs and one negative output. The three positive outputs use identical switching regulator circuits that can be set independently to any voltage between 3.3 V and 20 V at up to 1 A. The fourth output is a negative regulator capable of about 250 mA. As built, the supply has two fixed outputs and two variable outputs, but any module can be built with variable output. (Construction diagrams and instructions, a complete parts list, and additional design details are included with this book's downloadable supplemental content.)

The only dependency among the outputs is that they are all driven by a single transformer. The transformer used is rated at 25 V and 2 A

## Switchmode DC-DC Converters

Inexpensive dc-dc converter modules available online can reduce or increase dc voltage from common power sources, avoiding the need for a full power supply. For example, a 5 V dc USB charging port can be converted to 9 V, as described by Tom Wheeler, NØGSG, in the downloadable project article.

Figure 7.55 — The front panel of the four-output switching supply.

—good for 50 W. Assuming that the regulator IC being used has a 75% efficiency, a total of about 37 W is available from the power supply outputs.

One of the features of a switching regulator is that you can draw more current from the outputs than what the transformer is supplying — at a lower voltage, of course — as long as you stay within the 37 W limit and maximum current for the regulator. Most of the discussion in this article will be about the positive regulators as the negative regulator was an add-on after the original system was built.

### POSITIVE REGULATOR

Figure 7.56 is the circuit for the positive regulator modules — a buck-type regulator.

There are several variations of the circuit, any of which you can implement.

- L2 and C4 are optional. These two components implement a low-pass filter that will decrease high frequency noise that might otherwise appear at the output.

- The pads for R1 will accommodate a small, multi-turn potentiometer. You can insert one here or you can use the pads to connect a panel-mounted potentiometer.

- If you want a fixed output you can simply short out R1 and use R2 by itself.

- You can also insert a fixed resistor in the R1 position in the case where the calculated value is non-standard and you want to use two fixed resistors.

The formula for setting output voltage using the 3.3 V version of the regulator is based

on knowing the current (in mA) through the regulator's internal voltage divider =  $3.3 \text{ V} / 2.7 \text{ k}\Omega = 1.22 \text{ mA}$ . The sum of R1 and R2 must cause the voltage at the regulator FB pin to equal 3.3 V. Thus,  $R1 + R2$  in  $\text{k}\Omega = (V_{\text{out}} - 3.3) / 1.22$  and  $V_{\text{out}} = 1.22 (R1 + R2) + 3.3$ . If  $R1 = R2 = 0$ , a direct connection from the output voltage to the FB pin, the calculation results in an output of 3.3 V. The leakage current of the Error Amplifier in the regulator is somewhat less than 25 nA so it can be ignored. The values for R1 and R2 are shown in the caption for Figure 7.56.

The only critical parts are R1 and R2 which form the voltage dividers for the regulator module. Even their values can be changed, within reason, as long as the ratios are maintained. If you want to have an accurate, fixed

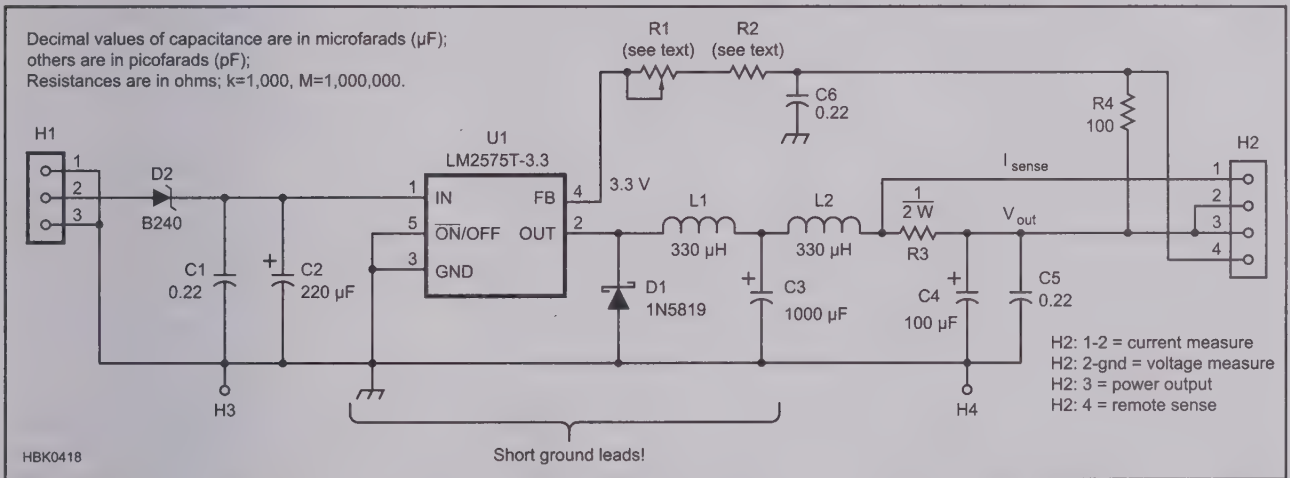

Figure 7.56 — The positive buck-type switching regulator uses the LM2575-3.3, a fixed-voltage regulator, with an external voltage-set resistor (R1 + R2). See text for details of the calculations needed to determine the value of R1 and R2. As noted in the text, these values are the total resistance for both parts, and can be made from one fixed resistor, one variable resistor or a combination. Some common values (R1 + R2 total) are: For a 12 V fixed supply, 7.1 kΩ; for 5 V, 1.4 kΩ; for a 3.3 to 20 V variable supply, 0-13.7 kΩ (use a 15 kΩ pot); for 5 to 15 V, 1.4-9.6 kΩ (use 1 kΩ fixed-value resistor and a 1 kΩ pot). A full parts list is included with this book's downloadable supplemental content.

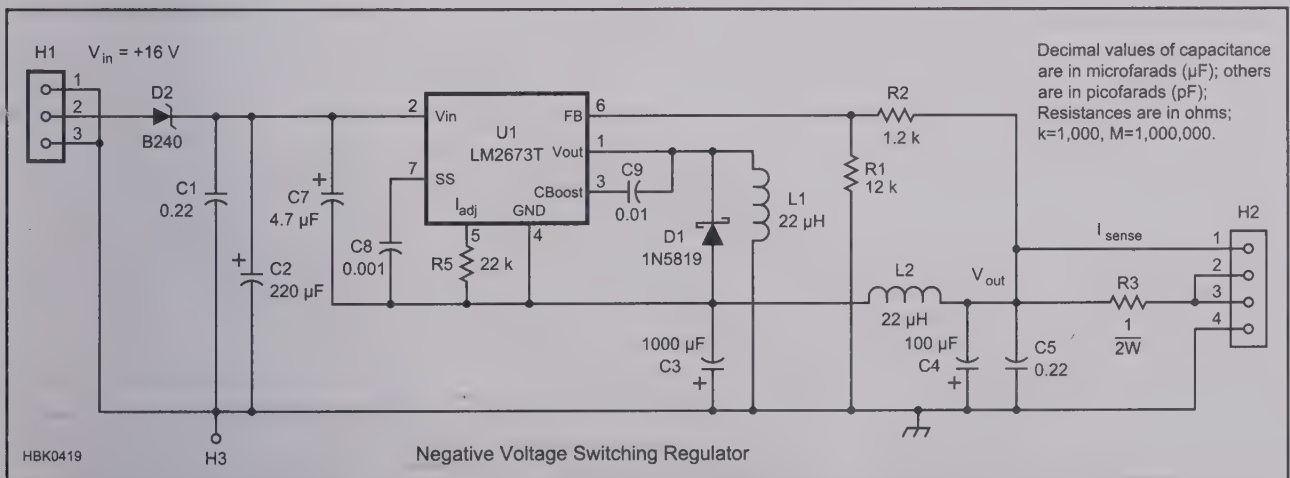

Figure 7.57 — The negative regulator uses the LM2673T in a buck-boost circuit. This circuit inverts the output voltage from the input voltage. A full parts list is included with this book's downloadable supplemental content.

output voltage, select a value for R2 that is lower than the calculated value and use a potentiometer for R1 to set the voltage exactly. The value of C3 is not especially critical; however, it should be a low-ESR (equivalent series resistance) type that is intended for use in switchmode circuits.

### NEGATIVE REGULATOR

The negative regulator is a buck-boost configuration — it converts a positive voltage into a negative one — see **Figure 7.57**. This design uses many of the same component values as the positive regulators except the regulator IC is an LM2673 to improve circuit stability. The author was unable to implement the current measuring circuit within a feedback loop. Several configurations introduced a significant low frequency noise component to the output voltage. There was also some 50 kHz noise present on the output, but an additional low-pass filter on the output reduced it considerably.

### REMOTE SENSING

Many power supplies use remote sensing to compensate electronically for the voltage drop in the wires carrying current to the load. Even with relatively short wires, there can be significant voltage drop between the regulator and its load. There is provision for remote sensing in this circuit described in the support information for this project included with this book's downloadable supplemental content.

If you are not going to use remote sensing then you should insert a jumper in place of R4 in **Figure 7.56**. R4 (100 Ω) is there for protection just in case the remote sense connection is missing. If you do not want to use remote sensing you can simplify the digital panel meter (DPM) switch wiring to use a two-pole switch instead of the three-pole model listed. In this case, do not use S2.2 and connect S1.2 to the common of S2.3 instead of S2.2.

### SUB-CIRCUIT INTERCONNECTION

**Figure 7.58** shows the connections among the parts of the system: regulator boards, the digital panel meter (DPM), and rectifier circuit. The components used for the main rectifier circuit can be mounted on a terminal strip and do not need to be on a printed-circuit board.

### THE DIGITAL PANEL METER

Another feature of the unit is the DPM which can be switched to measure the output voltage (H2 pin 1 to ground) as well as the current draw (voltage between H2 pins 1 and 2) for each of the positive supplies. **Figure 7.58** shows the 3-pole, 4-position rotary switch (S2) that selects which power supply to monitor and a 3PDT toggle switch (S1) that selects between measuring voltage and current.

In order to measure the voltage drop across

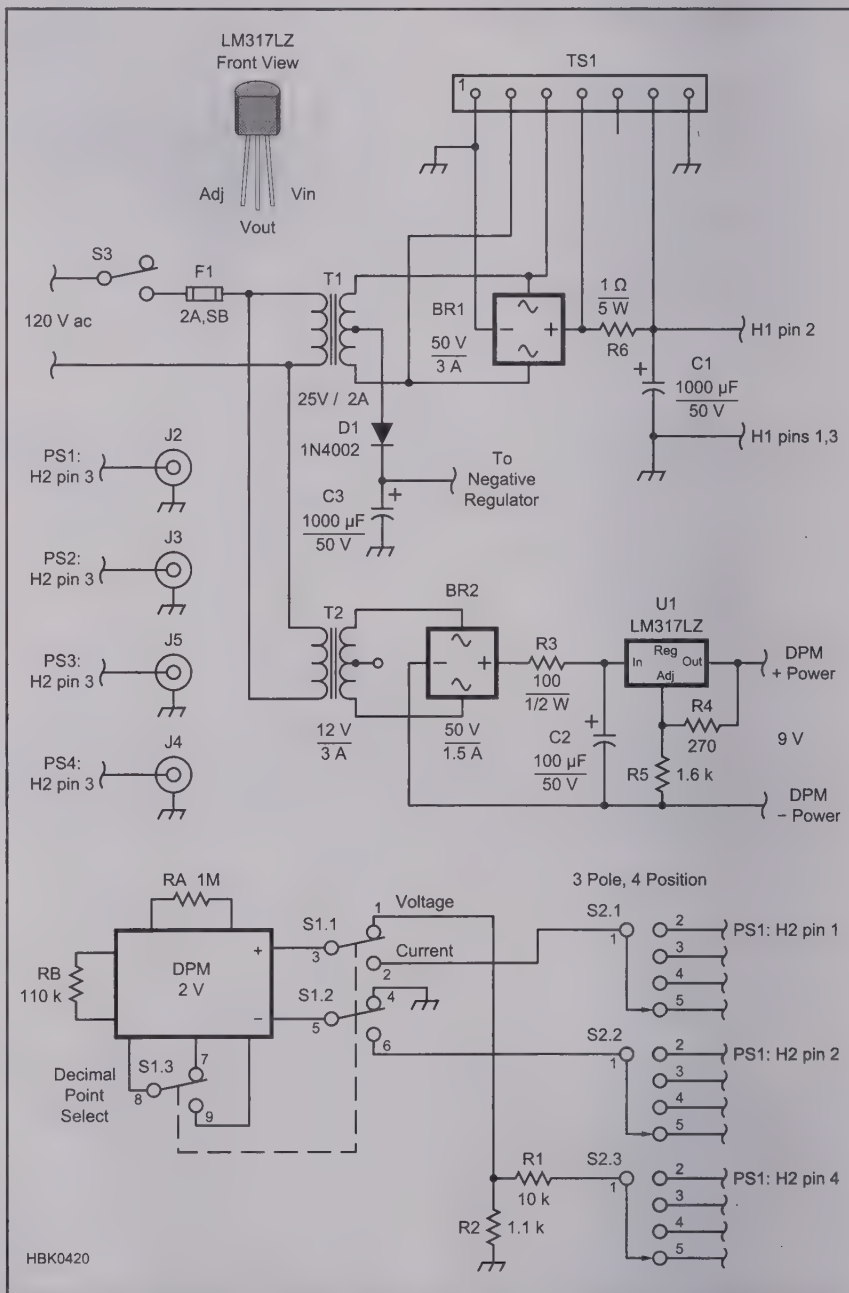

the 1 Ω current sense resistors, the DPM needs either an isolated power supply or some more circuitry. This system uses an isolated power supply. A series regulator is used simply because they are somewhat easier to implement and the DPM has a very low current requirement. All components except the transformer are mounted on a piece of perforated board. Since the 1.2 mA current for the feedback circuit flows through the current sense resistor

it will be included in the value displayed by the DPM when current is selected.

The DPM also has a set of jumpers that allow you to set the decimal point location. As can be seen in **Figure 7.58**, one pole of the toggle switch selects its location.

### CONSTRUCTION DETAILS

Both the DPM and the regulators use pin headers for all of the connections that come

**Figure 7.58** — Rectifier and metering schematic. The panel meter is switched between the four modules with a rotary switch (S2) and between voltage and current with a 3PDT toggle (S1). A separate rectifier provides power for the negative supply and a separate three-terminal regulator circuit provides power to the DPM. A full parts list is included with this book's downloadable supplemental content.

off the boards (see the parts list for details). This allows assembly of the subsystems without having to consider any attached wires. Wire lengths can be determined later, then install the mating connectors on the wires and simply push them onto the pins.

PC boards are available from FAR Circuits ([www.farcircuits.net](http://www.farcircuits.net)), a company that provides a lot of boards for ham-related projects. A caution regarding the circuit boards is in order—the boards do not have plated through holes so you will have to be sure that you solder the through-hole components on *both* sides of the board.

Artwork for the PC board layout, Gerber files, and a drill file are available with this book's downloadable supplemental content. The schematic capture software *DipTrace* was used in the development of this project. Source files for the schematic and PCB files are also included with this book's downloadable supplemental content.

### 7.16.2 12 V, 15 A Linear Power Supply

This power supply is a linear 12 V, 15 A design by Ed O'Carson, WA1TWX. It is suitable for typical mobile radios and offers adjustable output voltage and current limiting. Supply regulation is excellent, typically exhibiting a change of less than 20 mV from no load to 15 A. This basic design, with hefty components and additional pass transistors, can deliver over 30 A—enough to supply a 100 W class transceiver. (All numbered notes, additional circuit design information, a discussion of how to change the supply voltage and/or current ratings, construction and testing notes, a PCB template and a complete parts list are included with this book's downloadable supplemental content.)

#### CIRCUIT DESCRIPTION

**Figure 7.59** is the supply's schematic. The ac line input is fused by F1, switched on and off by S1 and filtered by FL1. F1 and S1 are rated at about ¼ of the output current requirement (for 15 A output, use a 4 or 5 A slow-blow fuse or a similarly rated circuit breaker). FL1 prevents any RF from the secondary or load from coupling into the power line and prevents RF on the power line from disturbing supply operation. If your ac power line is clean, and you experience no RF problems, you can eliminate FL1, but it's inexpensive insurance.

When discharged, filter capacitor C1 looks like a short circuit across the output of rectifier U2 when ac power is applied. That usually subjects the rectifier and capacitor to a large inrush current, which can damage them. Fortunately a simple and inexpensive means of inrush-current limiting is available. Keystone Carbon Company (and others) produce a line of inrush-current limiters (thermistors) for

this purpose. The device (RT1) is placed in series with one of the transformer primary leads. RT1 has a current rating of 6 A<sup>1</sup>, and a cold resistance of 5 Ω. When it's hot, RT1's resistance drops to 0.11 Ω. Such a low resistance has a negligible effect on supply operation. Thermistors run *hot* so they must be mounted in free air, and away from anything that can be damaged by heat.<sup>2,3</sup>

The largest and most important part in the power supply is the transformer (T1). If purchased new, it can also be the most costly. Fortunately, a number of surplus dealers offer power transformers that can be used in this supply.

T1 produces 17 V ac RMS at 20 A; the center tap is not used. Bridge rectifier U2 provides full-wave rectification. Full-wave rectification reduces the ripple component of current that flows in the filter capacitor, resulting in less power dissipation in the capacitor's internal resistance. U2's voltage rating should be at least 50 V, and its current rating about 25% higher than the normal load requirement; a 2 A bridge rectifier will do. U2 is secured to the chassis or a heat sink because it dissipates heat.

C1 is a computer-grade electrolytic. Any capacitor value from 15,000 to 30,000 μF will suffice. This version uses a 19,000 μF, 40 V capacitor. The capacitor's voltage rating should be at least 50% higher than the expected no-load rectified dc voltage. In this supply, that voltage is 25 V, and a 40 V capacitor provides enough margin.

R5, a 75 Ω, 20 W bleeder resistor, is connected across C1's terminals to discharge the supply when no load is attached or one is removed. Any resistance value from 50 Ω to 200 Ω is fine; adjust the resistor's wattage rating appropriately.

At the terminals of C1, we have a dc voltage, but it varies widely with the load applied. When keying a CW transmitter or switching a rig from receive to full output, 5 V swings can result. The dc voltage also has an ac ripple component of up to 1.5 V under full load. Adding a solid-state regulator (U1) provides a stable output voltage even with a varying input and load.

#### VOLTAGE REGULATOR IC AND PASS TRANSISTORS

The LM723 used at U1 has a built-in voltage reference and sense amplifier, and a 150 mA drive output for a pass-transistor array. U1's voltage reference provides a stable point of comparison for the internal regulator circuitry. In this supply, it's connected to the non-inverting input of the voltage-sense op amp. The reference is set internally to 7.15 V,

but the absolute value is not critical because an output-voltage adjustment (R12) is provided. What is important is that the voltage is stable, with a specified variation of 0.05% per 1000 hours of operation. This is more than adequate for the supply.

For the regulator to work properly, its ground reference must be at the same point as the output ground terminal. The best way to ensure this is to use the output GROUND terminal (J4) as a single-point ground for all of the supply grounds. Run wires to J4 from each component requiring a ground connection. Figure 7.59 attempts to show this graphically through the use of parallel connections to a single circuit node.

The output pass transistor array consists of a TIP112 Darlington-pair transistor (Q5) driving three 2N3055 power transistors (Q1-Q3). This two-stage design is less efficient than connecting the power transistors directly to the LM723, but Q5 can provide considerably more base current to the 2N3055s than the 150 mA maximum rating of the LM723. You can place additional 2N3055s in parallel to increase the output current capacity of the supply.

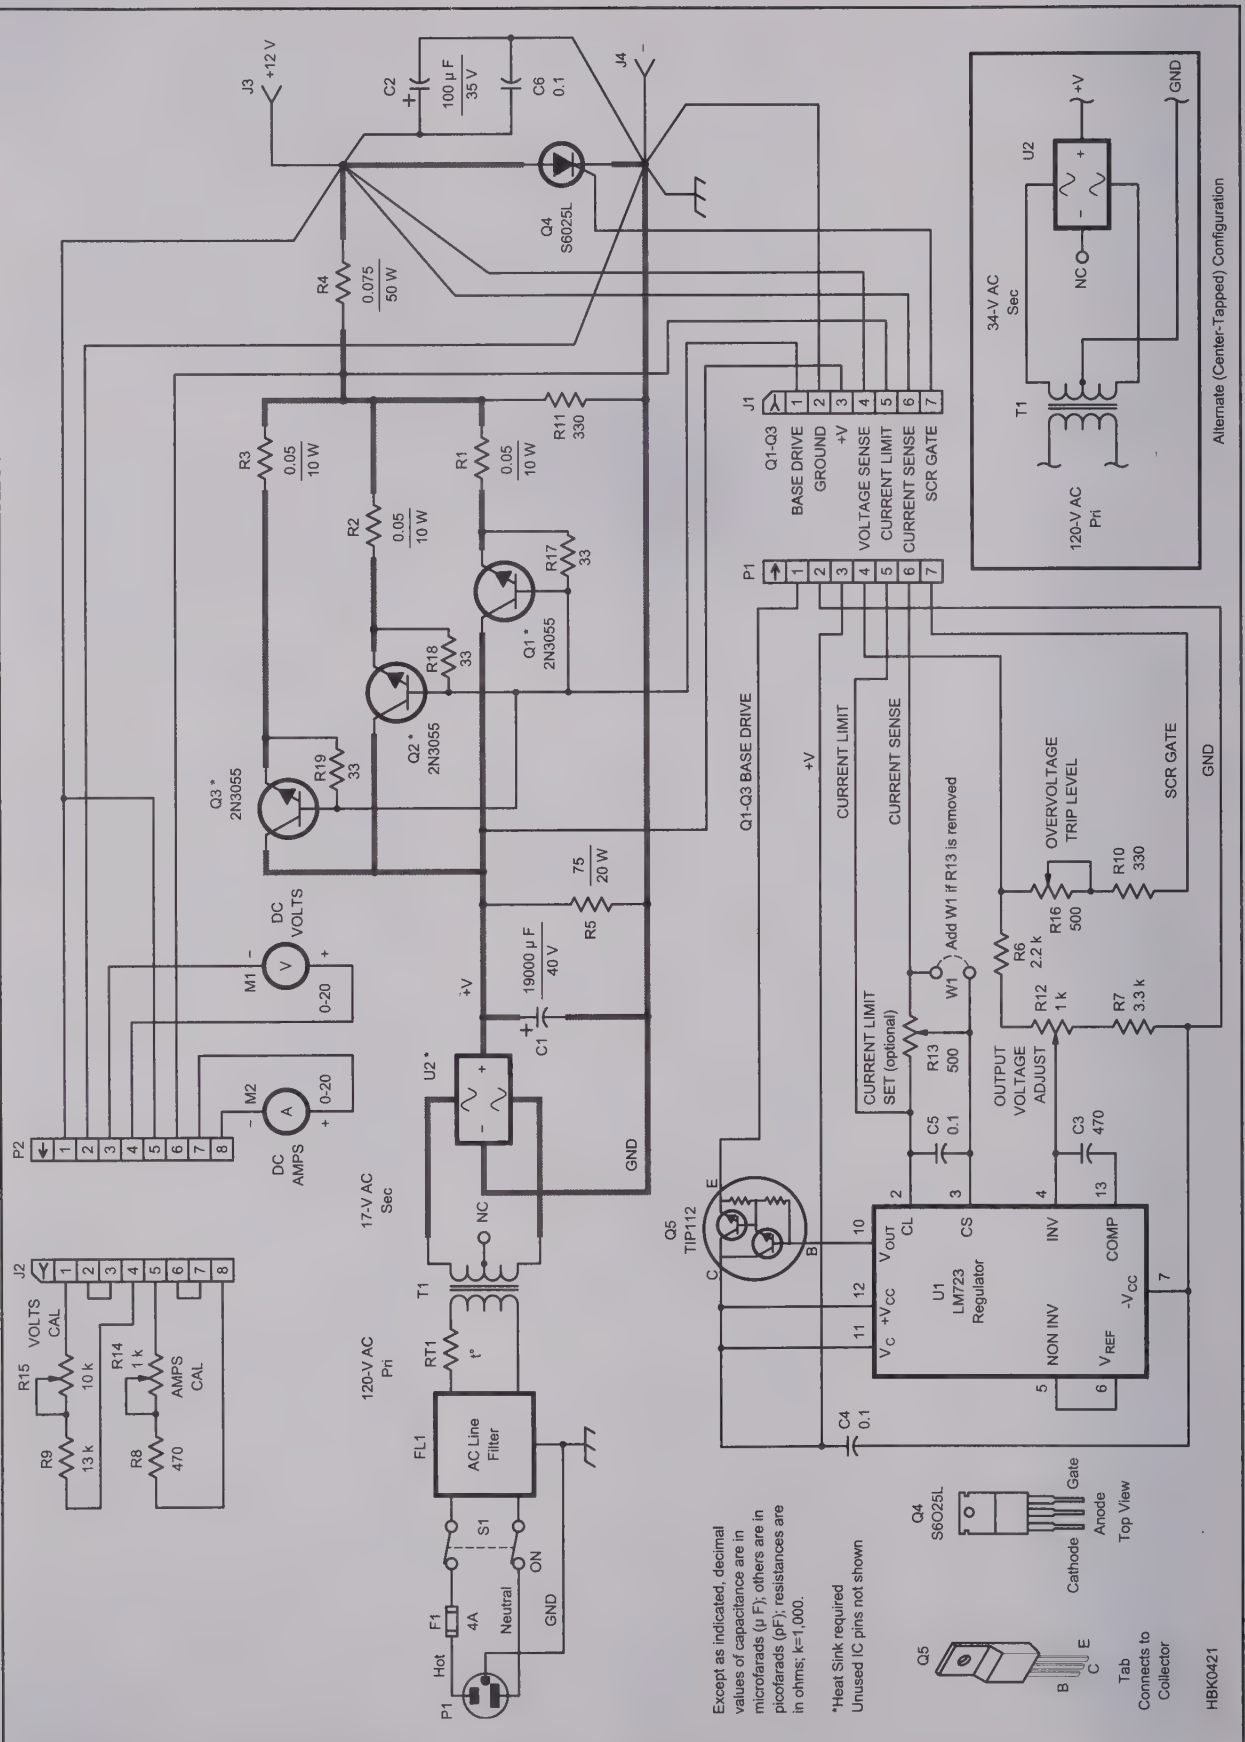

This design is not fussy about the pass transistors or the Darlington transistor used. Just ensure all of these devices have voltage ratings of at least 40 V. Q5 must have a 5 A (or greater) collector-current rating and a beta of over 100. The pass transistors should be rated for collector currents of 10 A or more, and have a beta of at least 10.<sup>5</sup>

Resistors R17, R18 and R19 prevent leakage current through the collector-base junction from turning on the transistor by diverting it around the base-emitter junction. When the pass transistors are hot, at the  $V_{CE}$  encountered in this design, the leakage current can be as high as 3 mA. The resulting drop across the 33 Ω resistors is 0.1 V—safely below the turn-on value for  $V_{BE}$ .

When unmatched transistors are simply connected in parallel they usually don't equally share the current.<sup>6</sup> By placing a low-value resistor in each transistor's emitter lead (emitter-ballasting resistors, R1-R3), equal current sharing is ensured. When a transistor with a lower voltage drop tries to pass more current, the emitter resistor's voltage drop increases, allowing the other transistors to provide more current. Because the voltage-sense point is on the load side of the resistors, the transistors are forced to dynamically share the load current.

With a 5 A emitter current, 0.25 V develops across each 0.05 Ω resistor, producing 1.25 W of heat. Ideally, a resistor's power rating should be at least twice the power it's called upon to dissipate. To help the resistors dissipate the heat, mount them on a heat sink, or secure them to a metal chassis. You can use any resistor with a value between 0.065 and

<sup>1</sup>See the full article included with this book's downloadable supplemental content for a list of numbered notes.

Except as indicated, decimal values of capacitance are in microfarads ( $\mu F$ ); others are in picofarads (pF); resistances are in ohms; k=1,000.

\*Heat Sink required  
Unused IC pins not shown

HBK0421

Figure 7.59 — Schematic of the 12 V, 15 A power supply. A parts list is included with this book's downloadable supplemental content. Equivalent parts can be substituted. The bold lines indicate high-current paths that should use heavy-gauge (#10 or #12 AWG) wire. This schematic graphically shows wiring to a single-point ground; see text. The majority of the parts used in this supply are available as surplus components.

0.1  $\Omega$ , but remember that the power dissipated is higher with higher-value resistors (10 W resistors are used here).

At the high output currents provided by this supply, the pass transistors dissipate considerable power. With a current of 5 A through each transistor and assuming a 9 V drop across the transistor — each device dissipates 45 W. Because the 2N3055's rating is 115 W when used with a properly sized heat sink, this dissipation level shouldn't present a problem. If the supply is to be used for continuous-duty operation, increase the size of the heat sink and mount it with the fins oriented vertically to assist in air circulation.

The output-voltage sense is connected through a resistive divider to the negative input of U1. U1 uses the difference between its negative and positive inputs to control the pass transistors that in turn provide the output current. C3, a compensation capacitor, is connected between this input and a dedicated compensation pin to prevent oscillation. The output voltage is adjusted by potentiometer R12 and two fixed-value resistors, R6 and R7.<sup>7</sup> The voltage-sense input is connected to the supply's positive output terminal, J3.

Current sensing is done through R4, a 0.075  $\Omega$ , 50 W resistor connected between the emitter-ballasting resistors and J3. R4's power dissipation is much higher than that of R1, R2 or R3 because it sees the total output current. At 15 A, R4 dissipates 17 W. At 20 A, the dissipated power increases to 30 W.

U1 provides current limiting via two sense inputs connected across R4. Limiting takes place when the voltage across the sense inputs is greater than 0.65 V.<sup>8</sup> For a 15 A maximum output-current limit, this requires a 0.043  $\Omega$  resistor. By using a larger-value sense resistor and a potentiometer, you can vary the current limit. Connecting potentiometer R13 across R4 provides a current-limiting range from full limit voltage (8.7 A limit) to no limit voltage. This allows the current limit to be fine-tuned, if needed, and also permits readily available resistor values (such as the author's 0.075  $\Omega$  resistors) to be used. A current limit of 20 A is at the top end of the ammeter scale.

R20 maintains a small load of 35-40 mA depending on power supply output voltage. This reduces the effect of leakage current in the pass transistors and keeps the regulator's feedback action active, even if no external load is connected.

### METERING

Voltmeter M1 is a surplus meter. R8 and potentiometer R15 provide for voltmeter calibration. If the correct fixed-value resistor is available, R15 can be omitted. The combined value of the resistor and potentiometer is determined by the full-scale current requirement of the meter used.<sup>9</sup>

Ammeter M2 is actually a voltmeter (also

surplus) that measures the potential across R4. The positive side of M2 connects to the high side of R4. R8 and potentiometer R14 connect between the positive output terminal (J3) and the negative side of M2 to provide calibration adjustment. The values of R8 and R14 are determined by the coil-current requirements of the meter used. (Digital panel meters or a dedicated DMM can be used instead of separate analog meters.)

### OUTPUT WIRING AND CROWBAR CIRCUIT

The supply output is connected to the outside world by two heavy-duty banana jacks, J3 and J4. C2, a 100  $\mu\text{F}$  capacitor, is soldered directly across the terminals to prevent low-frequency oscillation. C6, a 0.1  $\mu\text{F}$  capacitor, is included to shunt RF energy to ground. Heavy-gauge wire must be used for the connections between the pass transistors and J3 and between chassis ground and J4. The voltage-sense wire must connect directly to J3 and U2's ground pin must connect directly to J4 (see Figure 7.59). This provides the best output voltage regulation.

An over-voltage crowbar circuit prevents the output voltage from exceeding a preset limit. If that limit is exceeded, the output is shunted to ground until power is removed. If the current-limiting circuitry in the supply is working properly, the supply current-limits to the preset value. If the current limiting is not functioning, the crowbar causes the ac-line fuse to blow. Therefore, it's important to use the correct fuse size: 4 to 5 A for a 15 A supply.

The crowbar circuit is a simple design based on an SCR's ability to latch and conduct until the voltage source is removed. The SCR (Q4) is connected across output terminals J3 and J4. (The SCR can also be connected directly across the filter capacitor, C1, for additional protection.) R10 and potentiometer R16 in series with the Q4's gate provide a means of adjusting the trip voltage. The prototype crowbar is set to conduct at 15 V. The S6025L SCR is rated at 25 A and should be mounted on a metal chassis or heat sink. (Note: Some SCRs are isolated from their mounting tabs, others are not. The S6025L and the 65-ampere S4065J are isolated types. If the SCR you use is not isolated, use a mica washer or thermal pad to insulate it from the chassis or heat sink.)

The bold lines in Figure 7.59 indicate high-current paths that should use heavy-gauge (#10 or #12 AWG) wire. Traces that are connected to the output terminals in the schematic by individual lines should be connected directly to the terminals by individual wires. This establishes a 4-wire measurement, where the heavy wires carry the current (and have voltage drops) and the sense wires carry almost no current and therefore voltage errors are not caused by voltage drops in the wiring. If desired, the sense wire can be carried out

to the load, but that may introduce noise into the sense feedback circuit, so use caution if that is done.

### 7.16.3 13.8 V, 5 A Linear Power Supply

This power supply was designed by Ben Spencer, G4YNM, provides 13.8 V dc at 5 A, suitable for many low-power transceivers and accessories. It features time-dependent current limiting and short-circuit protection, thermal overload protection within the safe operating area of the regulator IC, and overvoltage protection for the equipment it powers. The prototype supply powers a 25 W transmitter that continually draws 4.5 A.

Construction, testing and calibration are straightforward, requiring no special skills or equipment. Many of the components can be found in junk boxes, or purchased at hamfests or from mail-order suppliers.

### CIRCUIT DESCRIPTION

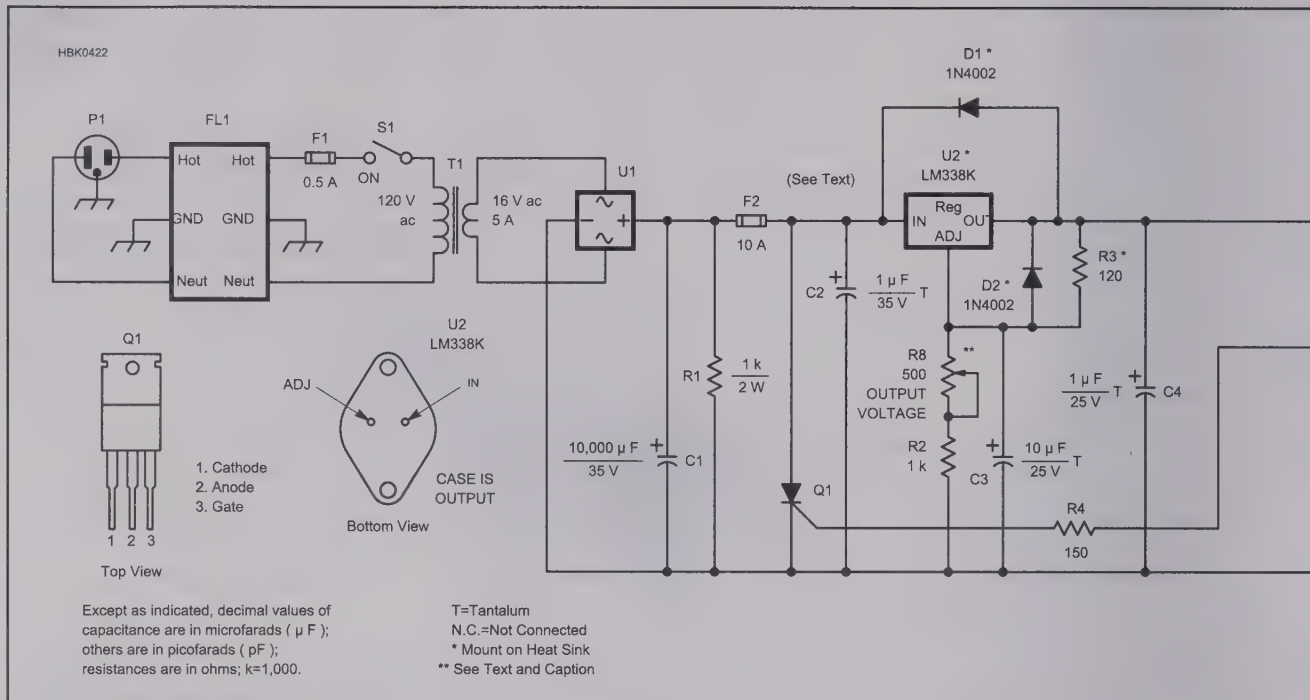

Figure 7.60 is the power supply schematic. Incoming ac line current is filtered by a chassis-mounted line filter (FL1) and, after passing through the fuse (F1), is routed S1 to T1.

U1 rectifies, and C1 filters, the ac output of T1. U2 is an LM338K voltage regulator. This IC features a current-limited continuous output of 5 A, with a guaranteed peak output of 7 A. It also has on-chip thermal and safe-operating-area protection for itself. U2's output voltage is set by two resistors (R2 and R3) and a trimmer potentiometer (R8), which allows for adjustment over a small range. U2's input and output are bypassed by C2, C3, and C4. D1 and D2 protect U2 against these capacitors discharging through it.

Overvoltage protection is provided by an SCR, Q1, across the regulator input. Normally, Q1 presents an open circuit, but under fault conditions, it's triggered and short-circuits the unregulated dc input to ground. This discharges C1 through F2 which is rated at 10 A in order for C1 to quickly discharge below 12 V, avoiding damage to connected equipment.

U3, an overvoltage-protection IC, continuously monitors the output voltage. When the output voltage rises above a predetermined level, U3 starts charging C5. If the overvoltage duration is sufficiently long, U3 triggers Q1. This built-in delay (about 1 ms) allows short transient noise spikes on the output voltage to be safely ignored while still triggering the SCR if a true fault occurs. The monitored voltage is set by R5 and R6 and trimmer potentiometer R9, which allows for adjustment over a limited range.

D3 protects the supply from reverse-polarity discharge from connected equipment. The presence of output voltage is indicated by an LED, DS1. R7 is a current limiting resistor for DS1.

**Figure 7.60** — Schematic for the 13.8 V, 5 A power supply. Unless otherwise specified, resistors are  $\frac{1}{4}$  W, 5% tolerance. A PC board and U3 are available from FAR Circuits ([www.farcircuits.net](http://www.farcircuits.net)). Early versions of the circuit board from FAR mislabel U1 vs Q1. Check the board traces to be sure the parts are installed correctly. The PC board has mounting holes and pads to allow for handling different trimmer-potentiometer footprints. A PC board template is included with this book's downloadable supplemental content. The author may be contacted at [sckits@charter.net](mailto:sckits@charter.net) for assistance in obtaining parts and printed-circuit boards.

C2, C4 — 1  $\mu\text{F}$ , 35 V tantalum.  
C3 — 10  $\mu\text{F}$ , 35 V tantalum.  
C5 — 0.1  $\mu\text{F}$ , 25 V ceramic disc.  
D1-D3 — 1N4002.  
DS1 — Red LED.  
F1 — Slow-blow 0.5 A fuse.  
F2 — Fast-acting 10 A fuses; three required (see text).  
FL1 — Ac-line filter.

Q1 — BT152 400 V, 25 A SCR in TO-220A package (NTE5554)  
R8 — 500  $\Omega$ , single-turn trimmer potentiometer.  
R9 — 500  $\Omega$  or 1 k $\Omega$ , single-turn trimmer potentiometer.  
S1 — SPST panel-mount switch.  
T1 — 120 V primary, 16- to 20 V, 5 A secondary.  
U1 — 100-PIV, 6 A bridge rectifier.

U2 — LM338K 5 A adjustable power regulator in a TO-3 package.  
U3 — MC3423P1 overvoltage protection IC.  
Misc: two panel-mount fuse holders; line cord; heat sinks for TO-3 case transistors; TO-3 mounting kit and heat-sink grease; black and red binding posts; chassis or cabinet; PC board; hardware, rubber hoods, heat-shrink tubing or electrical tape for F1 and FL1, hook-up wire.

## CONSTRUCTION

How you construct your supply depends on the size of the components and enclosure you use. General physical layout is not important, although there are a couple of areas that require some attention. In the unit shown in **Figure 7.61**, FL1, the fuse holders, S1, the heat sink, DS1 and the binding posts are mounted on the front and rear enclosure panels. T1 and the PC board are secured to the enclosure's bottom plate. C1's mounting clamp is attached to the rear panel. Bleeder resistor R1 is connected directly across C1's terminals. D3 is soldered directly across the output binding posts.

U2, D1, D2 and R3 are all mounted directly on the heat sink with the transistor pins and solder lugs acting as a terminal strip. It's important to keep R3 attached as closely as possible to U2's terminals to prevent instability. Use a TO-3 mounting kit and heat-conductive grease or thermal pad to electrically isolate

U2 from the heat sink.

Mount U2, C1, and the PC board close to each other and keep the wire runs between these components as short as possible. Excessively long wire runs may lead to unpredictable behavior.

Cover all ac-input wiring (use insulated wire and heat-shrink tubing) to prevent electrical shock and route the ac wiring away from the dc wiring. Mount the heat sink on the enclosure with fins oriented vertically. Louvers or ventilation holes in the cabinet will help cool internal components.

## TEST AND CALIBRATION

An accurate multimeter covering ranges of 30 V dc and 10 A dc is required. A variable resistive load with a power rating of 100 W is also needed; this can be made using a heat-sink-mounted 2N3055 power transistor and a couple of components as shown in the next project.

First, set R8 (OUTPUT VOLTAGE) fully clockwise and R9 (OVERVOLTAGE) fully counterclockwise. Insert a fuse in the dc line at F2. Connect the ac line, turn on S1 and check that DS1 lights. Measure the output voltage: it should be about 12 V. Adjust R8 counterclockwise until you obtain 14.2 V output; this sets the trip voltage. (Note that CCW adjustment increases voltage.)

While monitoring the output voltage, gradually adjust R9 clockwise until the voltage suddenly falls to zero. This indicates that the SCR has triggered and blown F2. Disconnect the ac line cord from the wall socket. *Don't make any adjustment to R9!* Instead, adjust R8 fully clockwise.

With the ac line cord removed, check that F2 is open. Replace F2 with a new fuse (now you know why two of the three fuses are called for). Reconnect the ac line cord, and while continually monitoring the output voltage,

gradually adjust R8 until Q1 again triggers at 14.2 V, blowing F2. If you find the adjustment of R9 to be too sensitive, use a 500 Ω potentiometer in its place and reduce the value of R5 (if necessary) to provide the required adjustment range.

Again disconnect the line cord from the wall socket, set R8 fully clockwise, replace F2 (there's the third fuse!) and reset R8 for 13.8 V. This completes the voltage calibration and overvoltage protection tests. The power supply is now set to 13.8 V output, with the overvoltage protection set for 14.2 V.

Adjust R2 of the variable resistive load in Figure 7.62 to maximum resistance (minimum load current) and connect it to the power supply output in series with the ammeter. Turn on the power supply and gradually adjust R2 until a current of 5 A flows. Decrease the resistance further and check that the current limits between 5.5 A and 0.5 A.

Finally, be thoroughly unpleasant and apply a short circuit via the ammeter. Check that the current-limiting feature operates correctly. The prototype limited at approximately 3.5 A. Disconnect the ac line cord and test

equipment, dose up the case and your power supply is ready for service.

### 7.16.4 Adjustable Resistive Load

Figure 7.62 shows the schematic of an adjustable resistive load that can be used to test and adjust power supplies at currents up to 10 A if the 2N3055 transistor is mounted on an adequate heat sink. R1 and R2 vary the base bias to control the collector current of Q1. For extended use, be sure to use a large heat sink with adequate ventilation. Use heavy wire through the current meter to the collector and from the emitter of Q1.

### 7.16.5 Inverting DC-DC Converter

It's often the case that you need +V and -V when all you have is +V. For example, you need +12 V and -12 V, but all that's available is +12 V. It would be really handy to have a "black box" that would give you -V out when you put +V in, and work over a range of voltages without adjustment. This project by Jim Stewart, which originally appeared in the January 2013 issue of *Nuts and Volts Magazine* ([www.nutsvolts.com](http://www.nutsvolts.com)), fills that need by using a switchmode voltage mirror to supply more than 100 mA without a significant drop in voltage.

The following text summarizes how the circuit works. A PDF version of the complete article is included with this book's downloadable supplemental content. It contains more

Figure 7.61 — Physical layout of the 13.8 V, 5 A power supply. On the rear panel, left, are the ac-line filter and F1. The regulator's heat sink is at the middle of the panel and F2 is to the right. At the bottom of the enclosure, in front of T1, is the diode bridge rectifier. Because C1 is too tall to mount vertically within the Hammond #1426O cabinet, its mounting clamp is secured to the inside rear panel. Immediately to the right of C1 is the PC board. On the front panel are the on/off switch, LED power-on indicator and output-voltage binding posts.

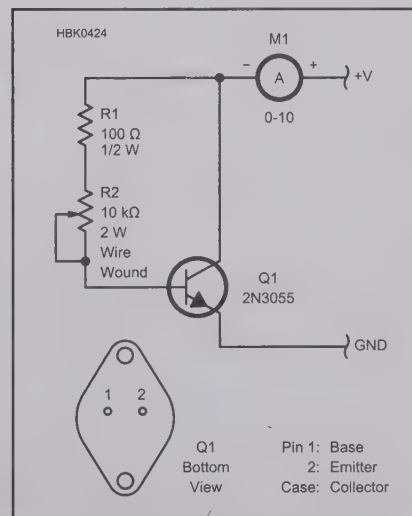

Figure 7.62 — An active resistive load to use in testing power supplies up to 10 A with adequate heat sinking. Adjustment of R2 is sensitive. M1 — Multimeter or ammeter capable of measuring 10 A. Q1 — 2N3055; mount on heat sink.

details about the circuit's design, plus construction and testing information. A PCB and parts kit is available from the *Nuts and Volts* online store, as well. An ExpressPCB file (PV2NV.PCB) is available for download at [www.nutsvolts.com/index.php?/magazine/article/january2013\\_Stewart](http://www.nutsvolts.com/index.php?/magazine/article/january2013_Stewart).

## CIRCUIT DESIGN

The circuit in **Figure 7.63** is a buck-boost dc-dc converter as described earlier in this chapter. This particular design has five important parameters:

- Input voltage:  $V_{IN}$
- Output voltage:  $V_{OUT}$
- Load resistance:  $R_{LOAD}$
- Oscillation frequency:  $f$
- Inductance value:  $L$

The parameters are related to each other by  $f \times L < (V_{IN} / V_{OUT})^2 \times (R_{LOAD} / 8)$ . For  $V_{IN} = V_{OUT}$ , the equation simplifies to  $f \times L < (R_{LOAD} / 8)$ . (See the complete article included with this book's downloadable supplemental content for the derivation of these equations.)

Figure 7.63 shows the schematic of the circuit. A square wave oscillator (U2) drives a MOSFET (Q2) that, in turn, drives a PNP switching transistor (Q3). The oscillator is enabled/disabled by the output of the comparator (U1) with inputs that are a set point voltage ( $V_S$  on the comparator's + input) and a feedback voltage ( $V_F$  at the comparator's - input). (Comparators are described in the

**Analog Fundamentals** chapter.) The frequency of the oscillator is  $f = 1 / 2.2 (R7 \times C3)$ .

When the output voltage,  $V_{OUT}$ , is the correct value,  $V_S$  exceeds  $V_F$  by a few  $\mu V$  and the oscillator is disabled by Q1 so that the PNP switch is off. When  $V_S$  is less than  $V_F$ , the oscillator is enabled and the PNP transistor switches on and off.  $V_S$  is half the input voltage  $V_S = V_{IN}/2$  as set by the R3-R4 voltage divider.

$V_F$  is set by the R1-R2 divider to equal  $V_{IN}/2$  when the output voltage  $V_{OUT} = -V_{IN}$ . D2 is a commutating diode that blocks +V from the output while charging the inductor. It then provides a current path for the discharging inductor to transfer charge to the output capacitor.

The switching action continues until the voltage on the capacitor equals  $-V_{IN}$ . At that point, the comparator disables the oscillator and Q3 stays OFF. When voltage across the capacitor drops, the comparator enables the oscillator and the inductor is pumped up again.

Since there is a single input voltage, each op-amp uses a resistor divider to "split the rail" to create a signal ground. That allows the negative input to sense positive and negative voltages with respect to the positive input. C2 and C4 bypass the signal grounds to the supply voltage ground.

C1 and C5 are low-ESR (equivalent series resistance—see the **Electrical Fundamentals** chapter) aluminum electrolytic capacitors.

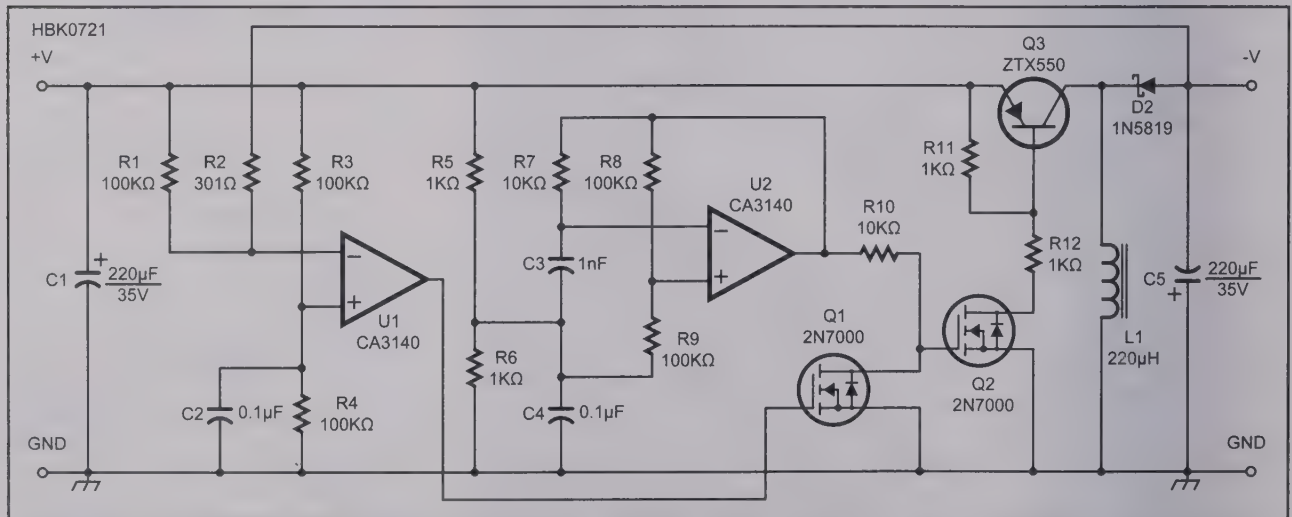

Tantalum capacitors might be a bit better, but are more expensive. ESR determines how much power the capacitor can safely dissipate.  $P_{DISS} = I_{RC}^2 \times ESR$ , where  $I_{RC}$  is the ac ripple current in the capacitor. The capacitors chosen are rated for a maximum ripple current of 840 mA.

D1 and D2 are Schottky diodes that can go from conducting to non-conducting very quickly, allowing a high switching frequency. They also have a low voltage drop when conducting to reduce power loss. D1 limits the output voltage in case the feedback fails.

Q3 is a ZTX550 PNP transistor, chosen because its specifications suit this application well:

- Maximum power dissipation,  $P_{MAX} = 1 \text{ W @ } 25^\circ \text{C}$
- Maximum continuous collector current,  $I_C = 1 \text{ A}$
- Maximum collector-base voltage,  $V_{CBO} = 60 \text{ V}$
- Maximum saturation voltage,  $V_{CE} = 0.25 \text{ V @ } I_C = 150 \text{ mA}$
- Transition frequency,  $f_T = 150 \text{ MHz}$  minimum
- Package: E-Line (slightly smaller than TO-92)

For this design, the chosen values are  $L = 220 \mu\text{H}$ ,  $f = 45 \text{ kHz}$ , and  $R_{LOAD} = 100 \Omega$ . Verifying that  $f \times L$  is less than  $R_{LOAD} / 8$ ,  $f \times L = (45 \times 10^3) \times (220 \times 10^{-6}) = 9900 \times 10^{-3} = 9.9 \Omega$  and  $R_{LOAD} / 8 = 100/8 = 12.5 \Omega$  which is less than  $R_{LOAD} / 8 = 12.5$ . Higher

**Figure 7.63** — A voltage mirror dc-dc power converter based on a buck-boost converter. The negative output  $-V$  is equal in magnitude to the positive input voltage  $+V$  at an output current up to approximately 100 mA

- C1 — 220  $\mu\text{F}$ , 35 V (Digi-Key part #493-1578-ND or equiv).
- C2 — 0.1  $\mu\text{F}$ , 50 V, ceramic.
- C3 — 1 nF film, 5% (Digi-Key part #399-5871-ND or equiv).
- C4 — 0.1  $\mu\text{F}$ , 50 V, ceramic.
- C5 — 220  $\mu\text{F}$ , 35 V (Digi-Key part #493-1578-ND or equiv).

- D1 — Not required, do not install.
- D2 — Schottky, 1 A, 1N5819 or equiv.
- L1 — 220  $\mu\text{H}$  (Digi-Key part #811-1316-ND or equiv).
- Q1, Q2 — 2N7000.
- Q3 — ZTX550 PNP.
- R1, R3, R4, R8, R9 — 100  $\text{k}\Omega$ ,  $\frac{1}{4} \text{ W}$ , 1%.

- R2 — 301  $\text{k}\Omega$ ,  $\frac{1}{4} \text{ W}$ , 1%.
- R5, R6, R11, R12 — 1  $\text{k}\Omega$ ,  $\frac{1}{4} \text{ W}$ , 1%.
- R7, R10 — 10  $\text{k}\Omega$ ,  $\frac{1}{4} \text{ W}$ , 1%.
- U1, U2 — CA3140.
- Terminal Blocks (optional) — Two-position, 5 mm spacing (Jameco part #2094485 or equiv).

values of  $R_{LOAD}$  (lower output current) also satisfy the equation. Increasing the value of  $L$  or  $f$  will require that the circuit be tested to verify that it works.

## 7.16.6 High-Voltage Power Supply

The downloadable supplemental content includes “A Deluxe High Voltage Supply” by Jim Garland, W8ZR, which is discussed here, and “A Small, Lightweight High-Voltage Switch-Mode Power Supply” by Ralph Crumrine, NØKC.

This two-level, high-voltage power supply was designed and built by Dana G. Reed, WILC. It was designed primarily for use with an RF power amplifier. The supply is rated at a continuous output current of 1.5 A, and will easily handle intermittent peak currents of 2 A. The 12 V control circuitry and the low-tap setting of the plate transformer secondary make it straightforward to adapt the design to homemade tube amplifiers.

The step-start circuit is straightforward and

ensures that the rectifier diodes are current-limited when the power supply is first turned on. A 6 kV meter is used to monitor high-voltage output.

Figure 7.64 is a schematic diagram of the bi-level supply. An ideal power supply for a high-power linear amplifier should operate from a 240 V circuit, for best line regulation. A special, hydraulic/magnetic circuit breaker also serves as a disconnect for the plate transformer primary. Don't substitute a standard circuit breaker, switch or fuses for this breaker; fuses won't operate quickly enough to protect the amplifier or power supply in case of an operating abnormality. The 100 k $\Omega$ , 3 W bleeder resistors are of stable metal-oxide film design. These resistors are wired across each of the 14 capacitors to equalize voltage drops in the series-connected bank. This choice of bleeder resistor value provides a lighter load (less than 25 W total under high-tap output) and benefits mainly the capacitor-bank filter by yielding much less heat as a result. A reasonable, but longer-bleed-down time to fully discharge the

capacitors results — about nine minutes after power is removed. A small fan is included to remove any excess heat from the power supply cabinet during operation.

### POWER SUPPLY CONSTRUCTION

The power supply can be built in a 23½ × 10¼ × 16-inch cabinet. The plate transformer is quite heavy, so use ½-inch aluminum for the cabinet bottom and reinforce it with aluminum angle for extra strength and stability. The capacitor bank will be sized for the specific capacitors used. This project employed ¾-inch thick polycarbonate for reasonable mechanical stability and excellent high-voltage isolation. The full-wave bridge consists of four commercial diode block assemblies.

### POWER SUPPLY OPERATION

When the front-panel breaker is turned on, a single 50  $\Omega$ , 100 W power resistor limits primary inrush current to a conservative value as the capacitor bank charges. After approximately two seconds, step-start relay K1 actuates, shorting the 50  $\Omega$  resistor and allowing

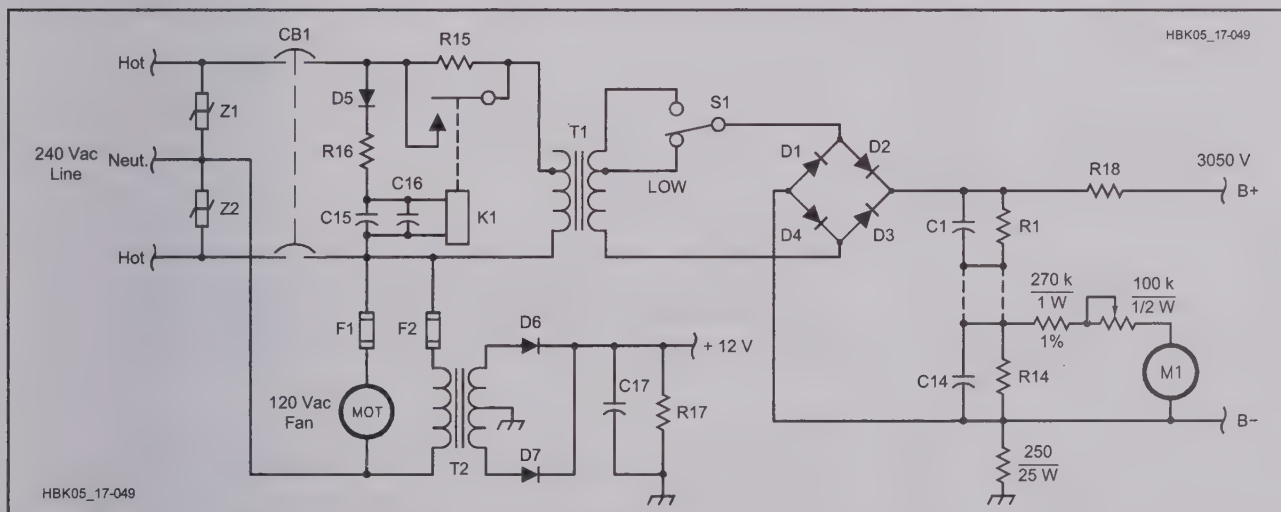

Figure 7.64 — Schematic diagram of the 3050 V/5400 V high-voltage power supply.

C1-C14 — 800  $\mu$ F, 450 V electrolytic.  
 C15, C16 — 4700  $\mu$ F, 50 V electrolytic.  
 C17 — 1000  $\mu$ F, 50 V electrolytic.  
 CB1 — 20 A hydraulic/magnetic circuit breaker (TE Connectivity/Potter & Brumfield W68-X2Q12-20 or equiv). 40 A version required for commercial applications/ service (TE Connectivity/Potter & Brumfield W92-X112-40).  
 D1-D4 — String of 1000 PIV, 6 A diodes (6A10 or equiv).  
 D5 — 1000 PIV, 3 A, 1N5408 or equiv.  
 D6, D7 — 200 PIV, 3 A, 1N5402 or equiv.  
 F1, F2 — 0.5 A, 250 V (Littelfuse 313 Series, 3AG glass body or equiv).  
 K1 — DPDT power relay, 24 V dc coil; both poles of 240 V ac/25 A contacts in parallel (TE Connectivity/Potter & Brumfield PRD-11DYO-24 or equiv).

M1 — High-voltage meter, 6 kV dc full scale. (Important: Use a 1 mA or smaller meter movement to minimize parallel-resistive loading at R14. Also, select series meter-resistor and adjustment-potentiometer values to calibrate your specific meter. Values shown are for a 1 mA meter movement.)  
 MOT1 — Cooling fan, 119 mm, 120 V ac, 30-60 CFM, (EBM Pabst 4800Z or equiv).  
 R1-R14 — Bleeder resistor, 100 k $\Omega$ , 3 W, metal oxide film.  
 R15 — 50  $\Omega$ , 100 W.  
 R16 — 3.9 k $\Omega$ , 25 W.  
 R17 — 30  $\Omega$ , 25 W.  
 R18 — 20  $\Omega$ , 50 W.  
 S1 — Ceramic rotary, 2 position tap-select switch (optional). Voltage rating between tap positions should be at least

2.5 kV. Mount switch on insulated or ungrounded material such as a metal plate on standoff insulators, or an insulating plate, and use only a nonconductive or otherwise electrically-isolated shaft through the front panel for safety.  
 T1 — High-voltage plate transformer, 220/240 V primary, 2000/3500 V, 1.5 A CCS JK secondary, Hypersil C-core (Hammond Engineering, www.hammsg.com). Primary 220 V tap fed with nominal 240 V ac line voltage to obtain modest increase in specified secondary voltage levels.  
 T2 — 120 V primary, 18 V CT, 2 A secondary (Mouser 41FJ020).  
 Z1-Z2 — 130 V MOV.

full line voltage to be applied to the plate transformer. No-load output voltages under low- and high-tap settings as configured and shown in Figure 7.64 are 3050 V and 5400 V, respectively. Full-load levels are somewhat lower, approximately 2800 V and 4900 V. If a tap-select switch is used as described in the schematic parts list, it should only be switched when the supply is off.

### 7.16.7 Reverse-Polarity Protection Circuits

The following material was collected from various public-domain sources by Terry Fletcher, WA0ITP ([www.wa0itp.com/revpro.html](http://www.wa0itp.com/revpro.html)) and published in the QRP Quarterly, Spring 2012 issue. ([www.qrparci.org](http://www.qrparci.org))

DC power is the standard for most amateur radios and accessories, usually a nominal 12 V (10.5 to 13.8 V). There are many different types of connectors used for dc power — from screw terminals to custom-molded multi-pin designs. This makes it easy to accidentally apply power with reversed polarity and damage equipment. Even a few milliseconds of reversed power can be sufficient to destroy a semiconductor or burn out a narrow PCB trace. This can be a particular problem when using 9 V batteries as it is easy to reverse the snap-on connector when changing or installing a battery.

The following collection of circuits illustrates ways to protect equipment from reverse-polarity dc power. The suitability of the circuits depends on the equipment and power source. All dc power sources, particularly batteries, should be fused or current-limited to mitigate fire hazards and other damage from overheating wires and other conductors.

Figure 7.65A-D shows several passive circuits that dissipate some power due to the series forward voltage drop of the diodes. At currents above 1 A, the power dissipated can easily exceed 1 W and the maximum junction temperature of the diode can be exceeded without some sort of thermal protection or heat sinking. (The shunt diode circuit in Figure 7.65D does not dissipate power.) Figure 7.65E-F shows two methods of using an electromechanical relay that avoid the forward voltage drop of diode-based protection circuits. Which circuit you choose depends on the type of equipment and constraints on power dissipation and voltage drop.

#### PASSIVE CIRCUITS

**Blocking diode (Figure 7.65A)** — A series diode is very simple and inexpensive. Its PIV rating should be at least twice the expected applied voltage — 50 V PIV is a good minimum value for automotive and 12 V dc use. Its maximum average forward current rating should be several times the expected maximum steady-state current draw.

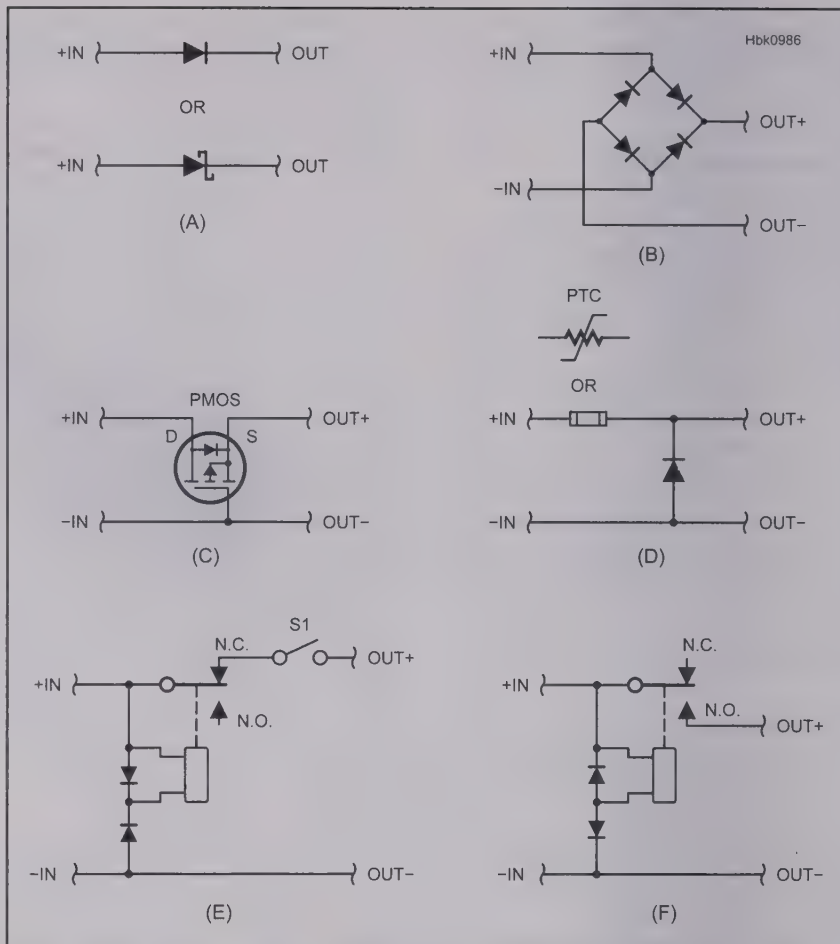

Figure 7.65 — Passive circuits for reverse-polarity protection. Series diode (A). Full-wave rectifier (B). PMOS MOSFET with integral body diode shown as separate component (C). Shunt diode (D). Schottky barrier diodes may be used in all circuits as a substitute for silicon junction rectifiers. See text for circuit comparison. Relay-based circuits can be based on normally-closed contacts (E) or normally-open contacts (F) as compared in the text.

Remember that a silicon junction diode's forward voltage drop,  $V_f$ , is at least 0.6 V and can approach 1.0 V at high forward current. This can result in significant power dissipation ( $P = V_f \times I_f$ ) and cause the diode's maximum rated junction temperature to be exceeded unless some means of cooling the diode is provided. See the article "Diode Voltage Drops Raise Battery Power Drain" in the downloadable supplemental information for more details.

The forward voltage drop of the diode will also reduce the voltage available to the equipment being powered. This will raise the minimum allowable power supply voltage for the equipment to operate properly. For example, if a piece of equipment is rated to operate properly at or above 11 V, a series diode with  $V_f = 0.6$  V raises the minimum allowable power supply voltage to  $11 + 0.6 = 11.6$  V. This may be significant in battery-powered installations.

The Schottky barrier diode shown as an alternate may be a better choice due to its forward voltage drop being lower by several tenths of a volt, reducing power dissipation. A Schottky diode may be used in place of any of the diodes in Figure 7.65. Be sure the reverse current leakage of the Schottky diode is acceptable.

**Full-wave bridge rectifier (Figure 7.65B)** — The full-wave circuit has the advantage of always supplying voltage with the proper polarity to the equipment being powered. Full-wave rectifiers are also available as integrated packages, making them easy to install. Remember that the forward voltage drop and power dissipation of this circuit will be twice that of the single series diode because two diodes are always in series with supply current.

**PMOS P-channel MOSFET (Figure 7.65C)** — This circuit uses a P-channel enhancement-mode (PMOS) MOSFET that

conducts current with the gate connected as shown. PMOS devices have low on-resistance ( $R_{ds(on)}$ ) and high maximum current ratings. Devices with on-resistance of  $0.050\ \Omega$  and lower are commonly available. For more information about using PMOS and NMOS devices for polarity protection see Maxim Electronics Application Note 636, "Reverse-Current Circuitry Protection" ([www.maxim-ic.com/app-notes/index.mvp/id/636](http://www.maxim-ic.com/app-notes/index.mvp/id/636)). N-channel devices may also be used in the current return or ground lead, but opening the return connection can create other problems inside the equipment and with other devices on the same power circuits.

**Shunt diode with fuse (Figure 7.65D)** — These configurations use a single diode that acts to blow a fuse (either a fusible-link or positive temperature coefficient PTC resettable device) if reverse polarity voltage is applied. The advantage of this circuit is that no power is dissipated by the diode during normal operation. The diode must be sufficiently rated to handle the high surge current from shorting the power source and have current ratings significantly higher than the fuse current rating.

If the diode fails shorted or in a low-resistance state, it will continue to blow the fuse until replaced. If the diode fails open or high-resistance, it will no longer protect the circuit. If shunt diode protection is used and the fuse opens, check the diode to be sure it has not failed as well.

## RELAY-BASED CIRCUITS

Relay-based circuits have the advantage of little to no voltage drop, even at high currents as long as the contact ratings are sufficient. The circuits are more complex than the diode-based circuits in the preceding section but can generally handle more current and are not damaged by reverse polarity voltages. The circuits reset themselves automatically.

**Relay with normally-closed contacts (Figure 7.65E)** — There is no current drain through the relay coil until reverse-polarity is applied. However, there will be a few milliseconds during which reverse polarity voltage is applied if no power switch (S1) is used or the power switch is closed. This is generally enough time for damage to occur so this circuit is only recommended if a power switch is used to turn the equipment ON and OFF.

**Relay with normally-open contacts (Figure 7.65F)** — The relay contacts close and supply power to the equipment only when applied voltage has the proper polarity. The relay coil draws current continuously during normal operation. This may be unacceptable for low-power and battery-powered equipment.

## ACTIVE CIRCUIT

The circuit in **Figure 7.66** uses a pair of P-channel MOSFETs to turn power on and

off, while blocking reverse current flow. The circuit can be controlled manually or with a control circuit, such as a microprocessor. Using low ON-resistance MOSFETs avoids the voltage drop of a series diode. The circuit is part of the QSX transceiver designed by Hans Summers, GØUPL, of QRP Labs ([qrp-labs.com](http://qrp-labs.com)) and is presented here with his permission.

Two P-channel MOSFETs in series provide the reverse-polarity protection. Note the orientation of drain and source and body diodes in Q1 and Q2 are reversed. If only Q2 is present, its body diode would allow reverse current to flow. Q1's body diode blocks reverse current. Both Q1 and Q2 must be on to allow forward current to flow. (If reverse polarity protection is not needed, Q1 and R3 can be removed.) To turn on a P-channel MOSFET,  $V_{gs}$ , the gate voltage must be negative with respect to the source by at several volts, typically 3V.

When external positive dc power is applied, the body diode of Q1 applies voltage to R3. This pulls the gates of both Q1 and Q2 to the external power voltage and turns the channels

of both Q1 and Q2 off. The body diode of Q2 is reverse biased and non-conducting.

When S1 is closed, both gates are pulled to ground or common, switching on both transistors and allowing current to flow through the switch. If S1 is a toggle switch, both R5 and Q3 are not needed. When S1 is re-opened, the gates of Q1 and Q2 are pulled up again and the switch turns off.

If S1 is a momentary switch such as a push-button, R4 can supply a signal to a control circuit indicating S1 is closed. The control circuit can then generate the Power Hold On signal to Q3 (typically +3V or more). This turns Q3 on, pulling the gates of Q1 and Q2 to ground and holding the switch on. When S1 is closed again, the control circuit can remove the Power Hold On signal, allowing the switch to turn off as soon as S1 is opened.

## 7.16.8 Simple Sealed Lead-Acid Battery Float Charger and Switch

This charger was designed by John Boal, K9JEB, to keep a sealed lead-acid (SLA) bat-

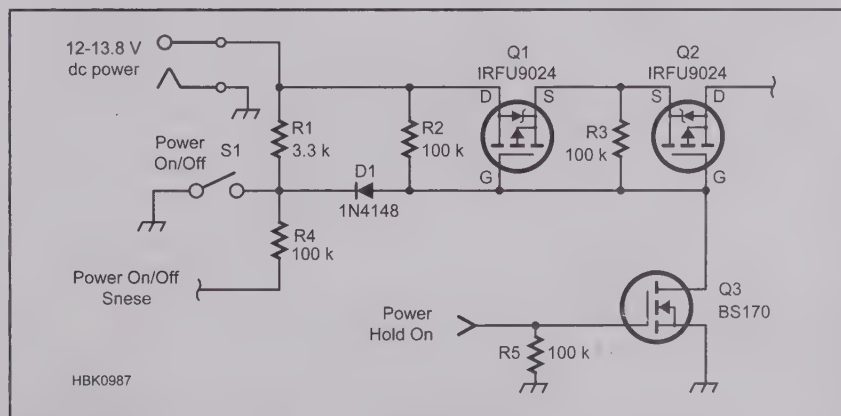

Figure 7.66 — Active switching circuit. See text for details.

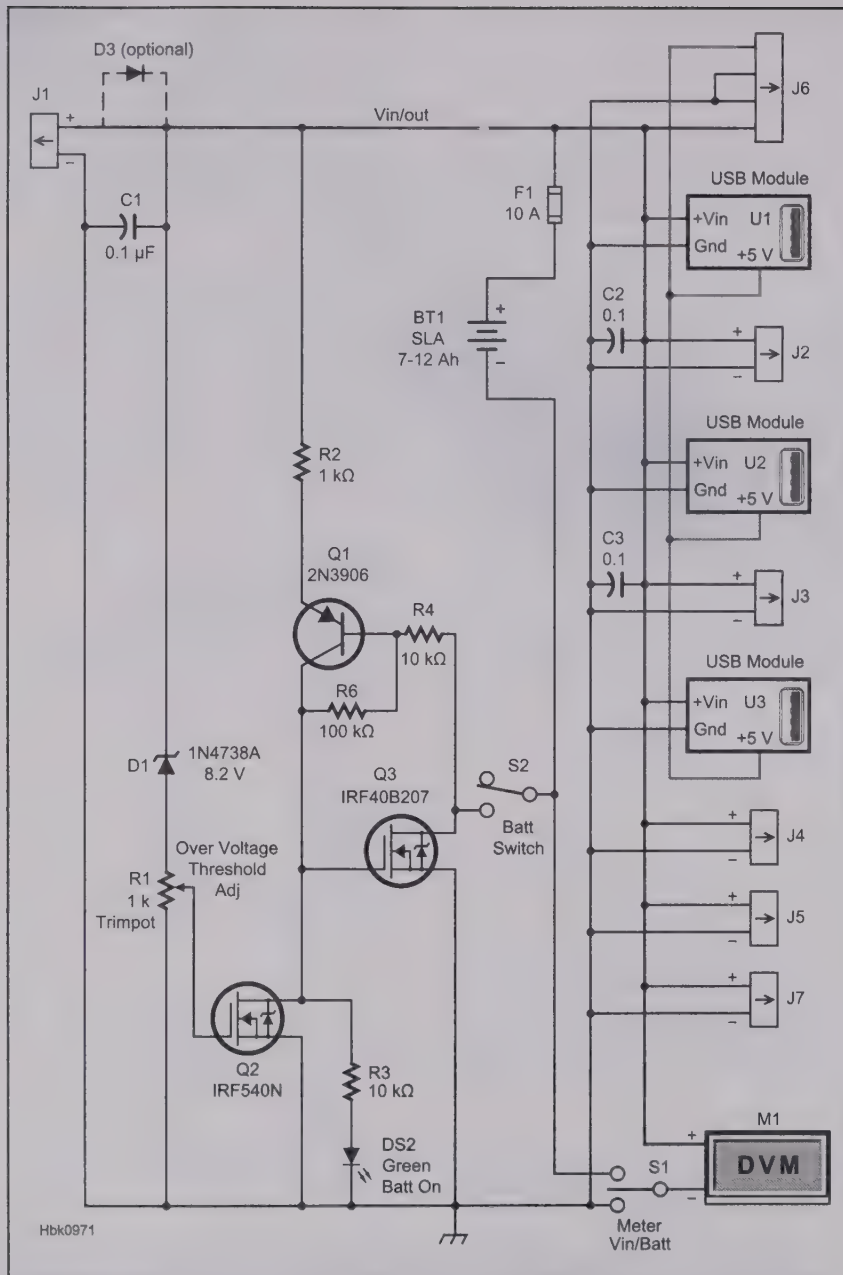

Figure 7.67 — The charging circuit shown mounted directly on a 9 Ah SLA battery. Note the USB charging module mounted next to J1 at the left-hand side of the board.

**Figure 7.68 — Schematic of the battery charger circuit. Resistors are 1/8 W, 5% tolerance. Equivalent parts may be substituted. A complete kit of parts with PC board as well as separate PC boards are available from the author at his website, [k9jeb.com](http://k9jeb.com). Enclosure design is the responsibility of the builder.**

- BT1 — SLA battery: 7-12 Ah (not supplied with parts kit)  
 C1, C2, C3 — 0.1 μF, 50 V ceramic  
 D1 — 1N4738A, 8.2 V Zener diode  
 D2 — LED, green  
 D3 — 10A10 10A Schottky diode (optional, install in series with J1)  
 F1 — 15A automotive blade fuse, standard  
 J1, J2, J3, J4, J5, J7 — Anderson Powerpole connector pair, including housing and contact  
 J6 — 0.1-inch DIP header, 2x2 (optional)

 Wire ties for securing the Powerpole connectors  
 PC board (available from [K9JEB](http://K9JEB) at [k9jeb.com](http://k9jeb.com))

tary charged from an external power source such as a vehicle, solar panel, or ac power supply. The battery will remain connected to the load if external power is removed or the power source voltage drops to below the battery voltage. The circuit float-charges the battery from the external power source and includes an overvoltage detection circuit to prevent overcharging the battery.

The circuit has a low-profile (1/2-inch height) battery-top size that matches 7 to 12 Ah SLA form factor batteries with F1 or F2 connectors. The assembled unit is shown mounted on such a battery in **Figure 7.67**. The schematic and parts list for the circuit are provided by **Figure 7.68**. The circuit is intended for use with batteries from 1 to 35 Ah. Wet-cell lead-acid batteries may be used if the cells are kept topped off with electrolyte. Do not use this charger with lithium, nickel, or other battery chemistries.

### POWER CONTROL

The input power source and the battery share the output load. The input source recharges the battery directly, as well. If the input source is disconnected, the battery takes over supplying the load. Low-power input sources can be used to charge the battery as long as their terminal voltage remains higher than the battery voltage.

D3 is an optional diode to prevent power from back-feeding current into the power source when the source voltage is lower than the battery voltage. D3 should be installed if the external power voltage can fall below the battery voltage, such as for automotive or solar power applications.

Q3 acts as the master battery ON/OFF switch. It is an ultra-low  $R_{ds-ON}$  40B207 MOSFET rated to carry dozens of amps continuously. It is connected as a *low-side switch* from the battery negative terminal to the circuit common and input negative or return terminal (ground).

Q1, a PNP transistor, is biased on by R4 and R6. It supplies enough current through R3 and D2 to raise the gate voltage of Q3 so that it is fully on. This lowers the resistance between the drain and source of Q3 to about 4 mΩ. R2 limits the total current through Q1 to about 13 mA. D2 is the Battery ON indicator.

Q3 dissipates heat while conducting according to  $P = I_{ds}^2 R_{ds}$ . The design of the PC board includes bare heat-sinking traces on top and bottom of the board, as well as the FET mounting screw and nut. Installed directly on the board, Q3 can dissipate up to 2W without damaging the device: if  $P=2W$  and  $R=4m\Omega$ , then  $I_{dsMAX}=22A$ . The 15 A battery fuse in the parts list should open at about 18 A continuous or 20 A surge. Even a 20 A fuse can probably be used safely if required.

S2 is a Battery OFF switch that physically

disconnects the battery's negative terminal. Since S2 carries the full battery current, be sure it is rated adequately for your battery and peak load current. (An alternative is to use a switch to ground the gate of Q3, turning it off along with D2. The battery remains connected to Q3 in this case.) The specified mini-toggle switch is rated at 5 A which is adequate for most 7 to 9 Ah battery applications. To carry higher currents, replace S2 with a heavier switch. If the Battery OFF function is not required, S2 can be replaced with a heavy jumper.

## POWER DISTRIBUTION

Anderson Powerpole connectors are used for both input and output power. Up to six output power connections are available. Any of the connectors can be used as the input power source connection. All of the power connectors are connected in parallel on a large-trace bus on the bottom of the board which should carry 25 to 30 A safely. If higher currents are required, #14 AWG wire can be soldered to the traces which are kept bare for this purpose. Power output cables may be hard-wired to the traces if required. It is recommended that the pairs of connectors be secured with wire-ties as shown in Figure 7.67.

While the circuit board and transistor can handle a higher load, the battery's terminals and internal plate construction should limit input or output current to 15 to 20 A maximum continuous load. Even loads of 25 A or more

are okay for a few seconds but should not be continuous. Radios in the 100 W class can be used at full power on SSB or CW. Digital modes should be used at reduced power to prevent battery or circuit overload. (S2 will have to be replaced by a heavier switch, however. Battery voltage below 12 V may cause erratic or improper operation of transceivers designed for 13.8 V supply voltages.)

## CHARGING CIRCUIT

The chemistry of the SLA battery allows it to be kept charged at a constant voltage between 13 and 13.8 V, with 13.8 V being the optimum voltage. The circuit keeps the battery connected to the input power source through Q3, so it can be kept fully charged. For a 7 to 12 Ah SLA battery discharged to about 11 V, inrush current to the battery through Q3 is about 4 A, decreasing to just a few mA within a few seconds as the battery voltage comes up to the input voltage. The battery is then float-charged by the external source. (A trickle-charger supplies a small amount of current to the battery at all times.)

## OVER-VOLTAGE CUTOFF CIRCUIT

The battery is disconnected by turning off Q3 if the input charging voltage is too high, which can damage the battery by overcharging it. Voltages above 13.8 V are common in automotive electrical systems and solar panels. Zener diode D1 drops the input voltage across trimpot R1 to  $V_{in} - 8.2$  V. As input voltage rises, the voltage on the wiper of R1

eventually turns on Q2, shorting the gate of Q3 to ground and turning it OFF. This also turns off the Battery ON indicator, D2.

The user should set the desired threshold voltage for the overvoltage protection circuit at about 13.7 or 13.8 V. Set the threshold by applying 13.8 V dc to the input, adjusting R1 until D2 goes out, then reverse the adjustment until D2 just turns back on. At this setting, the circuit will allow 13.8 V to charge the battery but disconnect the battery at any higher voltage. If the input voltage drops below 13.8 V, the battery will be reconnected and D2 will turn on again.

## USB CHARGING MODULES

Up to three +5 V, 2.5 A USB charger modules can be added in three places on the board, each replacing an Anderson Powerpole connector pair. One can be seen at the left-hand side of the PC board in Figure 7.67. These modules are widely available as commodity-type parts from a variety of sources.

Modules can be added along any of three edges of the board for flexibility in possible mounting configurations. All of the module +5 V outputs are connected in parallel and to J6 for external use if needed. As with all dc-dc converters, these modules are switched (at about 250 kHz) and may occasionally cause RF interference (RFI). If RFI from the USB charging modules is objectionable, a linear regulator such as the 2 A, +5V L78S05CV (with heatsink) can be used as a noise-free 5 V power supply, but it will generate about

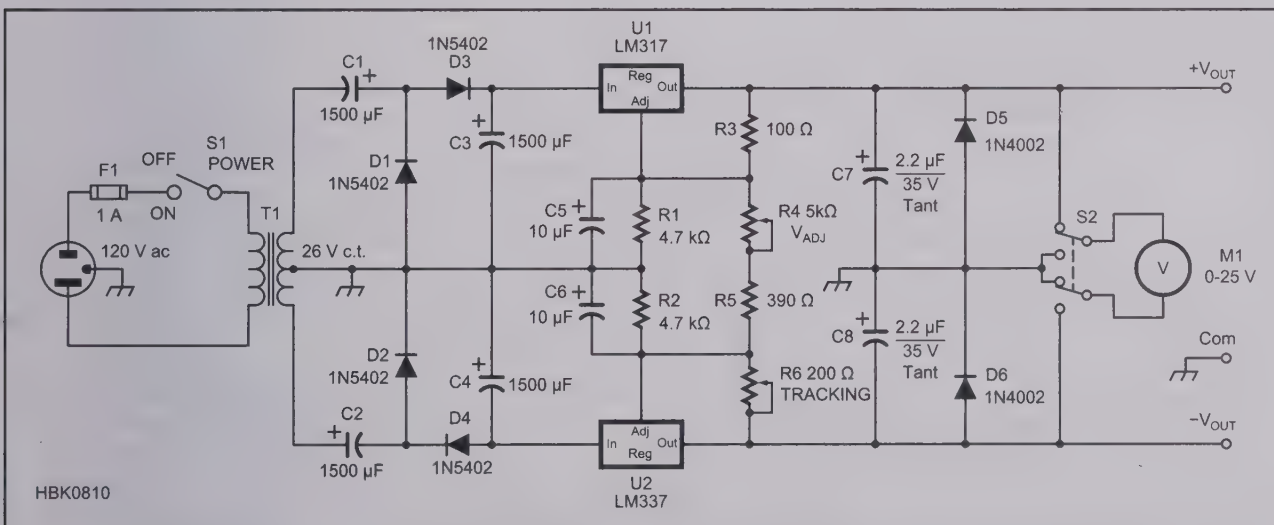

Figure 7.69 — Schematic of the adjustable tracking power supply. Regulators are mounted to the enclosure, which serves as a heat sink. Resistors are 1/4 W film, 5% tolerance unless noted otherwise.

C1-C4 — 1500 µF, 50 V electrolytic  
 C5, C6 — 10 µF, 50 V electrolytic  
 C7, C8 — 2.2 µF, 35 V, solid tantalum  
 D1-D4 — 1N5402 or equivalent  
 D5, D6 — 1N4002 or equivalent  
 F1 — 250 V, 1 A ac fuse and fuse holder

M1 — 0-25 V voltmeter or equivalent  
 R1, R2 — 4.7 kΩ  
 R3 — 100 Ω  
 R4 — 5 kΩ, panel-mount potentiometer  
 R5 — 390 Ω  
 R6 — 200 Ω trimmer potentiometer  
 S1 — SPST toggle switch

S2 — DPDT miniature toggle switch  
 T1 — 26 V CT at 2 A secondary or equivalent (see text)  
 U1 — LM317 adjustable positive voltage regulator  
 U2 — LM337 adjustable negative voltage regulator

9 W of heat for every 5 W delivered to the load. It also requires filter capacitors of 0.01  $\mu\text{F}$  and 100  $\mu\text{F}$ .

## MISCELLANEOUS

C1, C2, and C3 are 0.1  $\mu\text{F}$  capacitors to reduce HF and VHF noise on the dc power busses. Different values may be substituted if noise at higher or lower frequencies is encountered.

The DVM is a typical miniature 3-digit meter/display module available from many vendors. S1 switches the DVM to either display input voltage, turns it off, or to display the actual battery voltage.

J6 is an optional 2x2 pin header that provides a connection to both input and output voltages, +5 V dc from the USB charging modules if installed, and common (ground). Note that the input source connection to J6 is not fused.

### 7.16.9 Simple Adjustable Tracking Power Supply

This project by Bryant Julstrom, KCØZNG, was originally published in the Spring 2014 issue of the QRP ARCI *QRP Quarterly*. A PDF version of the original article, including all figures, is available with this book's downloadable supplemental content.

The typical experimenter's bench power supply provides an adjustable positive voltage of up to 25 V at up to 1 A of current. This suffices for many circuits and projects, but others require positive and negative voltages

of equal magnitude. Op-amp circuits, for example, often require  $\pm 15$  V.

## THE CIRCUIT

The circuit is implemented using two garden-variety ICs, an LM317 positive regulator and an LM337 negative regulator, both in TO-220 packages. (Note that the orientation of the input-common-output connections are different between the two regulators!) The input voltages of the circuit are limited only by the maximum inputs of the two regulators,  $\pm 40$  V. (An alternate implementation based on the LT1033 tracking regulator is shown in an article included with this book's downloadable supplemental content.) A voltmeter is switched between either of the supply's outputs and common.

Input power to the tracking regulator is supplied by a power transformer with a center-tapped secondary. The peak secondary output voltage on each side of the center-tap should be several volts higher than the maximum supply output at full load. See this chapter's section on power supply ripple to determine the minimum required filter capacitance.

In the author's case, the heaviest transformer available provided only 26 V CT (center-tapped) and the input to the regulator of  $\pm 13$  V was too low. One possible solution would be to use two identical transformers with their primary windings in parallel and their secondaries in series with the connection between secondaries serving as the center-tap.

Since 24 to 28 V CT is a common secondary voltage range, however, the author chose to

use the available transformer and back-to-back half-wave voltage doublers, one on either side of the secondary winding's center tap, to provide about  $\pm 26$  V to the tracking regulator. This halves the current that can be drawn from the transformer, but if the transformer secondary is rated at 2 A, the resulting maximum output current of 1 A in each leg of the supply is sufficient for a wide range of projects.

Figure 7.69 shows the circuit of the tracking power supply. The author used 1N5402 rectifiers in the voltage doublers because they were available, but any 100 V diode rated at 3 A or more of average forward current will work. The two 2.2  $\mu\text{F}$  capacitors should be solid tantalum types.

R4, a front-panel potentiometer, is used for voltage adjustment. R6, a 200  $\Omega$  trimmer potentiometer, provides for fine tracking adjustment. The 390  $\Omega$  resistor (R5) sets the regulator's minimum outputs at about  $\pm 3.6$  V for reasons described below.

## CONSTRUCTION

As constructed, the front panel holds three binding posts (positive output, negative output, and common), two miniature toggle switches (on/off and voltmeter switching), the voltage-adjustment potentiometer and its knob, and a voltmeter. Note that the common connection of the power supply is usually left floating from the enclosure ground which must be connected to the "third-wire" ac safety ground. If desired, a binding post

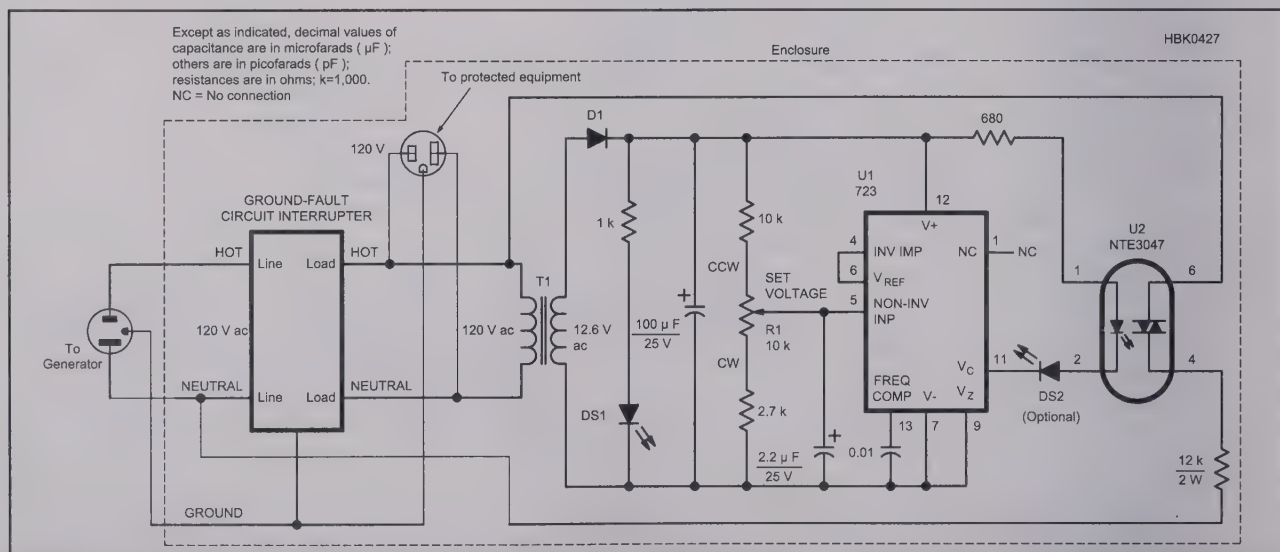

Figure 7.70 — Schematic of the Field Day equipment overvoltage-protection circuit. This circuit must be used in conjunction with a ground fault circuit interrupter (GFCI). A separate GFCI must be installed at each station. Unless otherwise specified, resistors are  $\frac{1}{4}$  W, 5% tolerance. A PC board is available from FAR Circuits ([www.farcircuits.net](http://www.farcircuits.net)).

D1 — 200 PIV, 1 A diode; 1N4003 or equiv.  
 DS1, DS2 — Small LEDs  
 R1 — 10 k $\Omega$  board-mounted, multi-turn potentiometer

T1 — 12.6 V ac transformer (see text)  
 U1 — 723 adjustable voltage regulator IC

U2 — Optoisolator with TRIAC output; NTE3047 or equiv

connected to the enclosure can be added so that a jumper can be used to connect the power supply common to the ac safety ground.

The voltmeter used by the author is a three-digit LED unit from Marlin P. Jones ([www.mpja.com](http://www.mpja.com); part number 30217 ME with blue digits, also available in green and red). The meter is powered by the voltage it measures, as long as the voltage is at least 3.6 V as determined by R5 as explained previously. An analog meter or a digital meter with a separate power supply would allow lower minimum output voltages. One could augment the supply's measurements with current metering or with simultaneous measurements of both outputs.

The enclosure holds the power transformer and two circuit boards. The two voltage doublers occupy one circuit board and the tracking regulator the other. The circuit is simple enough that perforated board ("Perf-board") was used with point-to-point wiring.

The LM317 and LM337 are mounted at the edge of the regulator board and attached to the back panel, which serves as a heat sink, using mica insulators, nylon bolts, and a thin coating of heat sink compound. The rear panel also holds a snap-in IEC three-wire ac line connector. (Photographs of the finished power supply are provided in an article included with this book's downloadable supplemental content.)

## ADJUSTMENT AND PERFORMANCE

The only internal adjustment in the supply is the tracking potentiometer (R6), which must be set so that the two voltages track each other accurately. This is touchy, but the two voltages can be made to match within 0.1 V throughout the supply's range. The completed supply provides closely matched positive and negative voltages from  $\pm 3.6$  V to about  $\pm 23$  V, and a maximum current of 1 A in each leg.

The tracking adjustment and the front-panel voltage adjustment (R4) are delicate. In both cases, multi-turn potentiometers would be much easier to set. The tracking control could also be replaced with a series resistor and a smaller-value potentiometer to make adjustment less sensitive.

### 7.16.10 Overvoltage Protection for AC Generators

When using portable generators, there is always a possibility of damage to expensive equipment as a result of generator failure, especially from overvoltage. If the generator supplying power to this equipment puts out too much voltage, you run the risk of burning up power supplies or other electronic components. This project, by Jerry Paquette, WB8IOW, addresses the problem of increased voltage (not lower voltage) or surges and spikes lasting for a few microseconds.

Using a portable generator overvoltage

protection circuit and ground-fault circuit interrupter (GFCI) as shown in **Figure 7.70** is good insurance. This overvoltage protection device must be used in conjunction with a GFCI at each station! (More information on GFCIs may be found in the **Safety** chapter.)

## CIRCUIT DESCRIPTION

Refer to Figure 7.70 for this description. R1 places an intentional fault on the load side of the GFCI. With the value resistor used, the fault is limited to 10 mA. (The normal tripping threshold of a GFCI is 5 mA. This current forces the GFCI to trip in just a few milliseconds. This circuit will not function at all without the use of a GFCI. A GFCI must be used at each station. If a single GFCI were used at the generator, rather than one at each location, premature tripping could occur. Several hundred feet of extension cords could have enough leakage to trip the GFCI.

You can see that the GFCI has separate lines (inputs) and loads (outputs). GFCI input terminals must be connected to the generator output. The GFCI ground must be tied to the ground of the generator. The load (computers, radios, etc) will plug into the GFCI or are wired to the load side of the GFCI. The primary of T1 is wired to the load side of the GFCI. The 12 k $\Omega$ /2 W resistor, however, must be wired to neutral on the *line* side of the GFCI in order for it to trip when used with

generators that have windings isolated from ground. For safety, construct the entire unit in a single enclosure including the GFCI and its wiring. The generator connection can be made through a wired plug or using a male receptacle mounted on the enclosure.

T1 can be any 120 V to 12.6 V transformer capable of delivering 100 mA or more. Mounting of this transformer varies depending on the type used. All remaining components mount on a circuit board. D1 rectifies the ac from T1 and the 100  $\mu$ F capacitor filters the dc. This voltage provides the power to the 723 voltage regulator.

Two fixed resistors and a potentiometer form the voltage-divider network supplying voltage to the LM723 input, pin 5. R1, the board-mounted potentiometer, has only three leads, but there are four pads on the circuit board, to accommodate different styles of pots. The 2.2  $\mu$ F capacitor provides a slight delay, to prevent false tripping when the circuit is powered up. The 0.01  $\mu$ F capacitor from pin 13 of the 723 to the negative supply bus should always be used. When the voltage at pin 5 goes higher than the reference voltage at pins 4 and 6, pin 11 goes low, turning on the trip indicator LED DS2 and the optical coupler LED. LED current is limited by the 1 k $\Omega$  resistor. The optical coupler turns on the TRIAC, which creates a 10 mA fault current between the hot wire and ground of the GFCI. DS2 will remain lit as an indicator until the 100  $\mu$ F capacitor is discharged.

## ADJUSTMENT

Adjustment is simple. You'll need a variable ac transformer (Powerstat or Variac). Turn R1 fully clockwise and use the variable transformer to adjust input to 130 V ac. Turn the pot counter-clockwise until the GFCI trips.

### 7.16.11 Overvoltage Crowbar Circuit

The overvoltage "crowbar" circuit in **Figure 7.71** is intended as a last line of defense against power supply output overvoltage failures. When an overvoltage condition is detected, the heavy-duty SCR is turned ON, presenting a short-circuit across the power supply output. The intent is to cause protective components in the supply, such as a fuse or circuit-breaker, to remove power. This protects equipment connected to the supply. A complete description of the circuit is provided in the downloadable supplemental information for this chapter.

## Additional Projects and Information

Additional power source projects and supporting files are included with this book's downloadable supplemental content.

**Figure 7.71** — Schematic of the over-voltage crowbar circuit. Unless otherwise specified, resistors are 1/4 W, 5% tolerance. A PC board is available from FAR Circuits ([www.farcircuits.net](http://www.farcircuits.net)).

### Supplemental Files

- Selected SDR: Simplified columns by Ray Mack, W5IFS, from QEX magazine

# DSP and SDR Fundamentals

This chapter was updated and edited by Doug Grant, K1DG, based on material originally created by Alan Bloom, N1AL. It explores the fundamentals of digital signal processing (DSP) and software defined radio (SDR). Material is also taken from *QEX* "SDR: Simplified" articles by Ray Mack, W5IFS. Key to DSP and SDR, analog-digital conversion and types of converters are covered, as well.

In recent years, DSP technology has progressed to the point where it is an integral part of our radio equipment. DSP is rapidly replacing traditional analog hardware circuits with digital processors and software, offering amateurs flexibility and features only dreamed of in the past.

Software defined radio is the biggest advance in radio technology since the superheterodyne was introduced nearly a century ago. SDR is only possible through DSP techniques implemented on the advanced platforms that have become available at amateur-friendly prices in the past few years.

This chapter begins with the fundamentals of DSP and extends them to SDR design. Subsequent chapters will cover DSP methods in more detail for implementing oscillators, modulation, filters, and the functions associated with receiving and transmitting.

For the fullest understanding of this chapter the reader should have a basic familiarity of the topics covered in the **Radio Fundamentals** chapter as well as some high-school trigonometry. (Various math tutorials are provided or referenced in the **Radio Mathematics** downloadable supplemental content provided with this book's online information.)

Additional background and support materials may be found online in the downloadable supplemental content material provided with this book.

## 8.1 Introduction to DSP

*Digital signal processing* (DSP) has been around a long time. The essential theory was developed by mathematicians such as Newton, Gauss, and Fourier in the 17th, 18th, and 19th centuries. It was not until the latter half of the 20th century, however, that digital computers became available that could do the calculations fast enough to process signals in real time. Today DSP is important in many fields, such as seismology, acoustics, radar, medical imaging, nuclear engineering, audio and video processing, as well as voice and data communications.

In all those systems, the idea is to process a digitized signal so as to extract information from it or to control its characteristics in some way. For example, an EKG monitor in a hospital extracts the essential characteristics of the signal from the patient's heart for display on a screen. A digital communications receiver uses DSP to filter and demodulate the received RF signal before sending it to the speaker, headphones, or waterfall/band-scope display. In some systems, the signal to be processed may have more than one dimension. An example is image data, which requires two-dimensional processing. Similarly, the controller for an electrically-steerable antenna array uses multi-dimensional DSP techniques to determine the amplitude and phase of the RF signal in each of the antenna elements. A CT scanner analyzes X-ray data in three dimensions to determine the internal structures of a human body.

A typical DSP system is conceptually very simple. It consists of only three sections, as illustrated in **Figure 8.1**. An ADC at the input converts an analog signal into a series of digital numbers that represent snapshots of the signal at a series of equally spaced sample times. The digital signal processor itself does some kind of calculations on that digital signal to generate a new stream of numbers at its output. A DAC then converts those numbers back into analog form.

Some DSP systems may not have all three components. For example, a DSP-based audio-frequency generator does not need an ADC. Similarly, there is no need for a DAC in a measurement system that monitors some sensor output, processes the signal, and stores the result in a computer file or displays it on a digital readout.

The term "DSP" is normally understood to imply processing that occurs in real time, at least in some sense. For example, an RF or microwave signal analyzer might include a DSP coprocessor that processes chunks of sampled data in batch mode for display a fraction of a second later.

Figure 8.1 — A generic DSP system.

## 8.2 Introduction to SDR

The concept of a *software-defined radio* (SDR) has been around for a long time, but became popular in the 1990s. By then, DSP and data converter technology had developed to the point that it was possible to implement almost all the signal-processing functions of a transceiver using inexpensive programmable digital hardware. The frequency, bandwidth, modulation, filtering, and other characteristics can be changed under software control, rather than being fixed by the hardware design as in a conventional analog radio. Adding a new modulation type or a new improved filter design is a simple matter of downloading new software.

Compared to analog radios, SDR has some major advantages. In analog radios, passive components such as capacitors, resistors, and even inductors are subject to changes in value due to temperature drift and aging. They also have loose initial value tolerances and often require adjustments or calibration. Likewise, active components such as amplifiers and mixers also are subject to variations in performance. If the function of these components can be replaced with software, most of these problems disappear.

SDR is appealing to regulatory bodies such as the FCC because it makes possible a communications system called *cognitive radio* in which multiple radio services can share the same frequency spectrum.<sup>1</sup> Each node in a wireless network is programmed to dynamically change its transmission or reception characteristics to avoid interference to or from other users. In this way, services that in the past enjoyed fixed frequency allocations but that only use their channels a small percentage of the time can share their spectrum with other wireless users with minimal interference.

There has been much, sometimes heated, discussion about the precise definition of a *software-defined radio* (SDR). Most feel that, at minimum, an SDR must implement in software at least some of the functions that have traditionally been done in hardware. Others feel that a radio doesn't count as an SDR unless nearly all the signal-processing functions, from the RF input to the audio output (for the receiver) and from the microphone ADC (analog-to-digital converter, or A/D) to the power amplifier input (for the transmitter), are done in software. Others add the requirement that the software must be reconfigurable by downloading new code, preferably open-source. For our purposes we will use a rather loose definition and consider any signal-processing function done in software to fall under the general category of SDR.

Some SDRs use a personal computer to do the computational work and external hard-

ware to convert the transmitted and received RF signals to lower-frequency signals that the computer's audio interface can handle. Some SDRs avoid the use of the PC's sound card by including their own audio *codec* (short for "coder-decoder," a chip that includes both A/D and D/A converter functions) and using analog audio for the user interface. Some SDRs transfer the downconverted (and possibly filtered) data to the PC via a USB port. Modern PCs provide a lot of computational power for the money and are getting cheaper and more powerful all the time. They also come with a large color display, a keyboard and mouse for easy data entry and navigation, a large memory and hard disk, which allows running logging programs and other software while simultaneously doing the signal processing required by the SDR.

Smaller, even less expensive, computing platforms such as Arduino, Raspberry Pi, Beaglebone, Red Pitaya and many others have become available. While they often lack the peripherals and user interfaces of a complete PC, some of them have sufficient computational power to be useful for SDR experimentation.

Some SDRs have almost no knobs or buttons on the box and none of the traditional features such as frequency display, meters, and so on. In such radios, all control functions are done on an external PC with control software provided by the manufacturer. The user interface is the PC keyboard, monitor, and mouse. Other SDRs look more like conventional analog radios and don't need an external PC for control. While the signal processing is done with one or more embedded DSPs, the user interface consists of knobs and pushbuttons which many users prefer to a mouse and keyboard and pull-down menus. Some newer SDRs use a touchscreen for the user interface to emulate the buttons.

Either method offers all the important advantages of applying DSP techniques to signal processing. The channel filter can have a much better *shape factor* (the ratio between the width of the passband and the frequency difference of the stopband edges). FIR filters are linear phase and have less ringing than analog filters of the same bandwidth and shape factor. Once the signal is in the digital domain all the fancy digital signal processing algorithms can be applied such as automatic notch filters, adaptive channel equalization, noise reduction, noise blanking, and feed-forward automatic gain control. Correcting bugs, improving performance or adding new features is as simple as downloading new software.

Following an overview of SDR systems, the details of the various blocks used in such

systems, including analog-digital conversion, are then explored. The chapter concludes with a discussion of the basic theory of discrete-time and digital signals, with emphasis on topics relevant to radio communications.

### 8.2.1 SDR Architecture Options

The transition between analog and digital signals can occur at any of several places in the signal chain between the antenna and the user interface. This choice is an important factor in determining the overall architecture of the SDR. This section presents several block-diagram-level concepts for software-defined radio and compared architecture options.

#### DSP AT AUDIO FREQUENCIES

The initial use of DSP by amateur operators was to implement audio-frequency filtering. By the early 1990s, converter costs were reasonable and the processing power required was available in relatively inexpensive microprocessors with enhanced math function capability. The flexibility of digital filters (see the [Analog and Digital Filtering](#) chapter) and the ability to alter bandwidth and perform noise reduction resulted in quick adoption of DSP techniques in amateur equipment.

In 1992, Dave Hershberger, W9GR, designed an audio-frequency DSP filter based on the TMS320C10, one of the earliest practical DSP chips available.<sup>2</sup> This filter was an external standalone unit that plugged into the headphone jack of a receiver and included filters with various bandwidths, an automatic multi-frequency notch filter, and an adaptive noise filter.

The advantage of DSP at audio frequencies is that it can be easily added to an unmodified analog radio as in [Figure 8.2](#). Many amateurs use a similar approach to implement digital modulation modes, using a PC and software as the outboard DSP processor. The software produces the required waveforms (and demodulates the received signal), using the PC's audio input and output connected to

Figure 8.2 — An outboard DSP processor.

the audio input and output of a conventional SSB transceiver.

## DOWNCONVERSION TO ANALOG BASEBAND

A related technique is to *downconvert* a slice of the radio spectrum to baseband audio using a technique similar to the direct-conversion receivers popular with simple low-power CW transceivers. (See the **Receiving** chapter.) This idea was pioneered by Gerald Youngblood, AC5OG (now K5SDR), with the SDR-1000 transceiver, which he described in a series of *QEX* articles in 2002 and 2003.<sup>3</sup> The receiver block diagram is shown in **Figure 8.3**. It uses a unique I/Q demodulator designed by Dan Tayloe, N7VE, to convert the RF frequency directly to baseband I (“In-phase”) and Q (“Quadrature”) signals.<sup>4</sup> I/Q modulation and quadrature signals are discussed in the **Modulation** chapter.)

The baseband signals are fed to the stereo input of a PC’s sound card, represented by the low-pass filters and analog-to-digital converters (A/D, or ADC) in the figure. Software in the PC does all the signal processing and demodulation, ultimately producing audio for the operator to hear or a display of decoded bits in the form of text on the screen. The transmitter is the same block diagram in reverse, with an I/Q modulator converting the I/Q signal from the sound card up to the RF frequency where it is filtered and amplified to the final power level.

The sound card method manages to achieve reasonable performance with simple, inexpensive hardware. Once the A/D converters in the sound card have digitized the signal, the DSP capability of the PC can do amazing things with it. In addition to implementing conventional transceiver functions such as several types of detector, variable-bandwidth filters, software AGC, an S-meter and speech compression, the software can include some

extra features such as an automatic notch filter, noise reduction, a panadapter spectrum display and decoding of signals such as RTTY, PSK, and WSJT modes.

The simple hardware of the SDR-1000 does impose some performance limitations. Because of imperfections in the analog down-converter, unwanted-sideband rejection is not perfect. This is called “image rejection” in the SDR-1000 literature. On the panadapter display, strong signals show up weakly on the opposite side of the display, equally-spaced from the center. DC offset in the analog circuitry causes a spurious signal to appear at the center of the bandwidth. To prevent an unwanted tone from appearing in the audio output, the software demodulator is tuned slightly off frequency, but that means interference at the image frequency can cause problems because of the imperfect image rejection. The dynamic range depends on the sound card performance as well as the RF hardware. Some newer SDRs include an

integrated audio codec optimized for the application so that the PC’s sound card is not needed.

## DIGITIZING AT IF

Another option for implementing software-defined radios involves performing the analog-digital conversion at an intermediate frequency. **Figure 8.4** shows such a design. In the receiver, placing the A/D converter after a crystal IF filter improves the *blocking dynamic range* (BDR) for interfering signals that fall outside the crystal filter bandwidth. BDR is the ratio, expressed in dB, between the noise level (normally assuming a 500 Hz bandwidth) and an interfering signal strong enough to cause 1 dB gain reduction of the desired signal. (See the **Receiving** chapter.) As shown, the downconversion to I/Q format still uses lower-speed A/D converters, but often the signal is actually at a low IF, say, 15 kHz or so. This allows an SSB-bandwidth signal to be contained within the 20 kHz band-

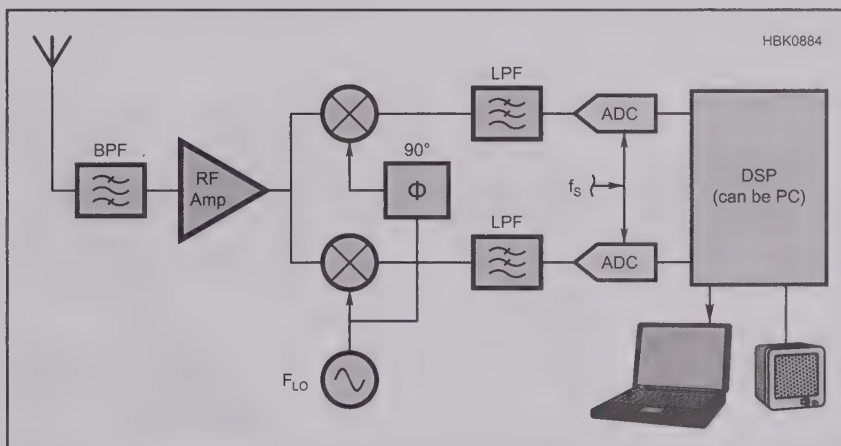

Figure 8.3 — Direct-to-baseband SDR receiver architecture.

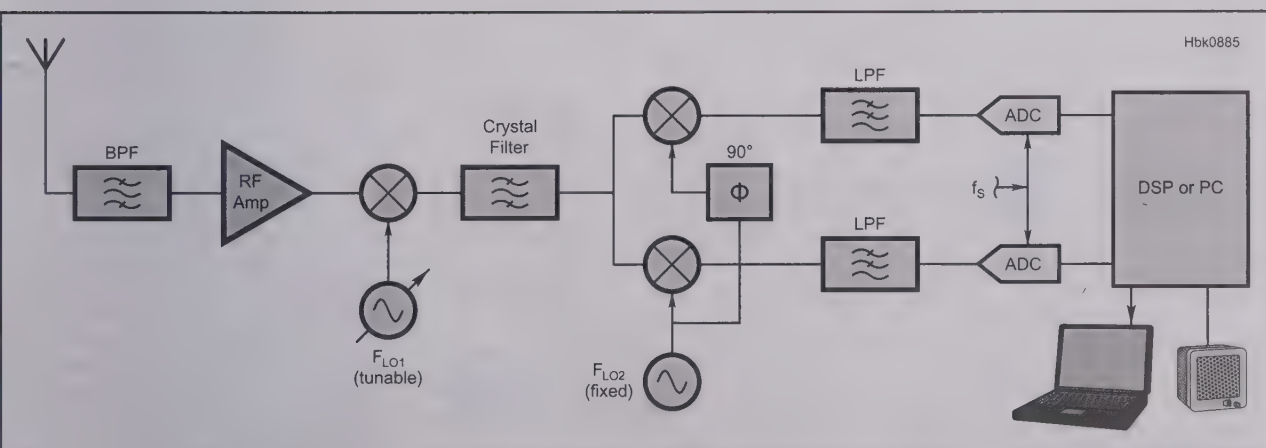

Figure 8.4 — Hybrid superhet/DSP SDR receiver architecture.

width of a typical audio codec and avoids errors due to dc offsets in the signal path. With careful design, a receiver with such an architecture can achieve 140 dB or more of BDR (if there are no other limiting factors such as LO phase noise). The third-order dynamic range is similar to that achieved with a conventional analog architecture since the circuitry up to the crystal filter, including amplifiers and mixer(s) is the same.

Another advantage of the IF-based approach compared to directly sampling the RF frequency is that the ADC does not have to run at such a high sample rate. In fact, because the crystal filter acts as a high-performance, narrow-bandwidth anti-aliasing filter, *undersampling* is possible if the A/D converter has sufficient sampling bandwidth (ADCs intended for audio applications generally do not). With bandwidths of a few kHz or less, sample rates in the tens of kHz can be used even though the center frequency of the IF signal is much higher, so long as the ADC's sample-and-hold circuit has sufficient bandwidth.

Some systems, especially in VHF/UHF applications such as cellular base stations which deal with signals that are tens of MHz wide, often use the approach shown in **Figure 8.5**. Here, a high-speed, high-bandwidth ADC digitizes an IF typically in the hundreds of MHz. The output data rate of such a converter is too high to be handled by a PC or even a low-cost programmable DSP microprocessor. The conversion from the original signal to I/Q components is done in a dedicated digital hardware block.

### DIRECT RF DIGITIZING

The ultimate SDR architecture is to convert between the analog and digital domains right at the frequency to be transmitted or received, or convert a wide range of frequencies and do all filtering in the digital domain. The receive path of such a design is shown in **Figure 8.6**. In this receiver, the only remaining analog components in the signal chain are a wide-band anti-aliasing filter similar to a preselector and an amplifier to improve the noise

figure of the ADC if necessary. The local oscillator, mixer, IF filters, AGC, demodulators and other circuitry are all replaced by digital hardware and software. The digital/software implementations of these functions are perfectly stable with time and temperature, and need no adjustments.

It has only been recently that low-cost high-speed ADCs have become available with specifications good enough to allow reasonable performance in an RF-sampling communications receiver. Today it is possible to achieve blocking dynamic range of 130 dB. That is not quite as good as the best analog or hybrid radios, but with every new generation of A/D converter that becomes available for use in SDR, the performance gap becomes narrower.

It is worth noting here that while huge BDR numbers can be measured in the laboratory, the performance achieved in a real-world environment with a receiver connected to an antenna is quite different. Often local noise sources raise the noise floor such that the receiver's full BDR cannot be utilized and other specifications become more important. In many of these specifications (dynamic range for close-spaced signals, and so on), RF-sampling SDRs can provide performance comparable or superior to conventional all-analog and IF-sampling receivers.

*Third-order dynamic range* (3IMD DR or  $IP_3$ ) is not a meaningful specification for this type of radio because it is based on the behavior of analog circuits. Calculation of 3IMD DR assumes that distortion products increase 3 dB for each 1 dB increase in signal level, which is not always true for an ADC. The level of the distortion products in an ADC tends to be more-or-less independent of signal level until the signal peak exceeds the ADC's full scale input, at which point the distortion increases dramatically. It is important to read the data sheet carefully and note the test conditions for the distortion measurements.

There are definite advantages to sampling at RF. For one thing, it saves a lot of analog circuitry. Even though a high-speed ADC is more expensive than an audio converter, the radio may be end up being cheaper to build because of the reduced component count and fewer adjustments. Performance is improved in some areas. For example, image rejection is no longer a worry, as long as the anti-aliasing filter is doing its job. (See the **Receiving** chapter.) The dynamic range of an SDR theoretically does not depend on signal spacing — close-in dynamic range is often better than with a conventional architecture that uses a wide IF filter. With no crystal filters in the signal chain, the entire system has a completely linear phase response, which can improve the quality of both analog and digital signals after demodulation.

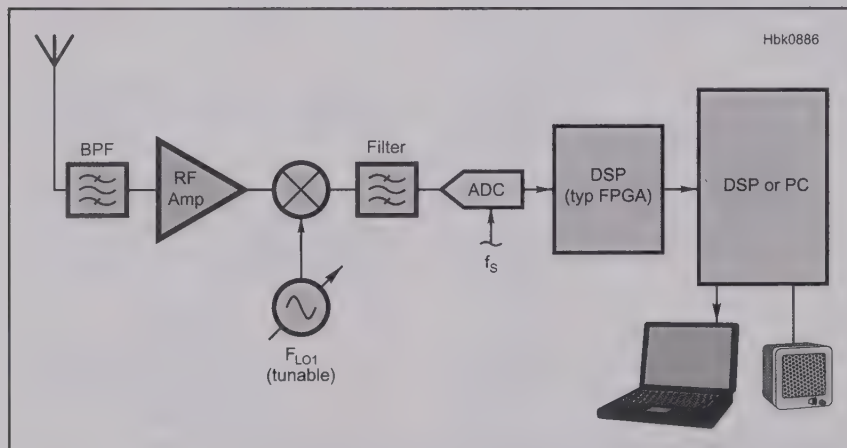

Figure 8.5 — High-IF sampling SDR receiver architecture.

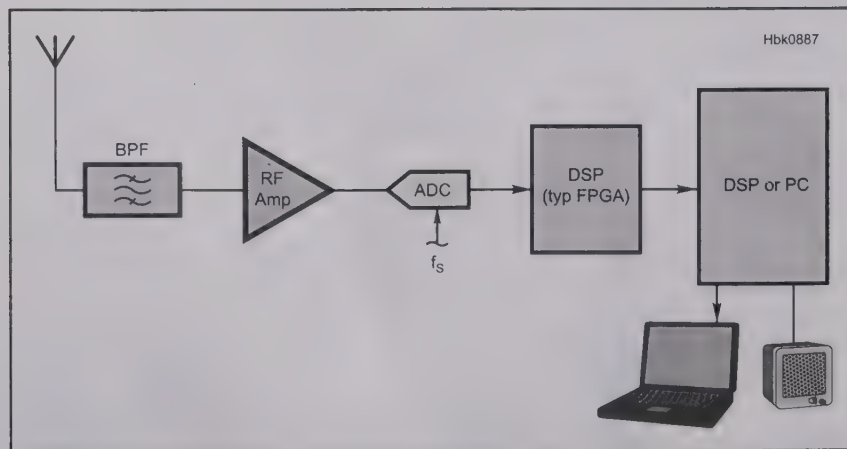

Figure 8.6 — Direct RF-sampling DSP SDR receiver architecture.

The biggest challenge with RF sampling is what to do with the torrent of high-speed data coming out of the receiver's ADC and how to generate transmit data fast enough to keep up with the DAC sample rate. To cover 0-54 MHz without aliasing requires a sample rate of at least 120 or 130 MHz, and commercial products typically operate the ADC at sample rates well over 200 MHz. That is much faster than a typical microprocessor or programmable DSP can handle. The local oscillator, mixer, and decimator or interpolator must be implemented in digital hardware so that the DSP can send and receive data at a more-reasonable sample rate. *Digital down-converters* (DDC) perform those functions and output a lower-sample-rate digital I/Q signal to the DSP. Stand-alone DDC ICs were available in the past, but the function is now usually integrated with the A/D converter. It is also possible to implement a DDC in an *infield-programmable gate array* or FPGA. (See the **Transceiver Design Topics** chapter.) *Digital upconverters* (DUC) do the same conversion in reverse for the transmitter and are available integrated with the D/A converter or can be implemented in an FPGA. Some commercial integrated DDC/DAC products even include the capability to encode several digital modulation formats such as GMSK, QPSK and  $\pi/4$  DQPSK. In an attempt to simplify the interface to the digital domain, many high-speed converters now use a standardized serial interface specification called JESD204B, capable of handling up to 12Gb/s. Code to implement this interface on the digital FPGA is readily available.

Some designers have been successful in repurposing a graphics processor (GPU) for this purpose, and some GPU manufacturers now offer FFT libraries to assist in the design process.

### 8.2.2 Advantages and Limitations of DSP and SDR

Digital signal processing has the reputation of being more complicated than the analog circuitry that it replaces. In reality, once the analog signal has been converted into the digital domain, complicated functions can be implemented in software much more simply than would be possible with analog components. For example, the traditional "phasing" method of generating an SSB signal without an expensive crystal filter requires various mixers, oscillators, filters and a wide-band audio-frequency phase-shift network built with a network of high-precision resistors and capacitors. To implement the same function in a DSP system requires adding one additional subroutine to the software program — and no additional hardware.

Many features that are straightforward with DSP techniques are difficult or impractical to implement with analog circuitry. A few examples drawn just from the communications field are imageless mixing, noise reduction, OFDM (orthogonal frequency division multiplexing) modulation and adaptive channel equalization. Digital signals can have much more dynamic range than analog signals, limited only by the number of bits used to represent the signal. For example, it is easy

to add an extra 20 or 30 dB of headroom to the intermediate signal processing stages to ensure that there is no measurable degradation of the signal in a filter, for example. It would be difficult or impossible to add that much dynamic range with analog circuitry. Replacing analog circuitry with software algorithms eliminates the problems of non-linearity and drift of component values with time and temperature. The programmable nature of most DSP systems means you can make the equivalent of circuit modifications without having to unsolder any components.

Despite its many advantages, we don't mean to imply that DSP is best in all situations. High-power and very high-frequency signals are still the domain of analog circuitry. Where simplicity and low power consumption are primary goals, a DSP solution may not be the best choice. For example, a simple CW receiver that draws a few milliamps from the power supply can be built with two or three analog ICs and a handful of discrete components. We are still a long way from that kind of low power radio using SDR.

In many high-performance systems, the performance of the analog-to-digital converter and digital-to-analog converter are the limiting factors. That is why, even with the latest generation of affordable ADC technology, it is still possible to obtain better blocking dynamic range in an HF receiver using a hybrid analog-digital system rather than going all-digital by routing the RF input directly to an ADC. This may change as A/D converter technology continues to evolve and performance rises.

## 8.3 Analog-Digital Conversion

Analog-digital conversion consists of taking data in one form, such as digital binary data or an analog ac RF waveform, and creating an equivalent representation of it in the opposite domain. Converters that create a digital representation of analog voltages or currents are called *analog-to-digital converters* (ADC), *analog/digital converters*, *A/D converters* or *A-to-D converters*. Similarly, converters that create analog voltages or currents from digital quantities are called *digital-to-analog converters* (DAC), *digital/analog converters*, *D/A converters* or *D-to-A converters*. The word "conversion" in this first section on the properties of converting information between the analog and digital domains will apply equally to analog-to-digital or digital-to-analog conversion.

Converters are typically implemented as

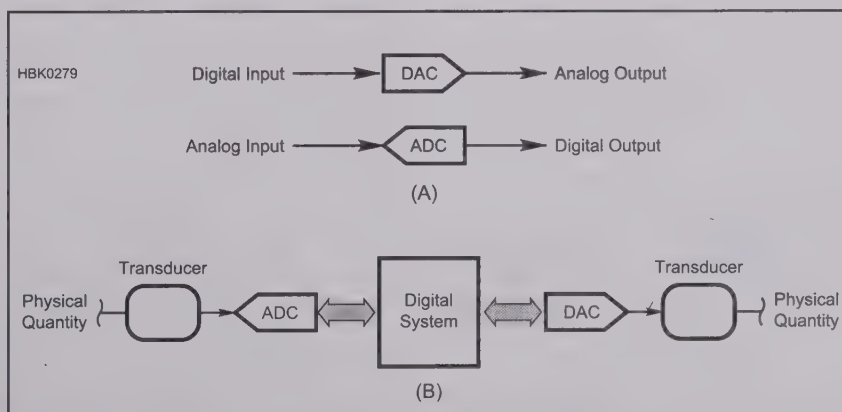

Figure 8.7 — Schematic symbols (A) for digital-to-analog converters (DAC) and analog-to-digital converters (ADC). The general block diagram of a system (B) that digitizes an analog signal, operates on it as digital data, then converts it back to analog form.

integrated circuits that include all of the necessary interfaces and sub-systems to perform the entire conversion process. Schematic symbols for ADCs and DACs are shown in **Figure 8.7**.

This section defines the basic elements of analog-digital conversion along with an overview of different types of converters and their key specifications and behaviors. The following section discusses the use of converters for DSP and SDR functions which are the most demanding application in radio.

### 8.3.1 Basic Conversion Metrics

**Figure 8.8** shows two different representations of the same physical phenomenon; an analog voltage changing from 0 to 1 V. In the analog world, the voltage is continuous and can be represented by any real number between 0 and 1. In the digital world, the number of possible values that can represent any phenomenon is limited by the number of bits contained in each value.

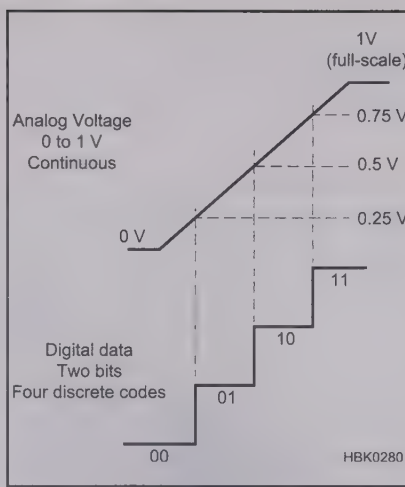

In **Figure 8.8**, there are only four two-bit digital values 00, 01, 10, and 11, each corresponding to the analog voltage being within a specific range of voltages. If the analog voltage is anywhere in the range 0 to 0.25 V, the digital value representing the analog voltage will be 00, no matter whether the voltage is 0.0001 or 0.24999 V. The range 0.25 to 0.5 V is represented by the digital value 01, and so forth.

The process of converting a continuous range of possible values to a limited number of discrete values is called *digitization* and each discrete value is called a *code* or a *quantization code*. If the code is a binary number, the number of possible codes that can represent an analog quantity is  $2^N$ , where N is the number of bits in the code. A two-bit number can have four codes as shown in **Figure 8.8**, a four-bit number can have sixteen codes, an eight-bit number 256 codes, and so forth. Assuming that the smallest change in code values is one bit, that value is called the *least significant bit (LSB)* regardless of its position in the format used to represent digital numbers.

*Binary-coded-decimal (BCD)* is a code in which groups of four bits represent individual decimal values of 0-9. In the *hexadecimal* code, groups of four bits represent decimal values of 0-15. Other types of codes that may be encountered include *Gray code* and *octal*.

#### RESOLUTION AND RANGE

The *resolution* or *step size* of the conversion is the smallest change in the analog value that the conversion can represent. The *range* of the conversion is the total span of analog values that the conversion can process.

**Figure 8.8** — The analog voltage varies continuously between 0 and 1 V, but the two-bit digital system only has four values to represent the analog voltage, so representation of the analog voltage is coarse.

The maximum value in the range is called the *full-scale (F.S.)* value. In **Figure 8.8**, the conversion range is 1 V. The resolution of the conversion is

$$\text{resolution} = \frac{\text{range}}{2^N}$$

In **Figure 8.8**, the conversion resolution is  $1/4 \times 1 \text{ V} = 0.25 \text{ V}$  in the figure. If each code had four bits instead, it would have a resolution of  $1/2^4 \times 1 \text{ V} = 0.083 \text{ V}$ . Conversion range does not necessarily have zero as one end point. For example, a conversion range of 5 V may span 0 to 5 V, -5 to 0 V, -2.5 to +2.5 V, and so on.

Analog-digital conversion can have a range that is *unipolar* or *bipolar*. Unipolar means a conversion range that is entirely positive (or negative), usually referring to voltage. Bipolar means the range can take on both positive and negative values.

Because each code represents a range of possible analog values, the limited number of available codes creates *quantization error*. This is the maximum variation in analog values that can be represented by the same code. In **Figure 8.8**, any value from 0.25 through 0.50 V could be represented by the same code: 01. The quantization error in this case is 0.25 V.

Resolution can also be defined by the number of bits in the conversion. The higher the number of bits, the smaller the resolution as demonstrated above. Since many converters have variable ranges set by external components or voltages, referring to percent resolution or as a number of bits is preferred. The

conversions between percent resolution and number of bits are as follows:

$$\% \text{ resolution} = \frac{1}{2^N} \times 100\%$$

and

$$N = \frac{\log\left(\frac{100\%}{\% \text{ resolution}}\right)}{\log 2}$$

Quantization error can also be specified as a number of least significant bits (LSB) where each bit is equivalent to the conversion's resolution.

#### ACCURACY

The number of bits of an A/D converter's resolution does not equate to the accuracy of the converter. A companion to resolution, *accuracy* refers to the ability of the converter to either assign the correct code to an analog value or create the true analog value from a specific code. As with resolution, it is most convenient to refer to accuracy as either a percentage of full scale or in bits. *Full-scale error* is the maximum deviation of the code's value or the analog quantity's value as a percentage of the full scale value. If a converter's accuracy is given as 0.02% F.S. and the conversion range is 5 V, the conversion can be in error by as much as  $0.02\% \times 5 \text{ V} = 1 \text{ mV}$  from the correct or expected value. Most A/D converters include provision for user adjustment to calibrate the converter's full-scale range. Some A/D converters include a reference voltage source internal to the device, while others require an external reference. External references can often provide higher accuracy and stability over temperature than internal references. *Offset* has the same meaning in conversion as it does in analog electronics — a consistent shift in the value of the conversion from the ideal value. It can also be adjusted if necessary by the user.

*Linearity error* represents the maximum deviation of the code transition points from the ideal code transition points after adjusting for the full scale and errors. This is also called *integral nonlinearity (INL)*. In the converter of **Figure 8.8**, ideal step transitions occur at 0.25 V intervals. If the linearity error for the conversion was given as 0.05% F.S., any actual step size could be in error by as much as  $0.05\% \times 5 \text{ V} = 2.5 \text{ mV}$  due to the transition to the next step being at the wrong point. *Differential nonlinearity* is a measure of how much any two adjacent step sizes deviate from the ideal step size. Errors can be represented as a number of bits, usually assumed to be least significant bits, or LSB, with one bit representing the same range as the conversion resolution. A typical A/D converter may specify its INL or DNL error as +/- 0.5 LSB (least-significant bits).

## CONVERSION RATE AND BANDWIDTH

Another important parameter of the conversion is the *conversion rate* or its reciprocal, *conversion speed*. A digital code that represents an analog value at a specific time is called a *sample*, so conversion rate,  $f_s$ , is specified in *samples per second* (sps) and conversion speed as some period of time per sample, such as 1 msec. Because of the mechanics by which conversion is performed, conversion speed can also be specified as a number of cycles of clock signal used by the digital system performing the conversion. Conversion rate then depends on the frequency of the clock.

According to the *Nyquist Sampling Theorem*, in order to accurately represent the input signal, a conversion must occur at a rate twice the highest frequency present in the analog signal. This minimum rate is the *Nyquist rate* and the maximum frequency allowed in the analog signal is the *Nyquist frequency*. In this way, the converter *bandwidth* is limited to one-half the conversion rate.

Referring to the process of converting analog signals to digital samples, if a lower rate is used, called *undersampling*, false signals called *aliases* will be created in the digital representation of the input signal at frequencies related to the difference between the Nyquist sampling rate and  $f_s$ . This is called *aliasing*. Sampling faster than the Nyquist rate is called *oversampling*.

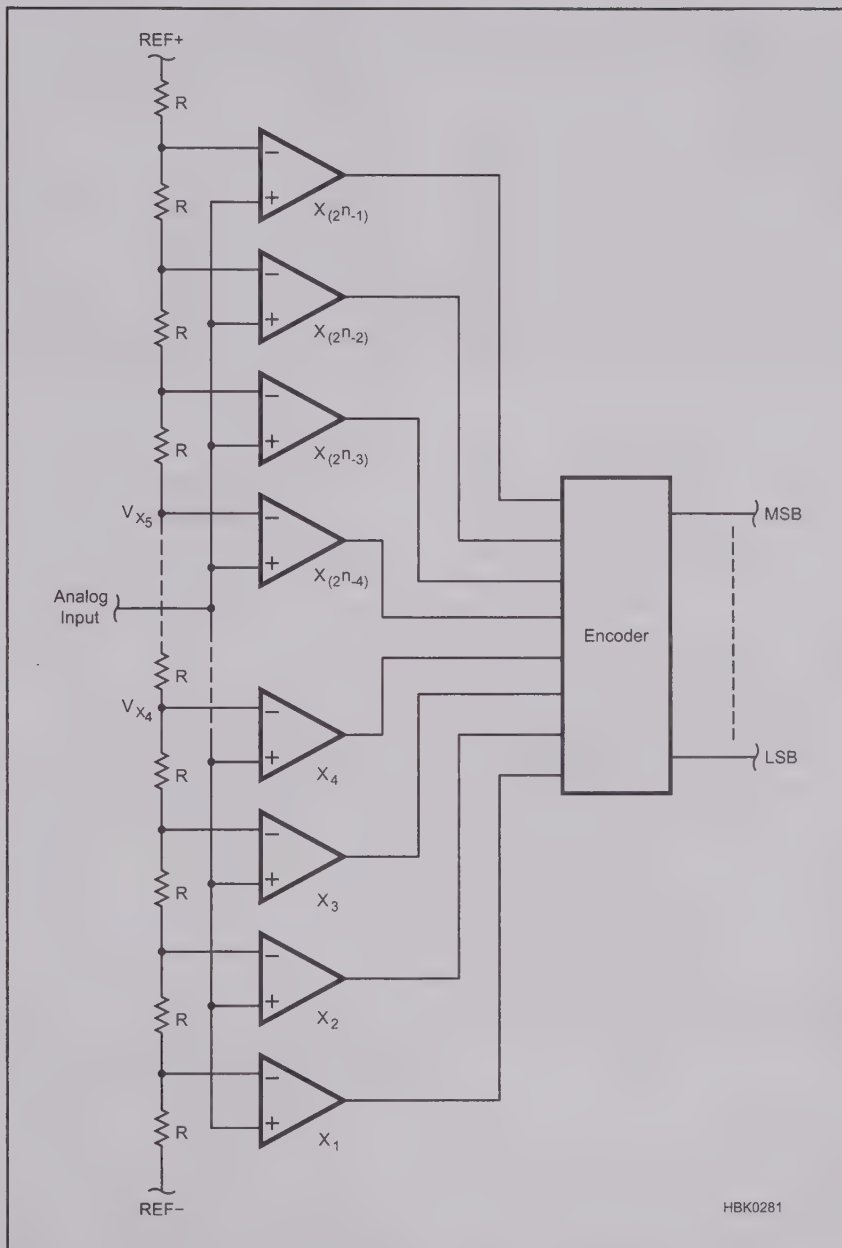

Because conversions occur at some maximum rate, there is always the possibility of signals greater than the Nyquist frequency being present in an analog signal undergoing conversion or that is being created from digital values. These signals would result in aliases and must be removed by *band-limiting filters* that remove them prior to conversion. The mechanics of the sampling process are discussed later in this and following chapters as they apply to specific functions.

### 8.3.2 Analog-to-Digital Converters

There are a number of methods by which the conversion from an analog quantity to a set of digital samples can be performed. Each has its strong points — simplicity, speed, resolution, accuracy — all affect the decision of which method to use for a particular application. In order to pick the right type of ADC, it is important to decide which of these criteria most strongly affect the performance of your application.

#### FLASH CONVERTER

The simplest type of ADC is the *flash converter*, shown in **Figure 8.9**. It continually generates a digital representation of the

**Figure 8.9** — The comparators of the flash converter are always switching state depending on the input signal's voltage. The decoder section converts the array of converter output to a single digital word.

analog signal at its input. The flash converter uses an array of comparators that compare the amplitude of the input signal to a set of reference voltages. There is one reference voltage for each step.

The outputs of the comparator array represent a digital value in which each bit indicates whether the input signal is greater (1) or less than (0) the reference voltage for that comparator. A digital logic *priority encoder* then converts the array of bits into a digital

output code. Each successive conversion is available as quickly as the comparators can respond and the priority encoder can create the output code. Flash converters are generally used for applications in which high speed is more important than bits of resolution.

Flash converters are the fastest of all ADCs (conversion speeds can be in the ns range, equivalent to sampling rates in the gigasamples/second range) but do not have high resolution because of the number of com-

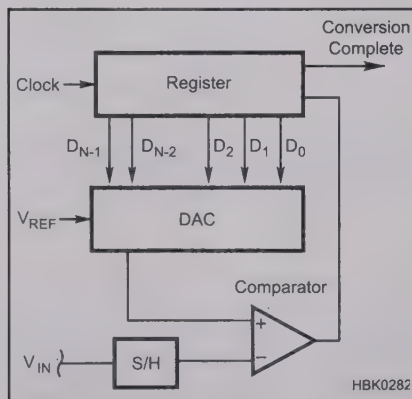

parators and reference voltages required. For example, an 8-bit flash converter requires 255 comparators, while a 12-bit version would require 4095 comparators.

One specialized variant of the flash converter is the *bar-graph display driver*. Such devices accept an analog input and deliver output signals capable of directly driving an LED display rather than a binary digital output word. These devices are commonly used to replace meters as front panel displays for signals that represent relatively slow-varying parameters such as transmitter output power. The LM3914 from Texas Instruments is one such device.

### SUCCESSIVE-APPROXIMATION CONVERTER

The *successive-approximation A/D converter* is one of the most widely-used types of converters. As shown in **Figure 8.10**, it uses a single comparator and DAC (digital-to-analog converter) to arrive at the value of the input voltage by comparing it to successive analog values generated by the DAC. This type of converter offers a good compromise of conversion speed and resolution.

The DAC control logic begins a conversion by setting the output of the DAC to 1/2 of the conversion range. If the DAC output is greater than the analog input value, the output of the comparator is 0 and the most significant bit of the digital value is set to 0. The DAC output then either increases or decreases by 1/4 of the range, depending on whether the value of the first comparison was 1 or 0. One test is made for each bit in digital output code and the result accumulated in a storage register, called the Successive-

**Figure 8.10** — The successive-approximation converter creates a digital word as it varies the DAC signal in order to keep the comparator's noninverting terminal close to the input voltage. A sample-and-hold circuit (S/H) holds the input signal steady while the measurement is being made.

Approximation Register, which is why such converters are often called "SAR" converters. The process is then repeated, forming a series of approximations, until a test has been made for all bits in the code.

While the digital circuitry to implement the SAR is more complex, it is less expensive to build and calibrate than the array of comparators and precision resistors of the flash converter, especially for higher resolutions. Each conversion also takes a known and fixed number of clock cycles. SAR A/D converters are used for speeds up to a few Msps. They are often used with an analog multiplexer in front so that multiple signals in a system can be measured relatively quickly, rather than using a separate converter for every signal.

### DUAL-SLOPE INTEGRATING CONVERTERS

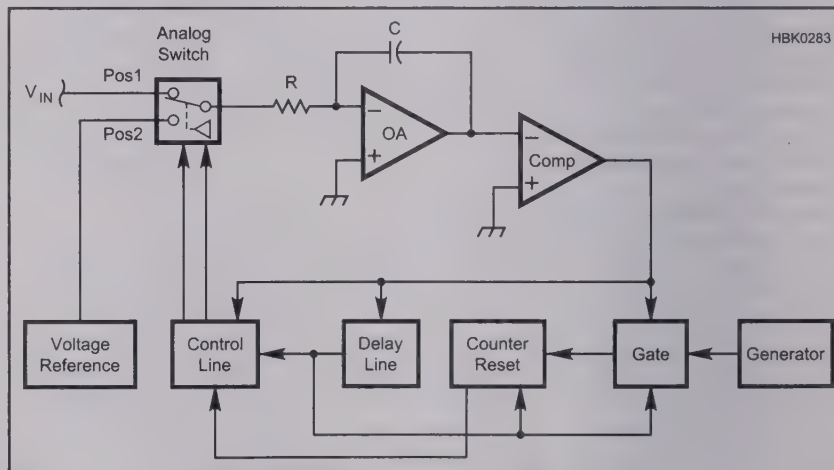

The *dual-slope integrating ADC* is shown in **Figure 8.11**. It makes a conversion by integrating the input signal by charging a capacitor for a fixed period of time then measuring the time it takes for the capacitor to discharge

back to its starting value. The integration period is often set to reject an interfering signal by integrating it over an exact number of cycles. For example, setting the integration period to 100 ms results in 6 full cycles of a 60 Hz sinusoidal interferer and 5 full cycles of a 50 Hz interferer.

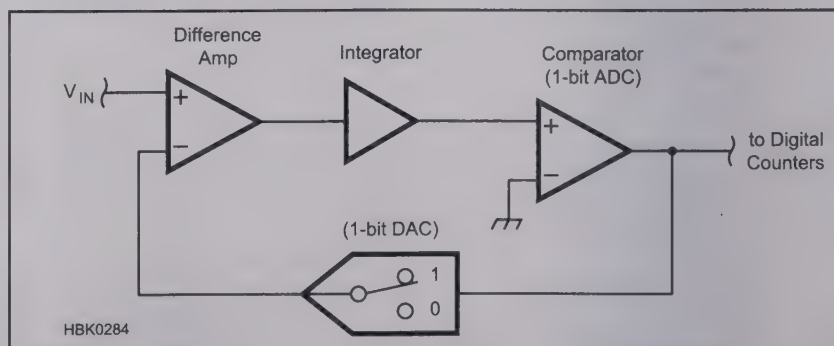

Dual-slope ADCs are low-cost and relatively immune to temperature variations. Due to the slow speed of the conversion these converters are generally only used in test instruments, such as multimeters, or measurement of slowly-varying dc signals.

### DELTA-ENCODED CONVERTERS

Instead of charging and discharging a capacitor from 0 V to the level of the input signal, and then back to 0 V, the *delta-encoded ADC* in **Figure 8.12** continually compares the output of a DAC to the input signal using a comparator. Whenever the signal changes, the DAC is adjusted until its output is equal to the input signal. Digital counter circuits keep track of the DAC value and generate the digital output code.

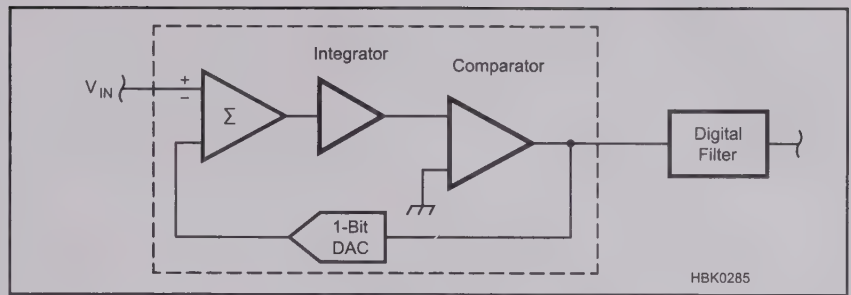

**Figure 8.11** — Dual-slope integrating converter. By using a constant-current source to continually charge a capacitor to a known reference voltage then discharge it, the resulting frequency is directly proportional to the resistor value.

**Figure 8.12** — Delta-encoded converter. The 1-bit DAC is operated in such a way that the bit stream out of the comparator represents the value of the input voltage.

## SIGMA-DELTA CONVERTERS

The *sigma-delta converter* also uses a DAC and a comparator in a feedback loop to generate a digital signal as shown in **Figure 8.13**. An integrator stores the sum of the input signal and the DAC output. (This is “sigma” or sum in the converter’s name.) The comparator output indicates whether the integrator output is above or below the reference voltage and that signal is used to adjust the DAC’s output so that the integrator output stays close to the reference voltage. (This is the “delta” in the name.) The stream of 0s and 1s from the comparator forms a high-speed digital bit stream that is digitally filtered to form the output code. Sigma-delta converters are used where high resolution (16 to 24 bits) is required at sampling rates in the kbps range, including very slowly-varying signals and even audio signals.

**Figure 8.13 — Sigma-delta converter.** Similar to the delta-encoded converter (**Figure 8.12**), the converter runs much faster than the output samples and uses a digital filter to derive the actual output value.

## OTHER A/D CONVERTER TYPES

There are many more A/D converter architectures but a detailed treatment is beyond the scope of this chapter. Some interesting variations combine multiple stages of converters. For example, multi-stage flash A/D converters apply the output code of a first-stage flash A/D to a D/A converter, and subtract the D/A’s output from the original analog input signal sample. The resulting error signal is amplified and applied to another stage of flash A/D conversion. This process may be repeated several times. The multiple stage digital outputs are combined digitally to yield more bits than a single-stage flash converter would produce. In addition, once the error signal has been sampled, the first stage is free to digitize the next sample. The result is a pipeline of output samples flowing continuously, without having to wait for all stages to complete.

**Figure 8.14 — Sample-and-hold (S/H).** An input buffer isolates the sampled voltage from the input signal by charging the capacitor  $C_{\text{HOLD}}$  to that voltage with the input switch closed and the output switch open. When a measurement is being taken, the input switch is open to prevent the input signal from changing the capacitor voltage, and the output switch is closed so that the output buffer can generate a steady voltage at its output.

When a conversion is started, a digital control signal opens the input switch, closes the output switch, and the capacitor’s voltage is measured by the converter. It is important that the capacitor used for  $C_{\text{HOLD}}$  have low *leakage* so that while the measurement is being made, the voltage stays constant for the few ms required. This is of particular importance in high-precision conversion.

## SINGLE-ENDED AND DIFFERENTIAL INPUTS

The input of most ADCs is *single-ended*, in which the input signal is measured between the input pin and a common ground. Shown in **Figure 8.15A**, this is acceptable for most applications, but if the voltage to be measured is small or is the difference between two nonzero voltages, an ADC with *differential inputs* should be used as in **Figure 8.15B**. Differential inputs are also useful when measuring current as the voltage across a small resistor in series with the current. In that case, neither side of the resistor is likely to be at ground, so a differential input is very useful. Differential inputs also help avoid the issue of noise contamination as discussed below.

**Figure 8.15 — Single-ended ADC inputs have a single active line and a ground or return line (A). Single-ended ADC input are often susceptible to noise and common mode signals or any kind of disturbance on their ground rails. In (B), the differential inputs used help the circuit “ignore” offsets and shifts in the input signal.**

## 8.3.3 Analog-to-Digital Converter Subsystems

### SAMPLE-AND-HOLD

ADCs that use a sequence of operations to create the digital output code must have a means of holding the input signal steady while the measurements are being made. This function is performed by the circuit of **Figure 8.14**. A high input-impedance buffer drives the external storage capacitor,  $C_{\text{HOLD}}$ , so that its voltage is the same as the input signal. Another high input-impedance buffer is used to provide a replica of the voltage on  $C_{\text{HOLD}}$  to the conversion circuitry.

### INPUT BUFFERING AND FILTERING

The input impedance of most ADCs is high enough that the source of the input signal

is unaffected. However, to protect the ADC input and reduce loading on the input source, an external buffer stage can be used. **Figure 8.16** shows a typical buffer arrangement with clamping diodes to protect against electro-

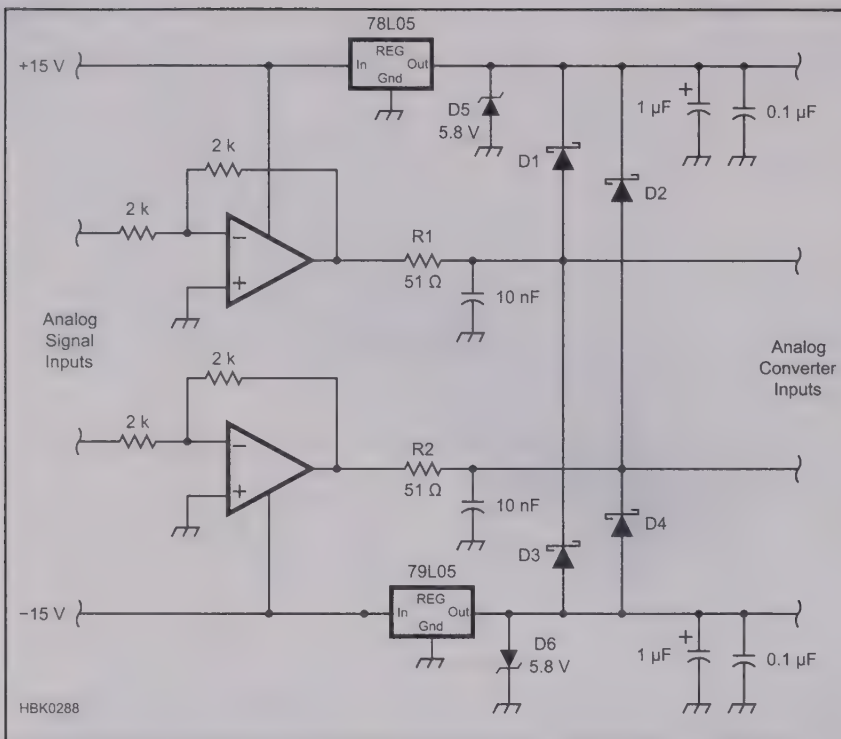

Figure 8.16 — Typical ADC input buffer-filter circuit. Unity-gain voltage followers help isolate the ADC from the input source. RC filters following the buffers act as band-limiting filters to prevent aliasing. Zener diodes are used to clamp the transient voltage and route the energy of transient into the power supply system.

static discharge (ESD) and an RC-filter to prevent RF signals or noise from affecting the input signal. In addition, to attenuate higher-frequency signals that might cause aliases, the input filters can also act as band-limiting filters.

### ANALOG AND DIGITAL “GROUND”

By definition, ADCs straddle the analog and digital domain. In principle, the signals remain separate and isolated from each other. In practice, however, voltages and currents from the analog and digital circuitry can be mixed together. This can result in the contamination of an analog signal with components of digital signals, and rarely, vice versa. Mostly, this is a problem when trying to measure small voltages in the presence of large power or RF signals.

The usual problem is that currents from high-speed digital circuitry find their way into analog signal paths and create transients and other artifacts that affect the measurement of the analog signal. Thus, it is important to have separate current paths for the two types of signals. The manufacturer of the converter will provide guidance for the proper use of the converter either in the device’s data sheet or as application notes. Look for separate pins on the converter, such as “AGND” or

“DGND” that indicate how the two types of signal return paths should be connected.

### 8.3.4 Digital-to-Analog Converters (DAC)

Converting a digital value to an analog quantity is considerably simpler than the reverse, but there are several issues primarily associated with DACs that affect the selection of a particular converter.

As each new digital value is converted to analog, the output of the DAC makes an abrupt *step change*. Even if very small, the response of the DAC output does not respond perfectly or instantaneously. *Settling time* is the amount of time required for the DAC’s output to stabilize within a certain amount of the final value. It is specified by the manufacturer and can be degraded if the load connected to the DAC is too heavy or if it is highly reactive. Settling time is critical in control applications and is also sets the limit on update sampling rate.

*Monotonicity* is another aspect of characterizing the DAC’s accuracy. A DAC is monotonic if in increasing the digital input value linearly across the conversion range, the output of the DAC increases with every step. Because of errors in the internal conversion circuitry, it is possible for there to be some steps that are too small or too large, leading to output values that seem “out of order.” These are usually quite small, but if used in a precision control application where the DAC is part of a feedback loop, monotonicity is important because the control system can go unstable.

### SUMMING DAC

A *summing DAC*, shown in Figure 8.17, is a summing amplifier with all of the inputs connected to a single reference voltage through switches. The digital value to be converted controls which switches are closed. The larger the digital value, the more switches are closed. Higher current causes the summing amplifier’s output voltage to be higher, as well.

The input resistors are *binary weighted* so that the summing network resistors representing the more significant bit values inject more current into the op amp’s summing junction. Each resistor differs from its neighboring resistors in the amount of current it injects into the summing node by a factor of

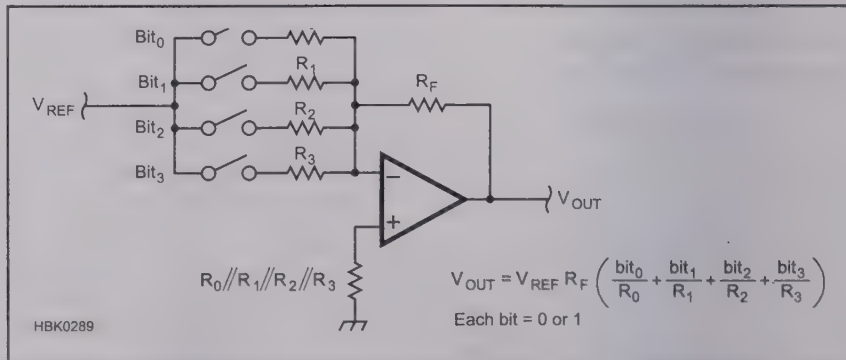

Figure 8.17 — Summing DAC. The output voltage is the inverted, weighted sum of the inputs to each summing resistor at the input. Digital data at the input controls the current into the summing resistors and thus, the output voltage.

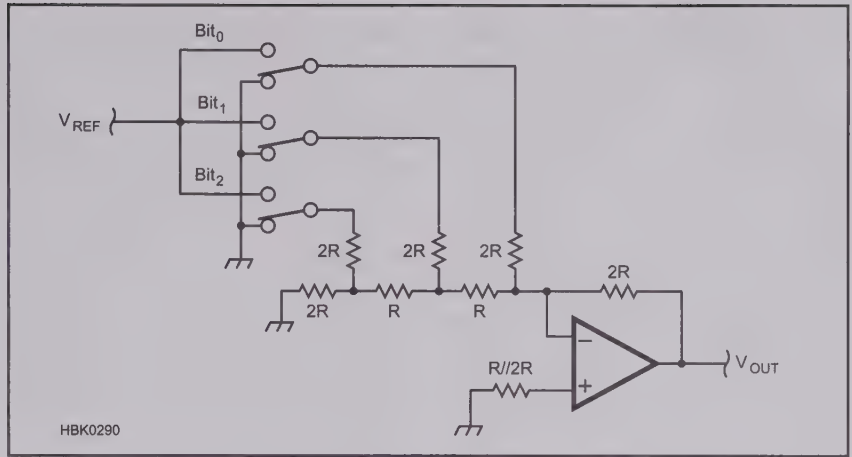

two, recreating the effect of each digital bit in the output voltage. At high resolutions, this becomes a problem because of the wide spread in resistor values — a 12-bit DAC would require a spread of 2048 between the largest and smallest resistor values. Summing DACs are generally only available with low resolution for that reason.

The *current output DAC* functions identically to the summing DAC, but does not have an op amp to convert current in the digitally-controlled resistor network to voltage. It consists only of the resistor network, so an external current-to-voltage circuit (discussed in the previous section on op amps) is required to change the current to a voltage. In some applications, the conversion to voltage is not required or it is already provided by some other circuit.

### R-2R LADDER DAC

The summing and current output DACs both used binary weighted resistors to convert the binary digital value into the analog output. The practical limitation of this design is the large difference in value between the smallest and largest resistor. For example, in a 12-bit DAC, the smallest and largest resistors differ by a factor of 2048 (which is  $2^{12-1}$ ). This can be difficult to fabricate in an IC since it is difficult to match a wide range of resistors values closely enough to maintain the desired binary-weighted relationship with sufficient accuracy. For DACs with high-resolutions of 8 bits or more, the R-2R ladder DAC of **Figure 8.18** is a better design. R-2R DACs can operate in either voltage mode or current mode.

The problems of manufacturing are greatly reduced when resistances are fairly close in value. By using the *R-2R ladder* shown in the figure, the same method of varying current injected into an op amp circuit's summing junction can be accomplished with resistors of only two values, R and 2R. In fact, since the op amp feedback resistor is also one of the IC resistors, the absolute value of the resistance R is unimportant, as long as the ratio of R:2R is maintained. This simplifies manufacturing greatly and is an example of IC design being based on ratios instead of absolute values. For this reason, most DACs use the R-2R ladder design and the performance differences lie mostly in their speed and accuracy.

**Figure 8.18 — R-2R Ladder DAC.** This is the most common form of DAC because all of the resistor values are similar, making it easier to manufacture. The similarity in resistor values also means that there will be less variation of the comparator with temperature and other effects that affect all resistors similarly.

### DIGITAL POTENTIOMETERS

Since D/A converters are commonly used to provide digitally-controlled adjustments, a special class of D/A converters has evolved, specifically intended for use as calibration/adjustment devices. These are known as “digital potentiometers”. They differ from traditional D/A converters in that they appear as three-terminal variable resistors of known value, and often include non-volatile control registers. They are specified in terms of resistance value, number of steps, and number of devices per package.

### 8.3.5 Choosing a Converter

From the point of view of performance, choosing a converter, either an ADC or a DAC, comes down to resolution, accuracy and speed. Begin by determining the percent resolution or the dynamic range of the converter. Use the equations in the preceding section to determine the number of bits the converter must have. Select from converters with the next highest number of bits. For example, if you determine that you need 7 bits of resolution, use an 8-bit converter.

Next, consider accuracy. If the converter is needed for test instrumentation, you’ll need to perform an *error budget* on the instru-

ment’s conversion processes, include errors in the analog circuitry. Once you have calculated percent errors, you can determine the requirements for FS error, offset error, and nonlinearities. If an ADC is going to be used for receiving applications, the spur-free dynamic range may be more important than high precision.

The remaining performance criterion is the speed and rate at which the converter can operate. Conversions should be able to be made at a minimum of twice the bandwidth of the signal you wish to reproduce. If the converter will be running near its maximum rate, be sure that the associated digital interface, supporting circuitry, and software can support the required data rates, too!

Having established the conversion performance requirements, the next step is to consider cost, amount of associated circuitry, power requirements, and so forth. For example, a self-contained ADC is easier to use and takes up less PC board space, but may not be as accurate as one that allows the designer to use an external voltage reference to set the conversion range. Other considerations, such as the nature of the required digital interface, as discussed in the next section, can also affect the selection of the converter.

## 8.4 Data Converters for SDR and DSP

In this section we will focus more closely on converters for use with DSP and SDR. The first requirement when selecting a DAC or ADC is that it be able to handle the required *sample rate*. For communications-quality voice (300-3000 Hz), a sample rate on the order of 8000 samples per second (8 ksp/s) is adequate and has been used in the public switched telephone network for decades. For CD-quality music (20-20,000 Hz), the standard sample rate is 44.1 ksp/s, while 48 ksp/s and even 96 or 192 ksp/s are used for newer audio formats and applications such as professional studio equipment.

In an SDR system intended to use microphone inputs and speaker or headphone outputs, there is a need to convert between analog and digital at audio rates. Fortunately, combination A/D and D/A chips and software packages called *codecs* (short for coder-decoder) are readily available to do this job. Both “audio codecs”, with sample rates consistent with high-fidelity audio up to 20 kHz or so, and “voice codecs”, intended for voice-quality audio up to 4 or 8 kHz) are available. The switched telephone network originally used 8-bit logarithmic codecs to digitize and reconstruct voiceband audio signals. Logarithmic coding was used to compress the dynamic range of a voice signal to reduce the number of bits to be transported.

Today, linear-coded devices have become preferable since DSP algorithms work on linear-coded data and often perform more efficient compression algorithms to reduce the number of bits needed to transport digitized voice. Since audio codecs are used in PC and other consumer systems they are very low cost (or are free if the PC is part of the SDR system). They have more than adequate performance for SDR applications dealing with relatively narrowband signals, such as CW, SSB, AM, and digital signals such as RTTY, PACTOR, and JT65 that use bandwidths comparable to SSB.

Processing wideband RF signals requires data converters with sample rates in the megasamples per second (Msp/s) range. Fortunately, manufacturers of digital communications infrastructure equipment for the cellular industry have similar needs, and manufacturers of data converter ICs have developed products that are produced in reasonable volume (which lowers the cost) and can be repurposed for amateur SDRs.

The resolution of a data converter expressed as the number of bits in the data words gives an approximation of the converter’s signal-to-noise ratio. For example, an 8-bit ADC can only represent the sampled analog signal as one of  $2^8 = 256$  possible numbers. The smallest signal that it can resolve is there-

fore  $1/256$  of full scale. In terms of signal-to-noise ratio, the rule of thumb is 6 dB per bit, so an ideal 8-bit converter should have a dynamic range of about 48 dB.

The actual formula is slightly different. In an ideal, error-free ADC, the *quantization error* is up to  $\pm 1/2$  of one least-significant bit (LSB) of the digital word, or  $\pm 1/512$  of full scale with 8-bit resolution. Similarly, a DAC can only generate the analog signal to within  $\pm 1/2$  LSB of the desired value. These unavoidable errors are indistinguishable from noise in a signal-processing system.

It can be shown mathematically that a series of uniformly-distributed random numbers between  $+0.5$  LSB and  $-0.5$  LSB has an RMS value of

$$\frac{\text{LSB}}{\sqrt{12}}$$

This represents the quantization noise of an A/D.

The **Radio Fundamentals** chapter shows that a sinusoidal signal of 2 volts peak-to-peak (1 V peak) has an RMS voltage equal to 0.707 volts, or  $\sqrt{2}/2$  volts. In the case of a full-scale sinusoidal signal applied to an ADC of  $N$  bits ( $2^N$  LSBs), the RMS signal voltage can be written as  $(2^{N-1}\text{LSB})/\sqrt{2}$ .

Combining that information results in the following equation for the signal-to-noise ratio in decibels for an ideal data converter word of width  $N$  bits:

$$\text{SNR} = 20 \log \left( \frac{2^{N-1} \text{LSB}}{\frac{\sqrt{2}}{\text{LSB}}} \right) / \sqrt{12}$$

which simplifies to

$$\text{SNR} = (6.02N + 1.76) \text{ dB}$$

The extra 1.76 dB arises from the fact that noise has a lower RMS value than a sine wave for the same peak-to-peak amplitude. Therefore, with an ideal 8-bit converter, SNR = 49.9 dB. A perfect 16-bit ADC would achieve a 98.1 dB signal-to-noise ratio. Of course, real-world devices are never perfect so actual performance is always somewhat less. Internally-generated noise degrades the SNR, and errors in the linearity of the converter’s transfer function give rise to distortion in the form of spurious spectral components and harmonics. (See also “Clocking the RF ADC: Should you worry about jitter or phase noise?” a Texas Instruments application note available for download at [www.ti.com/lit/an/slyt705/slyt705.pdf](http://www.ti.com/lit/an/slyt705/slyt705.pdf).)

### Distortion and Noise

Distortion and noise in a conversion are characterized by several parameters all related to linearity and accuracy. THD+N (Total Harmonic Distortion + Noise) is a measure of how much distortion and noise is introduced by the conversion. THD+N can be specified in percent or in dB. Smaller values are better. SINAD (Signal to Noise and Distortion Ratio) is related to THD+N, generally specified along with a desired signal level to show what signal level is required to achieve a certain level of SINAD or the highest signal level at which a certain level of SINAD can be maintained. (See the Analog Devices application note MT-003 by Kester in the Bibliography for further information about SINAD and other noise metrics.)

#### 8.4.1 Using Audio ADC for SDR

A/D and D/A converters used in audio systems and PC “sound cards” are often repurposed for use in hybrid SDRs. While they may offer as many as 24 bits of resolution in reality audio A/D converters only provide 110-120 dB of SNR and “dynamic range”, and the best “24-bit” audio D/A converters deliver 128 dB. According to the formula above, a 24-bit converter should have  $1.76 + (6.02 \times 24)$ , or 146.2 dB. What happened to the remaining 20-40 dB?

Part of the reason that audio converters use 24-bit data words is that the recording and playback formats for many systems (such as Blu-Ray Disc and studio equipment) are designed to accommodate 24-bit data words even if the lower-order bits are essentially meaningless. For reference, a least-significant bit for a typical 24-bit audio converter with a 5 V p-p signal range is about 100 nanovolts (0.1 microvolts) and it is difficult to keep noise that low in the real world.

Furthermore, the testing of A/D converters intended for use in audio systems is different from how we might specify them for radio applications. For example, the “dynamic range” specification in digital audio systems is tested by measuring the THD+N (Total Harmonic Distortion plus Noise) for a 1 kHz input signal at a level 60 dB below full-scale, converting the number to a positive value, then adding 60. For example, an audio D/A converter that delivers THD+N of -51 dB under this test condition can be specified as having a dynamic range of 111 dB. While this is not the same way that communications systems

define dynamic range, the goal of both audio and radio systems is to evolve towards higher dynamic range, so the performance generally heads in the right direction in both fields.

## SIGMA-DELTA CONVERTERS

The noise spectrum of an A/D converter occupies the bandwidth from dc to one-half the sampling frequency, and is more-or-less uniformly spread out over that range. Thus, in any smaller slice of the output spectrum, the noise is much lower compared to the full-scale output of the converter. Thus, if we have an A/D converter sampling at a very high rate relative to the bandwidth of interest, and then add a digital filter after the A/D converter that eliminates the noise components outside the spectrum of interest, we can in principle increase the SNR in the desired bandwidth. An A/D conversion system that operates this way is said to be *oversampling*.

Oversampling by a factor of  $N$  improves the SNR in a given bandwidth by the square root of  $N$  since the number of samples of the desired signal is multiplied by  $N$ , and the noise, which is uncorrelated, increases as the square root of  $N$ . This can be simplified to 3 dB SNR improvement for every doubling of the sample rate. Thus, a 4x oversampling rate is equal to adding another bit of resolution to a converter.

Audio converters are an example of oversampled converters, and usually use a technique known as *sigma-delta modulation*. The sigma-delta converter introduced earlier uses a DAC and a comparator in a feedback loop to generate a digital signal. An integrator stores the sum of the input signal and the DAC output. This is “sigma” or sum in the converter’s name. The comparator is in essence a one-bit A/D converter, and its output indicates whether the integrator output is above or below the reference voltage. That signal is used to adjust the DAC’s output so that the integrator output stays close to the reference voltage. This is the “delta” in the name. The stream of 0s and 1s from the comparator forms a high-speed digital bit stream that is digitally-filtered to form the output code, at a much lower output sample rate.

Most ADCs and DACs used in audio systems use an extreme form of oversampling, where the internal converter may oversample by a rate of 128 or 256 times the desired output rate. For example, the comparator of an audio A/D intended for a 48 ksp/s output rate may be clocked at  $256 \times 48$  ksp/s, or 12.288 MHz. In addition, sigma-delta audio converters use a technique called noise shaping to push most of the quantization noise to frequencies above the audio band, thereby reducing it in the audio spectrum. Noise shaping is accomplished by adding more integrators in the feedback loop of the simple sigma-delta modulator to form a “higher-order loop”

with a low-pass response for the signal, but a high-pass response for the noise. The digital low-pass filter then removes the noise and produces output data words of higher width at the desired sample rate. The high input sampling rate of the converter also relaxes the requirements for external band-limiting (anti-aliasing) filters on the input signal. **Figure 8.19** illustrates the relationship between loop order, sample rate, and improvements in signal-to-noise ratio.

Since audio A/D converters are the audio input device on many PC-based systems, they are quite inexpensive. The Left- and Right-channel stereo inputs can be repurposed and renamed “I” and “Q” for use in SDR appli-

**Figure 8.19** — The benefits of noise-shaping as the order of the sigma-delta converter feedback loop is increased.

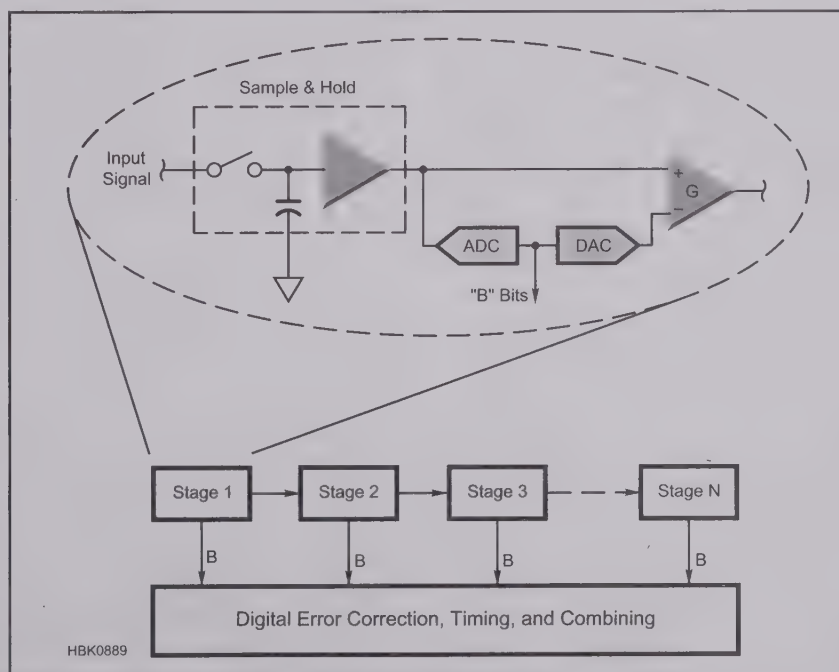

cations. Even if the converter specifications are not exactly ideal they provide adequate performance for a hybrid SDR.

## 8.4.2 High-Speed ADC for SDR

Commercial applications such as cellular base stations have driven the need for high-speed converters capable of sampling RF or high-IF signals directly. These have enabled the development of amateur radio HF transceivers using direct RF sampling. In addition to the usual specifications of linearity, etc., most manufacturers of high-speed data converters intended for use in wideband SDR systems now include a specification for *spurious-free dynamic range* (SFDR). This is the ratio, normally expressed in dB, between a (usually) full-scale sine wave and the worst-case spurious signal. It is a useful figure of merit for comparing such converters. (High-speed SDR hardware from several manufacturers and vendors is addressed in the column “SDR: Simplified” by Ray Mack, W5IFS, in the Jan/Feb 2013 issue of *QEX*.)

### PIPELINED ADC ARCHITECTURE

Most high-speed converters intended for SDR applications use a *pipelined* architecture. This type of A/D converter consists of multiple stages, each of which includes a sample-and-hold function, low-resolution A/D and D/A converter, and a gain stage. The first stage performs a coarse quantization

**Figure 8.20** — Block diagram of pipelined high-speed A/D converter.

of the input signal, of say, “B” bits, where B is typically 1 to 4 in commercial products. The resultant data word is applied to a D/A converter, and the output analog voltage is subtracted from the original input signal, producing an error signal. That error signal is amplified and passed to another, usually identical, converter stage with enough overlap to compensate for any errors in the previous conversion. Many stages can be connected together, with the last stage only including an A/D converter. The digital outputs from each stage are combined and corrected, as well as time-aligned, to produce a higher-resolution output. **Figure 8.20** illustrates the basic pipelined structure.

Since each stage is typically a low resolution flash converter, pipelined converters are capable of quite high resolution – up to 16 bits – and sample rates in the hundreds of Msps, even into the Gsps (Gigasamples per second) range. There is a delay before the first sample emerges, of course, since an N-stage pipeline converter must perform N conversions before the first valid output is available. However, each successive sample is produced at the full sample rate.

Some pipelined converters also include some basic digital down conversion on chip, with some degree of programmability.

The cost of an A/D or D/A converter is generally proportional to both speed and resolution, so it is important to avoid over specifying these components. Later in this chapter we will discuss how to determine the required sample rate and resolution for a given application.

While sample rate, resolution, and SFDR are the principal selection criteria for data converters in a DSP system, other parameters such as signal-to-noise ratio, harmonic and intermodulation distortion, full-power bandwidth, and aperture delay jitter can also affect system performance. Of course, basic specifications such as power requirements, interface type (serial or parallel), and cost also determine a device’s suitability for a

particular application. As with any electronic component, it is very important to read and fully understand the data sheet.

Most manufacturers of high-performance converters also include recommendations on support circuitry to be used with their devices to extract the best possible performance. For example, some ADCs require buffer amplifiers to drive the input, or external voltage references to set the full scale range. Many converters, especially high-speed and high-resolution devices are very sensitive to circuit layout, power supply decoupling and grounding. Most manufacturers provide evaluation boards to allow testing the converter IC on the bench, and the layout files can be copied into the final system design.

### CLOCKING HIGH-SPEED CONVERTERS

ADCs generally require some kind of clock function to set the sample rate. Any cycle-to-cycle variation in the sample timing (“jitter”) causes an error. It can be shown that in RF-sampling converters, sample-clock jitter is analogous to phase noise in the local oscillators of analog radios, and can degrade the performance of the converter substantially. **Figure 8.21** shows how this comes about.

As A/D and D/A converters achieve higher and higher sample rates and signal bandwidths, the clocking becomes critical. Most logic families produce output waveforms that have more timing jitter than can be tolerated.

The degradation of a high-frequency sampled signal due to sample jitter can be calculated and plotted. In **Figure 8.22** you can see that a 100 MHz signal sampled with a 1ps jitter sample clock (typical of ACT-series logic gates) will have just over 60 dB of signal-to-noise ratio, about equal to 10 bit performance, even if the A/D converter is capable of 16 bits! Improving the sample clock jitter to 0.125 ps using a specialized clock-distribution IC, improves the system performance to nearly 14 bits.

**Figure 8.21 — RMS jitter vs. rms noise effect of sampling uncertainty on signal-to-noise. [from Figure 1 of Analog Devices Application Note AN-501, available at [www.analog.com](http://www.analog.com), used with permission]**

## 8.5 Digital Signal Processors

The term *digital signal processor* (DSP) is commonly understood to mean a special-purpose microprocessor with an architecture that has been optimized for signal processing rather than data processing. And indeed, in many systems the box labeled “DSP” in Figure 8.1 is such a device. A microprocessor has the advantage of flexibility because it can easily be re-programmed. Even with a single program, it can perform many completely different tasks at different points in the code. On-chip hardware resources such as multipliers and other computational units are used efficiently because they are shared among various processes.

That is also the Achilles’ heel of programmable DSPs. Any hardware resource that is shared among various processes can be used by only one process at a time. That can create bottlenecks that limit the maximum computation speed. Some DSP chips include multiple computational units or multiple *cores* (basically multiple copies of the entire processor) that can be used in parallel to speed up processing.

### 8.5.1 Microprocessor-type DSP ICs

Programming a DSP IC is relatively easy. C compilers are available for most devices, so you don’t have to learn assembly language. Typically you include a connector on your circuit board into which is plugged an *in-circuit programmer* (ICP), which is connected to a PC via a serial or USB cable. The software is written and compiled on the PC and then downloaded to the DSP. The same hardware often also includes an *in-circuit debugger* (ICD) so that the program can be debugged on the actual circuitry used in the design. The combination of the editor, compiler, programmer, debugger, simulator and related software is called an *integrated development environment* (IDE).

Until recently, you had to use an *in-circuit emulator* (ICE), which is a device that plugs into the circuit board in place of the microprocessor. The ICE provides sophisticated debugging tools that function while the emulator runs the user’s software on the target device at full speed. Nowadays, however, it is more common to use the ICD function that is built into many DSP chips and which provides most of the functions of a full-fledged ICE. It is much cheaper and does not require using a socket for the microprocessor chip.

The architecture of a digital signal processor shares some similarities to that of a general-purpose microprocessor but also differs in important respects. For example, DSPs generally don’t spend much of their lives

handling large computer files, so they tend to have a smaller memory address space than processors intended to be used in computers. On the other hand, the memory they do have is often built into the DSP chip itself to improve speed and to reduce pin count by eliminating the external address and data bus.

Most microprocessors use the traditional *Von Neumann architecture* in which the program and data are stored in the same memory space. However, most DSPs use a *Harvard architecture*, which means that data and program are stored in separate memories. That

speeds up the processor because it can be reading the next program instruction at the same time as it is reading or writing data in response to the previous instruction. Some DSPs have two data memories so they can read and/or write two data words at the same time. Most devices actually use a modified Harvard architecture by providing some (typically slower and less convenient) method for the processor to read and write data to program memory.

Probably the key difference between general-purpose and digital-signal processors is

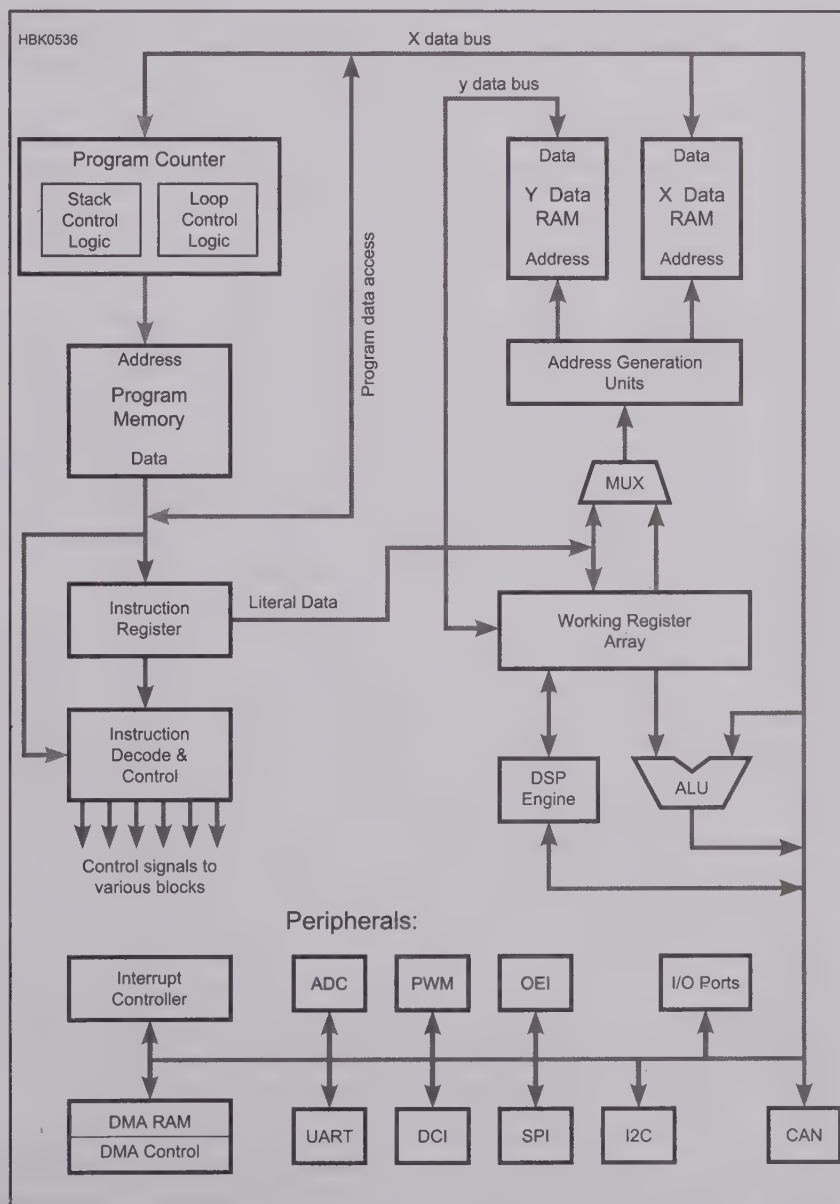

Figure 8.23 — Simplified block diagram of a dSPIC processor.

in the computational core, often called the *arithmetic logic unit* (ALU). The ALU in a traditional microprocessor only performs integer addition, subtraction and bitwise logic operations such as AND, OR, one-bit shifting and so on. More-complicated calculations, such as multiplication, division and operations with floating-point numbers, are done in software routines that exercise the simple resources of the ALU multiple times to generate the more-complicated results.

In contrast, a DSP has special hardware to perform many of these operations much faster. For example, the *multiplier-accumulator* (MAC) multiplies two numbers and adds (accumulates) the product with the previous results in a single step. Many common DSP algorithms involve the sum of a large number of products, so nearly all DSPs include this function. **Figure 8.23** is a simplified block diagram of the dsPIC series from Microchip. Its architecture is basically that of a general-purpose microcontroller to which has been added a DSP engine, which includes a MAC, a barrel shifter and other DSP features. It uses a modified Harvard architecture with two data memories that can be simultaneously accessed.

### 8.5.2 Fixed-Point versus Floating-Point

DSP microprocessors are sometimes differentiated on their ability to handle fixed-point (integer) or *floating-point* numbers.

A floating-point number is the binary equivalent of scientific notation. Recall that the decimal integer 123000 is expressed as  $1.23 \times 10^5$  in scientific notation. It is common practice to place the decimal point after the first non-zero digit and indicate how many digits the decimal point must be moved by the *exponent* of ten, 5 in this case. The 1.23 part is called the *mantissa*. In a computer, base-2 binary numbers are used in place of the base-10 decimal numbers used in scientific notation. The *binary point* (equivalent to the decimal point in a decimal number) is assumed to be to the left of the first non-zero bit. For example the binary number 00110100 when converted to a 16-bit floating point number would have an 11-bit mantissa of 11010000000 (with the binary point assumed to be to the left of the first “1”) and a 5-bit exponent of 00110 (decimal +6).

A floating point number can represent a signal with much more dynamic range than an integer number with the same number of bits. For example, a 16-bit fixed-point signed integer can vary from  $-32768$  to  $+32767$ . The difference between the smallest (1) and largest signal that can be represented is  $20 \log(65535) = 96$  dB. If the 16 bits are divided into an 11-bit mantissa and 5-bit exponent, the available range is  $20 \log(2048) = 66$  dB

from the mantissa and  $20 \log(2^{32}) = 193$  dB from the exponent for a total of 259 dB. The disadvantage is that the mantissa has less resolution, potentially increasing noise and distortion. Normally floating-point numbers are at least 32 bits wide to mitigate that effect.

Some DSPs can process floating-point numbers directly in hardware. Fixed-point DSPs can also handle floating-point numbers, but it must be done in software and that slows the computations down. The additional dynamic range afforded by floating-point processing is normally not needed for radio communications signals. The dynamic range of radio signals can usually be handled by the 16-bit data words used by most fixed-point DSPs. Using integer arithmetic and a fixed-point processor saves the additional cost of a floating-point processor or the additional computational overhead of floating-point calculations on a fixed-point device. However, it requires careful attention to detail on the part of the programmer to make sure the signal can never exceed the maximum integer value or get so weak that the signal-to-noise ratio is degraded. If cost or computation time is not an issue, it is much easier to program in floating point since dynamic range issues can be ignored for most computations.

The term *pipeline* refers to the ability of a microprocessor to perform portions of several instructions at the same time. The sequence of operations required to perform an instruction is broken down into steps. Since each step is performed by a different chunk of hardware, different chunks can be working on different instructions at the same time. Most DSPs have at least a simple form of pipelining in which the next instruction is being fetched while the previous instruction is being executed. Some DSPs can do a multiply-accumulate while the next two multiplicands are being read from memory and the previous accumulated result is being stored so that the entire operation can occur in a single clock cycle. MACs per second is a common figure of merit for measuring DSP speed. For conventional microprocessors, a more common figure of merit is millions of instructions per second (MIPS) or floating-point operations per second (FLOPS).

Many DSPs have a sophisticated address generation unit that can automatically increment one or more data memory pointers so that repetitive calculations can step through memory without the processor having to calculate the addresses. *Zero-overhead looping* is the ability to automatically jump the address pointer back to the beginning of the array when it reaches the end. That saves several microprocessor instructions per loop that normally would be required to check the current address and jump when it reaches a predetermined value.

While most DSPs do not include a full

hardware divider, some do include special instructions and hardware to speed up division calculations. A *barrel shifter* is another common DSP feature. It allows shifting a data word a specified number of bits in a single clock cycle. *Direct memory access* (DMA) refers to special hardware that can automatically transfer data between memory and various peripheral devices or ports without processor overhead.

### 8.5.3 DSP in Embedded Systems

An *embedded system* is a device that is not a “computer” but nevertheless has a microprocessor or DSP chip embedded somewhere in its circuitry. Examples are microwave ovens, automobiles, mobile telephones and software-defined radios. DSPs intended for embedded systems often include a wide array of on-chip peripherals such as various kinds of timers, multiple hardware interrupts, serial ports of various types, a real-time clock, pulse-width modulators, optical encoder interfaces, A/D and D/A converters and lots of general-purpose digital I/O pins. Some DSPs have architectures that are well-suited for general-purpose control applications as well as digital signal processing.

**Table 8.1** lists some manufacturers of DSP chips targeted to embedded systems. It should be mentioned that microprocessors made by Intel and AMD and intended for use as CPUs in personal computers also include extensive DSP capability. However, they are optimized for data-processing applications under an operating system such as Windows or Linux, and are not very efficient at signal-processing applications.

### 8.5.4 Typical DSP Processors

When selecting a DSP device for a new design, often the available development environment is more important than the characteristics of the device itself. Microchip’s dsPIC family of DSPs was chosen for the examples in this chapter because their integrated development environment is extensive and easy to use and the IDE software is available for free download from their website.<sup>5</sup> The processor instruction set is a superset of the PIC24 family of general-purpose microcontrollers, with which many hams are already familiar. The company offers a line of low-cost evaluation boards and starter kits as well as an inexpensive in-circuit debugger, the ICD 3. The free IDE software includes a simulator that can run dsPIC software on a PC (at a much slower rate, of course), so that you can experiment with DSP algorithms before buying any hardware.

The Microchip DSP family is limited to 70 million instructions per second. In a sys-

**Table 8.1**

tem with, say, a 70 kHz sample rate, 1000 instructions per sample are available which should be plenty if the calculations are not too complex. However if the sample rate is 1 MHz, then you get only 70 instructions per sample, which likely would be insufficient.

If more horsepower is required, you'll need to select a processor from a different manufacturer. Look for one with a well-integrated suite of development software that is powerful and easy to use. Also check out the cost and availability of development hardware such as evaluation kits, programmers and debuggers. Once those requirements are met, then you can move on to selecting a specific device with the performance and features required for your application. It can be helpful at the beginning of a project to first write some of the key software routines and test them on a simulator to estimate execution times, in order to determine how powerful a processor is needed.

When estimating execution time, don't forget to include the effect of interrupts. Most DSP systems require real-time response and make extensive use of interrupts to ensure that certain events happen at the correct times. Although this is hidden from the programmer's view when programming in C, the interrupt service routines contain quite a bit of overhead each time they are called (to save the processor state when responding and to recall the state just before returning from the interrupt). Sometimes an interrupt may be called more often than you expect, which can eat up processor cycles and so increase the execution time of other unrelated routines.

In the past, many embedded systems were written in assembly language so save memory and increase processing speed. Many early microprocessors and DSPs did not have enough memory to support a high-level language. Today, most processors have sufficient memory and processing speed to support a C kernel and library without difficulty. For anything but the simplest of programs, it is not only faster and easier to develop software in C but it is easier to support and maintain as well, especially if people other than the original programmer might become involved. Far more people know the C programming language than any particular processor's assembly language. It is true that the version of C used on a DSP chip is usually modified from standard ANSI C to support specific hardware features, but it would still be far easier to learn for a programmer familiar with writing C code on a PC or on a different DSP.

A common technique is first to write the entire application in C. Then, if execution time is not acceptable, analyze the system to determine in which software routines the bottlenecks are occurring. You can then rewrite those routines in assembly language. Having an already-working version written in C (even if too slow) can be helpful in testing and troubleshooting the equivalent assembly language.

### 8.5.5 DSP Without a Dedicated Processor

One way to speed up processing is to move

all or part of the computations from the programmable DSP to an *application-specific integrated circuit* (ASIC), which has an architecture that has been optimized to perform some specific DSP function.

You could also design your own application-specific circuitry using a PC board full of discrete logic devices. Nowadays, however, it is more common to do that with a *programmable-logic device* (PLD). This is an IC that includes many general-purpose logic elements, but the connections between the elements are undefined when the device is manufactured. The user defines those connections by programming the device to perform whatever function is required. PLDs come in a wide variety of types, described by an alphabet soup of acronyms.

*Programmable-array logic* (PAL), *programmable logic array* (PLA), and *generic array logic* (GAL) devices are relatively simple arrays of AND gates, OR gates, inverters and latches. They are often used as "glue logic" to replace the miscellaneous discrete logic ICs that would otherwise be used to interface various larger digital devices on a circuit board. They are sometimes grouped under the general category of *small PLD* (SPLD). A *complex PLD* (CPLD) is similar but bigger, often consisting of an array of PALs with programmable interconnections between them.

A *field-programmable gate array* (FPGA) is bigger yet, with up to millions of gates per device. An FPGA includes an array of *complex logic blocks* (CLB), each of which includes some programmable logic, often

**Table 8.2**

Xilinx	CPLD, FPGA	<a href="http://www.xilinx.com">www.xilinx.com</a>	One of the top FPGA vendors

implemented with a RAM *look-up table* (LUT), and output registers. *Input/output blocks* (IOB) also contain registers and can be configured as input, output, or bi-directional interfaces to the IC pins. The interconnections between blocks are much more flexible and complicated than in CPLDs. Some FPGAs also include higher-level circuit blocks such as general-purpose RAM, dozens or hundreds of hardware multipliers, and even entire on-chip microprocessors.

Some of the more inexpensive PLDs are *one-time programmable* (OTP), meaning you have to throw the old device away if you want to change the programming. Other devices are re-programmable or even *in-circuit programmable* (ICP) which allows changing the internal circuit configuration after the device has been soldered onto the PC board, typically under the control of an on-board microprocessor. That offers the best of both worlds, with speed nearly as fast as an ASIC but retaining many of the benefits of the reprogrammability of a microprocessor-type DSP. Most large FPGAs store their programming in *volatile memory*, which is RAM that must be re-loaded every time power is applied, typically by a ROM located on the same circuit board. Some FPGAs have programmable ROM on-chip.

Programming a PLD is quite different from programming a microprocessor. A microprocessor performs its operations sequentially — only one operation can be performed at a time. Writing a PLD program is more like designing a circuit. Different parts of the circuit can be doing different things at the same time. Special *hardware-description languages* (HDL) have been devised for programming the more complicated parts such as ASICs and FPGAs. The two most common industry-standard HDLs are Verilog

and VHDL. (The arguments about which is “best” approach the fervor of the *Windows vs Linux wars*!) There is also a version of the C++ programming language called SystemC that includes a series of libraries that extend the language to include HDL functions. It is popular with some designers because it allows simulation and hardware description using the same software tool.

Despite the speed advantage of FPGAs, most amateurs use microprocessor-type devices for their DSP designs, supplemented with off-the-shelf ASICs where necessary. The primary reason is that the design process for an FPGA is quite complicated, involving obtaining and learning to use several sophisticated software tools. The steps involved in programming an FPGA are:

1. Simulate the design at a high abstraction level to prove the algorithms.
2. Generate the HDL code, either manually or using some tool.
3. Simulate and test the HDL program.
4. Synthesize the gate-level netlist.
5. Verify the netlist.
6. Perform a timing analysis.
7. Modify the design if necessary to meet timing constraints.
8. “Place and route” the chip design.
9. Program and test the part.

Many of the software tools needed to perform those steps are quite expensive, although some manufacturers do offer free proprietary software for their own devices. Some principal manufacturers are listed in **Table 8.2**.

## 8.5.6 Using Graphics Processors for DSP

As PCs have become used for graphics-intensive applications such as games, developers quickly found out that the microprocessor chip in the PC was unable to provide enough computing horsepower to do complex graphics functions like 3D rendering, shading, etc. This gave rise to a new breed of specialized processors called Graphics Processing Units (GPU). These processors consist of simple computational blocks that are capable of only a few functions like multiplication and addition. However, unlike a typical PC CPU with a handful of cores to speed up processing, GPUs have hundreds or even thousands of cores! In addition, they are optimized for handling large arrays of data. This makes them well suited for DSP functions such as Fast Fourier Transforms.

Fortunately, some manufacturers of GPU have recognized that their products are useful for applications other than graphics, and are now providing libraries and programming support for using their products in communications systems such as SDR. GPU manufacturer Nvidia, for example, offers the CUDA parallel computing platform and programming model with the cuFFT library.

The inexpensive Linux-based Raspberry Pi computer board has become very popular among amateurs and experimenters. The BCM283x main processor is a system-on-chip device manufactured by Broadcom (now owned by Avago) that contains both a CPU and a GPU. At 700MHz to 1.2 GHz, the CPU is too underpowered for many of the DSP algorithms used in SDR. However, the graphics processor included in the processor can be programmed to do some of the FFT algorithms, and offers a 10x speed improvement.<sup>6</sup>

## 8.6 Digital (Discrete-time) Signals

Digital signals differ from analog signals in two ways. One is that they are digitized in time, a process called *sampling*. The other is that they are digitized in amplitude, a process called *quantization*. Sampling and quantization affect the digitized signal in different ways so the following sections will consider their effects separately.

### 8.6.1 Sampling — Digitization in Time

Sampling is the process of measuring a signal at discrete points in time and recording the measured values. An example from history is recording the number of sunspots. If an observer goes out at noon every day and writes down the number of observed sunspots, then that data can be used to plot sunspot number versus time. In this case, we say the *sample rate* is one sample per day. The data can then be analyzed in various ways to determine short and long-term trends. After recording only a few months of data it will quickly become apparent that sunspot number has a marked periodicity — the numbers tend to repeat every 27 days (which happens to be the rotation rate of the sun as seen from earth).

What if, instead of taking a reading once a day, the readings were taken only once per month? With a 30-day sample period, the 27-day periodicity would likely be impossible to see. Clearly, the sample rate must be at least some minimum value to accurately represent the measured signal. Based on earlier work by Harry Nyquist, Claude Shannon proved in 1948 that in order to sample a signal without loss of information, the sample rate must be greater than the *Nyquist rate*, which is two times the bandwidth of the signal. In other words, the bandwidth must be less than the *Nyquist frequency*, which is one-half the sample rate. This is known as the *Nyquist sampling criterion*.

That simple rule has some profound implications. If all the frequency components of a signal are contained within a bandwidth of  $B$  Hz, then sampling at a rate greater than  $2B$  samples per second is sufficient to represent the signal with 100% accuracy and with no loss of information. It is theoretically possible to convert the samples back to an analog signal that is exactly identical to the original.

Of course, a real-world digital system measures those samples with only a finite number of bits of resolution, with consequences that we will investigate in the section on quantization that follows. In addition, sampling theory assumes that there is absolutely no signal energy outside the specified bandwidth; in other words the stopband attenuation is infinity dB. Any residual signal in the stop-band shows up

as distortion or noise in the sampled signal.

To simplify the discussion, let's think about sampling a signal of a single frequency (a sine wave). **Figure 8.24** illustrates what happens if the sample rate is too low. As shown, the sample rate is approximately 7/8 the sine-wave frequency. You can see that the sampled signal has a period about 8 times greater than the period of the sine wave, or 1/8 the frequency. The samples are the same as if the analog signal had been a sine wave of 1/8 the actual frequency.

That is an example of a general principle. Sampling a signal produces an output with components at frequencies equal to the difference between the actual frequency of the analog signal and the sample rate. If the sampling rate is too low (or the input signal too high in frequency) the signal at  $(f_s - f_{sig})$  is indistinguishable from an in-band signal, which is why the new signal is called an *alias*. In the above example, the alias frequency  $f_o$  is

$$f_o = f_{sig} - f_s = (1 - 7/8)f_{sig} = (1/8)f_{sig}$$

where  $f_{sig}$  is the frequency of the signal before sampling and  $f_s$  is the sample rate.

The sampling process also creates aliases from any input signals around harmonics of

the sampling frequency. **Figure 8.25** shows the frequency-domain representation of the signal relationships in a sampled-data system. Figure 8.25A shows the spectrum of a single sine wave input signal, and Figure 8.25B shows the spectrum of the sampling clock and its harmonics. You can look at Figure 8.25C two ways. First, you can consider all the individual frequencies as the output signals generated by sampling the input signal at  $f_o$ . On the other hand, those are also the input signal frequencies that alias to  $f_o$ , calculated from the equation

$$f_{sig} = |f_o - Nf_s|$$

where  $N$  is the harmonic number. Experienced RF engineers will recognize this phenomenon as being very similar to image-generation in the mixing process of a heterodyne receiver. The sampled signal (equivalent to the mixer output) contains the sum and difference frequencies of the input signal and all the harmonics of the sample frequency. Figure 8.25D shows the more general case of sampling a band of signals between  $f_L$  and  $f_H$ . Note the inversion of the aliased spectrum that extends below  $f_s$ . If  $f_H$  is higher than  $f_s/2$ , the higher frequencies in the band will overlap

Figure 8.24 — Undersampled sine wave (A). Samples aliased to a lower frequency (B).

Figure 8.25 — Frequency relationships in a sampled-data system; Spectrum of an analog sine wave (A). The spectrum of the sampling function, including all harmonics (B). The spectrum of the sampled sine wave (C). The spectrum of a sampled band of frequencies between  $f_L$  and  $f_H$  (D).

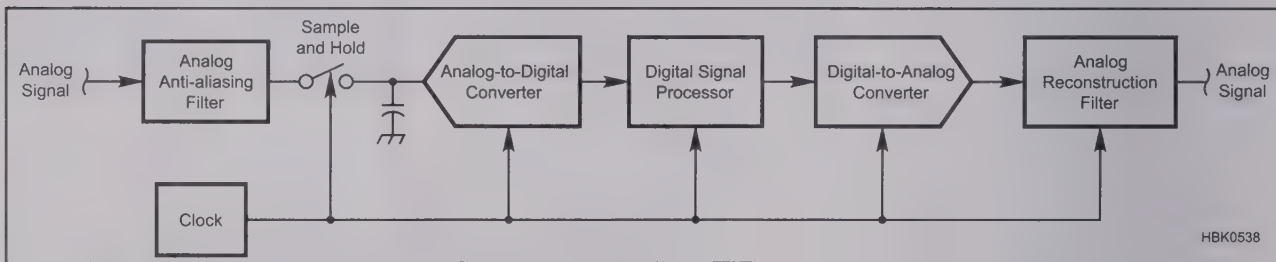

Figure 8.26 — A more complete block diagram of a DSP system.

the original band in the output spectrum and create artifacts.

An *anti-aliasing filter* before the sampler prevents unwanted signals from creating artifacts in the sampled data output, as shown in **Figure 8.26**. For a baseband signal (one that extends to zero Hz), the anti-aliasing filter is a low-pass filter whose stopband extends from the Nyquist frequency to infinity. Of course, practical filters do not transition instantaneously from the passband to the stopband, so the bandwidth of the passband must be somewhat less than half the sample rate.

Figure 8.24 showed each sample being held at a constant value for the duration of one sample period. However, sampling theory actually assumes that the sample is only valid at the instant the signal is sampled; it is zero or undefined at all other times. A series of such infinitely-narrow impulses has harmonics all the way to infinite frequency. Each harmonic has the same amplitude and is modulated by

the signal being sampled. See Figure 8.25D. When a digitized signal is converted back to analog form, unwanted harmonics must be filtered out by a *reconstruction filter* as shown in Figure 8.26. This is similar to the anti-aliasing filter used at the input in that its bandwidth should be no greater than one-half the sample rate. It is a low-pass filter for a baseband signal and a band-pass filter for an undersampled signal.

Most DACs actually do hold each sample value for the entire sample period. This is called *zero-order hold* and results in a frequency response in the shape of a sinc function

$$\text{sinc}(f) = \frac{\sin(\pi f)}{\pi f}$$

where  $f$  is normalized to the sample rate,  $f = \text{frequency} / \text{sample rate}$ .

The graph of the sinc function in **Figure 8.27** shows both positive and negative fre-

Figure 8.27 — The sinc function, where the horizontal axis is frequency normalized to the sample rate. At the bottom is the same function in decibels.

frequencies for reasons explained in the Analytic Signals section. Note that the logarithmic frequency response has notches at the sample rate and all of its harmonics. If the signal bandwidth is much less than the Nyquist frequency, then most of the signal at the harmonics falls near the notch frequencies, easing the task of the reconstruction filter. If the signal bandwidth is small enough (sample rate is high enough), the harmonics are almost completely notched out and a reconstruction filter may not even be required.

The  $\sin(\pi f)/\pi f$  frequency response also affects the passband. For example if the passband extends to  $f_s / 4$  ( $f = 0.25$ ), then the response is

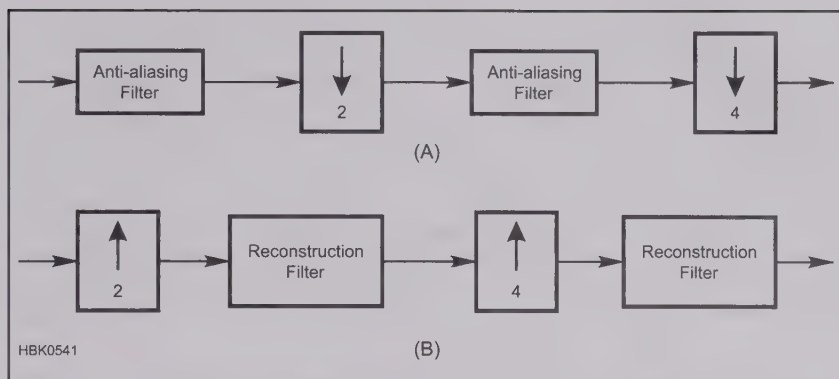

$$20 \log \frac{\sin(\pi \cdot 0.25)}{\pi \cdot 0.25} = -0.9 \text{ dB}$$

at the top edge of the passband. At the Nyquist frequency, ( $f = 0.5$ ), the error is 3.9 dB. If the signal bandwidth is a large proportion of the Nyquist frequency, then some kind of digital or analog compensation filter may be required to correct for the high-frequency rolloff. The interpolation filters used in digital audio systems have this correction included in the frequency response.

## 8.6.2 Decimation and Interpolation

The term *decimation* simply means reducing the sample rate. For example to decimate by two, simply eliminate every second sample. That works fine as long as the signal bandwidth satisfies the Nyquist criterion at the lower, output sample rate. If the analog anti-aliasing filter is not narrow enough, then a digital anti-aliasing filter in the DSP can be used to reduce the bandwidth to the necessary value. This must be done *before* decimation to satisfy the Nyquist criterion.

If you need to decimate by a large amount, then the digital anti-aliasing filter must have a very small bandwidth compared to the sample rate. As we will see later, a digital filter with a small bandwidth is computationally intensive. For this reason, large decimation factors are normally accomplished in multiple steps, as shown in **Figure 8.28A**. The first decimation is by a small factor, typically 2, so that the first anti-alias filter can be as simple as possible. The second decimation stage then does not have to decimate by such a large factor, simplifying its task. In addition, since it is running at only half the input sample rate it has more time to do its calculations. Generally it is most efficient to decimate by the smallest factor in the first stage, a larger factor in the second, and the largest factors in the third and any subsequent stages. The larger the total decimation factor, the greater the number of stages is appropriate but more than three stages is uncommon.

**Figure 8.28 — Decimation (A) and interpolation (B).** The arrow's direction indicates decimation (down) or interpolation (up) and the number is the factor.

*Interpolation* means increasing the sample rate. One way to do that is simply to insert additional zero-value samples, a process called *zero-stuffing*. For example, to interpolate by a factor of three, insert two zero-value samples after each input sample. That works, but may not give the results you expect. Recall that a sampled signal has additional copies of the baseband signal at all harmonics of the sample rate. All of those harmonics remain in the resampled signal, even though the sample rate is now higher. To eliminate them, the signal must be filtered after interpolation. After filtering, there is signal only at baseband and around the harmonics of the interpolated (higher-frequency) sample rate. It's as if the analog signal had been sampled at the higher rate to begin with, which relaxes the requirements on the reconstruction filter.

Just as with decimation, interpolation by a large factor is best done in stages, as shown in **Figure 8.28B**. In this case, the stage running at the lowest sample rate (again the first stage) is the one with the lowest interpolation factor.

Zero-stuffing followed by filtering is not the only way to interpolate. Really what you are trying to do is to fill in between the lower-rate samples with additional samples that “connect the dots” in as smooth a manner as possible. It can be shown that that is mathematically equivalent to zero-stuffing and filtering. For example, if instead of inserting zero-value samples you instead simply repeat the last input sample, you have a situation similar to the zero-order hold of a DAC output. It is equivalent to zero-stuffing followed by a low-pass filter with a frequency response of  $\sin(\pi f)/\pi f$ . If you do a straight-line interpolation between input samples (a “first-order” interpolation), it turns out that it is equivalent to a low pass filter with a frequency response of  $[\sin(\pi f)/\pi f]^2$ , which has a sharper cutoff and better stop-band rejection than a zero-order interpolation. Higher-order interpolations have smoother responses in the

time domain which translate to better filter responses in the frequency domain.

So far we have only covered decimation and interpolation by integer factors. It is also possible to change the sample rate by a non-integer factor, which is called *resampling* or *multi-rate conversion*. For example, if you want to increase the sample rate by a factor of 4/3, simply interpolate by 4 and then decimate by 3. That method can become impractical for some resample ratios. For example, to convert an audio file recorded from a computer sound card at 48 kHz to the 44.1 kHz required by a compact disc, the resample ratio is  $44,100 / 48,000 = 147 / 160$ . After interpolation by 147, the 44.1 kHz input file is sampled at 6.4827 MHz, which would result in excessive processing overhead.

In addition, the interpolation/decimation method only works for resample ratios that are rational numbers (the ratio of two integers). To resample by an irrational number, a different method is required. The technique is as follows. For each output sample, first determine the two nearest input samples. Calculate the coefficients of the Nth-order equation that describes the trajectory between the two input samples. Knowing the trajectory between the input samples and the output sample's relative position between them, the value of the output sample can be calculated from the equation.

## 8.6.3 Quantization — Digitization in Amplitude

While sampling (digitization in time) theoretically causes no loss of signal information, quantization (digitization in amplitude) always does. For example, an 8-bit signed number can represent a signal as a value from  $-128$  to  $+127$ . For each sample, the A/D converter assigns whichever number in that range is closest to the analog signal at that instant. If a particular sample has a value of 10, there is no way to tell if the original signal was 9.5,

10.5 or somewhere in between. That information has been lost forever.

### QUANTIZATION NOISE

When quantizing a complex signal such as speech, this error shows up as noise, called *quantization noise* as discussed in section 8.2.2. The error is random — it is equally likely to be anywhere in the range of  $-\frac{1}{2}$  to  $+\frac{1}{2}$  of a single step of the ADC. In **Figure 8.29** the smooth waveform is a band-limited analog noise signal plotted over a 4 ms period. The vertical axis of Figure 8.29A indicates the quantization error for each sample in LSB, represented by the staircase-like waveform. The spectrum of the signal is shown in **Figure 8.29B**, both before quantization and after quantization. While the original signal has the

frequency components above 1 kHz reduced by analog filtering, the digitized version has considerable noise in the 1-5 kHz band.

One critical point that is sometimes overlooked is that quantization noise is spread over the entire bandwidth from zero Hz to the sample rate. If you are digitizing a 3 kHz audio channel with a 48 kps sampler, only a fraction of the noise power is within the channel. For that reason, the effective signal-to-noise ratio depends not only on the number of bits but also the sample rate,  $f_s$ , and the signal bandwidth, B:

$$\text{SNR}_{\text{eff}} = \text{SNR} + 10 \log \left( \frac{f_s}{2B} \right) \text{ dB}$$

The reason for the factor of two in the denominator is that the bandwidth of a positive-

frequency scalar signal should be compared to the Nyquist bandwidth,  $f_s/2$ . When filtering a complex signal (one that contains I and Q parts), the 2B in the denominator should be replaced by B.

When choosing an A/D converter don't forget that the effective SNR depends on the sample rate. As an example, let's compare an Analog Devices AD9235 12-bit, 65 Msps ADC to an AD7653, which is a 16-bit 100 kps ADC from the same manufacturer. Assume a 10 kHz signal bandwidth.

An ideal 12-bit ADC has a SNR of  $1.76 + 6.02 \times 12 = 74.0$  dB. The AD9235's performance is not far from the ideal; its SNR is specified at 70.5 dB at its 65 Msps maximum sample rate. In a 10 kHz bandwidth, the effective SNR is  $70.5 + 10 \log(65,000/20) = 105.6$  dB.

An ideal 16-bit ADC has an SNR of 98.1 dB. The AD7653 is specified at 86 dB. The effective SNR is  $86 + 10 \log(100/20) = 93$  dB.

So the 12-bit ADC with 70.5 dB SNR is actually 12.6 dB better than the 16-bit device with 86 dB SNR in this application! Even an ideal 16-bit, 100 kps ADC would only have an effective SNR of  $98.1 + 10 \log(100/20) = 105.1$  dB, still worse than the actual performance of the AD9235 when measured with the same bandwidth. Note that to actually realize 105.6 dB of dynamic range the signal from the ADC would need to be filtered to a 10 kHz bandwidth while increasing the bits of data resolution.

*Oversampling* is the name given to the technique of using a higher-than-necessary sample rate in order to achieve an improved S/N ratio. Don't forget that when the high-sample-rate signal is decimated the data words must have enough bits to support the higher dynamic range at the lower sample rate. As a rule of thumb, the quantization noise should be at least 10 dB less than the signal noise in order not to significantly degrade the SNR. In the AD9235 example, assuming a 100 kHz output sample rate, about 18 bits would be required:  $1.76 + 6.02 \times 18 + 10 \log(100/20) = 117.1$  dB, which is 11.5 dB better than the 105.6 dB dynamic range of the ADC in a 10 kHz bandwidth.

Most ADCs and DACs used in high-fidelity audio systems use an extreme form of oversampling, where the internal converter may oversample by a rate of 128 or 256 times, but with very low resolution (in some cases just a 1-bit ADC!). In addition, such converters use a technique called noise shaping to push most of the quantization noise to frequencies near the sample rate, and reduce it in the audio spectrum. The noise is then removed in the decimation filter.

Although quantization error manifests itself as noise when digitizing a complex non-periodic signal, it can show up as discrete spurious frequencies when digitizing

**Figure 8.29** — Quantization error of a random noise signal that has been band-limited to 1 kHz to simulate an audio signal. (A) The sampler resolution is 8 bits and the sample rate is 10 kHz. Sample values are indicated by circles. Also shown is the quantization error, in units of LSB. Below is the frequency spectrum of the signal before and after quantization. (B).

a periodic signal. **Figure 8.30** illustrates a 1 kHz sine wave sampled with 8-bit resolution at a 9.5 kHz rate. On average there are 9.5 samples per cycle of the sine wave so that the sampling error repeats every second cycle. That 500-Hz periodicity in the error signal causes a spurious signal at 500 Hz and harmonics. As the signal frequency is changed, the spurs move around in a complicated manner that depends on the ratio of sample rate to signal frequency. In real-world ADCs, nonlinearities in the transfer function can also create spurious signals that vary unpredictably as a function of the signal amplitude, especially at low signal levels.

In many applications, broadband noise is preferable to spurious signals on discrete frequencies. The solution is to add *dithering*. Essentially this involves adding a small amount of noise, typically on the order of an LSB or two, in order to randomize the quantization error. Some DACs have dithering capability built in to improve the SFDR, even though it does degrade the SNR slightly. Dithering is also useful in cases where the input signal to an ADC is smaller than one LSB. Even though the signal would be well above the noise level after narrow-band filtering, it cannot be detected if the ADC input is always below one LSB. In many systems there is already sufficient noise from input amplifiers, other signals in the passband, as well as from the ADC itself, to cause natural dithering.

**Figure 8.30** — Quantization error of a 1 kHz sine wave sampled at 9.5 kHz with 8-bit resolution (A). Sample values are indicated by circles. Also shown is the quantization error, in units of LSB. Below is the frequency spectrum, showing the spurious frequencies caused by the quantization (B).

## 8.7 The Fourier Transform

The *Fourier transform* is the software equivalent of a hardware spectrum analyzer. It takes in a signal in the time domain and outputs a set of data (that can also be thought of as a signal) in the frequency domain that shows the spectral content of the input signal. The Fourier transform works on both periodic and non-periodic signals, but since the periodic case is easier to explain we will start with that. (Joseph Fourier was a French mathematician and physicist who introduced the transformation technique bearing his name in 1822. His contributions to physics, mathematics, and engineering were wide-ranging and at the heart of many technologies used today.)

A *periodic* signal is one that repeats every  $\tau$  seconds, where  $\tau$  is the period. That means that the signal can consist only of frequencies whose sinusoidal waveforms have an integer number of cycles in  $\tau$  seconds. In other words, the signal is made up of sinusoids that are at the frequency  $1/\tau$  and its harmonics. Fourier's insight was that you can determine if a frequency is present by multiplying the waveform by a sinusoid of that frequency and integrating the result. The result of the integration yields the amplitude of that harmonic. If the integration yields zero, then that frequency is not present.

To see how that works, look at **Figure 8.31**. For the purpose of discussion, assume the signal to be tested consists of a single tone

**Figure 8.31** — Signal to be tested for frequency content (A). Fundamental test frequency (B). Product of signal and fundamental (C). Second harmonic test frequency (D). Product of signal and second harmonic (E).

at the second harmonic as shown at (A). The first test frequency is the fundamental, shown at (B). When you multiply the two together you get the waveform at (C). Integrating that signal gives its average value, which is zero. However if you multiply the test signal by a sine wave at the second harmonic (D), the resulting waveform (E) has a large dc offset so the integration yields a large non-zero value. It turns out that all harmonics other than the second yield a zero result. That is, the second harmonic is *orthogonal* to all the others.

If the test waveform included more than one frequency, each of those frequencies would yield a non-zero result when tested with the equivalent-frequency sine wave. The presence of additional frequencies does not disturb the tests for other frequencies since they are all orthogonal with each other.

You may have noticed that this method only works if the test sine wave is in phase with the one in the signal. If they are  $90^\circ$  out of phase, the integration yields zero. The Fourier transform therefore multiplies the signal by both a sine wave and a cosine wave at each frequency. The results of the two tests then yield both the amplitude and phase of that frequency component of the signal using the equations

$$A = \sqrt{a^2 + b^2}$$

and

$$\phi = \arctan\left(\frac{b}{a}\right)$$

where  $A$  is the amplitude,  $\phi$  is the phase,  $a$  is the cosine amplitude and  $b$  is the sine amplitude.

If one period of the signal contains, say, 256 samples, then testing a single frequency requires multiplying the signal by the sine wave and by the cosine wave 256 times and adding the results 256 times as well, for a total of 512 multiplications and additions. (This is referred to as a *multiply-accumulate* for the processing instructions that are required.) There are 128 frequencies that must be tested, since the 128th harmonic is at the Nyquist frequency. The total number of calculations is therefore  $512 \times 128 = 256^2$  multiplications and additions. That is a general result. For any sample size,  $n$ , calculating the digital Fourier transform requires  $n^2$  multiply-accumulates.

An excellent visual representation of Fourier's discovery is available online at [blog.matthen.com/post/42112703604/the-smooth-motion-of-rotating-circles-can-be-used](http://blog.matthen.com/post/42112703604/the-smooth-motion-of-rotating-circles-can-be-used). The fundamental and harmonics are shown as a series of rotating vectors. Each vector traces out a circle, rotating at its as-

signed frequency and phase. When vectors are added together and the result is the desired waveform!

### 8.7.1 The Fast Fourier Transform (FFT)

The number of calculations grows rapidly with sample size. Calculating the Fourier transform on 1024 samples requires over a million multiply-accumulate cycles. However, you may notice that there is some redundancy in the calculations. When testing the second harmonic, for example, each of the two cycles of the test sine wave is identical. It would be possible to pre-add signal data from the first and second halves of the sequence and then just multiply once by a single cycle of the test sine wave. Also, the first quarter cycle of a sine wave is just a mirror-image of the second quarter cycle and the first half is just the negative of the second half.

In 1965, J. W. Cooley and John W. Tukey published an algorithm that takes advantage of all the symmetries inherent in the Fourier transform to speed up the calculations. The *Cooley-Tukey algorithm*, usually just called the *fast Fourier transform* (FFT), makes the number of calculations proportional to  $n \log_2(n)$  instead of  $n^2$ . For a 1024-point FFT, the calculation time is proportional to  $1024 \log_2(1024) = 10,240$  instead of  $1024^2 = 1,048,576$ , more than a 100-times improvement.

You'll notice that sample sizes are usually a power of two, such as  $2^7 = 128$ ,  $2^8 = 256$  and  $2^9 = 512$ . That is because the FFT algorithm is most efficient with sequences of such sizes. The algorithm uses a process called *radix-2 decimation in time*, that is, it first breaks the data into two chunks of equal size, then breaks each of those chunks into two still-smaller chunks of equal size, and so on. It is possible to squeeze even a little more efficiency out of the algorithm with a *radix-4* FFT which is based on decimation by four instead of by two. That is why you often see sample sizes that are powers of four, such as  $4^3 = 64$ ,  $4^4 = 256$  and  $4^5 = 1024$ . Other variations on the algorithm include decimation in frequency rather than time, mixed-radix FFTs that use different decimation factors at different stages in the calculation, and in-place calculation that puts the results into the same storage buffer as the input data, saving memory. The latter method causes the order of the output data to be scrambled by bit-reversing the address words. For example, address 01010000 becomes 00001010.

The heart of most FFT algorithms is a data flow pattern called a *butterfly*. **Figure 8.32** shows a two element butterfly. The input contains two elements  $x(0)$  and  $x(1)$ , and the

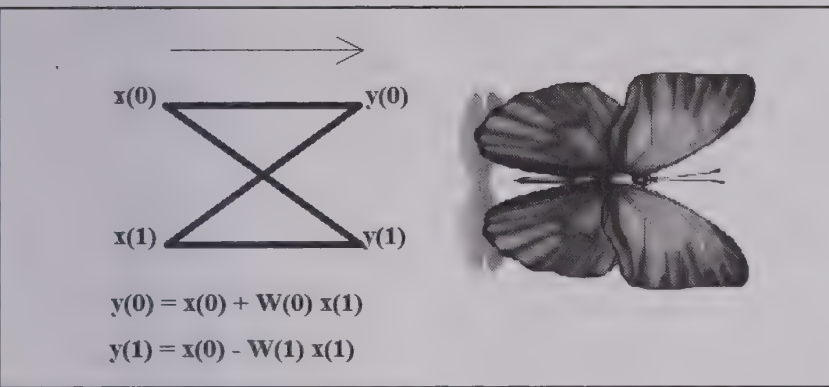

Figure 8.32 — A two-element “butterfly” signal flow diagram. The crossing of the lines makes the diagram look like stylized butterfly wings

output has two elements  $y(0)$  and  $y(1)$ . The equations for the butterfly are:

$$y(0) = x(0) + x(1) W^k$$

$$y(1) = x(1) - x(1) W^k$$

where  $W^k$  is the sum of the sine and cosine harmonics  $\cos(2k) + j\sin(2k)$ .

Figure 8.33 shows the data flow diagram of the scrambled in/natural out (the output is ordered from lowest to highest element). The number in the circle at each stage indicates the value of  $k$  for  $W^k$ . Notice that the first stage of calculation performs four  $2 \times 2$  butterfly operations, the second is two  $4 \times 4$  butterfly operations, and the final is one  $8 \times 8$  butterfly. Each stage has fewer butterfly operations so it is called a *decimation in time* algorithm.

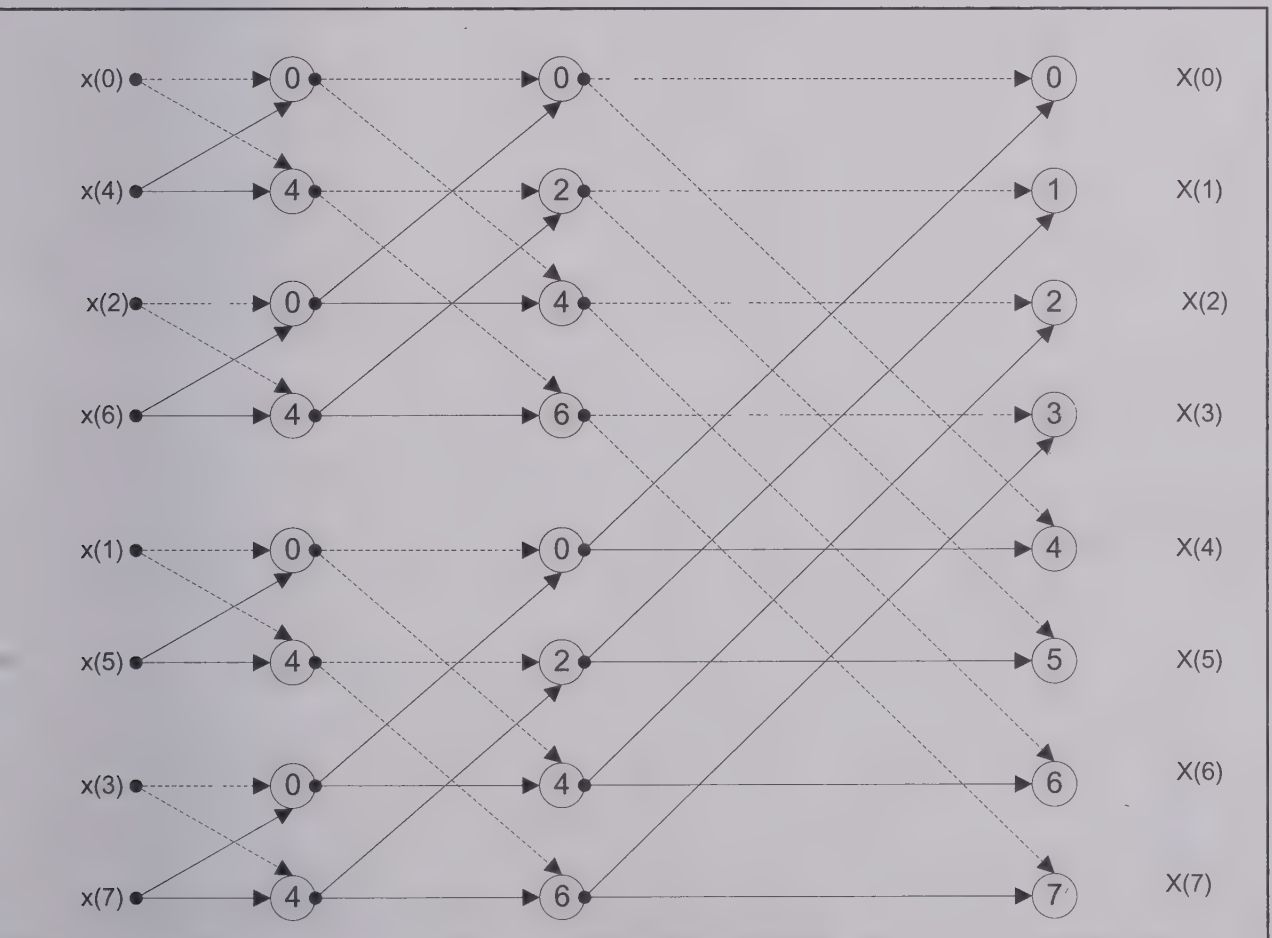

Figure 8.33 — A complete flow diagram for an 8-element FFT calculation. Each solid line represents a direct contribution of the element to the left. Each dashed line represents a contribution that is multiplied by the complex operator  $W^k$ . Each number in a circle represents the  $k$  value used for the multiplication. This example requires just 24 complex multiplication operations instead of a full 256 calculations.

### 8.7.2 Non-periodic Signals

So far we have assumed that the signal to be transformed is periodic, so that there is an integer number of cycles of each sine wave harmonic in the sequence. With a non-periodic signal, that is not necessarily so. The various frequencies in the signal are not exact

harmonics of  $1/\tau$  and are no longer orthogonal to the test frequencies. The result is *spectral leakage*; a single frequency in the signal may give a non-zero result when tested at a number of different harmonic frequencies. In **Figure 8.34**, (B) illustrates the FFT of a single sine wave at a non-harmonic frequency. You can see that the spurious response extends quite far from the actual frequency.

Those far-out spurious responses are primarily caused by the abrupt termination of the signal at the edges of the sequence. The spectrum can be cleaned up considerably by tapering the edges with a window, in the manner of digital filter coefficients as described in the **Analog and Digital Filtering** chapter. In fact, the same window functions are used for both. **Figure 8.34** part C illustrates the result of applying a Hamming window to the signal in (A) and the resulting improved spectrum is shown at (D). Just as with FIR filters, different windows excel in different areas. Windows with a gradual transition to zero at the edges do a better job of suppressing spurious responses but smear adjacent spectral lines, analogous to using a wider resolution bandwidth in an analog spectrum analyzer. Windows with a wider center section and a more abrupt transition to zero at the edges have less smearing but more spurious responses.

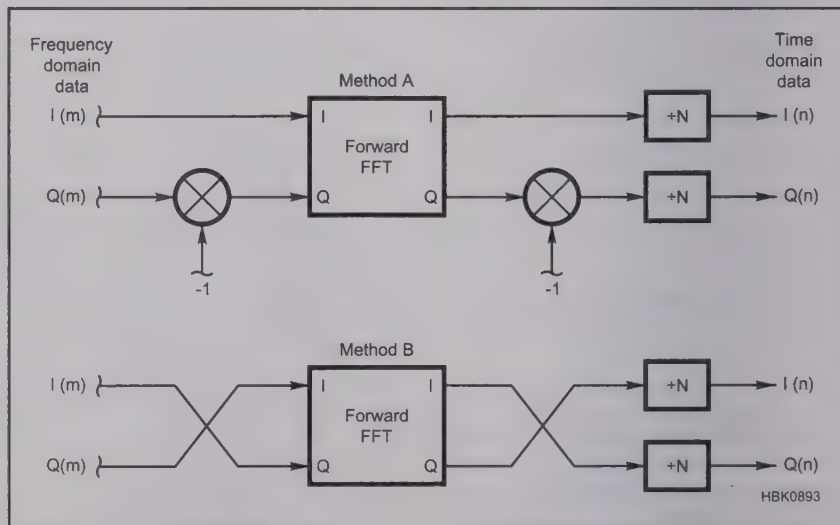

### 8.7.3 The Inverse Fourier Transform (IFT)

It is also possible to run the Fourier transform “in reverse,” changing frequency-do-

main data back into time-domain data. The IFT takes a collection of sine wave amplitude and phases and adds them together to create a waveform just as the “forward” Fourier transform changes the waveform into the collection of sine waves.

Just as clever ways of performing the Fourier transform led to the FFT, similarities in the calculations for the FFT and IFT allow the same calculations that perform the “forward” FFT to be used to perform the IFT. **Figure 8.35** shows two methods of implementing an IFT using the FFT algorithm on the I and Q channel data. Both methods have as their input the frequency-domain data,  $I(m)$  and  $Q(m)$ , which represent the amplitude and phase of sinusoidal components (harmonics). The output is a series of time-domain samples,  $I(n)$  and  $Q(n)$ , which represent the waveform. The divide-by-N functions are scaling factors required by the calculations. Advanced methods are even able to perform the FFT and IFT simultaneously on different streams of data, allowing one specialized set of hardware to do double duty.

Transceivers don’t generate transmittable signals using the IFT which is included in this discussion for completeness. Transmit chains usually perform I/Q modulation with digital data on the I and Q channel carriers, filter the output (either with analog or digital filters), and amplify it conventionally to useful levels. Nevertheless, the elegance of using the very same algorithm to convert between the time and frequency domains illustrate the deep mathematical connection between time and frequency.

**Figure 8.35** — Two methods of performing the Inverse Fourier Transform (IFT) using the “forward” FFT algorithm.

← **Figure 8.34** — Illustrating the use of windowing to minimize spectral leakage, the figures show (A) a cosine waveform not at a harmonic frequency, (B) the resulting unwindowed power spectrum, (C) the same cosine waveform with a Hamming window, and (D) the much narrower power spectrum of the windowed waveform.

## 8.8 Glossary

- Analog-to-digital converter (ADC)** — A device that samples an analog signal and outputs a digital number representing the amplitude of the signal.
- Anti-aliasing filter** — A band-limiting filter placed before a sampler to make sure the incoming signal satisfies the Nyquist criterion.
- Application-specific integrated circuit (ASIC)** — A non-programmable IC that is designed for a particular application.
- Arithmetic logic unit (ALU)** — The portion of a microprocessor that performs basic arithmetic and logical operations.
- Barrel shifter** — A circuit in a microprocessor that can bit-shift a number by multiple bits at one time.
- Baseband** — The low-frequency portion of a signal. This is typically the modulation.
- Binary point** — The symbol that separates the integer part from the fractional part of a binary number.
- Blocking dynamic range (BDR)** — The difference between the noise level (usually in a 500-Hz bandwidth) and the signal level that causes a 1 dB reduction in the level of a weaker signal.
- Circular buffers** — A buffer in which the final entry is considered to be adjacent to the first.
- Cognitive radio** — A radio system in which a wireless node automatically changes its transmission or reception parameters to avoid interference with other nodes.
- Complex number** — A number that contains real and imaginary parts.
- Complex PLD (CPLD)** — A programmable logic device that is more complex than a small PLD, such as a PAL, but with a similar architecture.
- Convolution** — A mathematical operation that modifies a sequence of numbers with another sequence of numbers so as to produce a third sequence with a different frequency spectrum or other desired characteristic. An FIR filter is a convolution engine.
- Cooley-Tukey algorithm** — Another name for the fast Fourier transform.
- Decimation** — Reduction of sample rate by an integer factor.
- Decimation in time** — The division of a sequence of numbers into successively smaller sub-sequences in order to facilitate calculations such as the Fourier transform.
- Digital downconverter (DDC)** — A device that translates a band of frequencies to baseband, typically at a lower sample rate.
- Digital signal processing** — The processing of sequences of digital numbers that represent signals.
- Digital signal processor (DSP)** — A device to do digital signal processing. The term normally is understood to refer to a microprocessor-type device with special capabilities for signal processing.
- Digital-to-analog converter (DAC)** — A device that converts digital numbers to an analog signal with an amplitude proportional to the digital numbers.
- Digital upconverter (DUC)** — A device that frequency-translates a baseband signal to a higher frequency, typically at a higher sample rate.
- Dithering** — Randomly varying the amplitude or phase of a signal in order to overcome quantization effects.
- Embedded system** — A system that includes a microprocessor for purposes other than general-purpose computing.
- Exponent** — The number of digits that the radix point must be moved to represent a number.
- Fast Fourier transform (FFT)** — An algorithm that can calculate the discrete Fourier transform with an execution time proportional to  $n \log(n)$ , instead of  $n^2$  as is required by the straight-forward application of the Fourier transform equation.
- Field-programmable gate array (FPGA)** — An IC that contains a large array of complex logic blocks whose function and connections can be re-programmed in the field.
- Floating-point** — Refers to a number whose value is represented by a mantissa and an exponent.
- Fourier transform** — A mathematical operation that derives the frequency spectrum of a time-domain signal.
- Hardware-description languages (HDL)** — A computer language to specify the circuitry of a digital device or system.
- Harmonic sampling** — The use of a sample rate that is less than twice the highest frequency of the signal to be sampled. The sample rate must be greater than two times the bandwidth of the signal.
- Harvard architecture** — A computer architecture in which the program and data are stored in separate memories.
- Imaginary number** — A real number multiplied by the square root of minus one.
- Impulse** — A pulse of finite energy with a width that approaches zero.
- In-circuit emulator (ICE)** — A device that emulates the operation of a microprocessor while providing debugging tools to the operator. The ICE normally plugs into an IC socket that normally holds the microprocessor.
- In-circuit debugger (ICD)** — A device that uses debugging features built into the microprocessor so that it can be tested while in the circuit.
- In-circuit programmable (ICP)** — A programmable IC that can be programmed while it is connected to the application circuit.
- In-circuit programmer (ICP)** — A device to facilitate programming of programmable ICs while they are connected to the application circuit.
- In-phase (I)** — The portion of a radio signal that is in phase with a reference carrier.
- Integrated development environment (IDE)** — An integrated collection of software and hardware tools for developing a microprocessor project.
- Interrupt service routine (ISR)** — A software subroutine that is called automatically when the main routine is interrupted by some event.
- Least-significant bit (LSB)** — When used as a measurement unit, the size of the smallest step of a digital number.
- Linear phase** — Refers to a system in which the delay is constant at all frequencies, which means that the phase is linear with frequency.
- Mantissa** — The decimal or binary part of a logarithm or floating-point number.
- Multiplier-accumulator (MAC)** — A device that can multiply two numbers and add the result to a previous result all in one operation.
- Multi-rate** — Refers to a system with more than one sample rate.
- Nyquist criterion** — The requirement that the sample rate must be at least twice the bandwidth of the signal.
- Nyquist frequency** — One half the sample rate.
- Nyquist rate** — Twice the signal bandwidth.
- One-time programmable (OTP)** — A programmable device that may not be re-programmed.
- Orthogonal** — Perpendicular. In analogy with the mathematics of perpendicular geometrical vectors, the term is used in communications to refer to two signals that produce zero when convolved.
- Oversampling** — Use of a sample rate higher than required by the Nyquist criterion in order to improve the signal-to-noise ratio.

**Phasor diagram** — A polar plot of the magnitude of the in-phase and quadrature components of a signal.

**Pipeline** — An arrangement of computational units in a microprocessor or other digital device so that different units can be working on different instructions or signal samples at the same time; also, an architecture commonly used for high-speed ADCs

**Programmable-array logic (PAL)** — A type of small PLD that consists of an array of AND gates, OR gates, inverters and latches.

**Programmable gate array (PGA)** — see *Field-programmable gate array*

**Programmable-logic device (PLD)** — A device with many logic elements whose connections are not defined at manufacturer but must be programmed.

**Quadrature (Q)** — The portion of a radio signal that is 90° out of phase with a reference carrier.

**Quantization** — The representation of a continuous analog signal by a number with a finite number of bits.

**Quantization error** — The difference in amplitude between an analog signal and its digital samples.

**Quantization noise** — Noise caused by random quantization error.

**Radix** — The base of a number system. Binary is radix 2 and decimal is radix 10.

**Radix point** — The symbol that separates the integer part from the fractional part of a number.

**Reconstruction filter** — A filter located after a digital-to-analog conversion or interpolation to filter out sampling spurs.

**Resampling** — Changing the sample rate by a non-integer ratio.

**Resolution** — The number of bits required to represent a digital number from its smallest to its largest value.

**Sample rate** — The rate at which samples are generated, processed or output from a system.

**Sampling** — The process of measuring and recording a signal at discrete points of time.

**Software-defined radio (SDR)** — A transmitter and/or receiver whose principal signal processing functions are defined by software.

**Spectral leakage** — In a Fourier transform, the indication of frequencies that are not actually present in the signal due to inadequate windowing.

**Undersampling** — Harmonic sampling.

**Von Neumann architecture** — A computer architecture that includes a processing unit and a single separate read/write memory to hold both program and data.

**Windowing** — Tapering the edges of a data sequence so that the samples do not transition abruptly to zero. This avoids passband and stopband ripple in an FIR filter and spectral leakage in a Fourier transform.

**Zero-order hold** — Holding of a data value for the entire sample period.

**Zero-overhead looping** — The ability of a microprocessor to automatically jump from the end of a memory block back to the beginning without additional instructions.

# Oscillators and Synthesizers

RF signals all begin with oscillators — circuits that generate a periodic output signal without any input signal. In general, we use sinusoidal waveforms for communication signals, and square-wave or pulse outputs for digital signals (clocks). Amateurs care greatly about oscillator design. In a crowded band, a stable and clean oscillator is necessary for the receiver to resolve each of the signals present. The same is required of oscillators in transmitters so that our signals use only the amount of spectrum necessary for communication. While this chapter includes a section on phase noise, the **RF Techniques** chapter discusses noise and noise metrics more generally.

This chapter includes material from Earl McCune, WA6SUH; Ulrich Rohde, N1UL; David Stockton, GM4ZNX; Fred Telewski, WA7TZY; and Jerry DeHaven, WA0ACF. These authors and others have contributed articles on phase noise and oscillator design that are included in the downloadable supplemental content for the *Handbook*.

The sheer number of different oscillator circuits seen in the literature can be intimidating, but their great diversity is an illusion that evaporates once their underlying pattern is seen. Despite the number of combinations that are possible, a manageably small number of oscillator types will cover all but very special requirements. Look at an oscillator circuit and “read” it: What form of filter — resonator — does it use? What form of amplifier? How have the amplifier’s input and output been coupled into the filter? How is the filter tuned? These are simple, easily answered questions that put oscillator types into appropriate categories and make them understandable. The questions themselves make more sense when we understand the mechanics of oscillation, in which resonance plays a major role.

Any oscillator is a fundamentally nonlinear device. Among other reasons, this circuit has an RF output even without any RF input. Any linear circuit can change the magnitude and phase shift on the signal only at its input.

## 9.1 How Oscillators Work

### 9.1.1 Resonance

We are all familiar with pendulums. A weight (a mass in a gravitational field) hanging from some kind of string will swing back and forth with a very regular period. It has been known for millennia that this period does not change as long as the length of the string does not change, regardless of the amount of weight or how far it swings. Only a few centuries ago did Isaac Newton invent enough calculus to show why this is true. Yet even before Newton’s seminal work, people were comfortable enough with this very predictable swinging period that pendulums were adopted as the basis of clocks and timekeeping.

Newton showed that the pendulum works by continuously exchanging its energy between potential (height) and kinetic (moving) forms. The mass moves fastest when it has minimum height (all energy is kinetic), and stops moving (all energy is potential) when it has maximum height. Further, when the energy is all in one form, the ingredients are in place to assure that conversion to the other form will happen. At the bottom, when the mass is moving fastest, its momentum assures that it will keep moving. The string constrains that movement and forces it to rise. When the mass stops rising, the string pulls on it in a different direction from gravity, which is pulling it down. This assures that the mass will fall and pick up speed — and the cycle repeats.

An electrical equivalent is created by the combination of an inductor and a capacitance. The inductor stores energy in a magnetic field when there is a current (motion of charge) flowing through it. The capacitor stores energy in an electric field when there is a voltage (presence of charge) in it. Connect the two together and the charge in the capacitor (electric potential energy) forces a current to begin flowing through the inductor. When the charge in the capacitor is zero, the current in the inductor is maximum (magnetic energy) and the magnetic field forces the current to continue, which recharges the capacitor with the opposite polarity. Just like the pendulum, the combination of inductor and capacitor trade energy back and forth between two types. Because energy is being stored in this circuit, we call this a *tank circuit*.

The common features between a pendulum and an electrical tank circuit are shown in **Figure 9.1**. For the pendulum, the speed of the mass and the displacement (height) are both

**Figure 9.1** — A resonator lies at the heart of every oscillatory mechanical and electrical system. A mechanical resonator (here, a pendulum) and an electrical resonator (here, a tuned circuit consisting of L and C in parallel) share the same mechanism: the regular movement of energy between two forms — potential and kinetic in the pendulum, electric and magnetic in the tuned circuit. Both of these resonators share another trait: Any oscillations induced in them eventually die out because of losses — in the pendulum, due to drag and friction; in the tuned circuit, due to the resistance, coupling to other circuits, and radiation. Note that the curves corresponding to the pendulum's displacement vs velocity and the tuned circuit's voltage vs current differ by one-quarter of a cycle, or 90°.

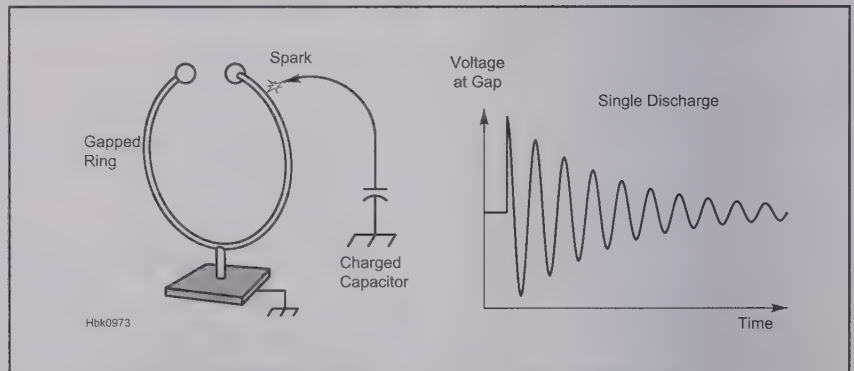

sinusoidal with time and offset in phase by 90 degrees. Similarly, the voltage and current in the LC tank circuit are sinusoidal and offset by 90 degrees.

Unfortunately, these oscillations do not continue forever. When you pull a pendulum aside and let it go, it will swing for a while and eventually stop. This is due to losses that take a little bit of energy away from the pendulum each time it swings. For a pendulum, one major loss mechanism is air drag: As the mass moves through the air, some energy is spent to move the air out of its way. There are losses from the string as well: Every time the string is bent, it warms up just a little bit. This also takes energy away from the pendulum. With these losses, the energy conversion is not complete between kinetic and potential forms, and each cycle of the oscillation is slightly smaller than the one before. We say that the oscillation is *damped*.

The electrical tank circuit works similarly. When an oscillation is started, say with a spark charging the capacitance as shown in **Figure 9.2**, we see that this oscillation is also damped. The primary losses include resistance in the inductor and interactions of the electric and magnetic fields with other conductors. There is also direct radiation of electromagnetic fields — exactly what we want to happen for radio communication, but counts as an energy loss from the resonator.

It was not hard to figure out that a damped oscillation is not very useful for radio communication. We need our signals to last for a longer time so they can carry useful information. The first attempt to solve this problem was to repeatedly apply sparks to the tank circuit in a manner like that of Figure 9.2B. This still is not a continuous sine wave and it is very noisy because, among other things, the timing of the sparks is extremely difficult to hold in exact synchronization with the tank oscillation. There has to be a better way...

**Figure 9.2** — Stimulating a resonance, 1880s style. Shock-exciting a gapped ring by a charged capacitor causes the ring to oscillate at its resonant frequency. The result is a damped wave, each successive alternation of which is weaker than its predecessor because of resonator losses. Repetitively stimulating the ring, such as with repeated discharges (i.e. — a spark transmitter), produces trains of damped waves, but oscillation is not continuous.

### 9.1.2 Maintained Resonance (CW: Continuous Waves)

What we need is a way to make up for the resonator losses, but only just enough to maintain the oscillation indefinitely. Invention of the escapement achieved this for the pendulum, and that's what provides the distinctive "tick-tock" of a pendulum clock. Electrically we use an amplifier to do the same thing.

By adding an amplifier to the tank circuit or resonator, we can take a small amount of the energy from the resonator, amplify it, and inject a part of the amplified tank signal back into the resonator. This process is shown in **Figure 9.3A**. Unlike in general amplifier design, here we are not interested in maximizing power transfer. Instead, we want to couple just enough energy into the resonator to overcome its losses, and to take only the minimum amount of energy out of the resonator needed to generate the restoring energy. Thus Figure 9.3A shows coupling networks instead of matching networks. We end up with a loop: The amplifier input comes from the output of the resonator, and the amplifier output goes to the input of the resonator.

The trick to oscillator design is to get the coupling networks and the amplifier gain working together just right. What this means is shown in Figure 9.3B. If we want to get a sine wave output, we need to get the loop gain — gain computed as the signal passes through the combination of amplifier, resonator, and both coupling networks — exactly equal to one, also called *unity*. If the loop gain is even slightly less than one, then not enough energy is supplied to overcome resonator losses and the damping still happens. If the loop gain is greater than one, then the magnitude of the sine wave will grow until the waveform is no longer sinusoidal.

There is more to making an oscillator work than getting the loop gain right. We also need to be sure that the energy from the amplifier output is applied to the resonator having the correct phase alignment with the oscillating signal in the resonator. Taken together these requirements are known as the *Barkhausen criteria*: to achieve oscillation the loop must 1) have a net zero phase shift (or some integer multiple of  $360^\circ$ ) and 2) have a loop gain equal to one. Both of these are critically important. If either of these criteria is not met, the circuit will not oscillate.

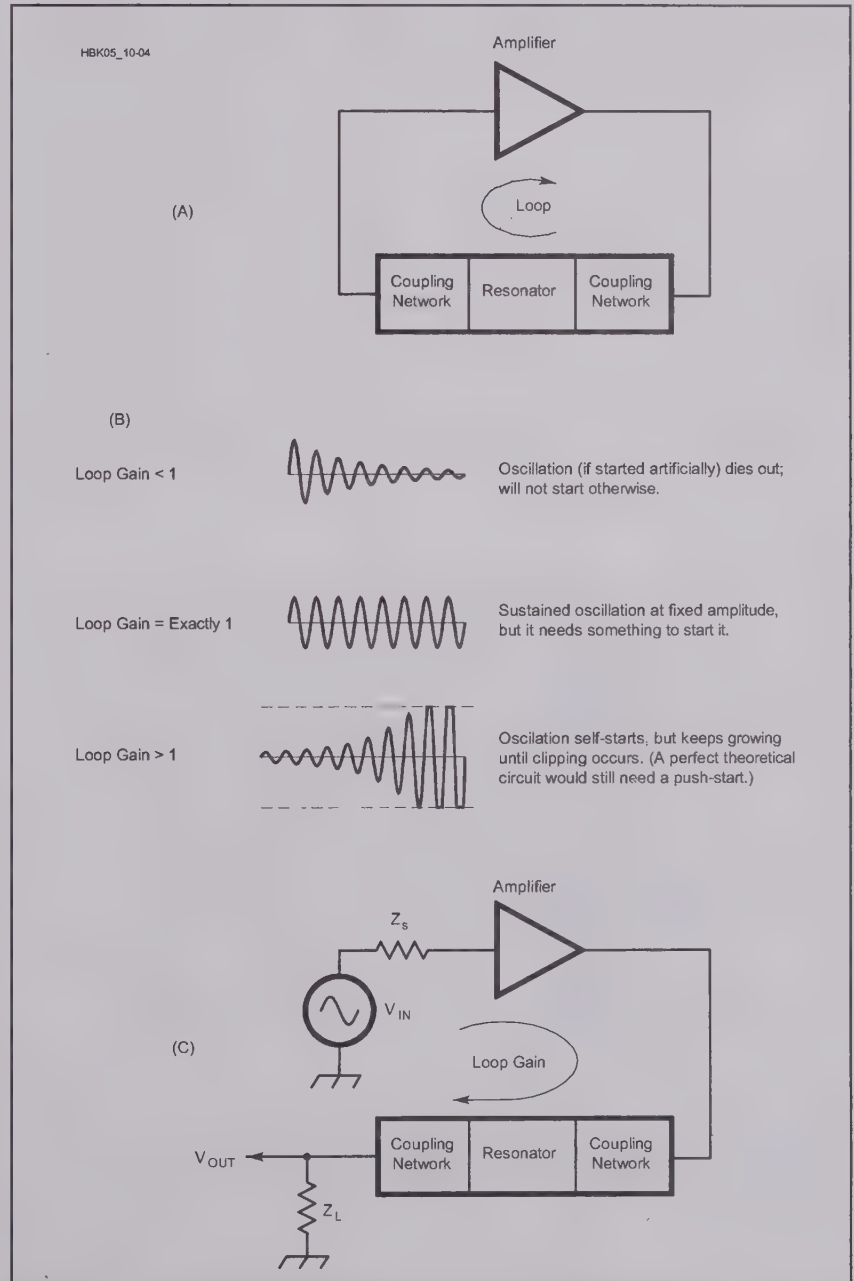

How do we find out if we are meeting the Barkhausen criteria? We need to break the loop, usually at the input of the amplifier as shown in Figure 9.3C. We apply a signal slightly below the desired oscillation frequency, then sweep the frequency through and slightly past the desired oscillation frequency. During the sweep we monitor both the magnitude and phase response at the

output of the resonator output coupling network. If everything is right, then at the desired frequency of oscillation the input and output signals will look exactly the same on an oscilloscope. If that doesn't happen, we have work to do.

Getting the phase response of the loop correct is usually the harder problem. Much of this difficulty comes from the many types of

resonators that can be used, including:

- LC tank
- Quartz crystal (and other piezoelectric materials)
- Transmission line (stripline, microstrip, open-wire, coax, and so on)
- Microwave cavities, YIG spheres, dielectric resonators
- Surface-acoustic-wave (SAW) devices

**Figure 9.3** — A practical oscillator requires networks to couple power in and out of the resonator (A). At (B), we see the amount of loop gain determines whether the oscillations will die out (loop gain < 1), grow until the waveform is no longer a sine wave (>1), or sustain at a steady amplitude (=1). Breaking the loop, inserting a test signal and measuring the loop's overall gain allows us to determine whether the system can oscillate, sustain oscillation or clip (C).

**Figure 9.4** — Phase shift through the resonator depends on resonator Q. The higher resonator Q, the more abruptly phase changes through the resonator as frequency changes.

Each of these also can be called a filter. It is true that any filter can also be used as a resonator in an oscillator. The more complicated phase responses of filters makes meeting both of the Barkhausen criteria more challenging, but certainly possible.

The phase response of the resonator is related to its Q (quality factor — see the **Electrical Fundamentals** chapter).

If we have a parallel LC tank, then at frequencies well below resonance the tank looks inductive ( $X_L \ll X_C$ ) and the current lags the voltage. At frequencies well above resonance the tank looks capacitive ( $X_C \ll X_L$ ) so the current leads the voltage. In between, the phase shift of the current relative to the voltage depends on the actual frequency. The rapidity of the phase shift with changing frequency is governed by resonator Q: the phase shift happens very rapidly when Q is high. This is shown in **Figure 9.4**. When the resonator Q is low then the phase changes much more slowly at different frequencies.

If we have a series resonator then the phase change profile is reversed (capacitive to inductive) but otherwise the shape is the same. There are an infinite number of combinations of L and C values that provide the same resonant frequency. If we are interested in high Q, for a series tank we want to select large inductor values and small capacitor values. For a high-Q parallel tank we want the opposite — large capacitor values and small inductor values. **Figure 9.5**, a modified

version of the reactance vs frequency chart in the **Electrical Fundamentals** chapter, shows these regions for a resonant frequency of 10 MHz.

### 9.1.3 Oscillator Start-Up

Looking at **Figure 9.3B** we see that the oscillation will build up in magnitude only when the loop gain is greater than unity. Thus this is an important additional criterion for oscillator design. The loop gain must be slightly greater than unity for it to start oscillating. Otherwise we have the undesired condition in which there is no signal in the resonator, so we sample nothing from it and put nothing back into it.

Still we need one more thing — noise. Some kind of signal needs to be injected into the resonator for the oscillation to start building up. We are fortunate that all amplifiers have output noise when power is applied, even if there is no input signal. It is this noise that allows any oscillator to start. Amplifier noise initiates a resonant signal in the tank, and if loop gain is slightly greater than unity, more signal is fed back into the resonator than the resonator loses. The output signal builds up until something stops it.

Here we take advantage of an amplifier characteristic where gain is reduced as the output reaches some predefined value. This is referred to as *compression*: when the output signal gets large enough, the amplifier gain is reduced a little bit. When compression balances steady output amplitude with a loop gain of exactly unity, the oscillator has reached steady state operation and we are ready to go!

Why don't we have noise at the oscillator output instead of a sine wave? Because of the filtering action of the resonator, the filtered noise waveform appears mostly sinusoidal. The narrower the bandwidth of the resonator (the higher its Q), the more sinusoidal the waveform, but it actually consists of very well-filtered noise. It is impossible to get only a pure sine wave. Noise is inevitable, and tremendous efforts are spent in reducing this noise. This is discussed in this chapter's section on Phase Noise. A demonstration by David Stockton, GM4ZNX, of oscillator design based on a simulation of how oscillators start up by the free *LTSpice* simulation program is available in the book's downloadable supplemental material.

**Figure 9.5** — There are an infinite number of combinations of L and C for a given resonant frequency. For a series-LC tank circuit, larger ratios of L to C result in higher values of Q and vice versa for parallel-LC tank circuits.

## 9.2 LC Variable Frequency Oscillator (VFO) Circuits

In this section we introduce some important oscillator circuits and provide well-tested guidelines on how to successfully build one. The following section presents a design example.

There are thousands of oscillator circuits, but just a few principal designs. One of the principal oscillator circuits is shown in **Figure 9.6**. An LC tank circuit is shown in **Figure 9.6A**. The usual single capacitance is replaced with two series capacitors having the same equivalent capacitance,  $C_{EQUIV}$ . The two capacitors act as an ac voltage divider, so that the voltage  $V_1$  at the midpoint is less than the total ac voltage of the tank,  $V_{TANK}$ .

What happens when we try to force  $V_1$  to be the same as  $V_{TANK}$  by adding an amplifier with unity voltage gain as shown in **Figure 9.6B**? The voltage division action of the capacitive divider does not change. If  $V_1$  is forced to be equal to  $V_{TANK}$  by the amplifier, then  $V_{TANK}$  will become greater than before. But then  $V_1$  will take on the new value of  $V_{TANK}$  and so forth. This is positive feedback and we have created an oscillator. Connecting an amplifier with low voltage gain to a split tank capacitance leads to the *Colpitts* group of oscillator designs.

It is certainly possible to “split” the inductor instead of the capacitor in a tank circuit and apply the same amplifier trick as before. This is shown in **Figure 9.6C** and describes the *Hartley* group of oscillators.

### 9.2.1 Basic Oscillator Circuits

(See also the papers “What You Always Wanted to Know About Colpitts Oscillators” by Ulrich Rohde, N1UL, and Anisha M. Apte, and “Calculation of FM and AM Noise Signals in the Time Domain” by Ulrich Rohde, N1UL, included with the downloadable supplemental material accompanying this book.)

The LC oscillators used in radio equipment are usually designed to be variable frequency oscillators (VFOs). Tuning is achieved by either varying part of the capacitance of the resonator or, less commonly, by using a movable magnetic core to vary the inductance. Since the early days of radio, there has been a huge quest for the ideal, low-drift VFO. Amateurs and professionals have made immense efforts in this pursuit. A brief search of the literature reveals a large number of VFO designs, many accompanied by claims of high stability. The quest for stability has been solved by the development of low-cost frequency synthesizers, which give crystal-controlled stability. Synthesizers are generally noisier than a good VFO, so the VFO still has much to offer in terms of signal cleanliness, cost, and power consumption,

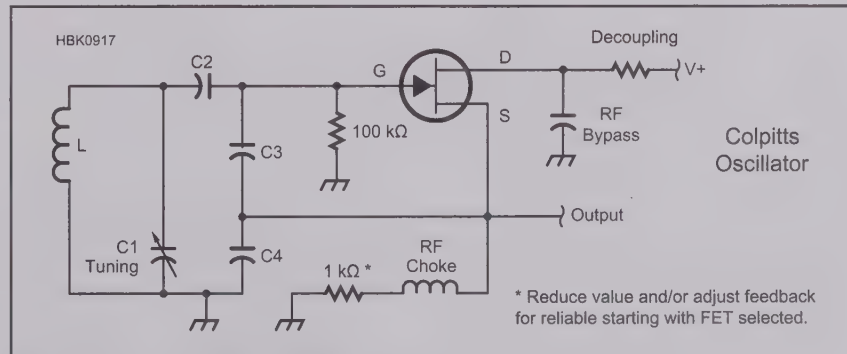

making it attractive for homebrew construction. No single VFO circuit has any overwhelming advantage over any other—component quality, mechanical design and the care taken in assembly are much more important.

Let’s take a look at three popular oscillator

circuits stripped of any non-essential components so they can be more easily compared. The original Colpitts circuit (**Figure 9.7**) is now often referred to as the parallel-tuned Colpitts because its series-tuned derivative (**Figure 9.8**) has become the most common. The Hartley version of the oscillator is shown

**Figure 9.6** — The capacitor in an LC tank circuit (A) can be split into two capacitors with the same equivalent capacitance,  $C_{EQUIV}$ , so that the resonant frequency of the tank circuit is unchanged. (B) shows a unity-gain amplifier connected so that it forces  $V_1 = V_{TANK}$ , creating positive feedback and a Colpitts oscillator results. (C) shows the same technique applied to the tank circuit inductor, creating a Hartley oscillator.

**Figure 9.7** — The Colpitts oscillator circuit.

**Figure 9.8** — The series-tuned Colpitts oscillator circuit.

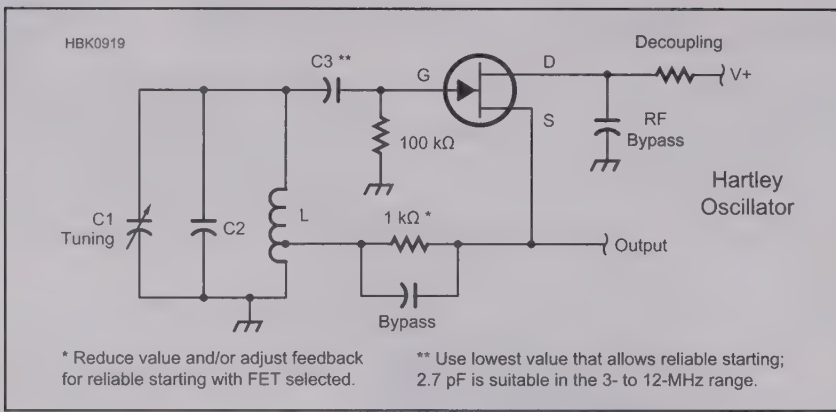

Figure 9.9 — The Hartley oscillator circuit.

in Figure 9.9. All three of these circuits use an amplifier with a voltage gain less than unity, but large current gain. The N-channel JFET source follower shown is the most popular current choice for the transistor amplifier circuit.

Rules of thumb for C3 and C4 in Figures 9.7 and 9.8 should be equal and valued such that their  $X_C = 45 \Omega$  at the operating frequency; for C2 in Figure 9.7,  $X_C = 100 \Omega$ . For best stability, use C0G or NP0 units for all capacitors associated with the FET gates and sources. Depending on the FET chosen, the 1-k $\Omega$  source-bias-resistor value shown may require adjustment for reliable starting.

### PARALLEL-TUNED COLPITTS VFO

In the parallel-tuned Colpitts, C3 and C4 are large values, perhaps 10 times larger than typical values chosen for C1 and C2 to resonate L at the desired frequency. This means only a small fraction of the total tank voltage is applied to the FET gate, and the FET can be considered to be only lightly coupled into the tank. Equally important, the values of C3 and C4 must be much larger than the FET device internal capacitances to provide good stability for the output frequency. This keeps small variations in the FET capacitances from having a significant effect on oscillator operation.

The FET is driven by the sum of the voltages across C3 and C4, while it drives the voltage across C4 alone. This means that the tank operates as a resonant, voltage-step-up transformer compensating for the less-than-unity-voltage-gain amplifier. The resonant circuit consists of L, C1, C2, C3 and C4. The resonant frequency can be calculated by using the standard formulas for capacitors in series and parallel to find the resultant capacitance effectively connected across the inductor, L, and then use the standard formula for LC resonance:

$$f = \frac{1}{2\pi\sqrt{LC}}$$

where

f = frequency in hertz

L = total inductance in henries

C = total capacitance in farads.

This equation holds for all cases. Its accuracy is dependent on the designer's ability to account for all of the contributions to tank inductance and capacitance. There are several rules of thumb that help a VFO designer identify the various "stray" contributions to tank inductance and capacitance:

1. Wherever there is voltage, stray capacitance must be considered.
2. Wherever there is current, stray mutual inductance must be considered.
3. All currents form loops, creating inductance.

These "rules" will help point out where to look for contributions to inductance and capacitance. At frequencies below 10 MHz the actual components you see and touch tend to be all you need to consider. As the oscillator frequency increases, consideration of stray capacitance and stray inductance — reactance effects that are not associated directly with a visible component — becomes increasingly important. If the oscillator frequency is noticeably lower than what you predict, it is almost certain that there are important stray reactances that you need to account for.

Getting back to the circuit of Figure 9.7, for a wide tuning range C2 must be kept small to reduce the swamping effect of C3 and C4 on the variable capacitor C1. (For more information on component selection, the chapters on oscillators in *Experimental Methods for RF Design and Introduction to Radio Frequency Design* listed in the References provide excellent material.) "Swamping" refers to a much larger value component reducing the effect of a small component connected to it.

A parallel-tuned Colpitts oscillator is the subject of the detailed paper "A Design Example for an Oscillator for Best Phase Noise and Good Output Power" by Ulrich Rohde, N1UL, available in the downloadable supplemental information for this book. The paper shows the design process by which both noise and power can be optimized in a simple oscillator.

### SERIES-TUNED COLPITTS VFO

The series-tuned Colpitts circuit (Figure 9.8) works in much the same way. The difference is that the variable capacitor, C1, is positioned so that it is well-protected from being swamped by the large values of C3 and C4. In fact, small values of C3, C4 would act to limit the tuning range. Fixed capacitance, C2, is often added across C1 to allow the tuning range to be reduced to that required without interfering with C3 and C4, which set the amplifier coupling. The series-tuned Colpitts has a reputation for better stability than the parallel-tuned original. Note how C3 and C4 swamp the capacitances of the amplifier in both versions.

### HARTLEY VFO

The Hartley oscillator of Figure 9.9 is similar to the parallel-tuned Colpitts, but the JFET amplifier source is connected to a tap on the tank inductance instead of the tank capacitance. A typical tap placement is 10% to 20% of the total turns up from the cold end of the inductor. (It's common to refer to the lowest-signal-voltage end of an inductor as "cold" and the other, with the highest signal voltage as "hot".) C2 limits the tuning range as required.

C3 is reduced to the minimum value that allows reliable starting. This is necessary because the Hartley's lack of the Colpitts' capacitive divider would otherwise couple the FET's internal capacitances to the tank more strongly than in the Colpitts, potentially affecting the circuit's frequency stability.

### VFO DESIGN NOTES

Generally, VFOs can be adapted to work at other frequencies (within the limits of the active device). To do so, compute an adjustment factor:  $f_{old} / f_{new}$ . Multiply the value of each frequency determining or feedback L or C by that factor. As frequency increases and amplifier gain drops, it may be required to increase feedback more than indicated by the factor.

In all three circuits, there is a 1 k $\Omega$  resistor in series with the source bias circuit. This resistor does a number of desirable things. It spoils (lowers) the Q of the inevitable low-frequency resonance of the choke with the tank tap circuit. It reduces tuning drift due to choke impedance and winding capacitance variations. It also protects against spurious oscillation at undesired frequencies due to

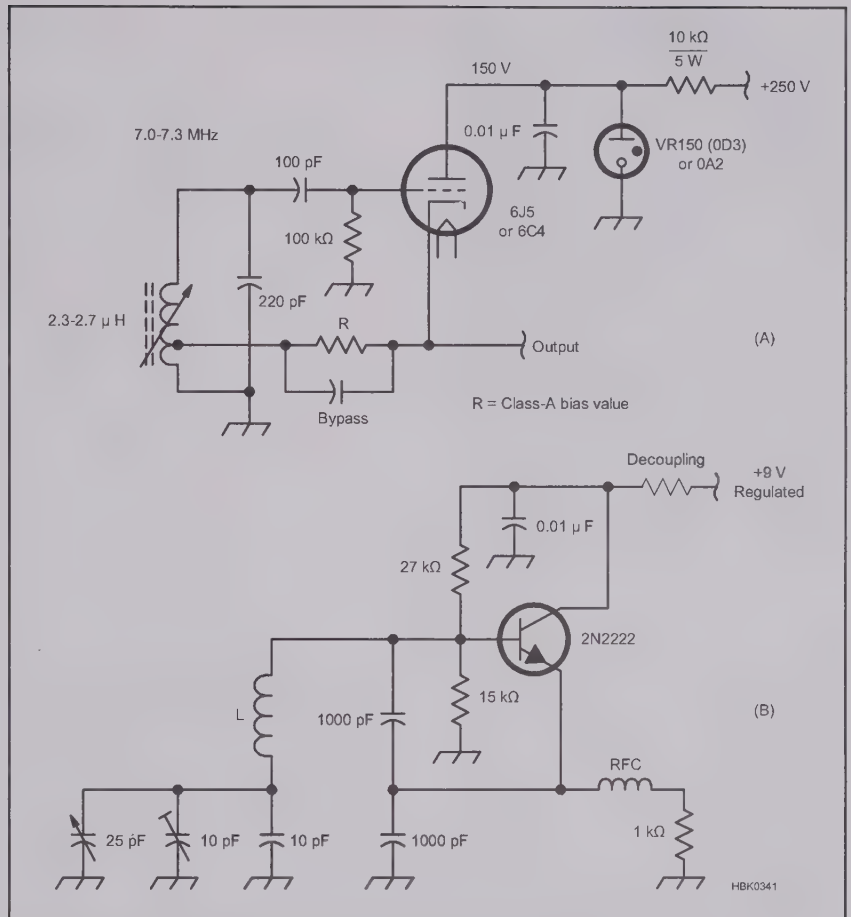

internal choke resonances. Less obviously, it acts to stabilize the loop gain of the built-in AGC action of this oscillator. Stable operating conditions act to reduce frequency drift.

Some variations of these circuits may be found with added resistors providing a dc bias to stabilize the system quiescent current. More elaborate still are variations characterized by a constant-current source providing bias. This can be driven from a separate AGC detector system to give very tight level control. The gate-to-ground clamping diode (1N914 or similar) long used by radio amateurs as a means of avoiding gate-source conduction has been shown by Ulrich Rohde, N1UL, to degrade oscillator phase-noise performance, and its use is virtually unknown in professional circles.

**Figure 9.10** shows two more VFOs to illustrate the use of different devices. The vacuum-tube triode Hartley shown features permeability tuning, which has no sliding contact like that of a capacitor's rotor and can be made reasonably linear by artfully spacing the coil turns. The slow-motion drive can be done with a screw thread. The disadvantage is that special care is needed to avoid backlash and eccentric rotation of the core. If a non-rotating core is used, the slides have to be carefully designed to prevent motion in unwanted directions. The Collins Radio Company made extensive use of tube-based permeability tuners, and a semiconductor version can still be found in a number of Ten-Tec radios.

Vacuum tubes cannot run as cool as competitive semiconductor circuits, so care is needed to keep the tank circuit away from the tube heat. In many amateur and commercial vacuum-tube oscillators, oscillation drives the tube into grid current at the positive peaks, causing rectification and producing a negative grid bias. The oscillator thus runs in Class C, in which the conduction angle reduces as the signal amplitude increases until the amplitude stabilizes. As in the FET circuits of Figures 9.7 through 9.9, better stability and phase-noise performance can be achieved in a vacuum-tube oscillator by moving its operating point out of true Class C — that is, by including a bypassed cathode-bias resistor (the resistance appropriate for Class A operation is a good starting value). Vacuum-tube radios are still maintained in operation and occasionally constructed for enjoyment but the semiconductor long ago achieved dominance in VFOs.

Compared to the more frequently used JFET, bipolar transistors like the one used in Figure 9.10B are relatively uncommon in oscillators because their relatively low input and output impedances are more difficult to couple into a high-Q tank without loading it excessively. Bipolar devices do tend to give better sample-to-sample amplitude uniformity for a given oscillator circuit, because

**Figure 9.10** — Two additional oscillator examples: at A, a triode-tube Hartley; at B, a bipolar junction transistor in a series-tuned Colpitts.

many of the bipolar transistor characteristics are due less to manufacturing than physics. This is not true for JFETs of any given type; JFETs tend to vary more in their characteristics because manufacturing variations directly affect their threshold or pinch-off voltage.

### SQUEGGING

The effect called *squegging* (or *squeezing*) can be loosely defined as oscillation on more than one frequency at a time, but may also manifest itself as RF oscillation interrupted at an audio frequency rate, as in a super-regenerative detector. One form of squegging occurs when an oscillator is fed from a power supply with high source impedance. The power supply charges up the decoupling capacitor until oscillation starts. The oscillator draws current and pulls down the capacitor voltage until it has starved itself of power and oscillation stops. The oscillator stops drawing current and the decoupling capacitor then recharges until oscillation restarts. The process, the low-frequency cycling of which is a form of relaxation oscillation, repeats indefinitely. The oscillator output can clearly be seen to be pulse modulated with an oscilloscope.

Squegging can be a consequence of poor design in battery-powered radios. As the cells become exhausted, their internal resistance often rises and circuits that they power can begin to misbehave. In audio stages, such misbehavior may manifest itself in the “putt-putt” sound of the slow relaxation oscillation called “motorboating.”

### 9.2.2 Two Low-Noise VHF Oscillators

The following section is excerpted from the May/June 2018 QEX article “An Optimized Grounded Base Oscillator Design for VHF/UHF,” by Ulrich Rohde, N1UL, and Ajay Poddar, AC2KG. The full article is available as a PDF file in this book’s downloadable supplemental information. Interested readers are encouraged to read the original article which includes a comprehensive set of references and all design details.

The design of VHF/UHF oscillators has been described in many books and journals with most of the emphasis on frequency stability and to some smaller part on output/efficiency. Since the introduction of reliable

phase noise measurements and the ability to predict/simulate the phase noise, the improvement of this important parameter with the help of CAD and analytic equations has gained more attention. The novel design concept described in the article with the downloadable supplemental content uses a time domain approach to provide both the best output power and the best phase noise performance. This very simple but powerfully scalable set of formulas for the oscillator synthesis provides extremely good results. In addition, the design principle for fixed or narrowband oscillators discussed here also applies to the broadband VCO design. This design methodology works over a multi-octave tuning range.

### CIRCUIT DESIGN GUIDELINES

The results we have obtained so far were based on mathematical calculations. Some of these calculations are difficult to obtain (see the original *QEX* article). However, there are certain relationships between the values of the capacitance of the tuned circuit and the two feedback capacitors, the collector-emitter capacitor and the emitter-to-ground capacitor. The following shows the set of recommended steps for easy design of such oscillators.

A very popular circuit for VHF/UHF oscillators is the grounded-base configuration, which is shown in **Figure 9.11**. Its phase noise can be made very good, since the RF voltage swing at the collector can be close to the supply voltage. The circuit is simple and has been used for decades. This oscillator type works well from RF frequencies such as 10 MHz to above 1000 MHz.

The oscillator function is based on the principle that power from the output is taken and fed to the emitter. This feedback arrangement generates a negative resistance at the output, compensating the losses of the output-tuned circuit, and starts oscillating and then stabilizing the oscillation amplitude. The circuit has simple design rules where  $C_E$  and  $C_F$  are the feedback capacitors that generate the negative resistance to compensate for the loss resistance in the resonator network comprised of  $L_E$  and  $C_L^*$ .

Theoretically, the grounded-base configuration can be rotated to be the Colpitts circuit. If we look at the performance, in the case of the Colpitts oscillator the RF voltage swing is limited by the base-emitter and emitter-to-ground voltage and as a result there is less energy stored in the circuit and because of loading the operational Q can be less than in the grounded-base configuration. The Colpitts oscillator is popular because of its simplicity, and its perceived high isolation as the output power is taken at the collector. However, due to the strong Miller effect at very high frequencies, this is not a true statement.

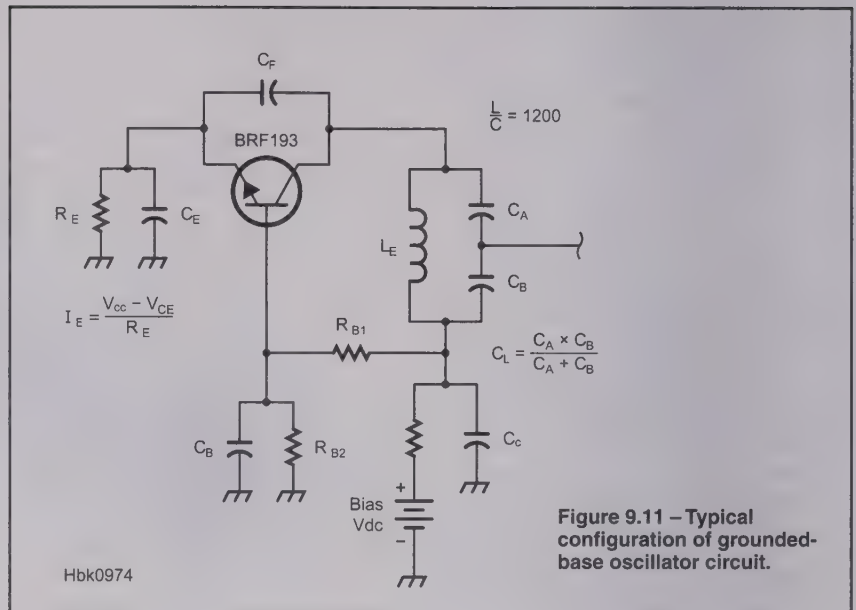

Figure 9.11 – Typical configuration of grounded-base oscillator circuit.

### SIMPLE DESIGN RULES

By setting the  $L/C$  ratio to a fixed value of 1200 (for optimum energy storage, group delay and energy transfer for a given cycle in the resonator network), the following should be used.

$$\frac{L}{C} = \left[ \frac{L_E}{C_L^*} \right]_{\text{Grounded-Base}} = 1200$$

$$\Rightarrow Z_0 = \sqrt{1200} \cong 34.6 \Omega$$

$$L = 1200 \times C$$

$$\Rightarrow L_E = 1200 \times C_L^*$$

$$f = \frac{1}{2\pi\sqrt{LC}} = \frac{1}{2\pi C\sqrt{1200}}$$

$$C_L^* = C_L + \frac{C_E C_F}{C_E + C_F}$$

where  $C_E$  and  $C_F$  are feedback capacitors.

$$C_L = \frac{C_A C_B}{C_A + C_B}$$

where  $C_A$  and  $C_B$  are feedback capacitors.

$$C_B = 10 C_A$$

The reader is reminded that this “recipe” was developed based on the Y-parameters, transconductance, and package parasitics for the BRF193 transistor. Using a transistor greatly different than the BRF193 requires the full design process to be performed as described in the original article.

### 144 MHz GROUNDED-BASE OSCILLATOR

The oscillator circuit in **Figure 9.12** is designed using the procedure of the preceding section.

$$C_L^* = \frac{1}{2\pi f\sqrt{1200}} \Rightarrow C \cong 31 \text{ pF}$$

$$L_L = \frac{1}{(2\pi f)^2 C} \Rightarrow L \cong 39 \text{ nH}$$

$$C_F = 0.3 \times C_L^* \cong 11 \text{ pF}$$

$$C_L = 2 \times C_F \cong 22 \text{ pF}$$

$$C_E = 4 \times C_F \cong 44 \text{ pF}$$

$$C_A = 22 \text{ pF}$$

$$C_B = 220 \text{ pF}$$

These results are frequency scalable with minor corrections possibly necessary.

Figure 9.12A shows the schematic of the 144 MHz oscillator at  $I_C = 10 \text{ mA}$ . The oscillator uses a lumped inductor of 39 nH and an unloaded Q of 200 at the operating frequency. Even at these frequencies the layout is quite critical. The example layout in Figure 9.12B shows an assembly of components where the lead inductances have been kept small. The inductor is a standard off the shelf component. (Note that the sample layout is given only as a guideline and not as a template.)

Figure 9.12C shows the CAD simulated phase noise plot. The output power is 11.5 dBm and the second and third harmon-

Figure 9.12 — 144 MHz oscillator circuit for  $I_E = 10$  mA (A), an example of the circuit layout using LC lumped inductor-capacitor resonator network (B), and simulated phase noise plot (C).

ics are about  $-28$  dBm and  $-34$  dBm. Using phase noise simulation, the result is  $-134$  dBc/Hz and  $-94$  dBc/Hz at 10 kHz and 100 Hz offset. Calculated, simulated, and measured results closely agree within 1 dB.

If the same transistor is operated at 30 mA, the phase noise at 10 kHz offset will improve to be  $-144$  dBc/Hz and the output power is increased to 20 dBm. This shows that for low phase noise design a more powerful transistor is a good choice. It is important to keep the dc dissipation of the device in mind, as the CAD process will probably not flag a misuse of the device.

### MODIFIED CIRCUIT FOR UHF (432 MHz) AND HIGHER CURRENT

At 432 MHz and at  $I_E = 30$  mA, the loading of the tank circuit decreases the operating Q significantly. The way around this to use a center-tapped inductor. As the coupling at these frequencies from winding to winding is not extremely high, two separate identical inductors can be used successfully.

Figure 9.13A shows the schematic of 432 MHz grounded base oscillator using the tapped inductor. This is a modification of the circuit we have used previously. In the case of a VCO, it would be advantageous to use

## The Vackar Oscillator

The original Vackar oscillator is named for Jirí Vackár, who invented the circuit in the late 1940s. The circuit's description — a refinement of the Clapp oscillator — can be found in older editions of the Radio Society of Great Britain's Radio Communication Handbook, with some further comments on the oscillator in RSGB's Amateur Radio Techniques. The circuit is also described in the Nov 1955 QST "Technical Correspondence" column by W9IK. The Vackar circuit optimized the Clapp oscillator for frequency stability: the oscillator transistor is isolated from the resonator, tuning does not affect the feedback coupling, and the transistor's collector output impedance is kept low so that gain is the minimum necessary to sustain oscillation.

a different output coupling scheme because in this configuration, the loading would vary with frequency. This can easily be achieved by adding some inductive coupling to the circuit. In case of a printed resonator this can be accomplished quite simply.

Figure 9.13B shows a sample guideline layout of the 432 MHz oscillator circuit using a buried printed coupled line resonator network (stripline resonator in the middle layer). The actual resonator would not be visible if the oscillator is visually inspected.

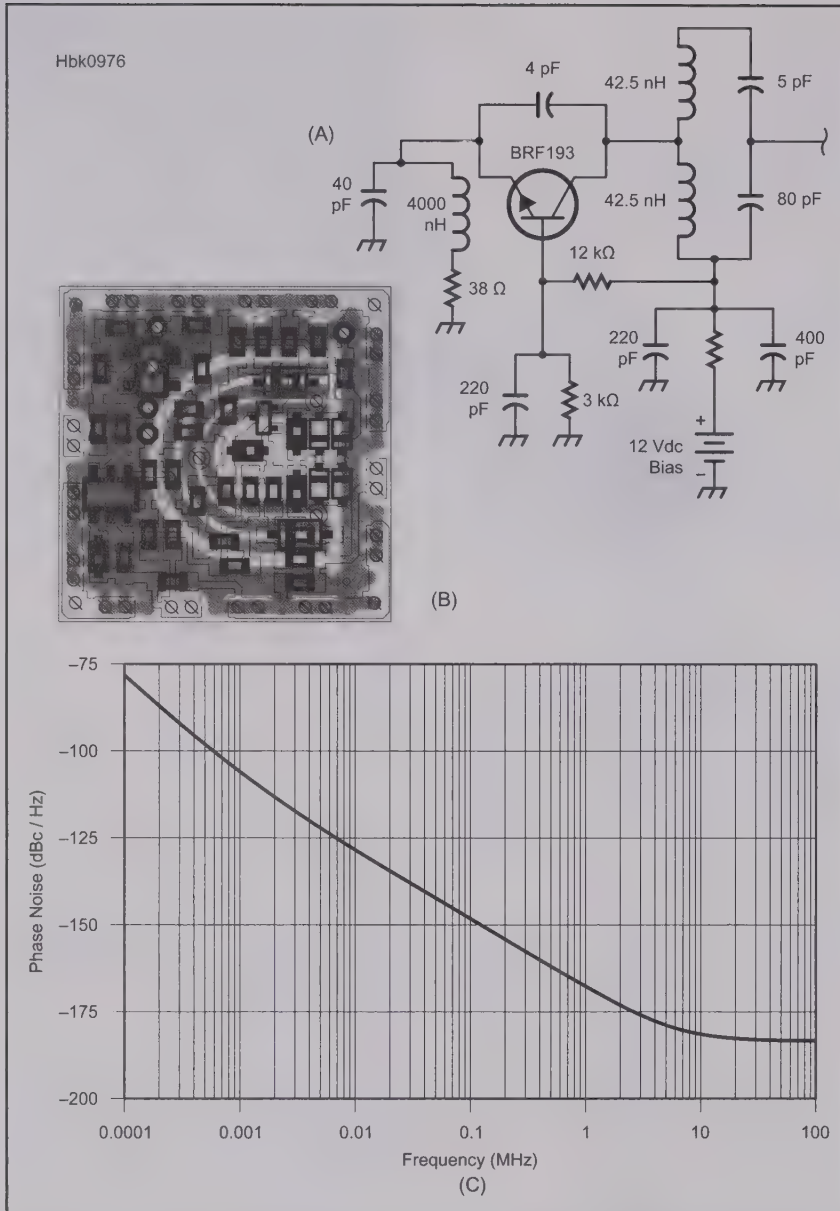

Figure 9.13C shows the simulated phase noise plot with the expected noise degradation of 9 dB, as the frequency is approximately three times higher. The resulting simulated output power at 432 MHz is 16 dBm, compared to 18 dBm at 144 MHz. This is due to internal package parasitics, which could not be compensated externally. The second harmonic is suppressed by 38 dB; this is due to the higher operating Q.

### 9.2.3 Three High-Performance HF VFOs

#### THE N1UL MODIFIED VACKAR VFO

The oscillator circuit of Figure 9.14A is contributed by Ulrich Rohde, N1UL. It is a modified Vackar design (see the sidebar) in which a small coupling capacitor (8 pF) and voltage divider capacitor (18 pF) isolate the resonator circuit (10  $\mu$ H and 50 pF tuning capacitor) from the oscillator transistor.

The oscillator transistor is followed by a buffer stage to isolate the oscillator from the load. Because the coupling between the transistor base and the resonator is fixed and light, stability of the oscillator is high across a wide tuning range from 5.5 to 6.6 MHz. Either the inductor or capacitor may be varied to tune the oscillator, but a variable capacitor is rec-

**Figure 9.13** — 432 MHz oscillator circuit using tapped inductor and  $I_E = 30$  mA (A), an example of the circuit layout using buried printed coupled line resonator (stripline resonator) in the middle layer of the board (B), and simulated phase noise plot (C).

ommended as more practical and gives better performance.

Because of the oscillator transistor's large capacitors from base to ground (220 pF) and collector to ground (680 pF), the various parameters of the oscillator transistor have little practical influence on circuit performance. The widely available 2N3904 performs well for both the oscillator and buffer transistors.

Practical resonator coil and the tuning capacitors will have a positive temperature coefficient. The 8 pF and the 18 pF capacitors should have an N150 temperature coefficient

to partially compensate for their drift. After 1 hour, the observed frequency drift for this circuit was less than 10 Hz / hour.

### THE K7HFD LOW-NOISE DIFFERENTIAL OSCILLATOR

The other high performance oscillator example, shown in **Figure 9.15**, is designed for low-noise performance by Linley Gumm, K7HFD, and appears on page 126 of the ARRL's *Solid State Design for the Radio Amateur* (out of print, but available used and through libraries). This circuit uses no unusual components and looks simple, yet it

is a subtle and sophisticated circuit. (An analysis and simulation of this circuit by its designer is included in the downloadable supplemental material for this book.)

The effects of limiting in reducing AM oscillator noise were covered previously. However, because AM noise sidebands can get translated into PM noise sidebands by imperfect limiting, there is an advantage to stripping off the AM as early as possible, in the oscillator itself. An ALC system in the oscillator will counteract and cancel only the AM components within its bandwidth, but an oscillator based on a limiter will do this over a broad bandwidth. K7HFD's oscillator uses a differential pair of bipolar transistors as a limiting amplifier. The dc bias voltage at the bases and the resistor in the common emitter path to ground establishes a controlled dc bias current, here 25 to 27 mA. The ac voltage between the bases switches this current between the two collectors. This applies a rectangular pulse of current into link winding L2, which drives the series-resonant tank L1-C1. The output impedance of the collector is high in both the current-on and current-off states. Along with the small number of turns of the link winding, this presents very high impedance to the tank circuit, which minimizes degradation of the tank Q. The input impedance of this limiter is also quite high and is applied across only a one-turn tap of L1, which similarly minimizes any impact on the tank Q. The input transistor base is driven into conduction only on one peak of the tank waveform. The output transformer has the inverse of the current pulse applied to it, so the output is not a low distortion sine wave, although the output harmonics will not be as extensive as simple theory would suggest because the circuit's high output impedance allows stray capacitances to attenuate high-frequency components. The low-frequency transistors used here also act to reduce the harmonic power.

With an output of +17 dBm, this is a power oscillator, running with nearly 300 mW of dc input power, so appreciable heating is present that can cause temperature-induced drift. The circuit's high-power operation is a deliberate ploy to create a high signal-to-noise ratio by having as high a signal power as possible. This also reduces the problem of the oscillator's broadband noise output. The limitation on the signal level in the tank is the transistors' base-emitter-junction breakdown voltage. The circuit runs with a few volts peak-to-peak across the one-turn tap, so the full tank is running at over 50 V<sub>p-p</sub>.

Excessive voltage levels for the transistors can easily be generated by this circuit. The single easiest way to damage a bipolar transistor is to reverse bias the base-emitter junction until it avalanches. Most devices are rated

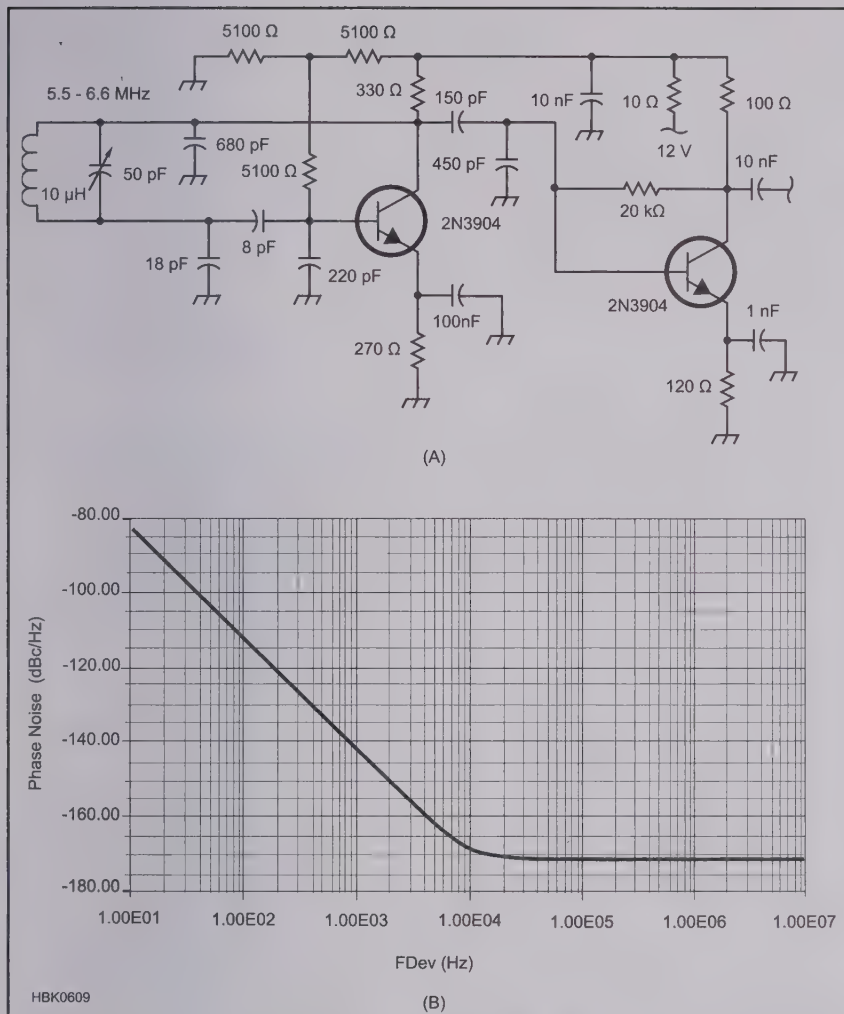

Figure 9.14 — At A, N1UL's Modified Vackar VFO is tuned from 5.5 to 6.6 MHz using the 50 pF capacitor. Tuning may be restricted to narrower ranges by placing a fixed capacitor in parallel with a smaller variable capacitor. The resonant frequency of the oscillator is determined by the 10 µH inductor and 50 pF tuning capacitor. B shows the excellent phase noise performance of the modified Vackar VFO in this *Harmonica* simulation. At 1 kHz from the carrier, noise is -144 dBc.

to withstand only 5 V applied this way, the current needed to do damage is small, and very little power is needed. If the avalanche current is limited to less than that needed to perform immediate destruction of the transistor, it is likely that there will be some degradation of the device, a reduction in its bandwidth and gain along with an increase in its noise. These changes are irreversible and cumulative. Small, fast signal diodes have breakdown voltages of over 30 V and less capacitance than the transistor bases, so one possible experiment would be to try the effect of adding a fast signal diode in series with the base of each transistor and running the circuit at even higher levels.

The oscillation amplitude is controlled by the drive current limit. The voltage on L2 must never allow the collector of the transistor driving it to go into saturation, for if this happens the transistor presents very low impedance to L2 and badly loads the tank, wrecking the Q and the noise performance. The circuit can be checked to verify the margin from saturation by probing the hot end of L2 and the emitter with an oscilloscope. Another, less obvious, test is to vary the power-supply voltage and monitor the output power. While the circuit is under current control, there is very little change in output power, but if the supply is low enough to allow saturation, the output power will

change significantly with varying supply voltage.

The use of the 2N3904 is interesting, as it is not normally associated with RF oscillators. It is a cheap, plain, general-purpose type more often used at dc or audio frequencies. There is evidence that suggests some transistors that have good noise performance at RF have worse noise performance at low frequencies, and that the low-frequency noise they create can modulate an oscillator, creating noise sidebands. Experiments with low-noise audio transistors may be worthwhile, but many such devices have high junction capacitances.

In the description of this circuit in *Solid State Design for the Radio Amateur*, the results of a phase-noise test made using a spectrum analyzer with a crystal filter as a preselector are given. Ten kilohertz away from the carrier, in a 3 kHz measurement bandwidth, the noise was more than 120 dB below the carrier level. This translates into better than  $-120 - 10 \log(3000)$ , which equals  $-154.8$  dBc/Hz, SSB, consistent with the modeled phase noise performance shown in Figure 9.15B. At this offset, -140 dBc is usually considered to be excellent. This VFO provides state-of-the-art performance by today's standards — in a 1977 publication.

### A JFET HARTLEY VFO

Figure 9.16 shows an 11.1 MHz version of a VFO and buffer closely patterned after that used in 7 MHz transceiver designs published by Roger Hayward, KA7EXM, and Wes Hayward, W7ZOI ("The Ugly Weekender") and Roy Lewallen, W7EL ("The Optimized QRP Transceiver"). In it, a Hartley oscillator using a 2N5486 JFET drives the two-2N3904 buffer attributed to Lewallen. This version diverges from the originals in that its JFET uses source bias (the bypassed 910 Ω resistor) instead of a gate-clamping diode and is powered from a low-current 7 V regulator IC instead of a Zener diode and dropping resistor. The 5 dB pad sets the buffer's output to a level appropriate for "Level 7" (+7 dBm LO) diode ring mixers.

The circuit shown was originally built with a gate-clamping diode, no source bias and a 3 dB output pad. Adjusting the oscillator bias as shown increased its output by 2 dB without degrading its frequency stability (200 to 300 Hz drift at power up, stability within ±20 Hz thereafter at a constant room temperature).

In recognition that precision mechanical tuning components are hard to obtain, the resonator uses "Bandset" and "Bandspread" variable capacitors. These terms are from the early days of radio: bandset is for coarse-tuning and bandspread is for fine-tuning.

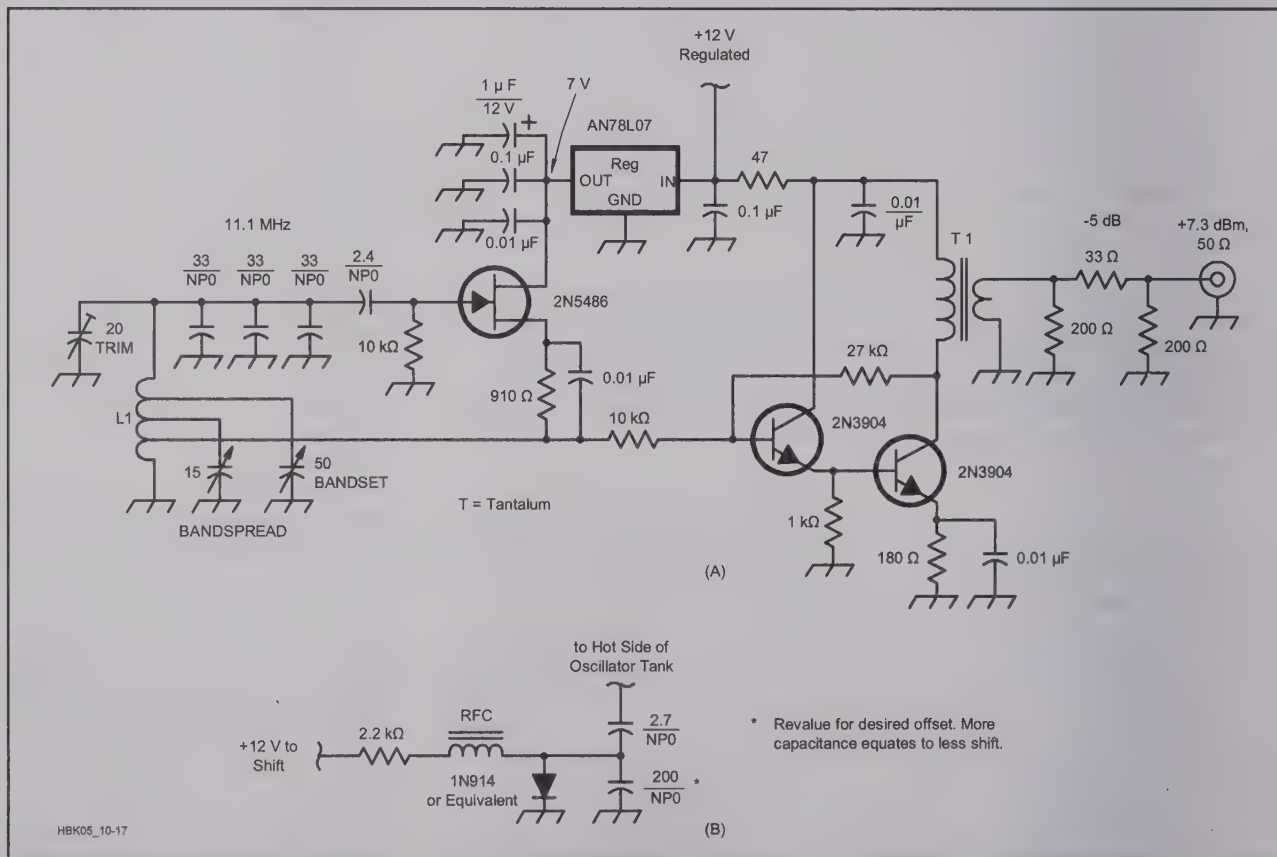

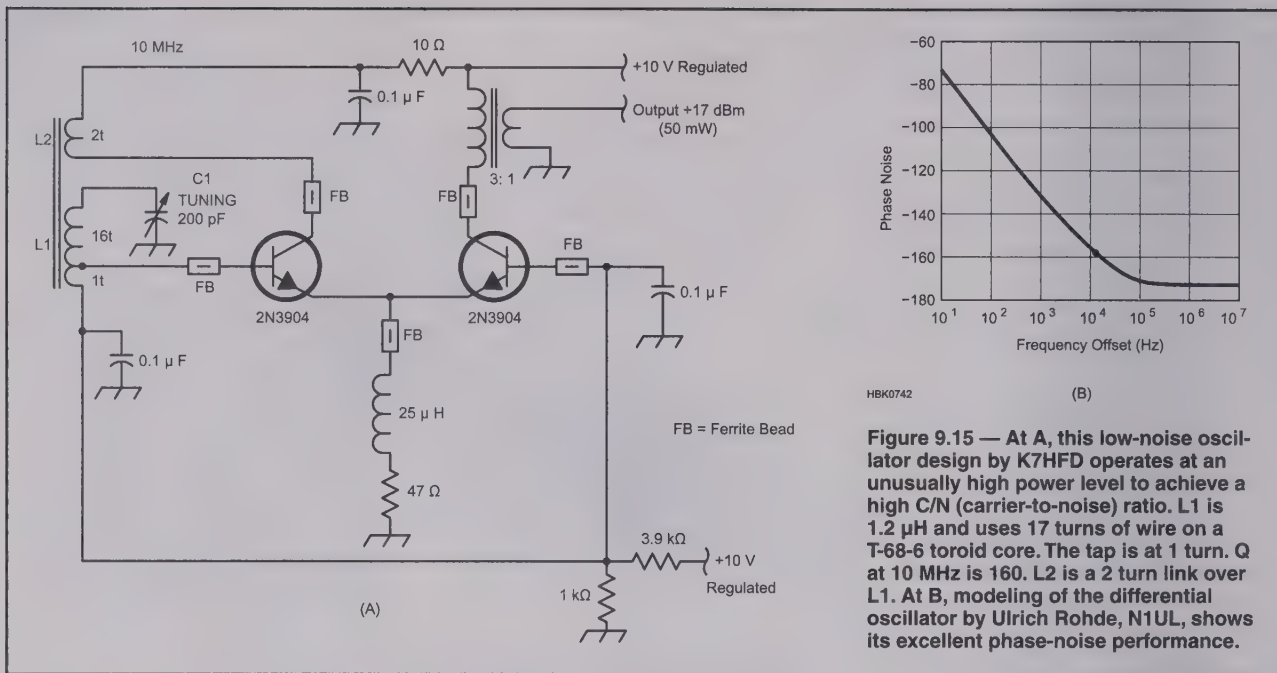

Figure 9.16 — Incorporating ideas from N1UL, KA7EXM, W7ZOI and W7EL, the oscillator at A achieves excellent stability and output at 11.1 MHz without the use of a gate-clamping diode, as well as end-running the shrinking availability of reduction drives through the use of bandset and bandspread capacitors. L1 consists of 10 turns of B & W #3041 Miniductor (#22 tinned wire, 1/8 inch in diameter, 24 turns per inch). The source tap is 2 1/2 turns above ground; the tuning-capacitor taps are positioned as necessary for bandset and bandspread ranges required. T1's primary consists of 15 turns of #28 enameled wire on an FT-37-72 ferrite core; its secondary, 3 turns over the primary. B shows a system for adding fixed TR offset that can be applied to any LC oscillator. The RF choke consists of 20 turns of #26 enameled wire on an FT-37-43 core.

## 9.3 Building an Oscillator

We've covered a lot of ground about how oscillators work, their limitations and a number of interesting circuits, so the inevitable question arises of how to design one. Let's make an embarrassing confession right here: Very few oscillators you see in published circuits or commercial equipment were designed by the equipment's designer. Almost all have been adopted from other sources. While recycling in general is important for the environment, it means in this case that very few professional or amateur designers have ever designed an oscillator from scratch. We all have collections of circuits we've "harvested," and we adjust a few values or change a device type to produce something to suit a new project.

Oscillators aren't designed, they evolve. They seem to have a life of their own. The Clarke & Hess book listed in the references contains one of the few published classical design processes. The ARRL book *Experimental Methods in RF Design* contains extensive material on oscillator circuits that is well worth reading.

### 9.3.1 VFO Components and Construction

#### TUNING CAPACITORS AND REDUCTION DRIVES

As most commercially made radios now use frequency synthesizers, it has become increasingly difficult to find certain key components needed to construct a good VFO. Slow-motion drives and variable capacitors are available from *QST* advertiser National RF ([www.nationalrf.com](http://www.nationalrf.com)), Dan's Small Parts and Kits ([www.danssmallpartsandkits.net](http://www.danssmallpartsandkits.net)), and Antique Electronic Supply ([www.tubesandmore.com](http://www.tubesandmore.com)). Variable capacitors should be a high-quality component with double ball-bearings and silver-plated surfaces and contacts.

An alternate approach is also available: Scavenge suitable parts from old equipment; use tuning diodes instead of variable capacitors — an approach that, if uncorrected through phase locking, generally degrades stability and phase-noise performance; or use two tuning capacitors, one with a capacitance range  $\frac{1}{2}$  to  $\frac{1}{10}$  that of the other, in a bandset/bandspread approach.

Assembling a variable capacitor to a chassis and its reduction drive to a front panel can result in *backlash* — an annoying tuning effect in which rotating the capacitor shaft deforms the chassis and/or panel rather than tuning the capacitor. One way of minimizing this is to use the reduction drive to support the capacitor, and use the capacitor to support the oscillator circuit board, which is then attached to the chassis.

Figure 9.17 — EIA capacitor temperature coefficients specify change in capacitance with temperature. See the Component Data and References chapter for a complete table of temperature coefficient identifiers and characteristics.

#### FIXED CAPACITORS

Use silvered-mica or other highly-stable capacitors for all fixed-value capacitors in the oscillator circuit. Power-supply decoupling capacitors may be any convenient type, such as ceramic or film.

Traditionally, silver-mica fixed capacitors have been used extensively in oscillators, but their temperature coefficient is not as low as can be achieved with other types, and some silver micas have been known to behave erratically. Polystyrene film has become a proven alternative. One warning is worth noting: polystyrene capacitors exhibit a permanent change in value should they ever be exposed to temperatures much above 70 °C; they do not return to their old value on cooling.

Particularly suitable for oscillator construction are the low-temperature-coefficient ceramic capacitors, often described as NP0 or COG types. (NP0 and COG are equivalent) These abbreviations are actually tempera-

ture-coefficient codes. Figure 9.17 contains graphs showing the behavior of three common temperature coefficients. Some ceramic capacitors are available with deliberate, controlled temperature coefficients so that they can be used to compensate for other causes of frequency drift with temperature. For example, the code N750 denotes a part with a temperature coefficient of  $-750$  parts per million per degree Celsius. These parts are now somewhat difficult to obtain, so other methods are needed. (Values for temperature coefficients and other attributes of capacitors are presented in the Component Data and References chapter.)

In a Colpitts circuit, the two large-value capacitors that form the voltage divider for the active device still need careful selection. It is tempting to use any available capacitor of the right value, because the effect of these components on the tank frequency is reduced by the proportions of the capacitance values in the circuit. This reduction is not as great as the difference between the temperature stability of an NP0 ceramic part and some of the low-cost, decoupling-quality X7R-dielectric ceramic capacitors. It's worth using low-temperature coefficient parts even in the seemingly less-critical parts of a VFO circuit — even for the bypass capacitors. Chasing the cause of temperature drift is more challenging than fun. Buy critical components like high-stability capacitors from trustworthy sources.

#### TUNING CAPACITOR NETWORKS

Often an available variable capacitor has greater capacitance than required for a desired frequency range. While plates can sometimes be removed, a better solution embeds the variable capacitor in a network of fixed capacitors. The evolution of this network is shown in the middle section of Figure 9.18. The variable capacitor,  $C_V$ , and  $C_2$  are paralleled to form the equivalent  $C_{2V}$ . This is then placed in series with  $C_1$  for the equivalent  $C_{12V}$ . This is, in turn, paralleled by  $C_3$  to form the total capacitor,  $C_{NET}$ . The overall frequency is calculated from the usual resonance relationship. The equations are shown, with capacitance in farads, inductance in henries, and frequency in Hz.

There is considerable flexibility available to the designer, afforded by picking  $C_1$  and  $C_2$  values. Some combinations with  $C_1$  much smaller than the variable capacitor can produce highly nonlinear tuning.

#### INDUCTORS

Ceramic coil forms can give excellent results, as can self-supporting air-wound coils (Miniductor). If the required inductance is small enough, wind the coil on a ceramic

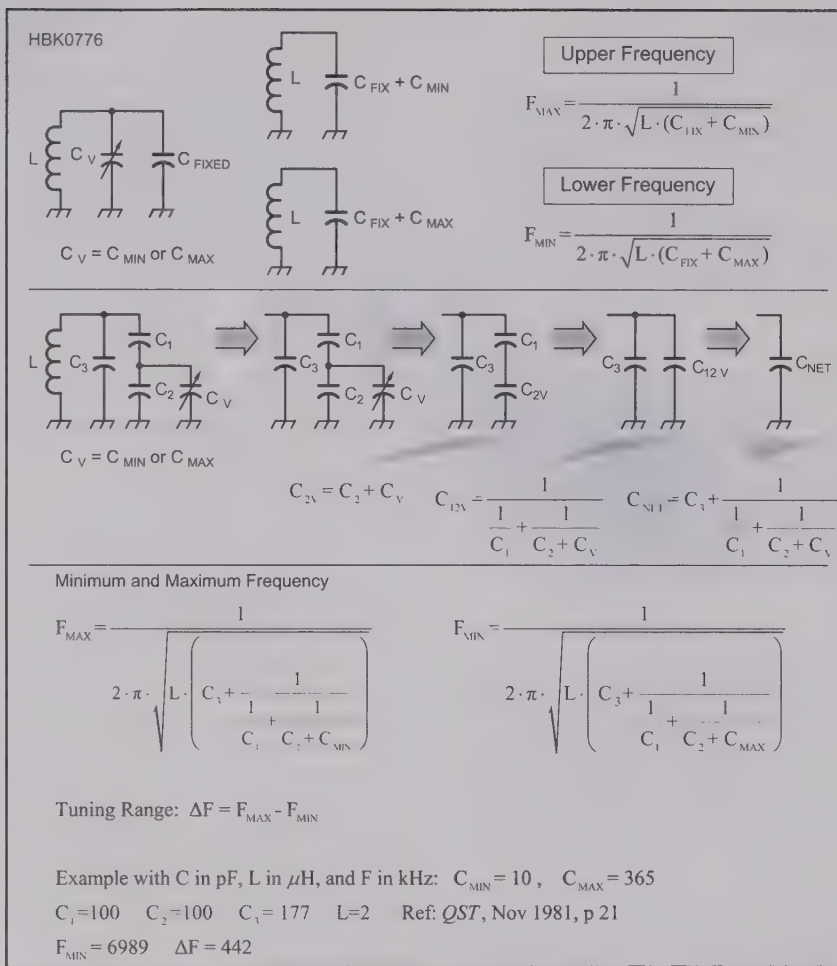

Figure 9.18 — A simple resonant circuit is tuned with parallel capacitors as shown in the top section. The tuning range is controlled by the ratio of the variable capacitance to the fixed capacitance.

form that is securely mounted.

If you use a magnetic core, use powdered iron and support it securely. Do not use ferrite because of its temperature instability. Stable VFOs have been made using toroidal cores. Micrometals mix #6 has a low temperature coefficient and works well in conjunction with NP0 ceramic capacitors. Other materials have to be assessed on an individual basis.

A material's temperature stability will not be apparent until you try it in an oscillator, but you can apply a quick test to identify those nonmetallic materials that are lossy enough to spoil a coil's Q. Put a sample of the coil-form material into a microwave oven along with a glass of water and cook it about 10 seconds on low power. Do not include any metal fittings or ferromagnetic cores. Good materials will be completely unaffected; poor ones will heat and may even melt, smoke, or burst into flame. (This operation is a fire hazard if you try more than a tiny sample of an unknown material. Observe your experiment

continuously and do not leave it unattended!)

W7ZOI suggests annealing toroidal VFO coils after winding. W7EL reports achieving success with this method by boiling his coils in water and letting them cool in air.

## VOLTAGE REGULATORS

VFO circuits must be powered by well-regulated, low-noise supplies. Three-terminal regulators are inexpensive and have low output noise. It is easy to include them locally with the oscillator circuit. If the regulator is not part of the oscillator circuit, include a decoupling R-C combination to act as a noise filter.

Many oscillator circuits include Zener diode regulators. Zeners have some idiosyncrasies that could spoil the oscillator. They are noisy, so decoupling is needed down to audio frequencies to filter this out. Zener diodes are often run at much less than their specified optimum bias current. Although this saves power, it results in a lower output voltage than intended and the diode's imped-

ance is much greater, increasing its sensitivity to variations in input voltage, output current and temperature. Some common Zener types may be designed to run at as much as 20 mA; check the data sheet for your diode family to find the optimum current.

True Zener diodes are low-voltage devices; above a couple of volts, so-called Zener diodes are actually avalanche types. The temperature coefficient of these diodes depends on their breakdown voltage and crosses through zero for diodes rated at about 5 V. If you intend to use nothing fancier than a common-variety Zener, designing the oscillator to run from 5 V and using a 5.1 V Zener will give you a free advantage in voltage-versus-temperature stability.

There are some diodes available with especially low temperature coefficients, usually referred to as reference or temperature-compensated diodes. These usually consist of a series pair of diodes designed to cancel each other's temperature drift. The 1N821A diode has a temperature coefficient of  $\pm 100$  ppm/ $^{\circ}\text{C}$ . Running at 7.5 mA, the 1N829A provides 6.2 V  $\pm 5\%$  and a temperature coefficient of just  $\pm 5$  parts per million (ppm) maximum per degree Celsius. A change in bias current of 10% will shift the voltage less than 7.5 mV, but this increases rapidly for greater current variation. The curves in Figure 9.19 show how the temperature coefficients of these diodes are dependent on bias current.

The LM399 is a complex IC that behaves like a superb Zener at 6.95 V,  $\pm 0.3$  ppm/ $^{\circ}\text{C}$ . Precision, low-power, three-terminal regulators are also available that are designed to be used as voltage references, some of which can provide enough current to run a VFO. There are comprehensive tables of all these devices between pages 334 and 337 of Horowitz and Hill, *The Art of Electronics*, 2nd ed.

## OSCILLATOR DEVICES

The 2N3819 FET, a classic from the 1960s, has proven to work well in VFOs but, like the MPF102 which is also long-popular with ham builders, it is manufactured to wide tolerances. Considering an oscillator's importance in receiver stability, you should not hesitate to spend a bit more on a better device. The 2N5484, 2N5485 and 2N5486 are worth considering; together, their transconductance ranges span that of the MPF102, but each is a better-controlled subset of that range. The 2N5245 is a more recent device with better-than-average noise performance that runs at low currents like the 2N3819. The 2N4416/A, also available as the plastic-cased PN4416, is a low-noise device, designed for VHF/UHF amplifier use, which has been featured in a number of good oscillators up to the VHF region. Its low internal capacitance contributes to low frequency drift. The J310 (plastic;

Figure 9.19 — The temperature coefficient of temperature-compensated diodes varies with bias current. To obtain the best temperature performance, use the specific bias current for the diode.

the metal-cased U310 is similar) is another popular JFET for use in oscillators.

The 2N5179 (plastic, PN5179 or MPS5179) is a bipolar transistor capable of good performance in oscillators up to the top of the VHF region. Care is needed because its absolute-maximum collector-emitter voltage is only 12 V, and its collector current must not exceed 50 mA. Although these characteristics may seem to convey fragility, the 2N5179 is sufficient for circuits powered by stabilized 6 V power supplies.

VHF-UHF capable transistors are not really necessary in LC VFOs because such circuits are rarely used above 10 MHz. (High-bandwidth transistors also increase high-frequency harmonic content in the output signal.) Absolute frequency stability is progressively harder to achieve with increasing frequency, so free-running oscillators are used only rarely to generate VHF-UHF signals for radio communication. Instead, VHF-UHF radios usually use voltage-tuned, phase-locked oscillators in some form of synthesizer. Bipolar devices like the BFR90 and MRF901, with  $f_T$  in the 5 GHz region and mounted in stripline packages, are needed for successful oscillator design at UHF.

The popular SA/NE602 mixer IC has a built-in oscillator and can be found in many published circuits. This device has separate input and output pins to the tank and has proved to be quite tame. It may not have been "improved" yet (so far, it has progressed from the SA/NE602 to the SA/NE602A, the A version affording somewhat higher dynamic range than the original SA/NE602). It might be a good idea for anyone laying out a board using one to take a little extra care to keep PCB traces short in the oscillator section to

build in some safety margin so that the board can be used reliably in the future. Professional designers know that their designs are going to be built for possibly more than 10 years and have learned to make allowances for the progressive improvement of semiconductor manufacture.

**MECHANICAL CONSTRUCTION**

- All oscillator components should be clean and attached to a solid support to minimize thermal changes and mechanical vibration.
- The enclosure should be solid and isolated from mechanical vibration.
- Keep component leads short and if point-to-point wiring is employed, use heavy wire (#16 to #18 AWG).
- Single-point grounding of the oscillator components is recommended to avoid stray inductance and to minimize noise introduced from other sources. If a PCB is used, include a ground plane.

It is often instructive to look at commercial or military equipment to see what techniques and materials are used for those demanding applications. The mechanical assemblies and parts can be removed from surplus equipment for home-built VFOs, as well.

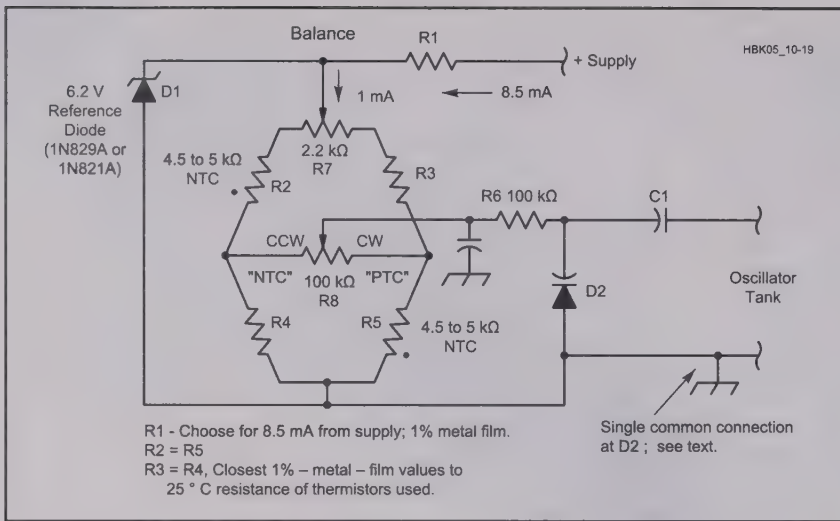

**9.3.2 Temperature Compensation**

The general principle for creating a high-stability VFO is to use components with minimal temperature coefficients in circuits that are as insensitive as possible to changes in components' secondary characteristics. Even after careful minimization of the causes of temperature sensitivity, further improve-

ment can still be desirable. The traditional method was to split one of the capacitors in the tank so that it could be apportioned between low-temperature-coefficient parts and parts with deliberate temperature dependency. Only a limited number of different, controlled temperature coefficients are available, so the proportioning between low coefficient and controlled coefficient parts was varied to "dilute" the temperature sensitivity of a part more sensitive than desired. This is a tedious process, involving much trial and error, an undertaking made more complicated by the difficulty of arranging means of heating and cooling the unit being compensated. (Hayward described such a means in December 1993 *QST*.) As commercial and military equipment have been based on frequency synthesizers for some time, supplies of capacitors with controlled temperature sensitivity are drying up. An alternative approach is needed.

A temperature-compensated crystal oscillator (TCXO) is an improved-stability version of a crystal oscillator that is used widely in industry. Instead of using controlled-temperature coefficient capacitors, most TCXOs use a network of thermistors and normal resistors to control the bias of a tuning diode. Manufacturers measure the temperature vs. frequency characteristic of sample oscillators, and then use a computer program to calculate the optimum normal resistor values for production. This can reliably achieve at least a tenfold improvement in stability. We here are not interested in mass manufacture, but the idea of a thermistor tuning a varactor is worth adopting. The parts involved are likely to be available for a long time.

Browsing through component suppliers'

**Figure 9.20** — Oscillator temperature compensation is difficult because of the scarcity of negative-temperature-coefficient capacitors. This circuit by GM4ZNX uses a bridge containing two identical thermistors to steer a tuning diode for drift correction. The 6.2 V Zener diode used (a 1N821A or 1N829A) must be a temperature-compensated part; just any 6.2 V Zener will not do.

catalogs shows ready availability of 4.5 to 5 k $\Omega$  bead thermistors intended for temperature-compensation purposes, at less than a dollar each. **Figure 9.20** shows a circuit based on this form of temperature compensation. Commonly available thermistors have negative temperature coefficients, so as temperature rises, the voltage at the counterclockwise (CCW) end of R8 increases, while that at the clockwise (CW) end drops. Somewhere near the center there is no change. Increasing the voltage on the tuning diode decreases its capacitance, so settings toward R8's CCW end simulate a negative-temperature-coefficient capacitor; toward its clockwise end, a positive-temperature-coefficient part. Choose R1 to pass 8.5 mA from whatever supply voltage is available to the 6.2 V reference diode, D1. The 1N821A/1N829A-family diode used has a very low temperature coefficient and needs 7.5 mA bias for best performance; the bridge takes the other 1 mA. R7 and R8 should be good-quality multi-turn trimmers. D2 and C1 need to be chosen to suit the oscillator circuit. Choose the least capacitance that provides enough compensation range. This reduces the noise added to the oscillator. (It is possible, though tedious, to solve for the differential varactor voltage with respect to R2 and R5, via differential calculus and circuit theory. The equations in Hayward's 1993 article can then be modified to accommodate the additional capacitors formed by D2 and C1.) Use a single ground point near D2 to reduce the influence of ground currents from other circuits. Use good-quality metal-film components for the circuit's fixed resistors.

The novelty of this circuit is that it is designed to have an easy and direct adjustment process. The circuit requires two

adjustments, one at each of two different temperatures, and achieving them requires a stable frequency counter that can be kept far enough from the radio so that the radio, not the counter, is subjected to the temperature extremes. (Using a receiver to listen to the oscillator under test can speed the adjustments.) After connecting the counter to the oscillator to be corrected, run the radio containing the oscillator and compensator in a room-temperature, draft-free environment until the oscillator's frequency reaches its stable operating temperature (rise over the ambient temperature). Lock its tuning, if possible. Adjust R7 to balance the bridge. This causes a drop of 0 V across R8, a condition you can reach by winding R8 back and forth across its range while slowly adjusting R7. When the bridge is balanced and 0 V appears across R8, adjusting R8 causes no frequency shift. When you've found this R7 setting, leave it there, set R8 to the exact center of its range and record the oscillator frequency.

Run the radio in a hot environment and allow its frequency to stabilize. Adjust R8 to restore the frequency to the recorded value. The sensitivity of the oscillator to temperature should now be significantly reduced between the temperatures at which you performed the adjustments. You will also have somewhat improved the oscillator's stability outside this range.

For best results with any temperature-compensation scheme, it's important to group all the oscillator and compensator components in the same enclosure, avoiding differences in airflow over components. A good oscillator should not dissipate much power, so it's feasible, even advisable, to mount all of the oscillator components in an unventi-

lated box. In the real world, temperatures change and if the components being compensated and the components doing the compensating have different thermal time constants, a change in temperature can cause a temporary change in frequency until the slower components have caught up. One cure for this is to build the oscillator in a thick-walled metal box that's slow to heat or cool, and so dominates and reduces the possible rate of change of temperature of the circuits inside. This is sometimes called a *cold oven*.

### 9.3.3 Shielding and Isolation

It is important to remember that any inductor acts as half of a transformer. Oscillators contain inductors running at moderate power levels and so can radiate strong enough signals to cause interference with other parts of a radio or with other radios. This is the tank (or other) inductor behaving as a transformer primary. Oscillators are also sensitive to radiated signals or other nearby varying magnetic fields. This is the tank (or other) inductor also behaving as a transformer secondary. Effective shielding is therefore vital.

Any oscillator is particularly sensitive to interference on the same or very nearby frequency. If this interference is strong enough an undesirable effect called *injection locking* will occur. The oscillator effectively stops oscillating and instead directly follows the interfering signal. For example, a VFO used to directly drive a power amplifier and antenna (to form a simple CW transmitter) can prove surprisingly difficult to shield well enough because of injection locking from any leakage of the power amplifier's high-level signal back into the oscillator. Even if injection locking does not fully kick in, the wrestling inside the VFO between its own oscillation and the interference can affect its frequency, resulting in an unstable transmitted signal. If the radio gear is in the station antenna's near field, there are also strong fields that are coherent with the VFO oscillation, making sufficient shielding even more difficult.

The following rules of thumb continue to serve ham builders well:

- Use a complete metal box, with as few holes drilled in it as possible, with good contact around surface(s) where its lid(s) fit(s) on.

- Use feedthrough capacitors on power and control lines that pass in and out of the VFO enclosure and on the transmitter or transceiver enclosure as well.

- Use buffer amplifier circuitry that amplifies the signal by the desired amount and provides sufficient attenuation of signal energy flowing in the reverse direction. This is known as *reverse isolation* and is a frequently overlooked loophole in shielding. Figures 9.14 and 9.16 include buffer circuitry

of proven performance. Another (and higher-cost) option is to consider using a high-speed buffer-amplifier IC (such as the LM6321N by National Semiconductor, a part that combines the high input impedance of an op amp with the ability to drive 50-Ω loads directly up into the VHF range).

- Use a mixing-based frequency-genera-

tion scheme instead of one that operates straight through or by means of multiplication. Such a system's oscillator stages can operate on frequencies with no direct frequency relationship to its output frequency. This essentially eliminates the possibility of injection locking the VFO.

- Use the time-tested technique of running

your VFO at a sub-harmonic of the output signal desired — say, 3.5 MHz in a 7 MHz transmitter — and multiply its output frequency in a suitably nonlinear stage for further amplification at the desired frequency. This does reduce the tendency to injection lock.

## 9.4 Crystal Oscillators

Because crystals afford Q values and frequency stabilities that are orders of magnitude better than those achievable with LC circuits, fixed-frequency oscillators usually use quartz crystal resonators. Master references for frequency counters and synthesizers are always based on crystal oscillators.

So glowing is the crystal's reputation for stability that newcomers to radio experimentation naturally believe that the presence of a crystal in an oscillator will force oscillation at the frequency stamped on the can. This impression is usually revised after the first few experiences to the contrary! There is no sure-fire crystal oscillator circuit (although some are better than others); reading and experience soon provide a learner with plenty of anecdotes to the effect that:

- Some circuits have a reputation of being temperamental, even to the point of not always starting.

- Crystals sometimes mysteriously oscillate on unexpected frequencies.

Even crystal manufacturers have these problems, so don't be discouraged from building crystal oscillators. The occasional uncooperative oscillator is a nuisance, not a disaster, and it just needs a little individual attention. Knowing how a crystal behaves is the key to a cure.

Ulrich Rohde, N1UL, has generously contributed a pair of detailed papers that discuss the crystal oscillator along with several HF and VHF designs. Both papers, "Quartz Crystal Oscillator Design" and "A Novel Grounded Base Oscillator Design for VHF/UHF Frequencies" are included with the downloadable supplemental material accompanying this book.

### 9.4.1 Quartz and the Piezoelectric Effect

Quartz is a crystalline material with a regular atomic structure that can be distorted by the simple application of force. Remove the force, and the distorted structure springs back to its original form with very little energy loss. This property allows *acoustic waves* — sound — to propagate rapidly

through quartz with very little attenuation, because the velocity of an acoustic wave depends on the elasticity and density (mass/volume) of the medium through which the wave travels.

If you heat a material, it expands. Heating may cause other characteristics of a material to change — such as elasticity, which affects the speed of sound in the material. In quartz, however, expansion and change in the speed of sound are very small and tend to cancel, which means that the transit time for sound to pass through a piece of quartz is very stable.

The third property of this wonder material is that it is *piezoelectric*. Apply an electric field to a piece of quartz and the crystal lattice distorts just as if a force had been applied. The electric field applies a force to electrical charges locked in the lattice structure. These charges are captive and cannot move around in the lattice as they can in a semiconductor, for quartz is an insulator. A capacitor's dielectric stores energy by creating physical distortion on an atomic or molecular scale. In a piezoelectric crystal's lattice, the distortion affects the entire structure. In some piezoelectric materials, this effect is sufficiently pronounced that special shapes can be made that bend *visibly* when a field is applied.

Consider a rod made of quartz. Any sound wave propagating along it eventually hits an end, where there is a large and abrupt change in acoustic impedance. Just as when an RF wave hits the end of an unterminated transmission line, a strong reflection occurs. The rod's other end similarly reflects the wave. At some frequency, the phase shift of a round trip will be such that waves from successive round trips exactly coincide in phase and reinforce each other, dramatically increasing the wave's amplitude. This is *resonance*.

The passage of waves in opposite directions forms a standing wave with antinodes at the rod ends. Here we encounter a seeming ambiguity: not just one, but a family of different frequencies, causes standing waves — a family fitting the pattern of  $\frac{1}{2}$ ,  $\frac{3}{4}$ ,  $\frac{1}{2}$ ,  $\frac{3}{4}$  and so on, wavelengths into the length of the rod. And this is the case: A quartz rod can resonate at any and all of these frequencies.

The lowest of these frequencies, where the crystal is  $\frac{1}{2}$  wavelength long, is called the *fundamental mode*. The others are named the third, fifth, seventh and so on, *overtones*. There is a small phase-shift error during reflection at the ends, which causes the frequencies of the overtone modes to differ slightly from odd integer multiples of the fundamental. Thus, a crystal's third overtone is very close to, but not exactly, three times its fundamental frequency. Many people are confused by overtones and harmonics. Harmonics are additional signals at exact integer multiples of the fundamental frequency. Overtones are not signals at all; they are additional resonances that can be exploited if a circuit is configured to excite them.

The crystals we use most often resonate in the 1 to 30 MHz region and are of the *AT-cut, thickness shear* type, although these last two characteristics are rarely mentioned. A 15 MHz fundamental crystal of this type is about 0.15 mm thick. Because of the widespread use of pressure-mounted FT-243 crystals, you may think of crystals as small rectangles on the order of a half-inch in size. The crystals we commonly use today are discs, etched and/or doped to their final dimensions, with metal electrodes deposited directly on the quartz. A crystal's diameter does not directly affect its frequency; diameters of 8 to 15 mm are typical. (Quartz crystals are also discussed in the **Analog and Digital Filtering** chapter.)

AT-cut is one of a number of possible standard designations for the orientation at which a crystal disc is sawed from the original quartz crystal. The crystal lattice atomic structure is asymmetric, and the orientation of this with respect to the faces of the disc influences the crystal's performance. *Thickness shear* is one of a number of possible orientations of the crystal's mechanical vibration with respect to the disc. In this case, the crystal vibrates perpendicularly to its thickness. This is not easy to visualize, and diagrams don't help much, but **Figure 9.21** is an attempt at illustrating this. Place a moist bathroom sponge between the palms of your hands, move one hand up and down, and you'll see thickness shear in action.

**Figure 9.21** — Thickness-shear vibration at a crystal's fundamental and third overtone (A); B shows how the modern crystals commonly used by radio amateurs consist of etched quartz discs with electrodes deposited directly on the crystal surface.

There is a limit to how thin a disc can be made, given requirements of accuracy and price. Traditionally, fundamental-mode crystals have been made up to 20 MHz, although 30 MHz is now common at a moderately raised price. Using techniques pioneered in the semiconductor industry, crystals have been made with a central region etched down to a thin membrane, surrounded by a thick ring for robustness. This approach can push fundamental resonances to over 100 MHz, but these are more lab curiosities than parts for everyday use. The easy solution for higher frequencies is to use a manufacturably-thick crystal on an overtone mode. All crystals have multiple modes, so if you order a 28.060 MHz, third-overtone unit for a little QRP transmitter, you'll get a crystal with a fundamental resonance somewhere near 9.35333 MHz, but its manufacturer will have adjusted the thickness to plant the third overtone exactly on the ordered frequency. An accomplished manufacturer can do tricks with the flatness of the disc faces to make the wanted overtone mode a little more active and the other modes a little less active. (As some builders discover, however, this does not *guarantee* that the wanted mode is the most active!)

Quartz's piezoelectric property provides a simple way of driving the crystal electrically. Early crystals were placed between a pair of electrodes in a case. This gave amateurs the opportunity to buy surplus crystals, open

them and grind them a little to reduce their thickness, thus moving them to higher frequencies. The frequency could be reduced very slightly by loading the face with extra mass, such as by blackening it with a soft pencil. Modern crystals have metal electrodes deposited directly onto their surfaces (Figure 9.21B), and such tricks no longer work.

The piezoelectric effect works both ways. Deformation of the crystal produces voltage across its electrodes, so the mechanical energy in the resonating crystal can also be extracted electrically by the same electrodes. Seen electrically, at the electrodes, the mechanical resonances look like electrical resonances. Their Q is very high. A Q of 10,000 would characterize a *poor* crystal today; 100,000 is often reached by high-quality parts. For comparison, a Q of over 200 for an LC tank is considered good.

### 9.4.2 Frequency Accuracy

A crystal's frequency accuracy is as outstanding as its Q. Several factors determine a crystal's frequency accuracy. First, the manufacturer makes parts with certain tolerances:  $\pm 200$  ppm for a low-quality crystal for use as in a microprocessor clock oscillator,  $\pm 10$  ppm for a good-quality part for professional radio use. Anything much better than this starts to get expensive! A crystal's resonant frequency is influenced by the impedance presented to its terminals, and manufacturers assume that once a crystal is brought within several parts per million of the nominal frequency, its user will perform fine adjustments electrically.

Second, a crystal ages after manufacture. Aging could give increasing or decreasing frequency; whichever, a given crystal usually keeps aging in the same direction. Aging is rapid at first and then slows down. Aging is influenced by the care in polishing the surface of the crystal (time and money) and by its holder style. The cheapest holder is a soldered-together, two-part metal can with glass bead insulation for the connection pins. Soldering debris lands on the crystal and affects its frequency. Alternatively, a two-part metal case can be made with flanges that are pressed together until they fuse, a process called *cold-welding*. This is much cleaner and improves aging rates roughly fivefold compared to soldered cans. An all-glass case can be made in two parts and fused together by heating in a vacuum. The vacuum raises the Q, and the cleanliness results in aging that's roughly 10 times slower than that achievable with a soldered can. The best crystal holders borrow from vacuum-tube assembly processes and have a *getter*, a highly reactive chemical substance that traps remaining gas molecules, but such crystals are used only for special purposes.

Third, temperature influences a crystal. A

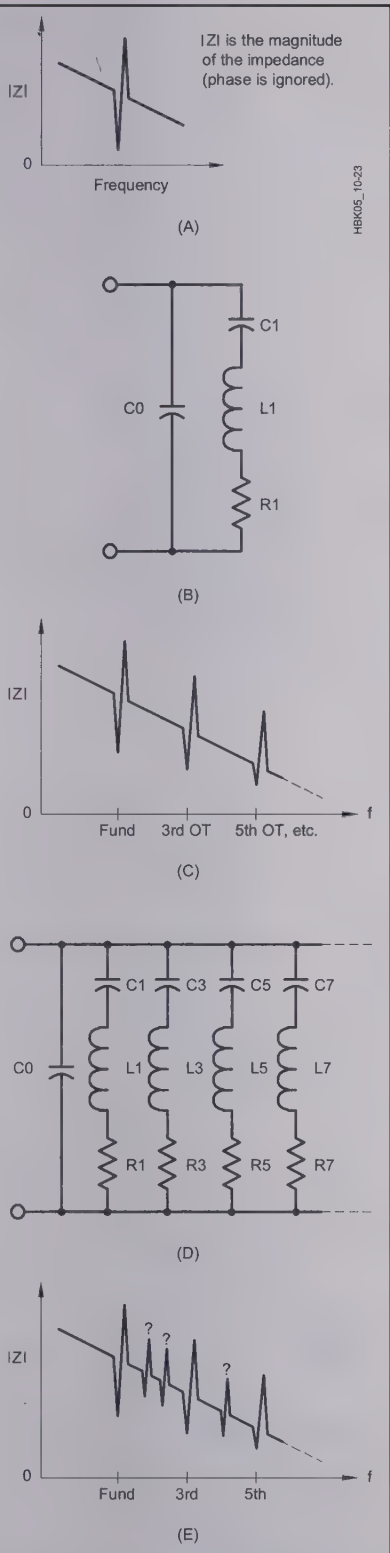

**Figure 9.22** — Slight changes in a crystal cut's orientation shift its frequency-versus-temperature curve.

reasonable, professional quality part might be specified to shift not more than  $\pm 10$  ppm over 0 to 70 °C. An AT-cut crystal has an S-shaped frequency-versus-temperature characteristic, which can be varied by slightly changing the crystal cut's orientation. **Figure 9.22** shows the general shape and the effect of changing the cut angle by only a few seconds of arc. Notice how all the curves converge at 25 °C. This is because this temperature is normally chosen as the reference for specifying a crystal. The temperature stability specification sets how accurate the manufacturer must make the cut. Better stability may be needed for a crystal used as a receiver frequency standard, frequency counter clock and so on. A crystal's temperature characteristic shows a little hysteresis. In other words, there's a bit of offset to the curve depending on whether temperature is increasing or decreasing. This is usually of no consequence except in the highest-precision circuits.

It is the temperature of the quartz that is important, and as the usual holders for crystals all give effective thermal insulation, only a couple of milliwatts dissipation by the crystal itself can be tolerated before self-heating becomes troublesome. Because such heating occurs in the quartz itself and does not come from the surrounding environment, it defeats the effects of temperature compensators and ovens.

The techniques shown earlier for VFO temperature compensation can also be applied to crystal oscillators. An after-compensation drift of 1 ppm is routine and 0.5 ppm is good. The result is a *temperature-compensated crystal oscillator (TCXO)*. Recently, oscillators have appeared with built-in digital thermometers, microprocessors and ROM look-up tables customized on a unit-by-unit basis to control a tuning diode via a digital-to-analog converter (DAC) for temperature compensation. These *digitally temperature-compensated oscillators (DTCXOs)* can reach 0.1 ppm over the temperature range. With automated production

HBK05\_10-23

and adjustment, they promise to become the cheapest way to achieve this level of stability.

Oscillators have long been placed in temperature-controlled ovens, which are typically held at 80 °C. Stability of several parts per billion can be achieved over temperature, but this is a limited benefit as aging can easily dominate the accuracy. These are usually called *oven-controlled crystal oscillators (OCXOs)*.

Fourth, the crystal is influenced by the impedance presented to it by the circuit in which it is used. This means that care is needed to make the rest of an oscillator circuit stable, in terms of impedance and phase shift.

Gravity can slightly affect crystal resonance. Turning an oscillator upside down usually produces a small frequency shift, usually much less than 1 ppm; turning the oscillator back over reverses this. This effect is quantified for the highest-quality reference oscillators.

### 9.4.3 The Equivalent Circuit of a Crystal

Because a crystal is a passive, two-terminal device, its electrical appearance is that of an impedance that varies with frequency. **Figure 9.23A** shows a very simplified sketch of the magnitude (phase is ignored) of the impedance of a quartz crystal. The general trend of dropping impedance with increasing frequency implies capacitance across the crystal. The sharp fall to a low value resembles a series-tuned tank, and the sharp peak resembles a parallel-tuned tank. These are referred to as series and parallel resonances. **Figure 9.23B** shows a simple circuit that will produce this impedance characteristic. The impedance looks purely resistive at the exact centers of both resonances, and the region between them has impedance increasing with frequency, which looks inductive.

C1 (sometimes called *motional capacitance, C<sub>m</sub>*, to distinguish it from the lumped capacitance it approximates) and L1 (*motional inductance, L<sub>m</sub>*) create the series resonance, and as C0 and R1 are both fairly small, the impedance at the bottom of the dip is very close to R1. At parallel resonance, L1 is resonating with C1 and C0 in series, hence the higher frequency. The impedance of the parallel tank is extremely high; the terminals are connected to a capacitive tap, which

causes them to see only a small fraction of what is still a very large impedance. The overtones should not be neglected, so **Figures 9.23C** and **9.23D** include them. Each overtone has series and parallel resonances and so appears as a series tank in the equivalent circuit. C0 again provides the shifted parallel resonance.

This is still simplified, because real-life crystals have a number of spurious, unwanted modes that add yet more resonances, as shown in **Figure 9.23E**. These are not well controlled and may vary a lot even between crystals made to the same specification. Crystal manufacturers work hard to suppress these spurs and have evolved a number of recipes for shaping crystals to minimize them. Just where they switch from one design to another varies from manufacturer to manufacturer.

Always remember that the equivalent circuit is just a representation of crystal behavior and does not represent circuit components actually present. Its only use is as an aid in designing and analyzing circuits using crystals. **Table 9.1** lists typical equivalent-circuit values for a variety of crystals. It is impossible to build a circuit with 0.026 to 0.0006 pF capacitors; such values would simply be swamped by strays. Similarly, the inductor must have a Q that is orders of magnitude better than is practically achievable, and impossibly low stray C in its winding.

The values given in **Table 9.1** are nothing more than rough guides. A crystal's frequency is tightly specified, but this still allows inductance to be traded for capacitance. A good manufacturer could hold these characteristics within a ±25% band or could vary them over a 5:1 range by special design. Similarly marked parts from different sources vary widely in motional inductance and capacitance.

Quartz is not the only material that behaves in this way, but it is the best. Resonators can be made out of lithium tantalate and a group of similar materials that have lower Q, allowing them to be *pulled* over a larger frequency range in VXOs. Much more common, however, are ceramic resonators based on the technology of the well-known ceramic IF filters. These have much lower Q than quartz and much poorer frequency precision. They serve mainly as clock resonators for cheap microprocessor systems in which every last cent must be saved. A ceramic resonator

**Table 9.1**  
Typical Equivalent Circuit Values for a Variety of Crystals

Crystal Type	Series L	Series C (pF)	Series R (Ω)	Shunt C (pF)
1 MHz fundamental	3.5 H	0.007	340	3.0
10 MHz fundamental	9.8 mH	0.026	27	6.3
30 MHz third overtone	14.9 mH	0.0018	27	6.2
100 MHz fifth overtone	4.28 mH	0.0006	45	7.0

**Figure 9.23** — Exploring a crystal's impedance (A) and equivalent circuit (B) through simplified diagrams. C and D extend the investigation to include overtones; E, to spurious responses not easily predictable by theory or controllable through manufacture. A crystal may oscillate on any of its resonances under the right conditions.

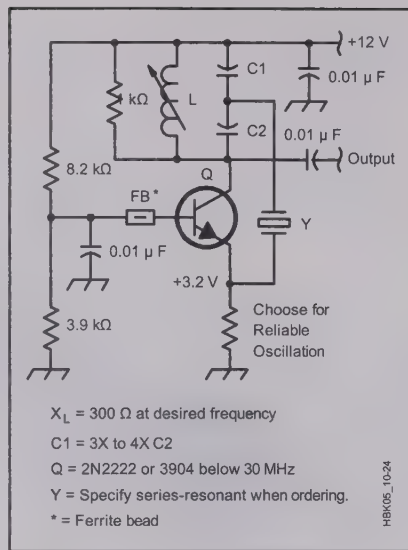

could be used as the basis of a wide range, cheap VXO, but its frequency stability would not be as good as a good LC VFO.

### 9.4.4 Crystal Oscillator Circuits

(See also the papers "What You Always Wanted to Know About Colpitts Oscillators," "Quartz Crystal Oscillator Design," "A Novel Grounded Base Oscillator Design for VHF/UHF Frequencies," and "Some Thoughts on Designing Very High Performance VHF Oscillators" by Ulrich Rohde, NIUL, included with the downloadable supplemental material accompanying this book.)

Crystal oscillator circuits are usually categorized as series- or parallel-mode types, depending on whether the crystal's low- or high-impedance resonance comes into play at the operating frequency. The series mode is now the most common; parallel-mode operation was more often used with vacuum tubes. **Figure 9.24** shows a basic series-mode oscillator. Some people would say that it is an overtone circuit, used to run a crystal on one of its overtones, but this is not necessarily true. The tank (L-C1-C2) tunes the collector of the common-base amplifier. C1 is larger than C2, so the tank is tapped in a way that transforms to lower impedance, decreasing signal voltage, but increasing current. The current is fed back into the emitter via the crystal. The common-base stage provides a current gain of less than unity, so the transformer in the form of the tapped tank is essential to give loop gain. There are *two* tuned circuits, the obvious collector tank and the series-mode one "in" the crystal. The tank kills the amplifier's gain away from its tuned frequency, and the crystal will only pass current at the series resonant frequencies of its many modes. The tank resonance is much broader than any of the crystal's modes, so it can be thought of as the crystal setting the frequency, but the tank selecting which of the crystal's modes is active. The tank could be tuned to the crystal's fundamental, or one of its overtones.

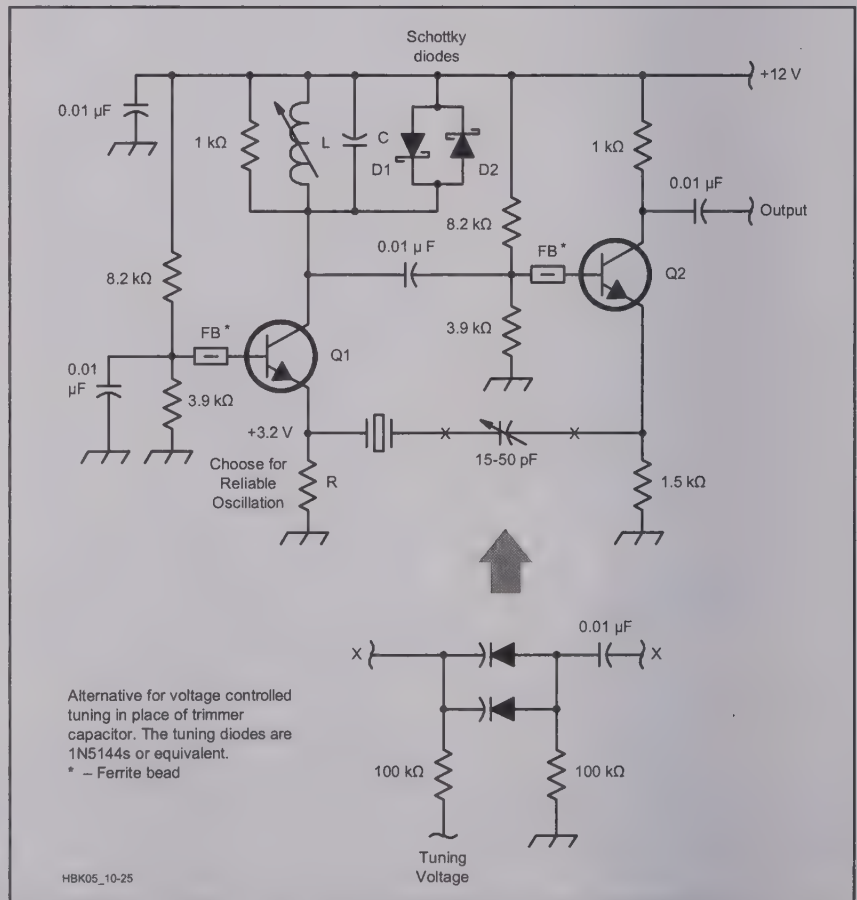

Fundamental oscillators can be built without a tank quite successfully, but there is always the occasional one that starts up on an overtone or spurious mode. Some simple oscillators have been known to change modes while running (an effect triggered by changes in temperature or loading) or to not always start in the same mode! A series-mode oscillator should present low impedance to the crystal at the operating frequency. In **Figure 9.24**, the tapped collector tank presents a transformed fraction of the 1-k $\Omega$  collector load resistor to one end of the crystal, and the emitter presents a low impedance to the other. To build a practical oscillator from this circuit, choose an inductor with a reactance of about 300  $\Omega$  at the wanted frequency and

**Figure 9.24** — A basic series-mode crystal oscillator. A 2N5179 can be used in this circuit if a lower supply voltage is used; see text.

calculate C1 in series with C2 to resonate with it. Choose C1 to be 3 to 4 times larger than C2. The amplifier's quiescent ("idling") current sets the gain and hence the operating level. This is not easily calculable, but can be found by experiment. Too little quiescent current and the oscillator will not start reliably; too much and the transistor can drive itself into saturation. If an oscilloscope is available, it can be used to check the collector waveform; otherwise, some form of RF voltmeter can be used to allow the collector voltage to be set to 2 to 3 V RMS. 3.3 k $\Omega$  would be a suitable starting point for the emitter bias resistor. The transistor type is not critical; 2N2222A or 2N3904 would be fine up to 30 MHz; a 2N5179 would allow operation as an overtone oscillator to over 100 MHz (because of the low collector voltage rating of the 2N5179, a supply voltage lower than 12 V is required). The ferrite bead on the base gives some protection against parasitic oscillation at UHF.

If the crystal is shorted, this circuit should still oscillate. This gives an easy way of adjust-

**Figure 9.25** — A Butler crystal oscillator with Q2 connected as an emitter follower to drive the crystal's low series-resonant impedance.

ing the tank; it is even better to temporarily replace the crystal with a small-value (tens of ohms) resistor to simulate its *equivalent series resistance* (ESR), and adjust L until the circuit oscillates close to the wanted frequency. Then restore the crystal and set the quiescent current. If a lot of these oscillators were built, it would sometimes be necessary to adjust the current individually due to the different equivalent series resistance of individual crystals. One variant of this circuit has the emitter connected directly to the C1/C2 junction, while

the crystal is a decoupler for the transistor base (the existing capacitor and ferrite bead not being used). This works, but with a greater risk of parasitic oscillation.

We commonly want to trim a crystal oscillator's frequency. While off-tuning the tank a little will pull the frequency slightly, too much detuning spoils the mode control and can stop oscillation (or worse, make the circuit unreliable). The answer to this is to add a trimmer capacitor, which will act as part of the equivalent series tuned circuit, in series

with the crystal. This will shift the frequency in one way only, so the crystal frequency must be re-specified to allow the frequency to be varying around the required value. It is common to specify a crystal's frequency with a standard load (30 pF is commonly specified), so that the manufacturer grinds the crystal such that the series resonance of the specified mode is accurate when measured with a capacitor of this value in series. A 15 to 50 pF trimmer can be used in series with the crystal to give fine frequency adjustment. Too

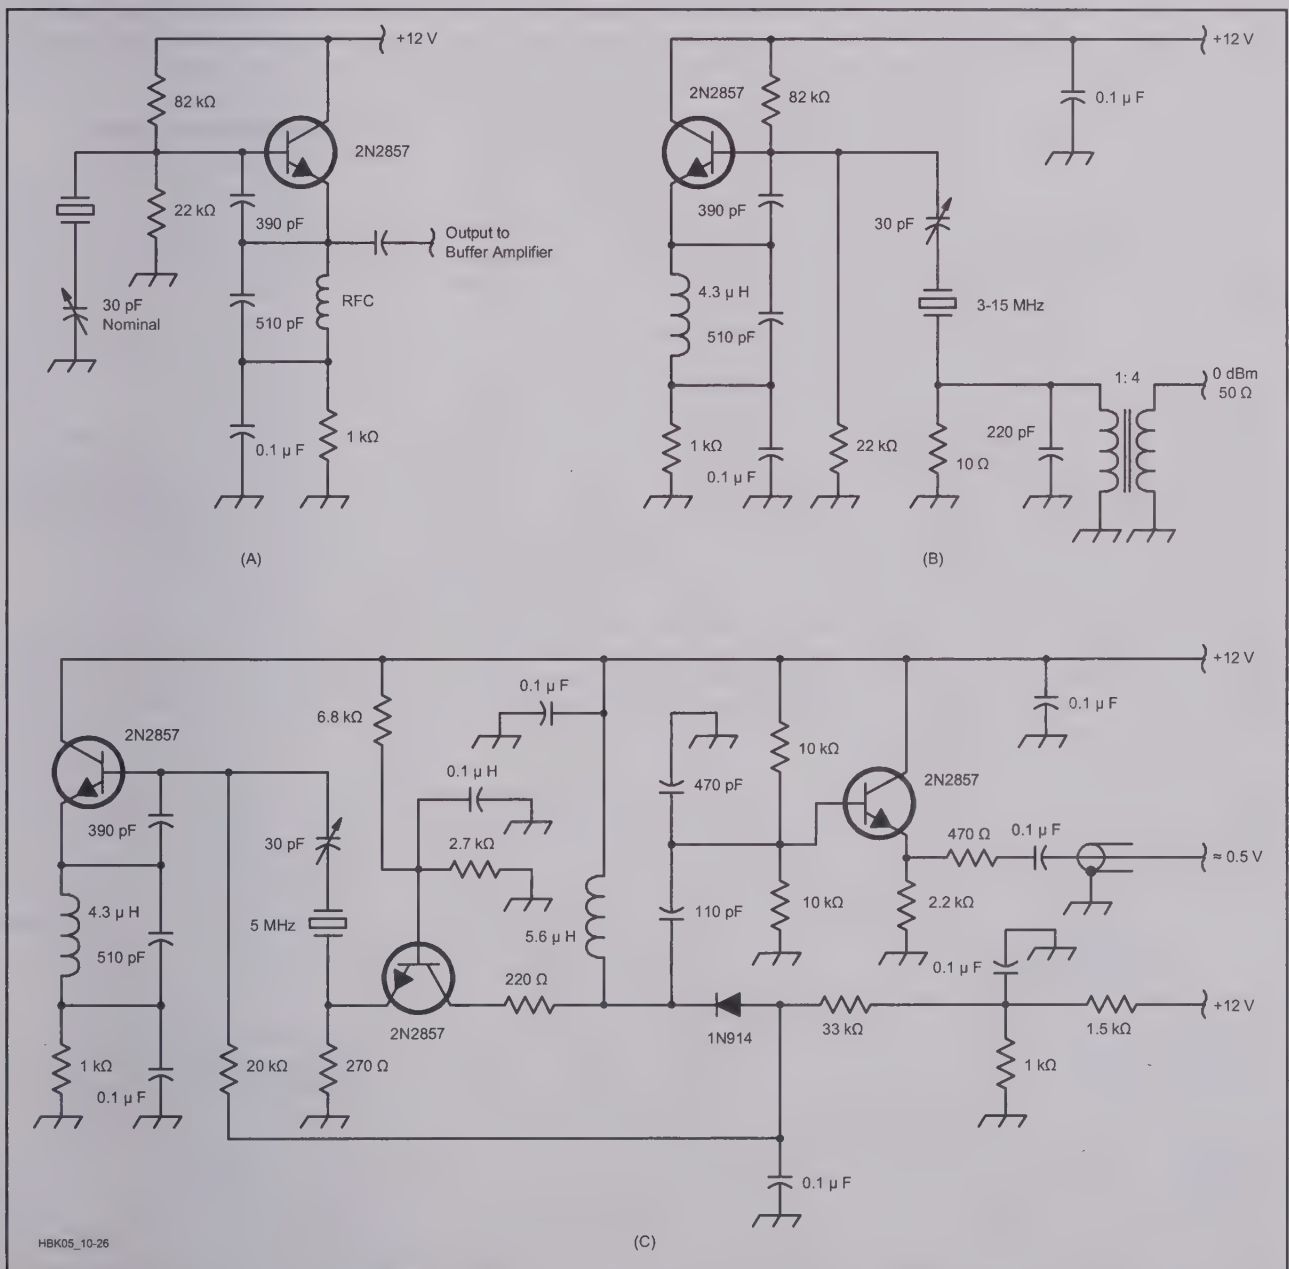

Figure 9.26 — The crystal in the series-tuned Colpitts oscillator at A operates in its series-resonant mode. B shows N1UL's low-noise version, which uses the crystal as a filter and features high harmonic suppression (from Rohde, *Microwave and Wireless Synthesizers Theory and Design*; see references). The circuit at C builds on the B version by adding a common-base output amplifier and ALC loop.

little capacitance can stop oscillation or prevent reliable starting. The Q of crystals is so high that marginal oscillators can take several seconds to start!

This circuit can be improved by driving the crystal's lower series-resonant impedance with an emitter follower as in **Figure 9.25**. This is the *Butler* oscillator. Again the tank controls the mode to either force the wanted overtone or protect the fundamental mode. The tank need not be tapped because Q2 provides current gain, although the circuit is sometimes seen with C split, driving Q2 from a tap. The position between the emitters offers a good, low-impedance environment to keep the crystal's in-circuit Q high. R, in the emitter of Q1, is again selected to give reliable oscillation. The circuit has been shown with a capacitive load for the crystal, to suit a unit specified for a 30 pF load. An alternative circuit to give electrical fine tuning is also shown. The diodes across the tank act as limiters to stabilize the operating amplitude and limit the power dissipated in the crystal by clipping the drive voltage to Q2. The tank should be adjusted to peak at the operating frequency, not used to trim the frequency. The capacitance in series with the crystal is the proper frequency trimmer.

The Butler circuit works well, and has been used in critical applications to 140 MHz (seventh-overtone crystal, 2N5179 transistor). Although the component count is high, the extra parts are cheap ones. Increasing the capacitance in series with the crystal reduces the oscillation frequency but has a progressively diminishing effect. Decreasing the capacitance pulls the frequency higher, to a point at which oscillation stops; before this point is reached, start-up will become unreliable. The possible amount of adjustment, called *pulling range*, depends on the crystal; it can range from less than 10 to several hundred parts per million. Overtone crystals have much less pulling range than fundamental crystals on the same frequency; the reduction in pulling is roughly proportional to the square of the overtone number.

### LOW-NOISE CRYSTAL OSCILLATORS

**Figure 9.26A** shows a crystal operating in its series mode in a series-tuned Colpitts circuit. Because it does not include an LC tank to prevent operation on unwanted modes, this circuit is intended for fundamental mode operation only and relies on that mode being the most active. If the crystal is ordered for 30 pF loading, the frequency trimming capacitor can be adjusted to compensate for the loading of the capacitive divider of the Colpitts circuit. An unloaded crystal without a trimmer would operate slightly off the exact series resonant frequency in order to create an inductive impedance to resonate with the divider capacitors. Ulrich Rohde, N1UL, in

**Figure 4-47** of his book *Digital PLL Frequency Synthesizers — Theory and Design*, published an elegant alternative method of extracting an output signal from this type of circuit, shown in **Figure 9.26B**. This taps off a signal from the current in the crystal itself. This can be thought of as using the crystal as a band-pass filter for the oscillator output. The RF choke in the emitter keeps the emitter bias resistor from loading the tank and degrading the Q. In this case (3 MHz operation), it has been chosen to resonate close to 3 MHz with the parallel capacitor (510 pF) as a means of forcing operation on the wanted mode. The 10-Ω resistor and the transformed load impedance will reduce the in-circuit Q of the crystal, so a further development substituted a common base amplifier for the resistor and transformer. This is shown in **Figure 9.26C**. The common-base amplifier is run at a large quiescent current to give a very low input impedance. Its collector is tuned to give an output with low harmonic content and an emitter follower is used to buffer this from the load. This oscillator sports a simple ALC system, in which the amplified and rectified signal is used to reduce the bias voltage on the oscillator transistor's base. This circuit is described as achieving a phase noise level of -168 dBc/Hz a few kilohertz out from the carrier. This may seem far beyond what may ever be needed, but frequency multiplication to high frequencies, whether by classic multipliers or by frequency synthesizers, multiplies the deviation of any FM/PM sidebands as well as the carrier frequency. This means that phase noise worsens by 20 dB for each tenfold multiplication of frequency. A clean crystal oscillator and a multiplier chain is still the best way of generating clean microwave sig-

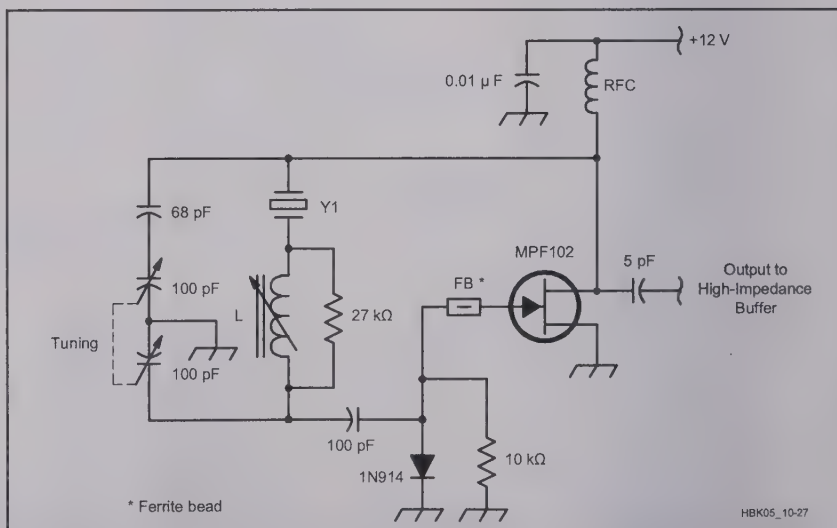

nals for use with narrow-band modulation schemes.

It has already been mentioned that overtone crystals are much harder to pull than fundamental ones. This is another way of saying that overtone crystals are less influenced by their surrounding circuit, which is helpful in a frequency-standard oscillator like this one. Even though 5 MHz is in the main range of fundamental-mode crystals and this circuit will work well with them, an overtone crystal has been used. To further help stability, the power dissipated in the crystal is kept to about 50 μW. The common-base stage is effectively driven from a higher impedance than its own input impedance, under which conditions it gives a very low noise figure.

### 9.4.5 Variable-frequency Crystal Oscillators (VXOs)

Some crystal oscillators have frequency trimmers. If the trimmer is replaced by a variable capacitor as a front-panel control, we have a *variable crystal oscillator (VXO)*: a crystal-based VFO with a narrow tuning range, but good stability and noise performance. VXOs are often used in small, simple QRP transmitters to tune a few kilohertz around common calling frequencies. Artful constructors, using optimized circuits and components, have achieved 1000-ppm tuning ranges. Poor-quality "soft" crystals are more pull-able than high-Q ones. Overtone crystals are not suited to VXOs. For frequencies beyond the usual limit for fundamental mode crystals, use a fundamental unit and frequency multipliers.

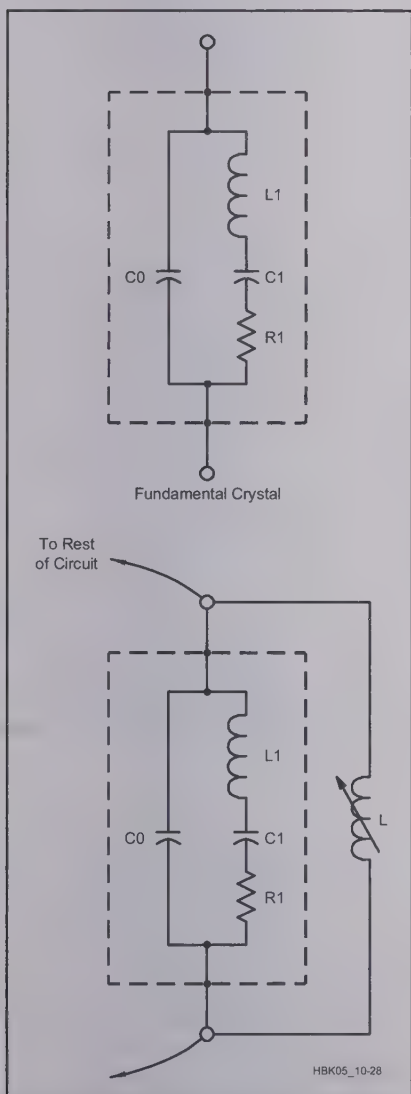

ICOM and Mizuho made some 2 meter SSB transceivers based on multiplied VXO local oscillators. This system is simple and

**Figure 9.27** — A wide-range variable-crystal oscillator (VXO) by W7ZOI and W1FB. It was originally designed for use in low-power radios without the usual wide-range VFO.

can yield better performance than many expensive synthesized radios. SSB filters are available at 9 or 10.7 MHz, to yield sufficient image rejection with a single conversion. Choice of VXO frequency depends on whether the LO is to be above or below signal frequency and how much multiplication can be tolerated. Below 8 MHz, multiplier filtering is difficult. Above 15 MHz, the tuning range per crystal narrows. A 50-200 kHz range per crystal should work with a modern front-end design feeding a good 9 MHz IF, for a contest quality 2 meter SSB receiver.

The circuit in **Figure 9.27** is a JFET VXO from Wes Hayward, W7ZOI, and Doug DeMaw, W1FB, optimized for wide-range pulling. Published in *Solid State Design for the Radio Amateur*, many have been built and its ability to pull crystals as far as possible

**Figure 9.28** — Using an inductor to “tune out” C0 can increase a crystal oscillator’s pulling range.

has been proven. Ulrich Rohde, NIUL, has shown that the diode arrangement as used here to make signal-dependent negative bias for the gate confers a phase-noise disadvantage, but oscillators like this that pull crystals as far as possible need any available means to stabilize their amplitude and aid start-up. In this case, the noise penalty is worth paying. This circuit can achieve a 2000-ppm tuning range with amenable crystals. If you have some overtone crystals in your junk box whose fundamental frequency is close to the wanted value, they are worth trying.

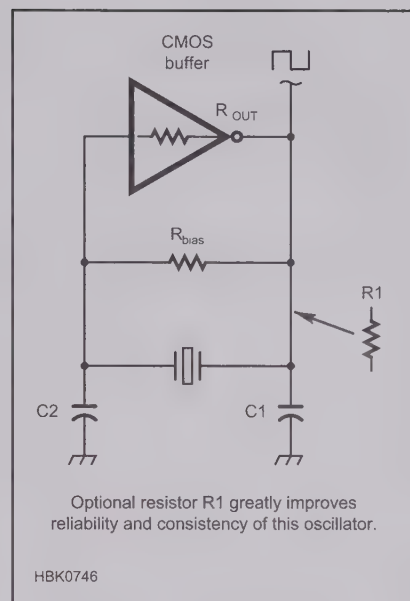

This sort of circuit doesn’t necessarily stop pulling at the extremes of the possible tuning range; sometimes the range is set by the onset of undesirable behavior such as jumping mode or simply stopping oscillating. L was a 16  $\mu\text{H}$  slug-tuned inductor for 10 MHz operation. It is important to minimize the stray and inter-winding capacitance of L since this dilutes the range of impedance presented to the crystal.

One trick that can be used to aid the pulling range of oscillators is to tune out the C0 of the equivalent circuit with an added inductor. **Figure 9.28** shows how. L is chosen to resonate with C0 for the individual crystal, turning it into a high-impedance parallel-tuned circuit. The Q of this circuit is orders of magnitude less than the Q of the true series resonance of the crystal, so its tuning is much broader. The value of C0 is usually just a few picofarads, so L has to be a fairly large value considering the frequency at which it is resonated. This means that L has to have low stray capacitance or else it will self-resonate at a lower frequency. The tolerance on C0 and the variations of the stray C of the inductor means that individual adjustment is needed. This technique can also work wonders in crystal ladder filters.

### 9.4.6 Logic-Gate Crystal Oscillators

The frequency-determining network of an RC oscillator has a Q of less than one, which means that phase shift changes very slowly with different frequencies (see the prior section on RC Oscillators). The Pierce crystal oscillator discussed previously is a converted phase-shift oscillator, with the crystal taking the place of one series resistor. The crystal provides a much higher phase shift than an RC stage, so the crystal “controls” the frequency of oscillation.

The actual frequency of oscillation is the frequency at which the Barkhausen criteria are met. The crystal must operate near its series resonance in order for the loop gain to be unity. Oscillation then settles at the frequency where the crystal phase shift, added to the RC phase shifts, equals 180 degrees. The crystal usually provides between 45 and 60 degrees of phase shift, so the oscillation

**Figure 9.29** — The simplified Pierce oscillator using a logic-gate for the inverting amplifier. Adding R1 improves oscillator design and reliability.

frequency is above the series resonance and below the parallel resonance of the crystal where the crystal behaves as a large inductor. (See the figure showing crystal response in the section Quartz Crystal Filters in the **Analog and Digital Filtering** chapter.)

The Pierce circuit is rarely seen in this full form. Instead, a cut-down version is the most common circuit in many microprocessors and other digital ICs that need a crystal-controlled clock. **Figure 9.29** shows this minimalist Pierce, using a CMOS logic inverter as the amplifier. R<sub>bias</sub> provides dc negative feedback to bias the gate into its linear region. This value is not critical, anything between 100 k $\Omega$  and 10 M $\Omega$  works fine. The RC phase shifts needed to make this work come from R<sub>out</sub>-C1 and R<sub>crystal</sub>-C2. This circuit has a reputation of being temperamental, mainly because neither R<sub>out</sub> nor R<sub>crystal</sub> are well documented or controlled in manufacturing. There is also a general belief that this circuit requires C1 = C2, which is not true.

A great improvement in performance is achieved by adding one resistor, R1, as shown in **Figure 9.29**. R<sub>bias</sub> remains connected directly across the CMOS inverter. R1 is inserted in series from the gate output to the feedback network. The benefits are multiple:

- The edge speed of modern CMOS gates is extremely fast, so R1C1 eliminates the possibility of this fast edge exciting overtone operation.
- Phase shift into the crystal can be intentionally designed by R1 and C1 value selection.

- Drive from the inverter output is reduced into the crystal, possibly saving it from being damaged.
  - Loop gain can now be controlled for best waveform and startup characteristics.
- Design values are strongly dependent on

the actual crystal frequency needed. C2 is selected first, to provide around 60 degrees of phase shift working against the crystal equivalent series resistance (usually a few tens of ohms, but the value needs to be verified!). The time constant R1 C1 is usefully

chosen to be the reciprocal of the crystal radian frequency ( $1/2\pi f_{XTAL}$ ). Higher values of R1 reduce the loop gain and provide better protection for the crystal, until the loop gain gets too small and oscillation stops.

## 9.5 Oscillators at UHF and Above

The traditional way to make signals at higher frequencies is to make a signal at a lower frequency (where oscillators are easier) and multiply it up to the wanted range. Frequency multiplication is still one of the easiest and best ways of making a clean UHF/microwave signal. The design of a multiplier depends on whether the multiplication factor is an odd or even number. For odd multiplication, a Class-C biased amplifier can be used to create a series of harmonics; a filter selects the one wanted. For even multiplication factors, a full-wave-rectifier arrangement of distorting devices can be used to create a series of harmonics with strong even-order components, with a filter selecting the wanted component. At higher frequencies, diode-based passive circuits are commonly used. Oscillators using some of the LC circuits already described can, with care in construction, be used in the VHF range. At UHF, different approaches become necessary.

### 9.5.1 UHF Oscillators: Intentional and Accidental

The biggest change when working at UHF and microwave frequencies is that stray reactances and resistance dominates everything, making lumped circuit elements impractical. Success at these high frequencies requires making peace with the situation and developing a very good sense of where stray circuit elements reside in your layout and their approximate magnitude.

Figure 9.30 shows a pair of oscillators based on a resonant length of line, which is a distributed circuit element. The first one is a return to basics: a resonator, an amplifier and a pair of coupling loops. The amplifier can be a single bipolar or FET device or one of the monolithic microwave integrated circuit (MMIC) amplifiers. The second circuit is really a Hartley oscillator, and one is made as a test oscillator for the 70 cm band from a 10 cm length of wire suspended 10 mm over an unetched PC board as a ground plane, bent down and soldered at one end, with a trimmer at the other end. The FET is a BF981 dual-gate device used as a source follower.

No free-running oscillator is really stable enough on these bands. Oscillators in this range are almost invariably tuned with tuning diodes controlled by phase-locked-loop syn-

thesizers, which are themselves controlled by a crystal oscillator. This transfers the same stability of the crystal oscillator to the UHF oscillator.

There is one extremely common UHF oscillator that is almost always an undesired accident, being a very common form of spurious VHF/UHF oscillation in circuitry intended to process lower-frequency signals. Figure 9.31A shows the circuit in its simplest form. Analyzing this circuit using a comprehensive model of the UHF transistor reveals that the emitter presents an impedance that is small, resistive, and negative to the outside world. If this negative resistance is large enough to more than cancel the effective series resistance of a tank placed on the emitter, oscillation will occur.

At UHF your schematic diagram probably will not show a tank circuit is present. But the high frequency transistor will know it is there, since it “sees” all of the stray reactances present in the layout. Figure 9.31B shows a very basic emitter-follower circuit with some capacitance to ground on both the input and output. If the capacitor shunting the input is

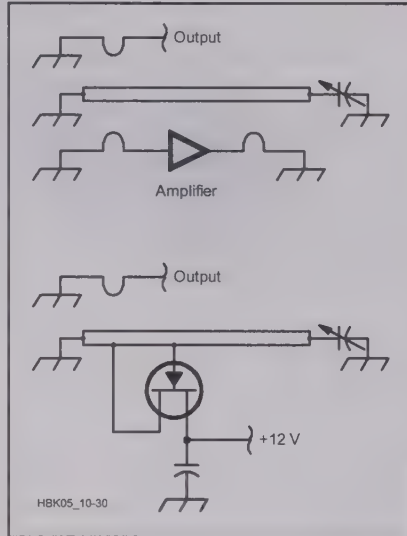

Figure 9.30 — Oscillators that use transmission-line segments as resonators. Such oscillators are more common than many of us may think, as Figure 9.31 reveals.

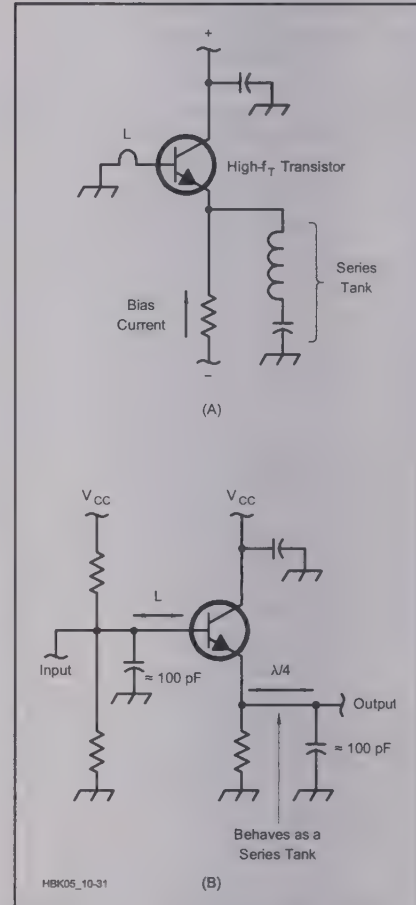

Figure 9.31 — High device gain at UHF and resonances in circuit board traces can result in spurious oscillations even in non-RF equipment.

a distance away from the transistor, the trace to the transistor’s base looks like an inductor. The trace at the emitter of the transistor also looks like an inductor, and any nearby conductor will look like a capacitor to that trace (two conductors separated by a dielectric, which here is air and the PC board material). Any intentional capacitors add to this. If the transistor has gain at any frequency where the phasing from all of these stray reactances is right for oscillation (see Barkhausen criteria in previous sections) then oscillation will happen. This circuit is effectively the same

as that in Figure 9.31A. This is a good reason to use the lowest-frequency transistor that you can for any application.

Stray reactances do not always have to cause headaches. Indeed you can use them, knowing that they are there. The circuit of Figure 9.31A can be deliberately built as a useful wide-tuning oscillator covering say, 500 MHz to 1 GHz! This circuit is well-suited to construction with printed-circuit inductors. Common FR4 glass-epoxy board is lossy at these frequencies; better performance is achieved by using (the much more expensive) glass-Teflon board. If you can get surplus pieces of this type of material, it has many uses at UHF and microwave, but it is difficult to use as the adhesion between the copper and the substrate can be weak. A high-UHF transistor with a 5 GHz  $f_T$  such as the BFR90 is suitable; the base inductor can be 30 mm of 1 mm trace folded into a hairpin shape (inductance, less than 10 nH).

The upshot of this is that there is no longer any branch of electronics where RF design and layout techniques can be ignored safely. A circuit must not just be designed to do what it should do; it must also be designed so that it cannot do what it should not do.

If you have an accidental oscillator, there are three ways of taming such a circuit: adding a small resistor of perhaps 50 to 100  $\Omega$  in the collector lead close to the transistor, or adding a similar resistor in the base lead, or by fitting a ferrite bead over the base lead under the transistor. Extra resistors can disturb dc conditions, depending on the circuit and its operating currents. Ferrite beads have the advantage that they can be easily added to existing equipment and have no effect at dc and low frequencies. Beware of some electrically conductive ferrite materials that can short transistor leads! If an HF oscillator uses beads to prevent any risk of spurs (such as shown in Figure 9.15), the beads should be anchored with a spot of adhesive to prevent movement which can cause small frequency shifts. Ferrite beads of Fair-Rite #43 material are especially suitable for this purpose; they are specified in terms of impedance, not inductance. Ferrites at frequencies above their inductive range become very lossy and can make a lead present a few tens of ohms of resistance.

**9.5.2 Microwave Oscillators**

Using conventional PC-board techniques with surface-mount components and extraordinarily careful layout allows the construction of circuits up to 4 GHz or so. Above this, commercial techniques and fancier materials become necessary unless we take the step to the ultimate distributed circuit — the cavity resonator.

Older than stripline techniques and far more amenable to home construction, cavity-based oscillators can give the highest possible

**Figure 9.32 — Evolution of the cavity resonator.**

**Figure 9.33 — Currents and fields in a cavity.**

performance at microwave frequencies. Air is a very low-loss dielectric with a dielectric constant of 1, so it gives high Q and does not force excessive miniaturization. Figure 9.32 shows a series of structures used by G. R. Jessop, G6JP, to illustrate the evolution of a cavity from a tank made of lumped components. All cavities have a number of different modes of resonance, the orientation of the currents and fields are shown in Figure 9.33. The cavity can take different shapes, but the one shown here has proven to suppress

**Figure 9.34 — A Gunn diode oscillator uses negative resistance and a cavity resonator to produce radio energy.**

unwanted modes well. The gap need not be central and is often right at the top. A screw can be fitted through the top, protruding into the gap, to adjust the frequency.

**SEMICONDUCTOR CAVITY OSCILLATORS**

To make an oscillator using a cavity, an amplifier is needed. Gunn and tunnel diodes have regions in their characteristics where their current falls with increasing bias voltage. This is negative resistance. If such a device is mounted in a loop in a cavity and bias is applied, the negative resistance can more than cancel the effective loss resistance of the cavity, causing oscillation. These diodes are capable of operating at extremely high frequencies and were discovered long before transistors were developed that had any gain at microwave frequencies.

A Gunn-diode cavity oscillator is the basis of many of the Doppler radar modules used to detect traffic or intruders and of the Gunnplexer 10 GHz transceiver modules used by amateurs. Figure 9.34 shows a common configuration. The coupling loop and coax output connector could be replaced with a simple aperture to couple into waveguide or a mixer cavity. Figure 9.35 shows a transistor cavity oscillator version using a modern microwave transistor, which can be either a FET or bipolar device. The two coupling loops are electrically completed by the capacitance of the feedthrough capacitors.

Figure 9.35 — A transistor can also directly excite a cavity resonator.

### DIELECTRIC-RESONATOR OSCILLATORS (DRO)

The dielectric-resonator oscillator (DRO) is a very common microwave oscillator, as it is used in the downconverter of satellite TV receivers. The dielectric resonator itself is a ceramic cylinder, like a miniature hockey puck, several millimeters in diameter. The ceramic has a very high dielectric constant, so the surface (where ceramic meets air in an abrupt dielectric mismatch) reflects electromagnetic waves and makes the ceramic body act as a resonant cavity. It is mounted on a substrate and coupled to the active device of the oscillator by a stripline that runs past it. At 10 GHz, a FET made of gallium arsenide (GaAsFET), rather than silicon, is normally used. The dielectric resonator elements are made at frequencies appropriate to mass applications like satellite TV. The setup charge to manufacture small quantities at special frequencies is likely to be prohibitive for the foreseeable future.

The challenge with these devices is to devise new ways of using oscillators on industry standard frequencies. Their chief attraction is their low cost in large quantities and compatibility with microwave stripline (microstrip) techniques. Frequency stability and Q are competitive with good cavities, but are inferior to that achievable with a crystal oscillator and chain of frequency multipliers.

### YIG TUNED OSCILLATORS (YTO)

The yttrium-iron garnet (YIG) oscillator is a fundamental microwave source with a very wide tuning range and a linear tuning characteristic. Many YIG oscillators can be tuned over more than an octave and some tune more than five octaves! They are complete units that appear as heavy blocks of metal with low-frequency connections for power supplies and tuning, and an SMA connector for the RF output. The manufacturer's label usually states the tuning range and often the power supply voltages. This is very helpful because, with new units being very expensive, it is important to be able to identify the characteristics of surplus units. The majority

Figure 9.36 — A yttrium-iron-garnet (YIG) sphere serves as the resonator in the sweep oscillators used in many spectrum analyzers.

of YTOs operate within the 2 to 18 GHz region, although units down to 500 MHz and up to 40 GHz are occasionally found. At microwave frequencies there is no octave-tunable device that can equal their signal cleanliness and stability. A typical stability for a 3 GHz YTO is less than 1 kHz per second drift. This may seem poor — until we realize that this is 0.33 ppm per second. Still, any YIG application involving narrow-band modulation will require some form of frequency stabilizer.

Nearly all surplus RF spectrum analyzers use YTOs as their first LO. For example, a 0 to 1500 MHz analyzer usually uses a 2 to 3.5 GHz YTO with a 2.0 GHz first IF. To understand the YTO tuning circuits, should there be need for troubleshooting and repair, a basic understanding of YIG oscillators definitely helps.

Figure 9.36 shows the construction of a YIG oscillator. A YTO is based on a YIG sphere that is carefully oriented within a coupling loop. This resonator is connected to a

negative-resistance device and the whole assembly is placed between the poles of an electromagnet. Negative-resistance (Gunn) diodes were originally used in these oscillators, but transistor circuits are now essentially universal and use much less power. The support for the YIG sphere often contains a controlled heater to reduce temperature variation. YIG spheres are resonant at a frequency controlled not only by their physical dimensions, but also by any magnetic field around them. Hence the electromagnet: by varying the current through the electromagnet's windings, a controlled variable magnetic field is applied across the YIG sphere. This tunes the oscillator across a very wide range. The frequency/current relationship can have excellent linearity, typically around 20 MHz/mA.

Magnetically-tuned oscillators bring some unique problems with them. The first problem is that magnetic fields, especially at low frequencies, are extremely difficult to shield. Therefore YTO tuning is influenced by any local magnetic fields, causing frequency

modulation. The YTO's magnetic core must be carefully designed to be all-enclosing in an attempt at self-shielding, and then one or more nested mu-metal cans are fitted around everything. It is still important to place the YTO away from obvious sources of magnetic fields, like power transformers. Cooling fans are also sources of fluctuating magnetic fields, with some fans generating fields 20 dB higher than from a well-designed 200 W 50/60-Hz transformer.

The second new problem is that the YTO's internal tuning coil needs significant current from the power supply to create the strong tuning field. This can be eased by adding a permanent magnet as a fixed "bias" field, but the bias shifts as the magnet ages. The main tuning coil still has many turns, and therefore high inductance (often more than 0.1 henrys). Large inductances require a high supply voltage for rapid tuning, with correspondingly high power consumption. The usual compromise is to have dual coils: One with many turns for slow tuning over a wide range, and a second coil with far fewer turns for fast tuning or FM over a limited range. This "FM coil" has a sensitivity around 1% to 2% of the main coil, perhaps 500 kHz/mA.

### 9.5.3 Klystrons, Magnetrons, and Traveling Wave Tubes

There are a number of thermionic (vacuum-tube) devices that are widely used as amplifiers or fundamental oscillators at microwave frequencies. Standard vacuum tubes (see the **RF Amplifiers** chapter for an introduction to vacuum tubes) work well for frequencies up to hundreds of megahertz. At frequencies higher than this, the amount of time that the electrons take to move between the cathode and the plate becomes a limiting factor. There are several special tubes designed to work at microwave frequencies, usually providing more power than can be obtained from solid-state devices.

## 9.6 Frequency Synthesizers

Like many of our modern technologies, the origins of frequency synthesis can be traced back to WW II. The driving force was the desire for stable, rapidly switchable and accurate frequency control technology to meet the demands of narrow-band, frequency-agile HF communications systems without resorting to large banks of switched crystals. Early synthesizers were cumbersome and expensive, and therefore their use was limited to only the most sophisticated communications systems. With the help of the same technologies that have taken computers from

Two of the following tubes (klystrons and traveling wave tubes) use the principle of *velocity-modulation* to extract RF energy from an electron beam. The general principles of velocity modulation and basic properties of devices using it are presented in the online tutorial [www.radartutorial.eu/druck/Book5.pdf](http://www.radartutorial.eu/druck/Book5.pdf). Additional resources are described below.

### THE KLYSTRON

The klystron tube uses the principle of velocity modulation of the electrons to avoid transit time limitations. The beam of electrons travels down a metal drift tube that has interaction gaps along its sides. RF voltages are applied to the gaps and the electric fields that they generate accelerate or decelerate the passing electrons. The relative positions of the electrons shift due to their changing velocities, causing the electron density of the beam to vary. This variation of electron beam density is used to perform amplification or oscillation.

Klystron tubes can be relatively large, and they can easily provide hundreds of watts to hundreds of kilowatts of microwave power. These power levels are useful for UHF broadcasting and particle accelerators, for example. Unfortunately klystrons have relatively narrow bandwidths, and may not be re-tunable for operation on amateur frequencies. A video titled "How a Klystron Tube Works" can be found online on YouTube.com and a detailed history and tutorial is available at [www.slac.stanford.edu/cgi-wrap/getdoc/slac-pub-7731.pdf](http://www.slac.stanford.edu/cgi-wrap/getdoc/slac-pub-7731.pdf).

### THE MAGNETRON

The magnetron tube is an efficient oscillator for microwave frequencies. Magnetrons are most commonly found in microwave ovens and high-powered radar equipment. The anode of a magnetron is made up of a number of coupled resonant cavities that surround the cathode. The applied magnetic field

causes the electrons to rotate around the cathode and the energy that they give off as they approach the anode adds to the RF electric field. The RF power is obtained from the anode through a vacuum window.

Magnetrons are self-oscillating with the frequency determined by the construction of their anodes; however, they can be tuned by coupling either inductance or capacitance to the resonant anode. The range of frequencies depends on how fast the tuning must be accomplished. The tube may be tuned slowly over a range of approximately 10% of the center frequency. If faster tuning is necessary, such as is required for frequency modulation, the range decreases to about 5%.

Excellent drawings showing how magnetrons work are available at [hyperphysics.phy-astr.gsu.edu/hbase/waves/magnetron.html](http://hyperphysics.phy-astr.gsu.edu/hbase/waves/magnetron.html) and a thorough introduction for the interested reader is can be downloaded from [www.cpii.com/docs/related/2/Mag%20tech%20art.pdf](http://www.cpii.com/docs/related/2/Mag%20tech%20art.pdf).

### THE TRAVELING WAVE TUBE

A third type of tube operating in the microwave range is the traveling wave tube (TWT). For wide-band amplifiers in the microwave range this is the tube of choice. Either permanent magnets or electromagnets are used to focus the beam of electrons that travels through the TWT. This electron beam passes through a helical slow-wave structure, in which electrons are accelerated or decelerated, providing density modulation due to the applied RF signal, similar to that in the klystron. The modulated electron beam induces voltages in the helix that provides an amplified output signal whose gain is proportional to the length of the slow-wave structure. After the RF energy is extracted from the electron beam by the helix, the electrons are collected and recycled to the cathode. Traveling wave tubes can often be operated outside their designed frequencies by carefully optimizing the beam voltage.

room-sized to now fitting into the palms of our hands, frequency synthesis techniques have become one of the most enabling technologies in modern communications equipment.

Every communications device manufactured today, be it a handheld transceiver, cell phone, pager, AM/FM entertainment radio, scanner, television, HF communications equipment, or test equipment, contains a frequency synthesizer. Synthesis is the technology that allows an easy interface with both computers and microprocessor controllers. It

provides amateurs with many desirable features, such as the feel of an analog knob with precision 10-Hz frequency increments, wide-band accuracy and stability determined by a single precision crystal oscillator, frequency memories, and continuously variable precision frequency splits. Now reduced in size to small integrated circuits, frequency synthesizers have long replaced the cumbersome chains of frequency multipliers and filters in VHF, UHF and microwave equipment, giving rise to the highly portable communications devices we use today. Frequency synthesis

has also had a major impact in lowering the cost of modern equipment, particularly by reducing manufacturing complexity.

Frequency synthesizers are categorized in two general types: *direct synthesizers*, where the output signal is the result of operations directly performed on the input signal; and *indirect synthesizers*, where selected characteristics of the input signal are transferred onto a separately generated output signal. One defining feature of any direct synthesizer is that no feedback is used, so there is never any dynamic stability problem. Indirect synthesizers always include feedback control loops, so dynamic stability is a major design concern.

Direct synthesizers include the major techniques of *direct analog synthesis* (DAS) and *direct digital synthesis* (DDS). Direct analog synthesizers consist primarily of frequency multipliers, frequency dividers, mixers, and filters. DAS is very useful for generating small numbers of signals, with widely spaced frequencies, from a reference oscillator. DAS is particularly useful when more than one output signal is required at the same time. Direct digital synthesizers are essentially dedicated microprocessors that have one program, to create an output signal waveform given a desired frequency (in digital form) using the applied reference signal. Unlike DAS, the output frequencies from a DDS can easily be separated by millihertz (0.001 Hz) while keeping all of the stability of the reference oscillator. Both being direct techniques, neither DAS nor DDS use feedback control loops, so switching from one frequency to another happens in nanoseconds.

Indirect synthesizers include the major techniques of frequency-locked loops (FLL) and phase-locked loops (PLL). The whole idea behind any indirect synthesizer is to transfer characteristics of one signal onto another separate signal. An FLL transfers only frequency characteristics of the input signal onto the output signal. Major FLL

applications used by radio amateurs include *automatic frequency control* (AFC) loops and tone decoders. PLLs are more precise because not only frequency characteristics of the reference oscillator, but also its phase characteristics, are transferred to the oscillator generating the output signal. There are two main application classes in which PLLs find wide use. The first is as a *frequency generator*, where we call it a *frequency synthesizer*. In transmitters this synthesizer may also include modulation, particularly for FM and FSK signals. The second PLL application class is as an angle (frequency or phase) demodulator, where we call it a *tracking demodulator* or *synchronizer*. Tracking demodulators used in deep space communication and clock recovery used in digital communication are major applications today.

It is curious to note that using modern digital circuitry, it actually is easier to make a PLL than an FLL. This turns out to be fortuitous! This section will focus on the PLL used as a frequency synthesizer. For readers interested in PLL use as a demodulator or as a synchronizer, there are many textbooks available that discuss these applications in great detail.

### 9.6.1 Digital Frequency Synthesis

A digital process is defined to be quantized in both value and time. (See the **DSP and SDR Fundamentals** chapter for background on digital signals and systems.) This is important to remember because there are sampled signal processes that are not digital. One is the sample-and-hold, which is discrete in time but analog in value. The opposite is the phase-frequency detector used in phase-locked loops, which is discrete in value but analog in time. Digital frequency synthesis is a true digital process.

The origins of digital frequency synthesis go back to 1972, even before the widespread

use of microprocessors. In essence, these techniques directly calculate the desired output waveform, including any modulations. When no feedback used these are called Direct Digital Synthesis (DDS), and sometimes you also see the name Direct Digital Frequency Synthesis (DDFS) used. The DDS name is older, though DDFS is more specific. Both names survive but here we will use the original DDS.

DDS has many attractive properties and two major drawbacks. Its attractions include very fine frequency resolution (microhertz is practical), essentially instant switching speed, no frequency drift, and absolute frequency set-ability. If modulation is included, this also happens with digital precision. Direct control of frequency, phase shift, and amplitude are available and independent of each other. For frequency and phase shift, this is new. Any analog oscillator does not have the ability to independently address frequency and phase.

DDS drawbacks are also significant. Being a digital process, DDS is a sampled data system and so must adhere to the Nyquist criterion for waveform reconstruction as explained in the **DSP and SDR Fundamentals** chapter. This effectively means that the output frequency from a DDS is restricted to being less than half of the DDS clock frequency. The practical upper limit is around 35-40% of the clock frequency. Interestingly, there is no effective lower limit. Any DDS can tune all the way down to zero hertz (dc) since 0 is a legitimate tuning command.

The second drawback is more operationally serious. We demand a high quality sine wave from our oscillators and DDS is no exception. But as a sampled data system, the DDS output is a sampled sine wave. Sampling a sine wave without error requires infinite resolution due to the properties of the sinusoid. We do not have infinite resolution available to our designs, so some errors creep in as the signal is constructed. These errors

Figure 9.37 — Direct digital synthesis is based on the accumulator circuit (A). For our purposes, we assign all of the possible states that the accumulator can have around a circle and call them “phase” (B). The accumulator continuously adds its input number, once each clock cycle, to the present count. When the adder overflows, the overflow is dropped and counting continues around the circle as in (C).

manifest themselves as non-harmonic spurious output signals, a.k.a. “spurs,” which can be a huge problem. Much DDS design spends a lot of time dealing with spurs.

## DDS PRINCIPLES

DDS is based on the simple counter structure of an accumulator, as shown in **Figure 9.37**. We choose to interpret the digital outputs from this counter as signal phase, and commonly represent the states as points around a circle, which means that one cycle through the accumulator states represents one output cycle from this synthesizer. The figure shows an example of the 16 digital states from a 4-bit accumulator. Action of this accumulator when its input number  $M$  is set to 3 is shown in (c), showing how the “wraparound” from one cycle to the next continues when the adder overflows. It is common to have the state progression from one output cycle to the next be a different state sequence. What is vitally important is that the jump size from one state to the next be exactly the same. This sets the phase change to be

$$\frac{\Delta\theta}{\Delta t} = \frac{\Delta \text{ PHASE}}{1 \text{ CLOCK CYCLE}} = M$$

Frequency is simply how fast phase changes with time, so this accumulator input  $M$  is our direct tuning control. For an  $N$ -bit accumulator then the DDS frequency control is given by

$$f_{\text{DDS}} = \frac{f_{\text{CLOCK}}}{2^N} \times M$$

Note that this relationship is perfectly linear. Also note that  $f_{\text{DDS}}$  is quantized, because the tuning number  $M$  must be an integer. There are some frequencies that a DDS cannot generate. But 0 Hz at  $M = 0$  is legitimate!

One of the really important properties of DDS, which makes it particularly useful, is that  $N$  can be a reasonably large number. As examples, for  $N=24$  the denominator  $2^N = 16,777,216$ .  $N = 32$  is common, and then  $2^N = 4,294,967,296$ . This means that the DDS frequency resolution, if a 100 MHz clock frequency is used, is 5.96 Hz when  $N = 24$ , and 0.023 Hz when  $N = 32$ . This is extremely fine frequency resolution and it is as accurate as the clock frequency. The only way that the DDS output frequency can drift is if the clock frequency drifts. Because everything else is digital, that cannot drift.

However, we need to have a sine wave output from our synthesizer. The full DDS block diagram is shown in **Figure 9.38**, where a new block called the waveform map is included. This is a digital process, usually implemented as a non-volatile memory, that converts the phase information from the accumulator into sinusoid waveform values which are then converted to a sampled waveform in

**Figure 9.38** — Complete block diagram of a DDS.

**Figure 9.39** — Waveform map quantization forces output waveform errors because the output signal values must remain at the intersection of the grid lines (A). This results in output non-harmonic spurious signals from the DDS (B).

a DAC. The output low-pass filter is critical to getting the desired sine wave.

## DDS NOISE

DDS is a frequency divider and by the rules of frequency division the output phase noise is lower than the input phase noise, which in any DDS comes from the clock. There is no VCO to add noise to the output signal, like we have in PLLs.

## ADDITIONAL DDS PRINCIPLES

In addition to very fine frequency resolution, extremely good tuning linearity, very low output phase noise, and tuning bandwidth that goes all the way down to dc, an additional important benefit of DDS is that it tunes very quickly. Indeed, as soon as the tuning number  $M$  is changed, the DDS immediately shifts to calculating the new output waveform. The tuning dynamics of PLLs are not present here. Likewise, the stability issues of a PLL do not happen in DDS designs.

The presence of non-harmonic spurious signals remains the biggest issue in successful application of DDS to amateur equipment. In principle, a 32-bit DDS can cover all HF amateur bands with 0.23 Hz resolution when

clocked at 100 MHz. No VCOs, no band-switching, no tuning — it sounds like a dream! — but we need to apply our RF design skills to get rid of those pesky spurs. The quantization level of modern waveform maps is sufficient to keep the sinusoid quantization noise spurs below -100 dBc. The largest remaining problem is the DAC.

The signal sampling theorem does not predict spurs other than those generated by quantization. That means any additional spurs are a result of the actual output wave form not being exactly what the signal digital quantization requires. Normal DAC specifications of integral nonlinearity (INL) and differential nonlinearity (DNL) turn out to not be very important in the DDS application. More important are the symmetry of output transition times for up and down steps, and having no overshoot on either transition direction. DACs with the latter two properties generally work very well for precision DDS use.

## 9.6.2 Phase-Locked Loops (PLL)

As mentioned in the introduction, the PLL is a key component of any indirect synthesizer. The sidebar “An Introduction to Phase-Locked Loops” provides an overview of this technology. This section presents a detailed discussion of design and performance topics of PLL synthesizers and the circuits used to construct them.

## ARCHITECTURE

The principle of the PLL synthesizer is straightforward. A tunable oscillator is first built to cover the required output frequency range; then the PLL system is constructed around this oscillator to keep it tuned to the desired frequency. This is done by continuously comparing the phase of the oscillator to a stable reference, such as a crystal oscillator, and using the result to steer tuning of the oscillator. If the oscillator frequency is too high, the phase of its output will start to lead that of the reference by an increasing amount. This is detected and is used to decrease the frequency of the oscillator. Too low a frequency causes an increasing phase lag, which is detected and used to increase the frequency of the oscillator. In this way, the oscillator is locked into a fixed-phase

relationship with the reference, which means that their frequencies are held exactly equal.

A representative block diagram of a PLL is shown in **Figure 9.40**. Measurement of any error in the output signal phase is made by the *phase detector* (PD). The measured error is supplied to the *loop filter* and *loop amplifier* which work together to tune the *voltage controlled oscillator* (VCO) just enough to make the error go to zero. The phase detector determines the actual frequency and phase of the VCO through the *feedback divider* ( $N$ ). The phase detector operates at a lower frequency which is a sub-multiple of both the crystal oscillator frequency reference ( $f_{XO}$ ) and the output frequency ( $f_{OUT}$ ). This lower frequency is correctly called the PLL *reference frequency* ( $f_{REF}$ ) because it sets the operating conditions of the PLL.

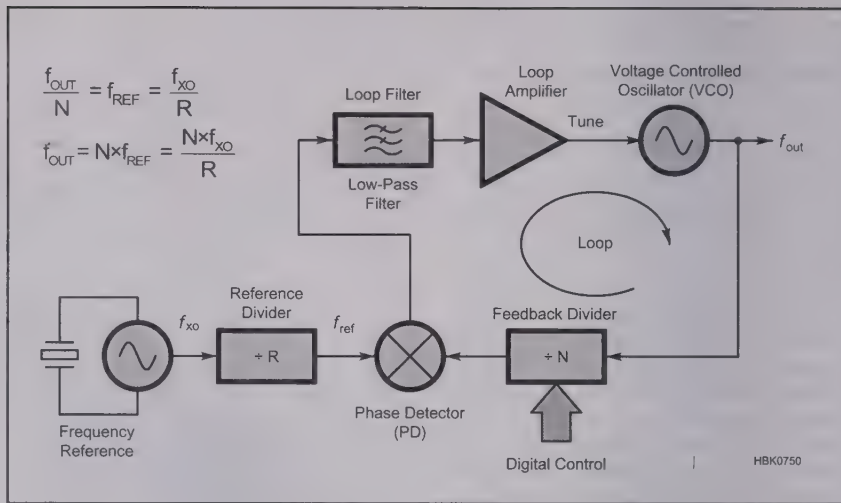

There is unfortunate history about the term reference frequency. It is often used to refer to both the operating frequency of the phase detector and to the frequency reference applied to the PLL. If the *reference divider* ( $R$ ) is not present then of course these two frequencies are the same. But in general, the reference divider is present and these frequencies are different. Ambiguity here is widespread and a big problem, even today many decades into the widespread use of PLLs. We must be very careful in the words we choose to use!

### FREQUENCY RESOLUTION (STEP SIZE)

Frequency of the output signal can be easily changed by changing the divide ratio of the feedback divider. For example if the reference frequency (at the phase detector!) is 100 kHz and the output frequency is 147.5 MHz, the feedback divider number must be  $N = 1475$ . If we changed the value of  $N$  to 1474, the frequency at the output of the feedback divider becomes 100.068 kHz. The phase detector notices that the frequency of the VCO is too high, and “tells” the loop filter to reduce the frequency of the VCO until the frequency out of the feedback divider becomes exactly 100.000 kHz. This will happen when the VCO is retuned to a frequency of 147.4 MHz.

By changing the value of  $N$  by 1, we have just tuned the frequency synthesizer by its smallest available step. This is called the *frequency resolution* of the synthesizer, or equivalently the synthesizer *step size*. Here we note that this step size is  $(147.5 - 147.4) = 0.1$  MHz. It is no accident that this frequency is exactly equal to the PLL reference frequency  $f_{REF}$ . This result is an important reason to avoid all ambiguity in the term “reference frequency.”  $f_{REF}$  is equal to the synthesizer output frequency step size.

There certainly are applications where we want the step size to be a small number, say

**Figure 9.40** — A basic phase-locked-loop (PLL) synthesizer acts to keep the divided-down signal from its voltage-controlled oscillator (VCO) phase-locked to the divided-down signal from its reference oscillator. Fine tuning steps are therefore possible without the complication of direct synthesis.

10 Hz. You might guess — correctly — that there are problems in building a PLL synthesizer for a very low  $f_{REF}$ . The usual solution is to combine multiple PLLs with some DAS techniques to get around these problems.

### DYNAMIC STABILITY AND LOOP BANDWIDTH

Because feedback control is required to transfer the frequency and phase characteristics from the crystal oscillator onto the VCO, all of the stability problems inherent in feedback control apply to PLL design. If the gain and phase responses are not well designed the PLL can oscillate. In this case instead of getting the stability transfer we want, the output is essentially a frequency modulated signal spread across the entire tuning bandwidth of the synthesizer — clearly a very bad thing. How to perform this design is discussed below.

For the moment let us assume that our PLL dynamics are properly designed. One other characteristic of feedback control is now important: how fast can the output frequency be changed from one value to another? This is controlled by the *loop bandwidth* of the PLL. For practical reasons the loop bandwidth should be less than 5% of  $f_{REF}$ . Using the example above in which  $f_{REF} = 100$  kHz, the loop bandwidth we design for cannot exceed 5 kHz. To answer our question, we can use the rule of thumb that in a well-designed loop, the settling time should be between 1 and 2 times the reciprocal of the loop bandwidth. For a 5 kHz loop bandwidth the settling time should not exceed  $2/5000 = 400 \mu s$ . We can begin to see one problem with PLL design if  $f_{REF}$  is very small: To get a 1

kHz step size from a PLL synthesizer the maximum loop bandwidth available is 50 Hz. This is impractically small.

This loop bandwidth also influences how we can modulate our PLL synthesizer in an FM transmitter. Imagine now that we apply a very small amount of FM to the reference oscillator  $f_{XO}$ . The amount of deviation will be amplified by  $N/R$  — but this is true only for low modulating frequencies. If the modulating frequency is increased, the VCO has to change frequency at a higher rate. As the modulating frequency continues to increase, eventually the VCO has to move faster than the available *settling time*. The PLL now acts as a low-pass filter, reducing the available deviation from higher modulating frequencies. The cut-off frequency of this PLL low-pass action is equal to this same loop bandwidth.

### PLL COMPONENTS

Let us continue our discussion of phase-locked loop synthesizers by examining the role of each of the component pieces of the system. They are the phase detector, the VCO, the dividers (with possible prescalers), the loop filter, and of course the reference oscillator.

#### Phase Detectors

Phase detection is the key operation in any PLL. Remembering that we are making a phase locked loop, what we really need is not *absolute* phase measurement but a *relative* phase measurement. We need to know only how the phase of the VCO output signal  $f_{OUT}$  is changing with respect to the phase of the crystal reference  $f_{XO}$ .

# An Introduction to Phase-Locked Loops

By Jerry DeHaven, WA0ACF

Phase locked loops (PLLs) are used in many applications from tone decoders, to stabilizing the pictures in your television set, to demodulating your local FM station or 2 meter repeater. They are used for recovering weak signals from deep space satellites and digging out noisy instrumentation signals. Perhaps the most common usage for PLLs in Amateur Radio is to combine the variability of an LC oscillator with the long term stability and accuracy of a crystal oscillator in PLL frequency synthesizers. Strictly speaking a PLL is not necessarily a frequency synthesizer and a frequency synthesizer is not necessarily a PLL, although the terms are used interchangeably.

## PLL Block Diagram

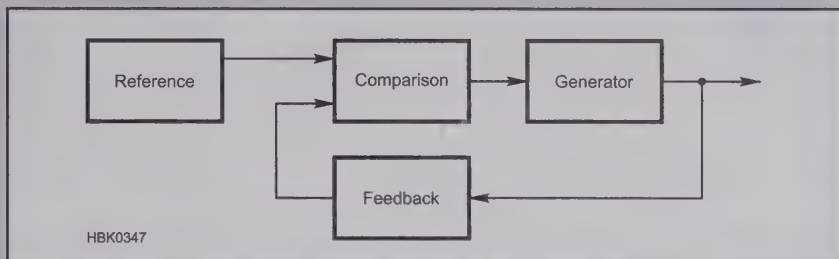

The block diagram in **Figure 9.41** shows a basic control loop. An example of a control loop is the furnace or air conditioning system in your house or the cruise control in your car. You input a desired output and the control loop causes the system output to change to and remain at that desired output (called a *setpoint*) until you change the setpoint. Control loops are characterized by an input, an output and a feedback mechanism as shown in the simple control loop diagram. The setpoint in this general feedback loop is called the reference.

In the case of a heating system in your house, the reference would be the temperature that you set at the thermostat. The feedback element would be the temperature sensor inside the thermostat. The thermostat performs the comparison function as well. The generator would be the furnace which is turned on or off depending on the output of the comparison stage. In general terms, you can see that the reference input is controlling the output of the generator.

Like other control loops, the design of a PLL is based on feedback, comparison and correction as shown in **Figure 9.41**. In this section we will focus on the concepts of using a phase locked loop to generate (synthesize) one or more frequencies based on a single reference frequency.

In a typical PLL frequency synthesizer there are six basic functional blocks as shown in **Figure 9.42**. The PLL frequency synthesizer block diagram is only slightly more complicated than the simple control loop diagram, so the similarity should be evident. After a brief description of the function of each block we will describe the operational behavior of a PLL frequency synthesizer.

In **Figure 9.42**, the general control loop is implemented with a bit more

**Figure 9.41** — Simple control loop. The Comparison block creates a control signal for the Generator by comparing the output of the Reference and Feedback blocks.

detail. The Reference block is composed of the Reference Oscillator and the Reference Divider. The Comparison block consists of the Phase Detector and Loop Filter. The Generator is replaced by the Voltage-Controlled Oscillator (or VCO) and the Feedback block is replaced by the Frequency Divider. The two signals being compared are both frequencies; the reference frequency and variable frequency signals. The output of the Loop Filter is made up of dc and low frequency ac components that act to change the VCO frequency. The output of the PLL is an integer multiple of the reference frequency (the output of the Reference Divider). It is probably not obvious why, but read on to find out!

**The Reference Oscillator** — The reference oscillator is usually a crystal oscillator with special attention paid to thermal stability and low mechanical and electronic noise. The main function of the reference oscillator is to generate a stable frequency for the PLL. Let us make a distinction between the reference oscillator frequency and the reference frequency. The output of the reference oscillator is at the crystal frequency, say 5.000 MHz. The choice of the actual crystal frequency depends on the PLL design, the availability of another oscillator in the radio, the avoidance of spurious responses in the receiver, and so on.

The reference frequency is the output of the reference (crystal) oscillator divided by the integer M to a relatively low frequency, say 10 kHz. In this case, 10 kHz is the reference frequency. The reference frequency equals the step size between the PLL output frequencies. In this simple example the crystal frequency can be any frequency that is an integer multiple of 10 kHz and within the operating range of the Reference Divider.

**The Phase Detector** — There are many types of phase detectors, but for now let us consider just a basic mixer, or a multiplier. The phase detector has two inputs and one output. In its simplest form, the output of the phase

detector is a dc voltage proportional to the phase difference between the two inputs. In practice, a phase detector can be built using a diode double-balanced mixer or an active multiplier.

The output of the mixer consists of products at many frequencies both from multiplication and from nonlinearities. In this application, the desired output is the low frequency and dc terms so all of the RF products are terminated in a load and the low frequency and dc output is passed to the PLL loop filter.

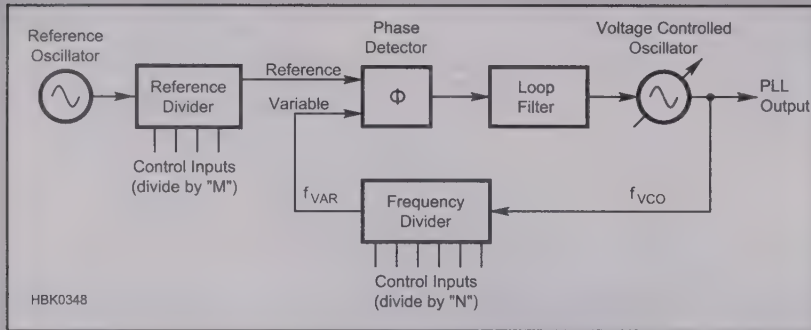

When the PLL is locked — meaning that the output frequency is the desired multiple of the reference frequency — the phase detector output is a steady dc voltage somewhere between ground and the PLL power supply voltage. When the PLL is commanded to change to another frequency, the phase detector output will be a complex, time-varying signal that gradually settles in on its final value.

**The Loop Filter** — The loop filter is a low-pass filter that filters the output of the phase detector. The loop filter can be a simple resistor-capacitor (RC) low-pass filter or an active circuit built with bipolar transistors or operational amplifiers. The cutoff frequency of the low pass filter is on the order of 100 Hz to 10 kHz. Although the frequencies involved are dc and low audio frequencies the design of the loop filter is critical for good reference suppression and low noise performance of the PLL frequency synthesizer.

The output of the loop filter is a dc voltage that “steers” the following stage, the Voltage Controlled Oscillator. The dc value can vary over a substantial portion of the PLL power supply. For example, if the loop filter runs off a 9 V power supply you may expect to see the output voltage range from about 2 V to 7 V depending on the VCO frequency range.

**Voltage Controlled Oscillator (VCO)** — The VCO is probably the most critical stage in the PLL frequency synthesizer. This stage is the subject of many con-

(continued on page next page)

**Figure 9.42 — PLL frequency synthesizer block diagram. The PLL is locked when the frequency PLL Output / N is the same as that of the Reference Oscillator / M.**

flicting design goals. The VCO must be electrically tunable over the desired frequency range with low noise and very good mechanical stability. Ideally, the output frequency of the VCO will be directly proportional to the input control voltage. A key characteristic is the VCO constant or tuning gain, usually expressed in MHz per volt (MHz/V). The VCO has one input, the dc voltage from the loop filter, and usually two outputs; one for the PLL output, the other driving the feedback stage — the frequency divider.

**The Frequency Divider** — The VCO frequency divider that acts as the feedback block is a programmable frequency divider or counter. The division ratio  $N$  is set either by thumbwheel switches, diode arrays or a microprocessor. The input to the divider is the VCO output frequency. The output of the divider is the VCO output frequency divided by  $N$ .

When the PLL is unlocked, such as when the PLL is first turned on, or commanded to change to another frequency, the frequency divider's output frequency will vary in a nonlinear manner until the PLL locks. Under locked conditions, the divider's output frequency (VCO Output /  $N$ ) is the same as the reference frequency (Reference Oscillator /  $M$ ).

The function of the frequency divider as the feedback element is easier to understand with an example. Let's assume that the desired PLL output frequency is 14.000 MHz to 14.300 MHz and it should change in steps of 10 kHz (0.010 MHz). A step size of 10 kHz means that the reference frequency must be 10 kHz. There are 31 output frequencies available — one at a time, not simultaneously. (Don't forget to count 14.000 MHz.) Let us arbitrarily choose the reference oscillator as a 5.000 MHz crystal oscillator. To generate the 10 kHz reference frequency, the reference divider must divide by  $M = 500 = 5,000 \text{ MHz} / 0.010 \text{ MHz}$ . (Use the same units, don't divide MHz by kHz.)

To generate a matching 10 kHz signal from the VCO output frequency, the Frequency Divider (the feedback stage) must be programmable to divide by  $N = 1400$  to  $1430 = 14,000$  to  $14,300 \text{ MHz} / 0.010 \text{ MHz}$ . The reference divisor ( $M = 500$ ) is fixed, but the Frequency Divider stage needs to be programmable to divide by  $N = 1400$  to  $1430$  in steps of 1. In this way, the output frequency of the PLL is compared and locked to the stable, crystal-generated value of the reference frequency.

#### PLL Start-up Operation

Let's visualize the PLL start-up from power on to steady state, visualizing in sequence what each part of the PLL is doing. Some portions of the loop will act quickly, in microseconds; other parts will react more slowly, in tens or hundreds of milliseconds.

The reference oscillator and its dividers will probably start oscillating and stabilize within tens of microseconds. The reference oscillator divider provides the reference frequency to one input of the phase detector.

The VCO will take a bit longer to come up to operation because of extensive power supply filtering with high-value capacitors. The VCO and the programmable dividers will probably reach full output within a few hundred microseconds, although the VCO will not yet be oscillating at the correct frequency.

At this point the phase detector has two inputs but they are at different frequencies. The mixer action of the phase detector produces a beat note at its output. The beat note, which could be tens or hundreds of kHz, is low-pass filtered by the PLL loop filter. That low-pass filter action averages the beat note and applies a complicated time-varying ac/dc voltage to the VCO input.

Now the VCO can begin responding to the control voltage applied to its input. An important design consideration is that the filtered VCO control sig-

nal must steer the VCO in the correct direction. If the polarity of the control signal is incorrect, it will steer the VCO away from the right frequency and the loop will never lock. Assuming correct design, the control voltage will begin steering the VCO in such a direction that the VCO divider frequency will now get closer to the reference frequency.

With the phase detector inputs a little bit closer in frequency, the beat note will be lower in frequency and the low pass filtered average of the phase detector output will change to a new level. That new control voltage will continue to steer the VCO in the right direction even closer to the "right" frequency. With each successive imaginary trip around the loop you can visualize that eventually a certain value of VCO control voltage will be reached at which the VCO output frequency, when divided by the frequency divider, will produce zero frequency difference at the inputs to the phase detector. In this state, the loop is locked. Once running, the range over which a PLL can detect and lock on to a signal is its *capture range*.

#### PLL Steady-state Operation

When the divided-down VCO frequency matches the reference frequency, the PLL will be in its steady-state condition. Since the comparison stage is a phase detector, not just a frequency mixer, the control signal from the loop filter to the VCO will act in such a way that maintains a constant relationship between the phase of the reference frequency and the frequency divider output. For example, the loop might stabilize with a  $90^\circ$  difference between the inputs to the phase detector. As long as the phase difference is constant, the reference frequency and the output of the frequency divider (and by extension, the VCO output) must also be the same.

As the divisor of the frequency divider is changed, the loop's control action will keep the divided-down VCO output phase locked to the reference frequency, but with a phase difference that gets closer to  $0^\circ$  or  $180^\circ$ , depending on which direction the input frequency changes. The range over which the phase difference at the phase detector's input varies between  $0^\circ$  and  $180^\circ$  is the widest range over which the PLL can keep the input and VCO signals locked together. This is called the loop's *lock range*.

If the divisor of the frequency divider is changed even further, the output of the loop filter will actually start to move in the opposite direction and the loop will no longer be able to keep the VCO output locked to the reference frequency and the loop is said to be *out of lock* or *lost lock*.

## Loop Bandwidth

Whether you picture a control loop such as the thermostat in your house, the speed control in your car or a PLL frequency synthesizer, they all have “bandwidth,” that is, they can only respond at a certain speed. Your house will take several minutes to heat up or cool down, your car will need a few seconds to respond to a hill if you are using the speed control. Likewise, the PLL will need a finite time to stabilize, several milliseconds or more depending on the design.

This brings up the concept of loop bandwidth. The basic idea is that disturbances outside the loop have a low-pass characteristic up to the loop bandwidth, and that disturbances inside the loop have a high-pass characteristic up to the loop bandwidth. The loop bandwidth is determined by the phase detector gain, the loop filter gain and cutoff frequency, the VCO gain and the divider ratio. Loop bandwidth and the phase response of the PLL determine the stability and transient response of the PLL.

## PLLs and Noise

Whether the PLL frequency synthesizer output is being used to control a receiver or a transmitter frequency, the spectral cleanliness of the output is important. Since the loop filter output voltage goes directly to the VCO, any noise or spurious frequencies on the loop filter output will modulate the VCO causing FM sidebands. On your transmitted signal, the sidebands are heard as noise by adjacent stations. On receive, they can mix with other signals, resulting in a higher noise floor in the receiver.

A common path for noise to contaminate the loop filter output is via the power supply. This type of noise tends to be audible in your receiver or transmitter audio. Use a well-regulated sup-

ply to minimize 120-Hz power supply ripple. Use a dedicated low-power regulator separate from the receiver audio stages so you do not couple audio variations from the speaker amplifier into the loop filter output. If you have a computer / sound card interface, be careful not to share power supplies or route digital signals near the loop filter or VCO.

A more complicated spectral concern is the amount of reference frequency feed-through to the VCO. This type of spurious output is above the audio range (typically a few kHz) so it may not be heard but it will be noticed, for example, in degraded receiver adjacent channel rejection. In the example above, Figure 9.42, the reference frequency is 10 kHz. High amounts of reference feed-through on the VCO control input will result in FM sidebands on the VCO output.

Loop filter design and optimization is a complicated subject with many trade-offs. This subject is covered in detail in the PLL references, but the basic trade-off is between loop bandwidth (which affects the speed at which a PLL can change frequency and lock) and reference rejection. Improved phase detectors can be used which will minimize the amount of reference feed-through for the loop filter to deal with. Another cause of high reference sidebands is inadequate buffering between the VCO output and the frequency divider stage.

One indication of PLL design difficulty is the spread of the VCO range expressed either in percent or in octaves. It is fairly difficult to make a VCO that can tune over one octave, a two-to-one frequency spread. Typically, the greater the spread of the VCO tuning range, the worse the noise performance gets. The conflicting design requirements can sometimes be conquered by trading off complexity, cost, size, and power consumption.

A common source of noise in the VCO is microphonics. Very small variations in capacitance can frequency modulate the VCO and impose audible modulation on the VCO output. Those microphonic products will be heard on your transmit audio or they will be superimposed on your receiver audio output. Under vibration, an air-wound inductor used in a VCO can move slightly relative to a metal shield for example. A common technique to minimize microphonics is to cover the sensitive parts with wax, epoxy, or a silicone sealer. As with the loop filter use a well-filtered, dedicated regulator for the VCO to minimize modulation by conducted electrical noise.

## Types of PLLs

One of the disadvantages of a single loop PLL frequency synthesizer is that the reference frequency determines the step size of the output frequency. For two-way radio and other systems with fixed channel spacing that is generally not a problem. For applications like amateur radio CW and SSB operation, tuning steps smaller than 10 Hz is almost a necessity. Like so many design requirements, there are trade-offs with making the reference frequency smaller and smaller. Most evident is that the loop filter bandwidth would have to keep getting lower and lower to preserve spectral cleanliness and loop stability. Because low frequency filters take longer to settle, a single-loop PLL with a 10 Hz loop bandwidth would take an unacceptably long time to settle to the next frequency.

Creative circuit architectures involving two or more PLLs operating together achieve finer tuning increments with only moderate complexity. Once you understand the basics of a single loop PLL you will be able to learn and understand the operation of a multi-loop PLL.

As usual, there are both analog and digital circuit techniques available to perform phase detection. For frequency synthesizer design the analog techniques are seldom used. Analog phase detectors are used only in receiver and demodulator applications. There are two that sometimes still appear in ham equipment, the multiplier/mixer of Figure 9.43A and the sampling phase detector shown in Figure 9.43B.

The mixer is a very low noise device when used as a phase detector, which explains why it is not yet completely gone from synthesizer design. It remains only in PLL designs where  $f_{REF}$  is very high, greater than 10-100 MHz. The main reason for this is that a PLL using a mixer for the PD is subject to a phenomenon

called *false lock*, where the PLL may act like it is locked even though it really isn't. Detecting and eliminating a false lock condition is much easier to do at higher frequencies. The sampling phase detector is now used only in synthesizers with output frequencies in the high microwave region, typically well above 10 GHz. The gain of this sampling circuit is very low, so it is used only if there is no viable alternative.

The most widely used digital phase detector is the exclusive-OR (XOR) gate shown in Figure 9.43C. If inputs A and B are almost in phase, the output will be low most of the time, and its average filtered value will be close to the logic 0 level. If inputs A and B are almost in phase opposition, the output

will be high most of the time, and its average voltage will be close to logic 1. The average voltage is near its mid-value when the inputs are shifted in phase by 90 degrees. In this respect the XOR gate is much like the analog mixer. To achieve this circuit's full output-voltage range, it's important that the reference and VCO signals at its input have a 50% duty cycle.

## Phase-Frequency Detector

One problem common to *all* phase detectors is the possibility of false lock. This happens because the output of any phase detector can have an average value of zero even when the frequencies at its inputs are not equal. This is a very serious problem that

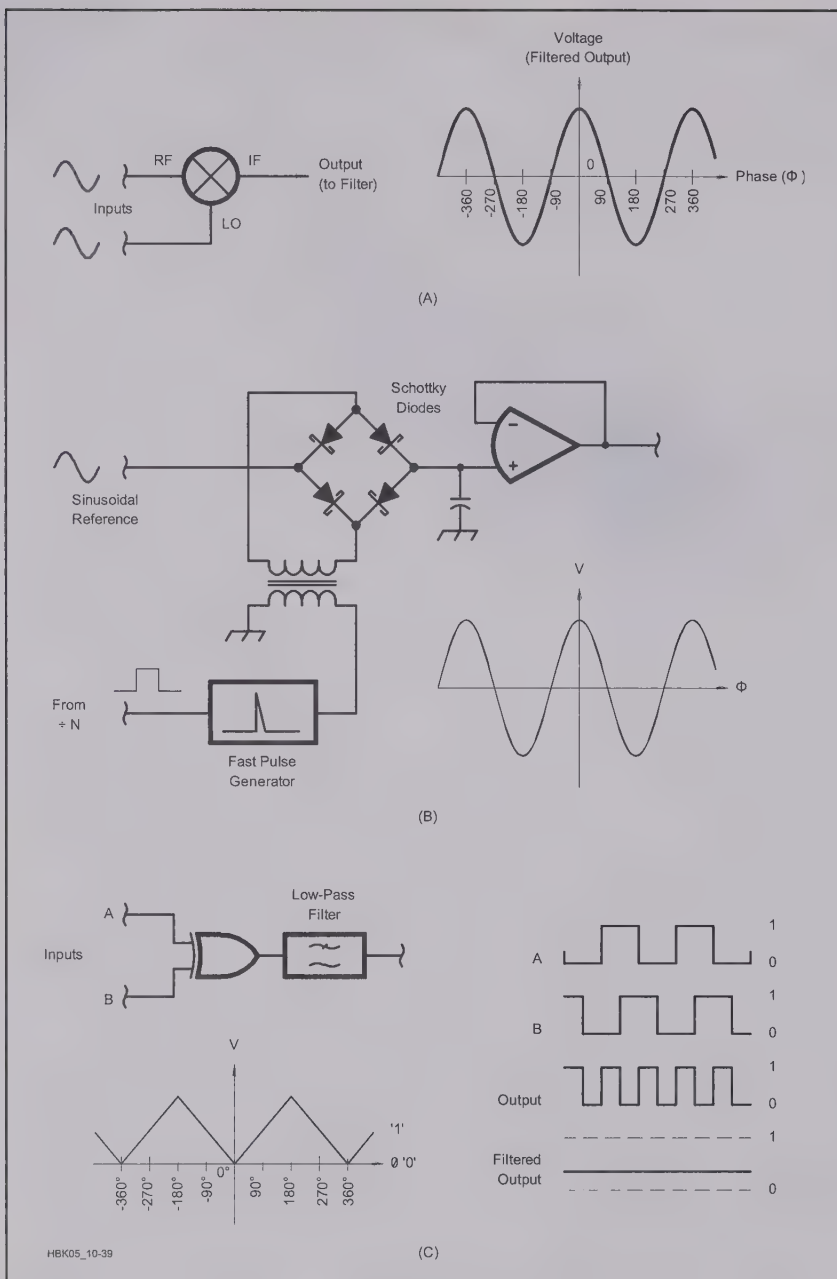

Figure 9.43 — Simple phase detectors: a mixer (A), a sampler (B) and an exclusive-OR gate (C).

requires any PLL using them to have additional circuitry to serve as an acquisition aid. If the PLL tries to settle when the PD inputs are not at the same frequency, this acquisition aid must prod the PLL to keep moving toward the true lock frequency. Such acquisition aids are not needed when a *phase-frequency detector* (PFD) is used.

The benefit of the PFD is that if the input signals are at different frequencies, even if they are at very different frequencies, the output is never zero. The PFD output always

produces a dc shift in the direction the PLL needs to move until the lock condition is achieved. No acquisition aids are ever needed. This alone is enough to explain its nearly universal adoption today.

As seen in **Figure 9.44A**, the PFD is a simple digital circuit. This also helps make it attractive to use in this era of CMOS integrated circuits. Other designs for the PFD exist, but they all follow the logic shown in **Figure 9.44A**. Of particular importance is that the PFD has two outputs.

The PFD operates by measuring the time difference between the rising edges of the reference signal and the divided VCO. The first signal to arrive sets its flip-flop. The second edge to arrive also sets its flip-flop, which immediately causes both flip-flops to be reset, ready for the next set of signal edges. By operating at high speed, the PFD is very sensitive to phase differences between the input signals. The PFD does require an equal number of edges for each signal, so it is not useful when the signals have varying numbers of edges, such as in a receiver's demodulator or a synchronizer.

If the VCO frequency is too low only the /U output is active, causing the loop filter to raise the VCO frequency. On the other hand, when the VCO frequency is high only the /D output is active, causing the loop filter to lower the VCO frequency. It is interesting to note that unlike the mixer and XOR phase detectors, which require the inputs to be in phase quadrature, the PFD locks when the input signals are in exact phase alignment.

Being an edge triggered circuit, PFD operation is essentially independent of input signal duty cycle. This eliminates the need for input waveform processing. If the input frequencies are different, the time differences measured by the PFD will be either constantly increasing or decreasing. As a result only one of the PFD output signals will be active, informing the PLL unambiguously which way to correct the controlled source to achieve phase lock.

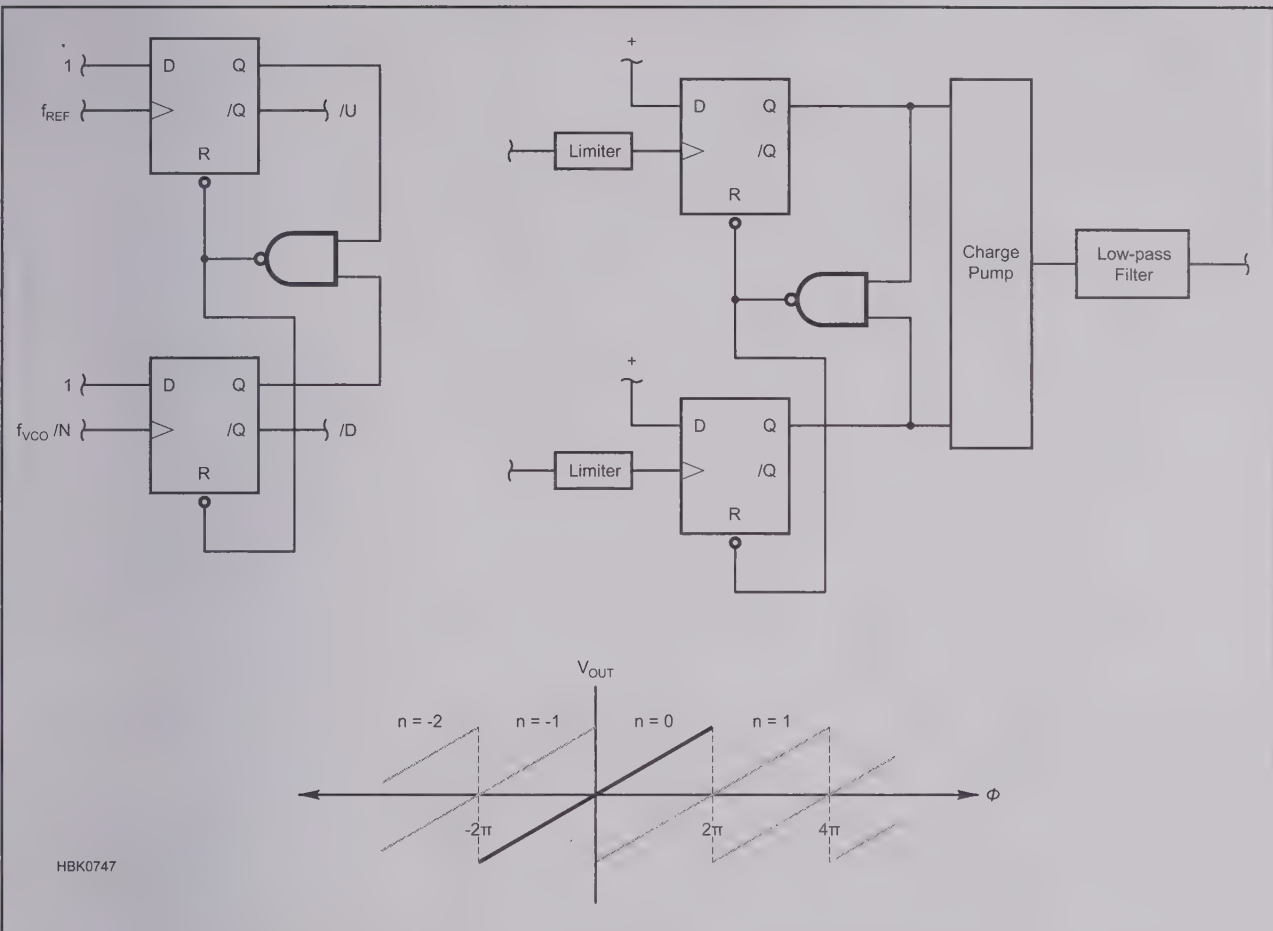

### Charge Pumps

Because the PFD has two outputs and most loop filters have only one input, something is needed to bridge the PFD and the loop filter. The usual technique is the *charge pump*, shown in **Figure 9.44B**. The charge pump gets its name by allowing current to flow only for the brief interval, here when the /D or /U outputs are active. Current flow in short bursts is equivalent to a finite charge transfer.

Charge pumps come in two configurations, voltage mode and current mode, as shown in **Figure 9.45**. Voltage mode (**Figure 9.45A**) was the original version, though now current mode (**Figure 9.45B**) is most widely used with integrated circuit PLLs.

The voltage mode charge pump directly connects voltage sources to the loop filter when the PFD output signals are active. When the PFD output signals are at rest (both high) both voltage sources are disconnected from the loop filter. These voltage spikes transfer charge to the integrator in accordance with the PLL loop filter time constant. One voltage source inputs current to the loop filter and the other removes it.

The current mode charge pump is architecturally similar to the voltage mode charge pump, with voltage sources replaced by cur-

HBK0747

Figure 9.44 — The phase frequency detector (PFD) makes a measurement of the time difference between two rising edges of the input signals.

rent sources. Like the voltage mode charge pump, this circuit disconnects both sources when the PFD output signals are at rest. In this case, current spikes transfer charge to and from the loop filter integrator. This transfer is independent of the loop filter series resistances.

The current mode charge pump has some advantages to the frequency synthesizer designer. Three are particularly significant:

- Pump current flows at a constant value independent of the loop filter voltage. Unless  $V_H$  and  $V_L$  are both very large compared with any possible loop filter voltage, the amount of charge transfer will vary with different loop filter voltage values.

- During the PFD reset time, both output sources are active. The voltage mode charge pump will attempt to connect both voltage sources to the loop filter during this brief period, which can generate some undesirably large power supply current spikes. During PFD reset, the current mode charge pump loads the power supply with a single current value of  $I_{QP}$ . If both current sources are well

matched, their currents completely cancel at the loop filter input, effectively disconnecting them that much earlier.

- At low offset frequencies, the loop gain flattens out with a voltage mode charge pump. Loop gain continues to increase with a current mode charge pump, effectively matching active filter performance.

### VCO

The design and characteristics of oscillators, including tunable oscillators, is the major topic of this chapter so it will not be repeated here. Of particular importance to PLL design are the tuning characteristic of the VCO and the VCO tuning bandwidth.

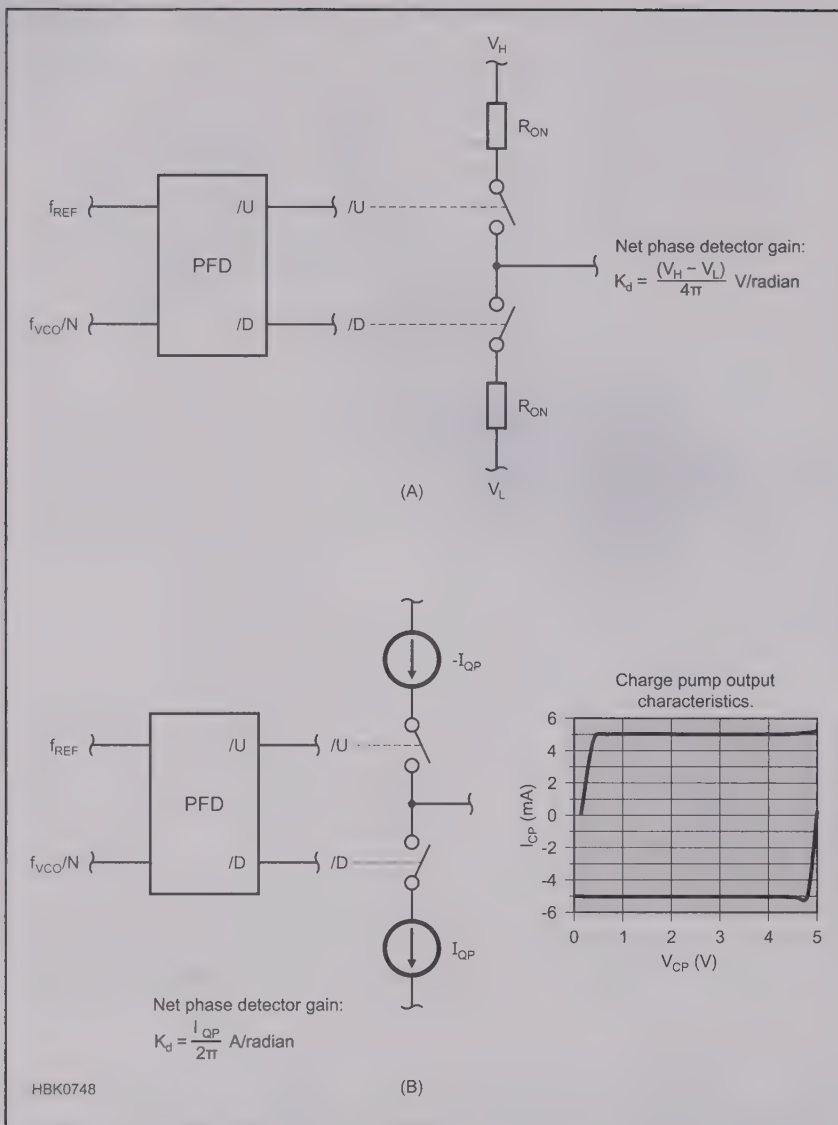

The tuning characteristic of an oscillator shows the output frequency versus the tuning voltage, such as the example of Figure 9.46A. The slope of this curve is called the VCO's modulation gain ( $K_0$ ) and it is this modulation gain that is most important to PLL design. For wideband VCOs the variation of  $K_0$  can exceed 5:1 from minimum to maximum frequency. The design method below shows how

a wide gain variation such as this is handled with a single loop filter design.

It is important to realize that the VCO has no idea that it is controlled by a PLL. While it is oscillating it continues to drift and jitter with time and temperature like any other oscillator. You must characterize these variations to be assured that the tuning capability has sufficient range for the PLL to "find" a tuning voltage value that will retune the VCO to the required frequency, under all circumstances.

The primary VCO characteristic of interest to the synthesizer designer is the tuning gain "constant,"  $K_0$ . Almost never a constant,  $K_0$  is a local measure of how much the VCO output frequency changes with a change in tuning voltage.

VCO designers go to great lengths to make  $K_0$  an actual constant. This additional effort often increases the VCO design complexity and usually results in a more expensive design. If no linearization effort is undertaken,  $K_0$  can easily vary from 3:1 to 10:1 over the tuning band. This also complicates

**Figure 9.45 — The charge pump delivers short bursts of current to the loop filter under the control of the phase frequency detector (PFD) outputs. A voltage mode charge pump is shown at A and a current mode charge pump at B.**

the frequency synthesizer design. Specific applications will dictate where effort needs to be expended: in the VCO design or the PLL design.

All PLL design algorithms assume that there is no delay between when the loop filter presents a tuning change command to the VCO and when the VCO frequency actually changes. This situation is true when the VCO tuning bandwidth is much greater than the PLL loop bandwidth. If the VCO tuning bandwidth is not much greater than the PLL loop bandwidth, there are additional phase shifts that will cause problems with PLL stability. It is usually much easier to narrow the loop bandwidth than to redesign the VCO. If redesigning the VCO is a possibility, reduce the capacitance seen at the tuning input to

increase the tuning bandwidth.

The VCO tuning bandwidth is important mainly for PLL designs that have wide loop bandwidths. Measuring the frequency deviation as the modulating frequency varies is best done by looking at the FM sidebands on a spectrum analyzer, as shown in Figure 9.46B. For constant deviation, FM sidebands follow the top profile. When the modulating frequency doubles, the sidebands drop below the profile by 6 dB, and if it triples, by 10 dB. The first FM sideband must exceed all other sidebands by 10 dB for proper VCO characterization — the process of determining the VCO’s characteristic parameters such as the tuning sensitivity, noise spectrum, dynamic response to changes in the tuning input signal, and so on. (See the Agilent application note

“Boosting PLL Design Efficiency” in the References section.) VCO tuning bandwidth is determined by the point at which increasing the modulating frequency deviates from (drops below) the profile shown in Figure 9.46B.

### Reference Divider

The reference divider is one of the easiest parts of a PLL to design, though technically it is outside the PLL. The input frequency is well known — it is the crystal reference. The output frequency is also well known, being the phase detector frequency  $f_{REF}$ . The ratio of these two frequencies is the required counter divide-by ratio or *modulus*.

When designing PLL synthesizers,  $f_{REF}$  is usually specified but  $f_{XO}$  is not. This provides some flexibility in design to use easy counter implementations if the resulting  $f_{XO}$  is also easy to get. The easiest digital counters to use for any divider are those operating with binary numbers (divide by 2, 4, 8, 16, ..., 128, ...). For example, if  $f_{REF} = 20$  kHz and you choose  $R = 512$  then  $f_{XO} = 10.24$  MHz, which is a readily available crystal frequency.

### Feedback Divider and Prescalers

The feedback divider is more of a challenge. First and foremost, this divider must work properly with whatever possible frequency it may ever see at its input. Whatever the highest and lowest frequencies the VCO may be, the divider must handle them all.

The feedback divider is almost always programmable so that the output frequency can be changed. Programmable counters are always slower than non-programmable designs, so some speed limitation occurs. Fortunately in this era of tiny CMOS integrated circuits the problems of past years in getting programmable counters to operate at hundreds of MHz are nearly over. Older equipment still has feedback divider designs that are carefully crafted to handle the frequencies at which they must operate.

### Fixed Prescaler

When the programmable counter does not have sufficient speed to handle the frequencies required, then the VCO frequency must be divided down ahead of the programmable counter to assure that everything works reliably. This additional divider usually has a fixed binary value so it will go fast enough without using too much power. Called a *prescaler*, as long as the output frequency from the prescaler is always within the operating range of the programmable divider the PLL will be reliable.

Of course, there are consequences: when a prescaler is used, the PLL step size is multiplied by the prescaler divider value. For our  $f_{REF} = 100$  kHz, if we adopt a divide-by-16 prescaler then the step size increases by a

Figure 9.46 — (A) Measurement of the VCO tuning characteristic provides a curve describing frequency versus tuning voltage. The VCO tuning gain at a particular frequency (or tuning voltage) is the slope of this curve at that point. (B) A spectrum analyzer is used to measure frequency deviation of the VCO and the modulating frequency varies. FM sideband peak amplitudes follow the top profile when deviation is constant.

factor of 16 to 1.6 MHz. The direct way to correct for this is to reduce  $f_{REF}$  by the same factor of 16, which unfortunately means that the PLL loop bandwidth is also reduced by a factor of 16. Is there a solution with fewer compromises?

**Dual-Modulus Prescaling**

Yes, there is such a solution. If the prescaler is designed to divide by two values separated by 1, say 16 and 17, or 8 and 9, then we call this a *dual-modulus P/P+1 prescaler*. Using dual-modulus prescaling we can leave  $f_{REF}$  unchanged, keeping our step size and loop bandwidth while gaining much higher oper-

ating frequency for the feedback divider.

Dual modulus prescaling is a cooperative effort between a high speed prescaler and a much lower speed programmable counter. The result of this cooperation is a programmable counter that operates at a very high input frequency while maintaining unit division resolution. Dual-modulus prescaling works by allocating quotient and remainder values from the division  $N/P$  as shown in **Figure 9.47A**.

The improvement comes from viewing the operation of division in a slightly different way. The division ratio ( $N$ ) of any two integers will always provide a quotient ( $Q$ ) and

a remainder ( $R$ ). If  $Q$  counts of prescaled  $f_{in}/P$  are followed by  $R$  counts of  $f_{in}$  directly, then  $N = QP + R$ . One way to build this counter would be to first count a quotient's worth of prescaled input, and then count a remainder's amount of the input frequency directly. This last step is hard because of the high frequency.

A second approach is to add the remainder counts to the prescaled output as follows: If  $Q - R$  counts of prescaled  $f_{in}/P$  are followed by  $R$  counts of prescaled  $f_{in}/(P + 1)$ , then  $N = (Q - R)P + R(P + 1)$ . This is the same as  $N = QP - RP + RP + R = QP + R$ .

If the remainder counts are distributed among the quotient counts by increasing the prescaler modulus by one from  $P$  to  $P + 1$  for the remainder's amount of cycles, then returning the prescaler to its nominal division ratio while the rest of the quotient counts are made, the same result is achieved. This design always operates the programmable counter at a much lower frequency than the input frequency, which is a much more robust design.

The catch, however, is that there have to be enough quotient counts over which to distribute any amount of remainder counts. If you run out of quotient counts before remainder counts the technique falls apart and that particular loop divisor will not be *realizable*. For real dividers, all of the terms —  $Q$ ,  $P$ , and  $R$  — must be positive integers, so  $Q - R$  must be greater than zero for  $N = QP + R$  to be realizable.

The maximum remainder,  $R_{max} = P - 1$ . The minimum quotient is equal to  $R_{max}$ . So the minimum remainder,  $R_{min} = 0$ . That means:

$$N_{min} = Q_{min}P + R_{min} = (P - 1)P + 0 = P^2 - P$$

If the PLL design always requires  $N$  to be greater than  $P^2 - P$  then there are no problems. If  $N$  does need to go below  $P^2 - P$ , then the only solution is to choose a dual modulus prescaler with a smaller value of  $P$ . Various values of  $P$  and  $N_{min}$  are:

P	$N_{min}$
8	56
16	240
64	4032
128	16256

Dual-modulus prescaling therefore implies a minimum divisor value before continuous divider value coverage is realized. The value of this minimum divisor depends on the base modulus of the prescaler,  $P$ , and increases quadratically. Proper choice of prescaler modulus is one of the important decisions the frequency synthesizer designer has to make.

Figure 9.47B shows how a typical dual-modulus prescaler is implemented. Each cycle of the system begins with the last output pulse having loaded the frequency control

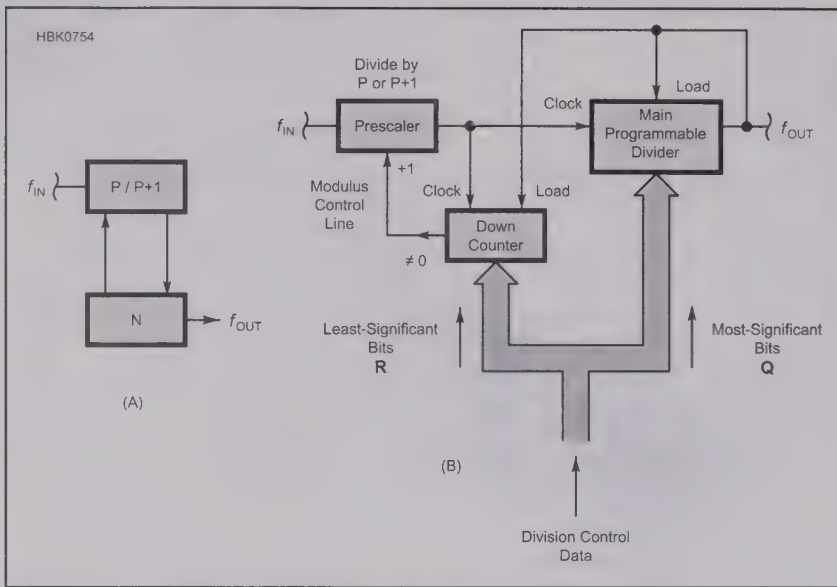

Figure 9.47 — A typical implementation of a dual-modulus prescaler.

word, shown as “Division Control Data,” into both the main divider and the prescaler controller. If the division control data’s least significant bits (which make up R) loaded into the prescaler controller are not zero, the prescaler is set to divide by  $P + 1$ , 1 greater than its normal ratio, P. The main divider counts Q pulses from the prescaler.

Each cycle out of the prescaler then clocks the down counter. Eventually, the down counter reaches zero, and two things happen: The counter is designed to hold (stop counting) at zero (and it will remain held until it is next reloaded) and the prescaler is switched back to its normal ratio, P, until the next reload.

Because the technique is widely used, dual-modulus prescaler ICs are widely used and widely available. Devices for use to a few hundred megahertz are cheap, and devices in the 2.5 GHz region are commonly available. Common prescaler IC division ratio pairs are: 8-9, 10-11, 16-17, 32-33, 64-65 and so on. Many ICs containing programmable dividers are available in versions with and without built-in prescaler controllers.

### Loop Filter

When designing PLL synthesizers we usually just have to measure and accept the VCO characteristics of  $K_0$  and the PFD output characteristics. Output frequency range and step size are also not flexible. We pull all of these together into a working and stable synthesizer by proper design of the loop filter.

Loop filter design is usually shrouded in mystery, which has given PLL synthesizer design an aura of a “black art.” This is not at all warranted because very reliable design

algorithms have been around for decades. Unfortunately these have usually been published in obscure places so they are not well known. The best algorithms are presented below. These methods have served extremely well for over 30 years and should provide you with fast design times and very stable PLL synthesizers. No iteration should be needed.

Loop filters come in active and passive structures. In general the easiest designs use passive (RC) loop filters if the output voltage range from the phase detector (including the PD or PFD and its charge pump) is sufficient to tune the VCO over its required frequency range. If the VCO needs a larger tuning voltage range then an active loop filter structure is necessary.

Passive loop filter circuits for current mode charge pump outputs are shown in Figure 9.48. The loop filter time constant is set by the charge pump current and C1, independent of R and of the loop filter output voltage. R provides a phase leading zero for PLL stability. The first-order filter in Figure 9.48A has a minimum parts count and results in loop dynamics that are consistent with the output frequency.

A second-order filter has the undesirable characteristic of allowing step and impulse changes in the input to appear at the output. This results in significant reference sidebands — a bad thing. Figure 9.48B shows a third-order filter in which C2 changes step changes at the input to slower ramps by rolling off the high frequency response of the loop filter. This results in a significant reduction in reference sidebands.

Active loop filters offer more structures that work well and are easier to design, though

Figure 9.48 — Passive loop filters for current mode charge pump PFD outputs.

Figure 9.49 — Third-order active loop filter isolates the loop filter output voltage from the charge pump outputs.

more complicated to build. When a voltage mode charge pump is being used, an active loop filter is strongly desired since it removes the PLL response variations with different loop filter voltage values.

In Figure 9.49, the gain of the op-amp isolates the actual loop filter output voltage from the charge pump output voltage, controlling the loop so that the charge pump output voltage is  $V_{REF}$ . Each passive component has the same basic function here as in the passive filter.

The third-order active filter in Figure 9.49 adds an additional pole within the feedback loop and reference frequency sidebands are significantly reduced. Charge pump current impulses now cause ramps instead of steps in the output voltage, but they still cause problems at the amplifier inputs. Good design algorithms include this extra pole as part of the fundamental dynamics — not as a disturbance of conventional second-order dynamics.

**Figure 9.50** — Adding additional low-pass filtering by splitting the input resistor and adding  $C_A$  improves loop stability and reduces reference frequency sidebands. This design is well-suited for differential-output PFDs.

Though the design in **Figure 9.50** adds another capacitor by splitting the input resistor, the added complexity is usually well worth it. Charge pumps put out very narrow, spiky signals that are usually of sufficient amplitude and duration to temporarily drive the op-amp input into saturation. If this happens the PLL response becomes non-linear and problems often arise.

The improvement of this design is to low-pass filter the charge pump pulses before being applied to the op-amp input. The op-amp far prefers the resulting ramps, remaining linear and therefore predictable in behavior. This results in further reduction in reference frequency sidebands and is easily adapted to difference-output digital PDs, including the PFD.

Design equations for these loop filters will be presented after the remaining PLL component blocks are discussed.

### Reference Oscillator

Any PLL is simply a stability transfer mechanism, so the behavior of the reference oscillator will not be improved on. The fractional frequency error of the overall frequency synthesizer will match that of the reference oscillator. For example if the output of the PLL synthesizer changes 1 kHz at an output frequency of 1 GHz [1000/1,000,000,000 = 1:1 million, or 1 part per million (ppm)] then the reference has changed that same fractional amount. If the crystal reference is 10 MHz (a very common frequency for crystal references) its frequency drift was (1 ppm) × (10 MHz) = 10 Hz. This is not much frequency drift, but it is significant to the ultimate output frequency.

### 9.6.3 PLL Loop Filter Design

When it is time to design a PLL synthesizer, it is best to do it in steps. Begin with knowing

how the hardware you are using behaves:

- VCO tuning characteristics,  $K_0$
- PFD characteristic (with charge pump),  $K_s$
- Crystal reference frequency,  $f_{XO}$
- Output frequency range,  $f_{OUT}$
- Output frequency step size,  $f_{STEP}$

Next, list the requirements of your application. Now you are ready to choose the two main design parameters:

- Loop bandwidth — this should not exceed 5% of  $f_{REF} = f_{STEP}$
- Phase Margin — this sets the overall stability of the PLL and can be any value between 50 and 60 degrees. A good value is 54 degrees.

With all of this information in place it is time to calculate the values for the two frequency dividers and the loop filter components. Begin with the divider values:

$$R = f_{XO}/f_{REF}$$

$$N = f_{OUT}/f_{REF}$$

$$N_{MIN} = f_{OUT,MIN}/f_{REF}$$

$$N_{MAX} = f_{OUT,MAX}/f_{REF}$$

The best design algorithm for stable PLL design calls for using the geometric mean of the feedback divider value range in the loop filter design. This same idea is used to manage the range of VCO gain values for  $K_0$ .

$$N_{DESIGN} = \sqrt{N_{MAX} \times N_{MIN}}$$

$K_0$  design target value =

$$\sqrt{K_{0,MAX} \times K_{0,MIN}}$$

PFD gain depends on whether the charge pump is voltage mode or current mode:

$$\text{(voltage mode) } K_d = (V_H - V_L)/4p$$

$$\text{(current mode) } K_d = I_{QP}/2\pi$$

For all of the active loop filter structures use the voltage mode value.

Everything is now ready. Place these design values into the appropriate design equations for the selected loop filter structure. For a passive loop filter use **Figure 9.51**. If you are using an active loop filter the appropriate equations are in **Figure 9.52** or **Figure 9.53**. The resistor and capacitor values from these calculations are not critical. Choose values within 30% of what you calculate and the design will be fine. Truly!

Following any loop filter design, it is always a good idea to check the results by directly calculating the filter time constants from the components chosen. Compare these

**Figure 9.51** — Design equations for passive loop filters.

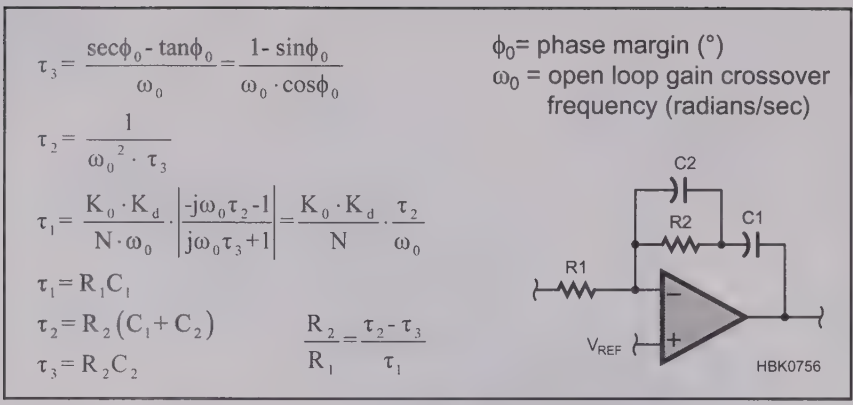

Figure 9.52 — Design equations for third-order active loop filters

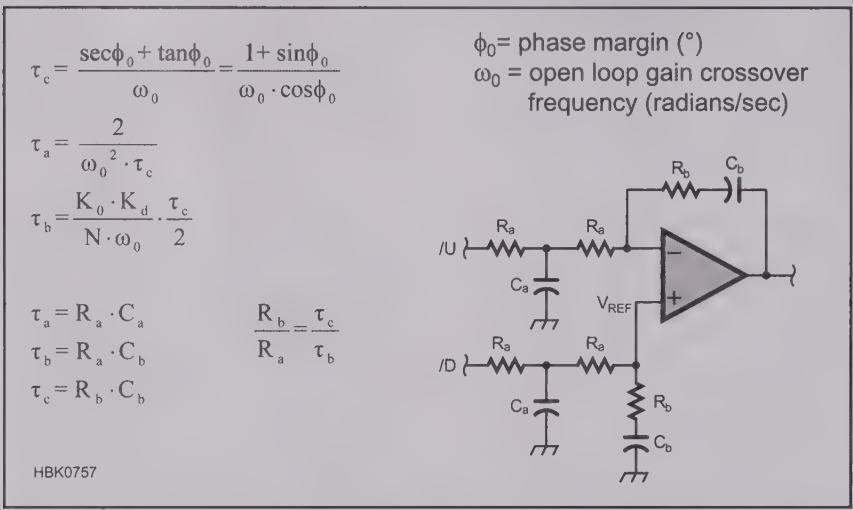

Figure 9.53 — Design equations for differential-input active loop filters

time constants with those derived theoretically. If they match within 10-20%, there should be no problem with loop stability.

The passive third order loop filter design equations of Figure 9.51 look very similar to those of its active filter counterpart. The major difference is that this procedure yields two time constants instead of three, and a term equaling the sum of both filter capacitances.

Unlike the active filter form, there are no arbitrary component choices with the passive filter. From the time constants and the total capacitance, all three loop filter components are uniquely determined.

Since the concepts of natural frequency and damping no longer apply (by definition) in a third-order filter, the more general stability concepts of gain crossover and phase margin are used. A value of 50-60 degrees is usually used for the design phase margin.

The equations for Figure 9.52 and Figure 9.53 include the rolloff pole within the loop dynamics, rather than treating it as a loop perturbation. This allows a greater amount

of high frequency rolloff to be achieved as it "kicks in" at a much lower frequency than perturbation techniques would allow.

A usual design strategy is to choose the resistors first to achieve the design ratio. This may provide several possible resistor pairs. Calculate the resulting capacitor values for each resistor pair possibility, and choose the set that provides the closest realizable values.

### 9.6.4 Fractional-N Synthesizers

The simplest frequency synthesizer is the single PLL with a programmable counter as a frequency divider in the feedback path. It can now all be integrated onto a single semiconductor device, though better performance may be available with some sections done discretely. These synthesizers are well suited to channelized radios where the channel spacing is fairly wide. Millions of them can be found in VHF/UHF radios, cell phones, TV tuners and so on. However, apart from VHF/

UHF FM transceivers, most Amateur Radio operation requires fine-resolution synthesizers to simulate the look and feel of a free-tuning VFO.

To this point in the chapter, the PLL synthesizer designs have assumed that the feedback divider operates as a single programmed integer value. This design is referred to as an *integer-N PLL*. These PLLs have an unavoidable trade-off of the step size versus every other performance parameter. Making a fine resolution loop by using a very high value of N forces a very low phase detector frequency and low open loop gain. This leads to extremely slow settling, bad phase noise, and poor suppression of spurs.

Multiple PLL loops can be used to give fine resolution without invoking other performance limitations other than cost, size and power consumption. PLL/DDS hybrids can do the same job and save some cost, size, and power consumption. The holy grail is a fine resolution synthesizer with a clean output, small size, low cost and low power consumption but that has not yet been attained. There is another thread of development particularly suited to high levels of integration, although it, too, has limitations. It is called *fractional-N* or *frac-N synthesis*.

### THE ORIGIN

A single PLL would have fine resolution, if the divide-by-N stage in its feedback path weren't constrained to divide only by integers. The dividers are implemented as digital counters, counting cycles of the VCO frequency. Counting in anything smaller than integers would need something running faster than the VCO to act as an interpolator. To get steps much finer than the increments given by integers would need an interpolator running at a very large multiple of the VCO frequency, which is impractical.

One solution is to vary the value of N so that the average value of N, taken over a long enough time period, gives the required resolution. This can be done, and it doesn't need impossibly fast logic. For example, consider the 2 meter synthesizer discussed in the previous section on Frequency Resolution: if N is varied in a repeating pattern of 8 divisions by 1474 followed by 2 divisions by 1475, the average is  $(8 \times 1474 + 2 \times 1475) / 10 = 1474.2$ . A PLL operating with this type of variable division in the feedback loop is called a *fractional-N PLL*.

The resulting problem with such a PLL is that it is never exactly on the desired frequency. It switches between too-high and too-low, even though its average might be just right. We could view this as wide deviation FM, where the modulation is a rectangular pulse of controlled mark-space ratio. Such a spectrum will have high noise levels and huge sidebands which are quite undesirable.

Nevertheless, designers of such systems

have tried to slow the loops so that they could not follow the switching and sat on the average frequency. The problem with obtaining sufficient filtering of the sidebands was that the loop became too slow and all the problems mentioned above appeared, making the solution worse than single-N synthesis.

## ANALOG PHASE INTERPOLATION

Variable-N synthesizers were not used in Amateur Radio transceivers, but it was common in test equipment from the 1980s and 1990s without the tuning and noise requirements of radio equipment. This type of synthesizer is described in the context of using or repairing test equipment. (For example, see the HP 3335A Synthesizer service manual's Theory of Operation section.)

PLLs can be phase modulated, quite easily, within their bandwidths by summing in a modulating voltage after the phase detector. The phase effect of the switching of the N number can easily be calculated. A digital system can be made to do this, but an extra analog system must be added to interpolate the results of the digital system. This hybrid circuit can compute a phase modulation waveform which cancels all the effects of the frequency switching, but leaves the average intact. Cancellation is never perfect but manufactured synthesizers were developed that suppressed the unwanted sidebands to around -80 dBc (decibels with respect to the carrier level).

This is a complex system and can be hard to understand. Sometimes a second way of viewing it may be easier: If a ramp waveform is added after a phase detector in a PLL, the loop will be phase modulated with a ramping phase, or in other words, a frequency offset. If the ramp slope is controlled, any amount of resolution is possible. The problem is that ramps cannot go on forever, and the phase detector will soon hit the end of its range. The solution is to increase the N number of the divider just once at the same time that the ramp is reset by a cycle's worth of phase. A sampling system is used to disguise the disturbance of the transient phase shift and ramping resumes.

This is a large system needing careful, individual, trimming to get the analog circuitry to mesh seamlessly with the digital circuitry. The digital parts are integrated into a custom IC, but the discrete analog parts require a lot of board space. The performance was acceptable for mid-range equipment at the time. State of the art equipment used it as part of a hybrid structure as the least significant of three PLLs. The resulting fractional-N loop gave the system much finer resolution than the previous generation of 5-loop hybrids.

## NOISE SHAPING

These early schemes switched the PLL divider between N and N+1 in simple, repet-

itive patterns, so the inevitable sideband energy was concentrated into large, obvious components. One variant of the filtering scheme used "rate multiplier" logic devices to control N to N+1 switching and reduced the amplitude of the unwanted components by spreading them out. While still not clean enough to be generally useful, other technologies were maturing: oversampling 1-bit DACs for audio, pseudo-random binary sequences for simulating telephone traffic for error rate testing, and the addition of dither to ADCs.

An integer-N PLL is a sort of DAC. You put data in as modulation, and the result is a change of frequency rather than voltage. The principles of an extreme oversampling DAC can be applied to it just as much as to the output buffer of a 1-bit DAC in a CD player. These systems scramble the sideband energy and make it much less conspicuous — a good thing. The sideband energy is also spread over a wider frequency range than the bandwidth of the loop filter. This is even better because it means more energy can be filtered out. Further, the scrambling process can be engineered to control the spectrum of the noise-like sidebands, called *noise shaping*, pushing most of the noise energy high enough in frequency that filtering can do a good job. The logic systems which shape the noise are higher-order delta modulators. They take up a lot of logic elements on an IC, but can be highly integrated and are therefore small, cheap, and have low power consumption. As a result, the noise-shaped fractional-N synthesizer looks like a simple PLL with a large amount of logic processing the data fed to its programmable divider.

Delta-modulators above the second order are inherently unstable. Audio converters have various proprietary schemes to stabilize them, and these little subtleties are carefully guarded secrets. The MASH (Multi-stAge noise Shaping) DAC arrangement adds together a series of low-order modulators, rather than trying to make one very high-order modulator. Fixing the stability problem requires that the output doesn't just jump between two states, N and N+1 in PLL terms, but it dances over a limited range.

## LIMITATIONS

With the division factor varying in a pseudo-random way, the operating point of the phase detector is also varying over a wide range and the phase detector needs to have a similarly wide operating range. Since filtering only happens *after* the phase detector and large amounts of noise at high offset frequencies are present, the phase detector must be very linear.

The noise-shaping scrambler keeps the close-in frequency range clean, but any non-linearity in the phase detector allows the strong high frequency noise components to

intermodulate. Intermodulation creates products at close-in frequencies, spoiling the noise performance of the close-in range.

This limits how clean the noise-shaping synthesizer can be made. The best examples are useful for many purposes but still aren't good enough for a high-grade HF receiver or any system requiring superior adjacent channel rejection. For such uses, they are combined with a high performance integer-N PLL in a hybrid structure similar to how the original fractional-N loop was used.

## AVAILABILITY

Fractional-N synthesizers have been available in chip form for several years. Analog Devices, National Semiconductor, and other manufacturers have offered families of PLL ICs for a long time, and their ranges include devices with all the noise shaping logic on-board. Some even have GHz VCOs on-board as well, with dividers down to more mundane frequency ranges.

These synthesizers have become an RF design building block. The RFMDRFFC2071, for example has a pair of medium-level active mixers with an entire synthesizer all on one die. Handheld transceivers that also receive 0.5 to 999.999999 MHz are likely to be made with these parts. If you are choosing one of these devices, look carefully at the noise sideband performance: the higher frequency version of the RF2071 IC has noise sidebands a few dB lower than the lower frequency version.

## WHAT NEXT?

The RF semiconductor industry is currently focused on mass-market applications such as mobile phones, WiFi and so on. The existing fractional-N synthesis parts are adequate for these systems and while there may be progressive increases in the scale of integration, there is little need for higher performance.

Development of fractional-N systems is within the range of the interested amateur, either by using the general-purpose parts on the market, or by developing their own using programmable logic array devices. A moderately-sized FPGA contains enough logic for a number of fractional-N synthesizers. For example, see the July/August 1998 *QEX* article by Ulrich L. Rohde, NIUL "A High-Performance Fractional-N Synthesizer" which describes a design covered by US patent 6509800 (2001).

A figure of merit for a fractional-N system is the maximum frequency at which the phase detector can operate. Higher frequencies allow the scrambled noise to be spread over a greater frequency range, making it easier to filter. The obvious approach is to develop faster and faster logic, but there is an alternative: Several fractional-N dividers with several separate phase detectors may have their

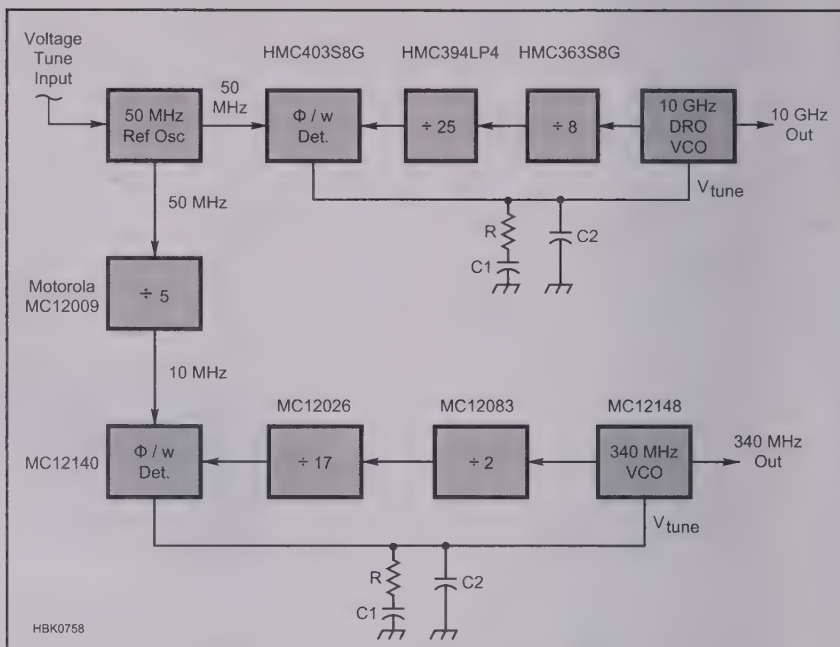

outputs combined. The phases of the outputs from the separate dividers may be offset from each other by programming registers differently in each scrambler, and the reference signals to the phase detectors may be offset to match.

Several phase detectors can thus act sequentially over each detector's cycling period, making a system with an effective phase detector frequency several times that of a single phase detector. The effective phase detector frequency can even be higher than the output frequency. A further elaboration would be to seed the pseudo-random noise generators in each divider differently. In this way the noise components from each divider will not correlate, though the tuning components correcting the VCO frequency will correlate. This means that the tuning components add more strongly, as voltages, while the noise components add more weakly as power. Each doubling of the number of dividers has the potential for a 3 dB improvement in noise performance of the system. This multiple divider arrangement is currently covered by a patent, but individuals are free to read them, to experiment and to perhaps find a better way. Patents eventually expire and their technology enters the public domain. Each increase in the density of programmable logic makes it easier.

### 9.6.5 A PLL Design Example

As our design example, let us consider a synthesized local oscillator chain for a 10 GHz transmitter. **Figure 9.54** is a simplified block diagram of this 10 GHz converter. This example is chosen because it is a departure from the traditional multi-stage multiply-and-filter approach. It permits realization of the oscillator system with two simple loops and minimal RF hardware. It is also representative of what is achievable with current hardware, and can fit in a space of 2 to 3 square inches. This example is intended to be a vehicle to explore the loop design aspects and is not offered as a "construction project." The multiple design details required are beyond the scope of this chapter.

Two synthesized frequencies, 10 GHz and 340 MHz, are required. Since 10.368 GHz is one of the popular X-band traffic frequencies, we initially mix this with the 10 GHz LO to produce an IF of 368 MHz. The 368 MHz IF signal is subsequently mixed with the 340 MHz LO to produce a 28 MHz final IF, which can be fed into the 10 meter input of any amateur transceiver. We focus our attention on the design of the 10 GHz synthesizer only. Once this is done, the same principles are applied to the 340 MHz section. Our goal is to design a low-noise LO system (by adopting minimum division ratios) with a loop reference oscillator that is an integer multiple of 10 MHz. Using this technique allows the entire system to be

**Figure 9.54** — A simplified block diagram of a PLL local oscillator for a 10 GHz converter.

locked at a later time to a 10 MHz standard for precise frequency control.

For the microwave synthesizer we consider using a line of microwave integrated circuits made by Hittite Microwave in gallium-arsenide (GaAs) material. These devices include a selection of prescalers operating to 12 GHz, a 5-bit counter that operates to 2.2 GHz and a phase/frequency detector that operates up to 1.3 GHz. If we use a crystal reference frequency  $f_{XO}$  of 100 MHz, and also apply that as  $f_{REF}$  into the PFD (therefore  $R = 1$ ), then the feedback divider number needs to be  $N = 10,000/100 = 100$ . One way to realize this in hardware is to represent  $100 = 4 \times 25$ , starting with a divide-by-4 prescaler and finishing with the 5 bit counter programmed to divide by 25. The divide-by-4 prescaler output at lock will be 2500 MHz, which is too high for the 2200 MHz limited programmable counter. We need a design change.

The obvious solution is to select a divide-by-8 prescaler, providing a 1250 MHz output from the 10 GHz input. We cannot program the counter to half of 25, so we need to leave it programmed at 25. This makes the output from the feedback divider at  $10,000/(8 \times 25) = 50$  MHz. We need to set  $R = 2$ .

Before even thinking about designing the loop filter, we need to know the VCO gain, VCO noise performance, divider noise performance, phase detector gain, phase detector noise performance and finally reference noise performance. For the 10 GHz VCO, we are always looking for parts that are easily available, useable and economical, so salvaging a dielectric resonator from a Ku band LNB is

promising (see "SHF Super Regenerative Reception by Andre Jamet, F9HX, in Jan-Feb 2002 *QEX*). These high-Q oscillators can be fitted with a varactor and tuned over a limited range with good results. The tuning sensitivity of our dielectric resonator VCO is about 10 MHz per volt and the phase noise at 10 kHz offset is  $-87$  dBc/Hz, and  $-107$  dBc/Hz at 100 kHz.

The phase detector and divider information is available from the device data sheets. The HMC363 divide-by-8 operates up to 12 GHz and has a programmable charge pump that sets the phase detector gain  $K_d$ . It is usually good to keep this gain high, so we choose to use a 2 mA charge pump current, giving  $K_d = 0.32$  mA/radian. The data sheet also says that this PFD has an output noise floor of  $-153$  dBc/Hz measured at 100 kHz offset. The HMC394 programmable divider operated up to 2.2 GHz with the same output noise floor. The HMC984 PFD operated up to 350 MHz with a noise figure of merit (FOM) of  $-231$  dBc/Hz/ $f_{REF}$ , so with  $f_{REF} = 50$  MHz the PFD output noise floor is  $-231 + 10 \log(50,000,000) = -154$  dBc/Hz. Assuming the R divider is implemented in CMOS, the output noise floor from it is  $-163 + 10 \log(50,000,000/125000) = -137$  dBc/Hz. This noise is much higher than the noise from the GaAs dividers, so it is actually better here to use a GaAs divide-by-2 for the R counter instead of using CMOS.

The logic noise floor for the entire PLL is the sum of the individual noises from each divider and the PFD. The result is  $-147$  dBc/Hz. This is determined at the PFD. To calcu-

Figure 9.55 — Comparisons of the theoretical and actual PLL dynamics show extremely good correspondence.

late how this noise will measure at the PLL output we need to add  $20\log N = 46$  dB. Thus the output noise floor due to PLL logic devices is  $-101$  dBc/Hz. This is close to the VCO phase noise at an offset of 100 kHz, so minimum noise design suggests that we select 100 kHz as our loop bandwidth.

An alternative is to eliminate the R counter and directly use a 50 MHz reference. An excellent choice for a low noise reference is the one described by John Stephensen on page 13 in Nov/Dec 1999 *QEX*. The noise performance of this VCXO is in the order of  $-160$  dBc/Hz at 10 kHz offset at the fundamental frequency. Translating this to the output frequency means adding  $20 \log N$ , for a result of  $-114$  dBc/Hz. Eliminating the R counter also lowers the logic noise floor to  $-104$  dBc/Hz at the output. The translated reference oscillator noise is 10 dB below the noise floor from the logic devices, so the logic noise floor dominates.

Using this information we can now design the loop filter. Assuming that the VCO tuning voltage is between 0.5 and 4.5V we can directly use the charge pump included in this PFD and therefore select the passive third order loop filter from Figure 9.48. We use the equations in Figure 9.46 and calculate loop filter component values of  $R = 6977$  ohms,  $C1 = 724$  pF, and  $C2 = 80$  pF. We therefore select 6.8k, 820 pF, and 82 pF for these component values respectively. The Bode plot of the theoretical and actual PLL dynamics is shown in Figure 9.55. It is nearly impossible to tell them apart!

If the VCO requires higher tuning voltages, you can insert a non-inverting op-amp gain stage between the output of this loop filter and the VCO. Choose a low input current op-amp to minimize leakage from the loop filter capacitors. Be careful—the gain of this amplifier stage changes the effective VCO

gain that the loop experiences. When designing the loop filter components the “design” VCO gain must be replaced by the product of the actual VCO gain and the amplifier gain. It is also essential to assure that the 1 dB bandwidth of the voltage amplifier greatly exceeds the loop bandwidth so that it does not degrade the PLL phase response and hence loop stability.

## 9.6.6 PLL Measurements and Troubleshooting

### VCO GAIN

One of the first things we need to measure when designing a PLL is the VCO gain. The tools needed include a voltmeter, some kind of frequency measuring device like a receiver or frequency counter and a clean source of variable dc voltage. The circuit in Figure 9.56 containing one or more 9 V batteries and a 10-turn, 10 kΩ pot does nicely. One simply varies the voltage some amount and then records the associated frequency of the VCO. The gain of the VCO is then the change in f divided by the change in voltage (Hz / V).

### LOOP BANDWIDTH

Measuring the actual bandwidth of the PLL usually means measuring the entire gain and phase responses of the PLL. There is a much easier way that needs only a square-wave generator and an oscilloscope. This method uses the PLL testing structure of Figure 9.57 developed by Glenn Ewart that injects a low-value square wave into the loop at a low impedance point so that impulse response can be observed directly. The test signal is also ground-referenced and is independent of the loop locking voltage.

Start by swapping the series RC components in the loop filter so the resistor is con-

Figure 9.56 — Clean, variable dc voltage source used to measure VCO gain in a PLL design.

Figure 9.57 — A simple testing structure for PLL dynamics.

nected to ground and the capacitor attaches to the VCO tuning line. Then split the resistor into two resistances that together add up to the total resistance needed by the filter. The bottom resistor connected to ground is very small—50 Ω is a nice choice when the total resistor value is much greater than 50 Ω. The top resistor is temporarily replaced by a potentiometer that can make up the desired remaining resistance. Across the bottom resistor we connect the square-wave generator and set it to a small amplitude (100 or 200 mV is common) at a frequency a few percent of the loop bandwidth, and operate the PLL. Looking at the VCO tuning line with an oscilloscope we see the impulse response of the PLL.

Now adjust the potentiometer way off-value to the low side. The impulse response will now show ringing. The frequency of this ringing is a good approximation of the PLL loop bandwidth.

### SETTLING TIME

Having measured the loop bandwidth, readjust the potentiometer back to its nominal value. The impulse response should look much cleaner! It is tempting to look at the settling time of the impulse response and say that this is the settling time of the PLL. This unfortunately is not quite true.

The PLL is not fully settled until capacitor

C1 is fully charged. This usually takes slightly longer than what the impulse response itself shows. Move the scope probe to the “ground” side of C1 and measure when this voltage reaches zero. This means there is no more current flowing through the filter resistors and the capacitor is fully charged.

### TROUBLESHOOTING PLLS

Here are some frequently encountered problems in PLL designs:

- The outputs of the phase detector are inverted. This results in the loop slewing to one or the other power supply rails. The loop cannot possibly lock in this condition. Solution: Swap the phase detector outputs.

- The loop cannot comply with the tuning voltage requirements of the VCO. If the loop runs out of tuning voltage before the required voltage for a lock is reached, the locked condition is not possible. Solution: Re-center the VCO at a lower tuning voltage or increase the rail voltages on the op amp.

The loop is very noisy and the tuning voltage is very low. The tuning voltage on the varactor diodes in the VCO should not drop below the RF voltage swing in the oscillator tank circuit. Solution: Adjust the VCO so that the loop locks with a higher tuning voltage.

### 9.6.7 Commercial Synthesizer ICs

In this section, we explore using commercially available synthesizer chips and the role of DDS in more recent hybrid architectures. The following is not intended to be project oriented, but rather is designed to expose the reader to additional concepts that cannot be fully explored here. The reader, being made aware of these ideas, may wish to examine them in detail using references at the end of this chapter.

Many synthesizer chips have been introduced in recent years for cellular and Wi-Fi applications. One might reasonably ask if any of these devices are well suited to amateur applications. The short answer is — probably not. Applications using these chips strive for a minimum of external components, so they are usually not flexible in design. These chips conform to a strict applications profile in which the communication link is typically sending a few tens of megabits for distances of less than 3 miles (5 km). Some are even designated as “low noise” with respect to other chips of their ilk, but these noise levels are not really low with respect to most amateur requirements. The phase noise, while adequate for their intended application, is not good enough for many HF, VHF and UHF applications without additional measures being taken.

Despite all this, they do have some interesting properties and capabilities that can be exploited with additional design. Some prop-

erties that can be exploited are programmable charge pump current, a rich set of division options for creating multiple-loop synthesizers and typically low power consumption.

One of the easiest ways to improve the overall performance is to follow one of these chips with additional frequency division. Consider the following example: One of these chips could be used as a 500 to 550 MHz synthesizer, followed with two cascaded decade dividers for a total division of 100. This division would reduce the phase noise profile by 40 dB, making a reasonably quiet synthesizer for the 5 to 5.5 MHz range. The step size would also be reduced by a factor of 100, making the spacing required in the 500 to 550 MHz range equal to 1 kHz for a step size of 10 Hz at 5 MHz. This would make a good local oscillator for a simple traditional radio that covers 80 and 20 meters using both mixer products against a 9 MHz SSB generator.

There are also other techniques that can prove helpful. Decoupling the VCO from the chip will permit one to avoid much of the “on chip” noise that VCOs are susceptible to at the expense of some more complexity. If the VCO is implemented externally, there is an opportunity to design it with increased operating Q, thereby improving the overall phase noise performance. An external VCO also opens other opportunities.

As mentioned earlier, these chips are designed for operation at a  $V_{CC}$  of 3 to 5 V, typically using an internal charge pump to generate the operating voltage. This limits the tuning voltage swing to  $V_{CC}$ . One must be able to fit the entire tuning range voltage and the ac voltage excursion in the VCO tank circuit within the  $V_{CC}$  range. As mentioned at the end of the earlier section Improving VCO Noise Performance, this problem can be overcome with the addition of voltage gain in an external operational amplifier, running at a higher voltage. This allows the signal-to-noise ratio of the oscillator to be improved by increasing the tank voltage swing and still having adequate voltage range to perform the tuning function. There are certainly more examples of how the performance of these devices could be improved for amateur applications.

### USE OF DDS IN HYBRID SYNTHESIZERS

One method of incorporating DDS within a hybrid synthesizer system is to have the DDS supply the least significant digits of the frequency resolution and to sum that DDS output into a conventional divide-by-N loop that supplies the most significant digits. If desired, this signal can be passed through a sufficiently narrow filter to further attenuate any DDS spurious signals. This method is employed in a number of commercial signal generators as well as some of the more mod-

ern transceivers.

Another widely used approach is to take advantage of the extremely small step size available from DDS devices and use this as the reference frequency into a conventional PLL synthesizer. The loop bandwidth of the PLL acts now as a tracking band-pass filter to reduce the DDS output spurious signals. Most modern FM broadcast transmitters use the latter technique when broadcasting CD-ROM and other digitized material.

### 9.6.8 Analog Frequency Synthesis

Even though the term ‘analog’ seems old-fashioned in the present age, these techniques still have wide use in modern radio designs. They are briefly covered here.

#### FREQUENCY MULTIPLICATION

It is useful to view frequency multiplication as an increased slope of phase with time, as shown in **Figure 9.58A**. For harmonic

**Figure 9.58 — Frequency multiplication and division: A — multiplication increases the rate that signal phase changes with time. This is often an integer (harmonic generation), but it can be non-integer in some applications (PLL); B — frequency division decreases the rate that signal phase changes with time. This is nearly always an integer.**

generation, this multiplication factor is an integer. More complicated frequency multipliers, such as phase-locked loops, can readily provide frequency multiplication with non-integer values.

**FREQUENCY DIVISION**

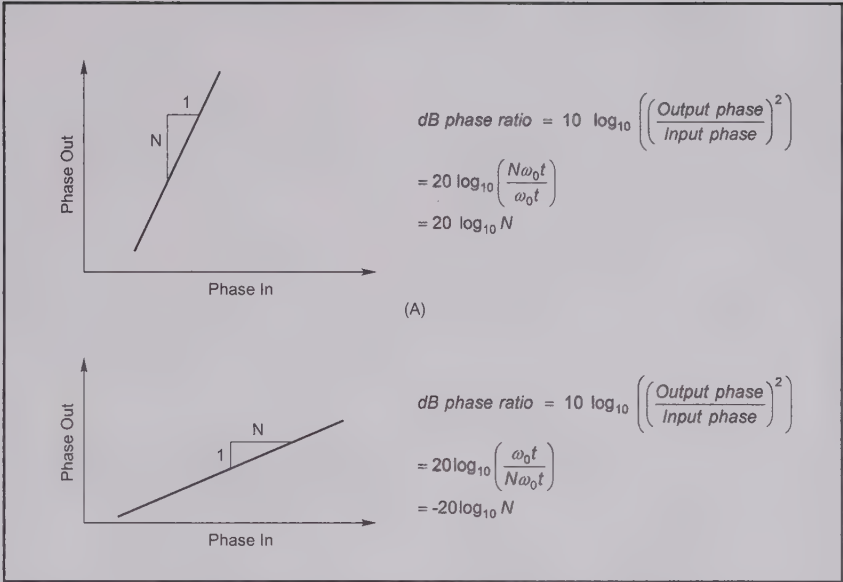

In the same way, frequency division is usefully viewed as a reduction in the slope of output signal phase with time. This is shown in Figure 9.58B. Frequency multiplication and division are inverse process of each other.

Noise behavior of frequency multipliers and dividers also has an inverse relationship. Phase noise encounters the same processes that the signal phase encounters. **Figure 9.59** shows that the phase noise out of any frequency multiplier is at least  $+20\log_{10}(N)$  higher than the phase noise on the input signal. This is unavoidable. It is also a big problem when the multiplication factor  $N$  is large. We are motivated to have input signals into a phase multiplier with very low phase noise.

Fortunately the output phase noise of a frequency divider is lower than that on its input signal. This effect is also symmetrical. This effect is often used in very low noise synthesizer design.

**FREQUENCY MIXING**

Mixers implement frequency addition and subtraction. The problem is that mixers do both at the same time, which means that some filtering is required to intentionally select whether the sum frequency, or the difference frequency, proceeds along to later stages of the radio. In **Figure 9.60** a particular example of frequency mixing is presented. Here the output is a close ratio of the input frequency, such a  $2/3$  or  $3/2$  when  $N = 2$ , or when  $N = 8$  the outputs can be  $7/8$  or  $9/8$ .

**Figure 9.59 — Noise behavior of frequency multipliers and dividers: A — frequency multiplication increases output phase noise; B — frequency division decreases output phase noise.**

**Figure 9.60 — One example of frequency mixing, where a signal is mixed with a divided version of itself to get a frequency ratio.**

**9.7 Phase Noise**

(This section deals specifically with phase noise generated by oscillators. A more general discussion of noise can be found in the **RF Techniques** chapter.) No oscillator output signal is perfect. Viewing an oscillator as a filtered-noise generator is relatively modern. The older approach is to think of an oscillator making a pure sine wave with an added, unwanted noise signal. These are just different ways of visualizing the same thing. They are equally valid views which are used interchangeably, depending on which best makes some point clear.

For example, it is instructive to use the pure-sine-wave-plus-noise view to see relationships between AM (amplitude) noise and PM (phase) noise processes, shown in **Figure 9.61**. Adding Gaussian noise to a pure sine wave is usefully modeled using phasors as

shown in Figure 9.61B. This generates both AM due to noise, and PM due to noise as shown in Figure 9.61C. Passing this signal through a limiter process, such as an amplifier in compression or through a switching mixer, leaves only the phase noise depicted in Figure 9.61D. Because it is so easy to remove AM noise but not phase noise, there is essentially no discussion about oscillator AM noise. Phase noise is the critical problem.

Phase modulation (PM) and frequency modulation (FM) are closely related. (See the **Modulation** chapter for a detailed description of each.) Phase is the integral of frequency, so phase modulation resembles frequency modulation, where the frequency deviation increases with increasing modulating frequency. Thus, there is no need to talk of “frequency noise” because phase noise

already covers it.

A thorough analysis of oscillator phase noise is beyond the scope of this section. However, a detailed, state-of-the-art treatment by Ulrich Rohde, NIUL, of free-running oscillators using nonlinear harmonic-balance techniques and the sources of noise in the Colpitts oscillator circuit is presented in the downloadable supplemental information accompanying this book. Also see the Reference entry for Dacus regarding low-noise synthesizer design.

Because of the dynamic range required to measure phase noise, it is one of the most difficult measurements in all of electrical engineering. The section on ARRL Lab Measurement of Transmitter Phase Noise illustrates the lengths to which one must go to obtain repeatable, reliable measurements.

Figure 9.61 — At A, a vector (left) and phasor (right) diagram of an ideal oscillator with no noise. Added noise creates a region of uncertainty in the phasor's length and position (B). AM noise varies the phasor's length; PM noise varies the phasor's relative angular position (C). Limiting a signal that contains both AM and PM noise strips off the AM and leaves the PM (D).

An additional article on measuring receiver phase noise is included with this book's downloadable supplemental material.

### 9.7.1 Effects of Phase Noise

Phase noise becomes a problem when it is more noticeable than other limitations. It degrades all signals, but whether it is important or not depends on the application. For voice signals it sounds like background "hiss" in headphones or speakers. It also limits the dynamic range of receivers with closely separated signals, or receiving signals with widely different input powers.

Phase noise became a significant problem for amateurs when the use of frequency synthesizers supplanted conventional LC VFOs in amateur equipment. For reasons discussed in the Frequency Synthesizers section of this chapter, it is a major task to develop a synthesizer that tunes in steps fine enough for use with SSB and CW operation while competing with the phase-noise performance of a reasonable-quality LC VFO. Many synthesizers fall far short of this target. Along with the problems with frequency synthesizers, phase noise always gets worse at higher frequencies.

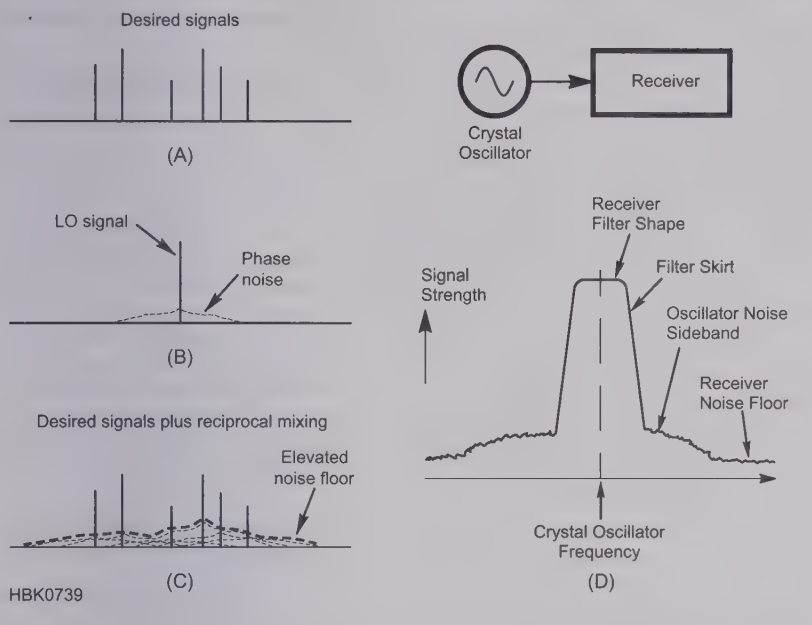

General-coverage, up-converting receiver architectures require local oscillators to operate at higher and higher frequencies, aggravating phase noise performance. As SDR techniques expand, however, phase noise performance is improving on both receive and transmit.

### 9.7.2 Reciprocal Mixing

All mixers are symmetrical, meaning that the output IF signal depends on the characteristics of both input signals: the local oscillator (LO) and the desired signal. A change to either signal shows up at the IF, where there is no way of knowing if the signal characteristics seen are from the input signal itself, or from the LO. We usually assume that the LO is very pure so only input signal modulations show up at the IF.

When there is phase noise on the LO signal, the situation changes. Noise on the LO transfers to *all* input signals at the mixer output as if it was originally present on each input signal and the LO was perfectly clean — the IF circuits can't tell the difference. This process is called *reciprocal mixing*, where noise on the LO appears as noise on the desired output signal. This is a serious limitation on a receiver's weak-signal ability.

How reciprocal mixing of LO phase noise can limit receiver dynamic range is shown in Figure 9.62. One possible scenario of band activity is shown as the set of input signals in Figure 9.62A. Figure 9.62B shows the phase noise profile for the LO of this receiver. Reciprocal mixing is illustrated in Figure 9.62C, showing that the LO phase noise is

**Figure 9.62** — A typical set of input signals is shown at A and an LO signal with phase noise at B. When the LO signal at B is mixed with the input signals at A, the result is a set of mixing products each having phase noise added, raising the noise floor across the band as shown at C. Phase noise in your receiver can be heard by tuning to a strong, clean crystal-oscillator signal as shown in D.

added to each of the signals in the band in proportion to its input power. The total noise seen by the receiver demodulator is the sum of all transferred phase noise profiles at the received frequency. This raises the apparent noise floor of the receiver.

Another receiver problem due to LO phase noise occurs if a very large signal appears in the receiver passband but at a frequency well removed from the desired signal. One example of this is shown in **Figure 9.63**. If the LO phase noise is excessive, then reciprocal mixing with this large signal can completely block the ability to demodulate the desired signals. Indeed, it is possible to make a wide sweep of spectrum relatively useless.

Reciprocal mixing in a receiver does not affect the operating ability of other stations. The solution is to reduce the phase noise on the receiver's LO.

### 9.7.3 A Phase Noise Demonstration

Healthy curiosity demands some form of demonstration so the scale of a problem can be judged "by ear" before measurements are attempted. We need to be able to measure the noise of an oscillator alone (to aid in the development of quieter ones) and we also need to be able to measure the phase noise of the oscillators in a receiver (a transmitter can be treated as an oscillator). Conveniently, a receiver contains most of the functions

**Figure 9.63** — A strong received signal can also cause such severe reciprocal mixing that desired signals are completely obscured by noise. If the signal is transmitted with phase noise from the transmitter LO, the effect is the same as noise covers the desired signals, sometimes across a very wide range of frequencies.

needed to demonstrate its own phase noise.

Because reciprocal mixing adds the LO's sidebands to clean incoming signals, in the same proportion to the incoming carrier as they exist with respect to the LO carrier, all we need do is to apply a strong, clean signal wherever we want within the receiver's tuning range. This signal's generator must have lower phase noise than the radio being evaluated. A general-purpose signal generator is unlikely to be good enough; a crystal oscillator is needed.

It's appropriate to set the oscillator's signal level into the receiver to about that of a strong

broadcast carrier, say  $S9 + 40$  dB. Set the receiver's mode to SSB or CW and tune around the test signal, looking for an increasing noise floor (higher hiss level) as you tune closer toward the signal, as shown in **Figure 9.62D**. Switching in a narrow CW filter allows you to hear noise closer to the carrier than is possible with an SSB filter. This is also the technique used to measure a receiver's effective selectivity, and some equipment reviewers kindly publish their plots in this format. *QST* reviews, done by the ARRL Lab, often include the results of specific phase-noise measurements.

### 9.7.4 Transmitted Phase Noise

Phase noise on an LO used to generate a transmitted signal will also be amplified and transmitted along with the desired output signal. This obscures reception by raising the noise floor even for receivers with low phase noise because they also receive the noise from the transmitter. In this case, the phase noise is generated externally to the receiver and must be removed at the transmitter.

If the transmitter is operating linearly, the strength of the transmitted noise is of the same proportion to transmitter output power as the phase noise is to the oscillator signal power. The noise may even extend well beyond the band in which the desired signal is transmitted unless the signal passes through narrow-band filtering that limits its bandwidth.

This transmitted noise is wasted power that is not useful for communication and unfortunately makes for a noisier band. If you are working a weak station and a nearby transmitter with a noisy oscillator comes on the air with a high power signal on a different frequency, it is possible that the output noise from this off-frequency transmitter may completely block your ability to continue working that weak station.

In bad cases, reception of nearby stations can be blocked over many tens of kilohertz above and below the frequency of the offending station. This is seen in **Figure 9.63**, where the offending signal and its associated noise are from a nearby transmitter. Frequencies close to that of the nearby transmitter are suddenly useless.

Transmitted phase noise can present serious problems for multi-station operation such as at Field Day or during emergency communications where several transmitters and receivers are in close proximity. This is a particular problem with transceivers that use early PLL-synthesized VFOs. If you are planning such an operation, be sure the level of transmitted phase noise is acceptable for the transceivers you plan on using.

At your receiver there is nothing you can do about transmitted phase noise. When there is noise power present at the same frequency

as a weak (far) signal you are receiving, your receiver cannot separate them. The only solution is for the problem station to use a transmitter with a “cleaner” LO (less phase noise). This is a more serious problem than reciprocal mixing since this transmitted noise affects the ability of many other stations to use that band.

### 9.7.5 PLL Synthesizer Phase Noise

Differences in resonator Q usually make the phase-noise sidebands of a loop’s reference oscillator much smaller than those of the VCO. Within its loop bandwidth, a PLL acts toward matching the phase-noise components of its VCO to those of the reference. There are several processes which get in the way of this actually happening, which are outlined here.

Dividing the reference oscillator signal  $f_{XO}$  to produce the signal  $f_{REF}$  which is applied to the phase detector also divides the deviation of the reference oscillator’s phase-noise sidebands. (See the previous section on PLL.) This division results in a 20 dB reduction in phase noise per decade of division. This models as a factor of  $-20 \log(R)$  dB, where R is the reference divisor value, since  $f_{REF}$  is less than  $f_{XO}$ . We also know that within its loop bandwidth the PLL acts as a frequency multiplier and this multiplies the deviation of the phase noise sidebands present at the PFD, again by 20 dB per decade or equivalently by a factor of  $20 \log(N)$  dB, where N is the loop divider’s value. Between the reference oscillator and the PLL output, the sidebands on the reference signal are increased by 20 log (N/R) dB.

### COUNTER AND PFD NOISE

Logic circuits have a noise characteristic that is extremely important to PLL design. Any circuit, when you really get down to it, is always an analog circuit. In this case the switching threshold of the logic circuits has a tiny amount of noise on it. This small amount of noise manifests itself in a very slight variation in when the logic circuit actually switches, even if the input clock is perfectly clean. We can think of this small timing jitter as a small shift in the output signal “zero crossing,” which is directly equivalent to a phase modulation.

The amount of this timing jitter is constant, no matter the operating frequency. Thus, the amount of phase shift this represents depends on the operating frequency: 1 nanosecond of jitter at 1 kHz is very small, but represents 36 degrees at 100 MHz. As a result we get different measures of the noise floor from digital circuits that depend on the frequency at which they are operating. This digital noise floor interferes with the PLL action to match the VCO noise to the divided reference oscillator noise as measured at the PFD inputs.

### VCO NOISE

The PLL can track only slowly moving noise, well within its bandwidth. Therefore VCO noise components that change slowly enough for the PLL to measure and track will be increasingly canceled successfully. Any VCO noise component that changes at a rate faster than the PLL bandwidth will not be changed at all. At offset frequencies beyond the PLL bandwidth the VCO noise is still present as if the PLL were not even there.

Does this imply that to get a low-noise synthesizer we are encouraged to make the PLL bandwidth very wide? Well, yes, to a certain degree. When we build PLL synthesizers we soon find that the logic noise from the digital section begins to get in the way if the loop bandwidth gets too wide. When this happens the total PLL output noise actually begins to increase as the bandwidth gets wider. There is a range of loop bandwidth values where the total PLL output noise has a minimum. This range is centered at the offset frequency where the logic noise floor, multiplied by  $20 \log(f_{OUT}/f_{REF})$ , has the same value as the VCO intrinsic phase noise.

Clearly, having a VCO design with minimum phase noise is very important to a good, low-noise PLL synthesizer. Much effort has been expended on this area in industry. A summary of important results from these noise reduction efforts is presented in the section Improving VCO Noise Performance below.

### FRACTIONAL DIVISION NOISE

From the brief discussion on fractional-N principles, we note that this whole idea is based on changing the feedback divider value in a semi-randomized way. This inherently jitters the output from the feedback divider, which is a source of phase noise into the PFD.

This noise source is algorithmic instead of physical, but the noise is a big problem nonetheless.

### OTHER NOISE SOURCES

Phase noise can be introduced into a PLL by other means. Any amplifier stages between the VCO and the circuits that follow it (such as the loop divider) will contribute some noise, as will microphonic effects in loop- and reference-filter components (such as those due to the piezoelectric properties of ceramic capacitors and the crystal filters sometimes used for reference-oscillator filtering). Noise on the power supply to the system’s active components can modulate the loop. The fundamental and harmonics of the system’s ac line supply can be coupled into the VCO directly or by means of ground loops.

### 9.7.6 Improving VCO Noise Performance

It is tempting to regard VCO design as a matter of coming up with a suitable oscillator topology with a variable capacitor, simply replacing the variable capacitor with a suitable varactor diode and applying a tuning voltage to the diode. Unfortunately, things are not this simple (as if even this is simple!). There is the matter of applying the tuning voltage to the diode without significantly disturbing the oscillator performance. There is also an issue of not introducing parasitic oscillation with the varactor circuit.

Next, as mentioned earlier, one would not like the tuning voltage to drop below the voltage swing in the oscillator tank. If this is allowed to occur, the tuning diodes go into conduction and the oscillator noise gets worse. A good first approach is to use varactor diodes back to back as shown in **Figure 9.64**. This allows the tank voltage

**Figure 9.64** — A practical VCO. The tuning diodes are halves of a BB204 dual, common-cathode tuning diode (capacitance per section at 3 V, 39 pF) or equivalent. The ECG617, NTE617 and MV104 are suitable dual-diode substitutes, or use pairs of 1N5451s (39 pF at 4 V) or MV2109s (33 pF at 4 V).

swing to be developed across two diodes instead of one, as well as allow for a more balanced loading of the oscillator's tank. The semiconductor industry has realized this and there are a number of varactors available prepackaged in this configuration today.

### IMPROVING VCO OPERATING Q

Often the Q of passive capacitors available for use in an oscillator tank exceeds the Q of available varactors. One way of reducing the influence of the varactor is to use only the amount of varactor capacitance required to tune the oscillator over its desired range. The balance of the capacitance is supplied to the tank in the form of a higher-Q fixed capacitor. This has the advantage of not requiring the varactor to supply all the capacitance needed to make the circuit function, and often allows for the use of a lower capacitance varactor.

Lower capacitance varactors typically exhibit higher Q values than their larger capacitance counterparts. This concept can be extended by splitting the oscillator tuning range, say 70 MHz to 98 MHz (for a typical lower-side up-converter receiver design popular in recent analog architectures), into multiple bands. For this example let us consider four oscillators, each with 7 MHz of tuning range. We desire the varactor Q effects to be swamped by high-Q fixed capacitors. This can be further improved through the use of a "segment-tuned VCO" discussed below. A secondary but important benefit of this is to reduce the effective tuning gain (MHz/volt,  $K_0$ ) of the oscillators, making them less susceptible to other noise voltage sources in the synthesizer loop. These noise sources can come from a variety of places including, but not limited to, varactor leakage current, varactor tuning drive impedance and output noise of the driving operational amplifier or charge pump.

Segment-tuned VCOs provide the designer with additional benefits, but also with additional challenges. By segmented we mean that circuit elements, which could be both inductance and capacitance, are selected for each range that the VCO is expected to tune. **Figure 9.65** shows the frequency range-switching section of a typical VCO in which several diode switches are used to alter the total tank circuit inductance in small steps. These segments create a type of "coarse tuning" for the VCO, and the output of the PLL loop filter performs "fine tuning" with the varactor diode. Usually the component values are arranged in some sort of binary tree. In some integrated designs, 64 or even 128 subbands are available from the VCO.

Many times the segmented-VCO concept is applied to an oscillator design that is required to cover several octaves in frequency. For example, this would be the case with a single-IF radio with the IF at about 8 MHz. The VCO would be required to cover 8 MHz

**Figure 9.65** — The resonator portion of an inductor-switched segment-tuned VCO. A varactor diode provides tuning over a small range. Diode switches will alter the total inductance, changing the frequency in larger steps. Inductor-switched, capacitor-switched, and combinations are all used in VCO designs. (From Hayward, *Introduction to Radio Frequency Design*, Chapter 7. See references.)

to 48 MHz for 100 kHz to 50 MHz coverage of a typical transceiver.

While segmentation allows one to build a multi-octave tunable oscillator, segmentation also imposes some additional constraints. Recalling the earlier section in this chapter on oscillators, the condition for oscillation is an oscillator loop gain of 1 at a phase angle of 0 degrees. Over several octaves, the gain of the oscillating device (typically a transistor) varies, decreasing as operating frequency increases. While conventional limiting in the oscillator circuit will deal with some of this, it is not good practice to let the normal limiting process handle the entire gain variation. This becomes the role of automatic gain control (AGC) in multi-octave oscillator designs. Application of AGC allows for the maintenance of the oscillation criteria, a uniform output and good starting characteristics, and lower noise across the operating bandwidth.

Finally, a properly designed segmented VCO can improve synthesizer switching speed. The segmentation allows the designer to "pre-steer" the PLL system and reduce the time required for the loop filter to slew the VCO to the desired frequency for lock. Frequency-locked loops (FLL) are often employed for this steering operation to be sure that it happens properly.

### 9.7.7 ARRL Lab Transmitter Phase Noise Measurement

(This section was written by ARRL Lab Staff Engineers, Zack Lau, W1VT, and Bob Allison, WB1GCM.) Receiver performance has improved dramatically over the past generation or two of transceivers. With the widespread use of better filtering and improvements in digital signal processing, the effects of intermodulation distortion (IMD) at close signal spacing have been reduced greatly.

Many software defined receivers (SDRs) now experience little to no reciprocal mixing or reduction of audio level on the received frequency from strong adjacent signals. Signals generated within the receiver during reception of one or more strong nearby signals are not the problem they once were, and it's possible to operate effectively in a crowded band.

Although today's receivers can hear weak signals very close to adjacent strong signals, even the best receivers cannot eliminate the effects of a wide signal from an adjacent transmitter. Transmitted signal issues include excessive keying bandwidth on CW, poor suppression of transmitted IMD products (which causes splatter on SSB), or transmitted phase noise (which raises a receiver's noise floor) in the speaker. ARRL Lab Product Review test reports include transmitter IMD products (both typical and worst case), a plot showing keying sidebands, and a plot showing transmitted phase noise.

### PHASE NOISE

Phase noise is essentially the noise generated above and below an oscillator's frequency, also called sideband noise. All oscillators generate some level of phase noise. This is most evident when a close adjacent signal is very strong and the receiver's background noise increases. This is due to the mixing of the first local oscillator's phase noise with the incoming signal at the first IF (reciprocal mixing). The Lab reports the effects of reciprocal mixing in the receiver as "reciprocal mixing dynamic range" or RMDR. In many receivers we've tested, RMDR is the limiting dynamic range. In other words, third order IMD dynamic range and blocking dynamic range are better than RMDR. (See the **Receiving** chapter.)

A transmit oscillator, the heart of the transmitter, has phase noise too. A transmitter's

**Figure 9.66** — The ARRL Lab's Rohde & Schwarz FSUP 26 Signal Analyzer, used for transmitter phase noise testing.

**Figure 9.67** — Sample phase noise plot for an amateur HF transceiver as published in Product Review in *QST*. This is the Icom IC-7851.

phase noise is a fixed characteristic and, at times, can be a nuisance to other operators. A good example of observed phase noise can happen at Field Day or other environments where several transmitters are operating in close proximity. When two stations are operating on one band, the CW station blasts the phone operator's ears with bursts of noise, and vice versa. Using a transmitter exhibiting high phase noise with an RF amplifier magnifies the problem.

The solution for the reduction of both transmitted phase noise and receiver reciprocal mixing is the employment of high quality oscillators by the manufacturer. Generally, the better the oscillator (the lower the phase noise), the better the RMDR and the lower the transmitted phase noise.

### ARRL LAB TESTING

At the ARRL Laboratory, we use a Rohde & Schwarz FSUP 26 Signal Source Analyzer (Figure 9.66), which allows us to measure phase noise on any frequency up to 26.5 GHz.

A crystal oscillator with very low phase noise is used to calibrate the system. We use an attenuator after the transmitter to bring the signal down to a suitable level for the phase noise test set.

A sample phase-noise plot for an amateur transceiver is shown in Figure 9.67. It was produced with the test setup shown in Figure 9.66. In this case, measurements for 14 MHz and 50 MHz are shown. These plots do not necessarily reflect the phase-noise characteristics of all units of a particular model.

The reference level (the top horizontal line on the scale in the plot) represents 0 dBc/Hz. Because each vertical division represents 20 dB, the plot shows the noise level between 0 dBc/Hz (the top horizontal line) and -180 dBc/Hz (the bottom horizontal line). The horizontal scale is logarithmic, with one decade per division (the first division shows noise from 100 Hz to 1 kHz Hz offset, whereas the last division shows noise from 100 kHz through 1 MHz offset).

### WHAT DO THE PHASE-NOISE PLOTS MEAN?

Although they are useful for comparing different radios, plots can also be used to calculate the amount of interference you may receive from a nearby transmitter with known phase-noise characteristics. An approximation is given by

$$A_{QRM} = NL + 10 \times \log(BW)$$

where

- $A_{QRM}$  = Interfering signal level, dBc
- NL = noise level on the receive frequency, dBc
- BW = receiver IF bandwidth, in Hz

For instance, if the noise level is -90 dBc/Hz and you are using a 2.5 kHz SSB filter,

the approximate interfering signal will be -56 dBc. In other words, if the transmitted signal is 20 dB over S-9, and each S unit is 6 dB, the interfering signal will be as strong as an S-3 signal.

The measurements made in the ARRL Lab apply only to transmitted signals. It is reasonable to assume that the phase-noise characteristics of most transceivers are similar on transmit and receive because the same oscillators are generally used in the local-oscillator (LO) chain or for generating DDS signals.

In some cases, the receiver may have better phase noise characteristics than the transmitter. Why the possible difference? The most obvious reason is that circuits often perform less than optimally in strong RF fields, as anyone who has experienced RFI problems can tell you. A less obvious reason results from the way that many high-dynamic-range receivers work. To get good dynamic range, a sharp crystal filter called a *roofing filter* is often placed immediately after the first mixer in the receive line. This filter removes all but a small slice of spectrum for further signal processing. If the desired filtered signal is a product of mixing an incoming signal with a noisy oscillator, signals far away from the desired one can end up in this slice. Once this slice of spectrum is obtained, however, unwanted signals cannot be reintroduced, no matter how noisy the oscillators used in further signal processing. As a result, some oscillators in receivers don't affect phase noise.

The difference between this situation and that in transmitters is that crystal filters are seldom used for reduction of phase noise in transmitting because of the high cost involved. Equipment designers have enough trouble getting smooth, click-free break-in operation in transceivers without having to worry about switching crystal filters in and out of circuits at 40 WPM keying speeds!

## 9.8 Glossary of Oscillator and Synthesizer Terms

**Buffer** — A circuit that amplifies the output of a circuit while isolating it from the load.

**Bypass** — Create a low ac impedance to ground at a point in the circuit.

**Cavity** — A hollow structure used as an electrical resonator.

**Closed-loop** — Operation under the control of a feedback loop (see also **open-loop**).

**Coupling** — The transfer of energy between circuits or structures.

**Damping (factor)** — the characteristics of the decay in a system's response to an input signal. The **damping factor**,  $\zeta$ , is a numeric value specifying the degree of damping. An **underdamped** system alternately overshoots and undershoots the eventual steady-state output. An **overdamped** system approaches the steady-state output gradually, without overshoot. A **critically-damped** system approaches the steady-state output as quickly as possible without overshoot.

**dBc** — Decibels with respect to a carrier level.

**DC-FM** — control of a signal generator's output frequency by a dc voltage.

**Decouple** — To provide isolation between circuits, usually by means of filtering.

**Direct digital synthesis (DDS)** — Generation of signals by using counters and accumulators to create an output waveform.

**Distributed** — Circuit elements that are inherent properties of an extended structure, such as a transmission line.

**ESR** — Equivalent series resistance.

**Free-running** — Oscillating without any form of external control.

**Fundamental** — Lowest frequency of natural vibration or oscillation.

**Integrator** — A low-pass filter whose output is approximately the integral of the input signal.

**Intermodulation** — Generation of distortion products from two signals interacting in a nonlinear medium, device, or connection.

**Isolation** — Preventing signal flow between two circuits or systems.

**Reverse isolation** refers to signal flow against the desired signal path.

**Jitter (phase jitter)** — Random variations of a signal in time, usually refers to random variations in the transition time of digital signals between states.

**Linearization** — Creation of a linear amplification or frequency characteristic through corrections supplied by an external system.

**Loop gain** — The total gain applied to a signal traveling around a feedback control loop.

**Lumped (element)** — Circuit elements whose electrical functions are concentrated at one point in the form of an electronic component.

**Match** — Equal values of impedance.

**Modulus** — The number of states of a digital counter or divider.

**Motional capacitance (inductance)** — The electrical effect of a crystal's mechanical properties, modeled as a capacitance (inductance).

**Natural frequency ( $\omega_n$ )** — Frequency at which a system oscillates without any external control.

**Noise bandwidth** — The width of an ideal rectangular filter that would pass the same noise power from white noise as the filter being compared (also called **equivalent noise bandwidth**).

**Open-loop** — Operation without controlling feedback.

**Oscillation** — Repetitive mechanical motion or electrical activity created by the application of positive feedback.

**Overtones** — Vibration or oscillation at frequencies above the **fundamental**, usually harmonically related to the fundamental.

**Permeability tuning** — Varying the permeability of the core of an inductor used to control an oscillator's frequency.

**Phase-lock** — Maintain two signals in a fixed phase relationship by means of a control system.

**Phase noise** — Random variations of a signal in time, expressed as variations in phase of a sinusoidal signal.

**Phasor** — Representation of a sinusoidal signal as an amplitude and phase, often drawn as a vector.

**Power density** — Amount of power per unit of frequency, usually specified as dBc/Hz or as RMS voltage/ $\sqrt{\text{Hz}}$ .

**Prescaler** — A frequency divider used to reduce the frequency of an input signal for processing by slower circuitry.

**Preselector** — Filters applied at a receiver's input to reject out-of-band signals.

**Pull** — Change the frequency at which a crystal oscillates by changing reactance

of the circuit in which it is installed.

**Quadrature** — A 90° phase difference maintained between two signals.

**Reciprocal mixing** — Noise in a mixer's output due to the LO's noise sidebands mixing with those of the desired signal.

**Relaxation oscillation** — Oscillation produced by a cycle of gradual accumulation of energy followed by its sudden release.

**Resonator** — Circuit or structure whose resonance acts as a filter.

**Simulation** — Calculate a circuit's behavior based on mathematical models of the components.

**Spurious (spur)** — A signal at an undesired frequency, usually unrelated to the frequency of a desired frequency.

**Squegg (squeeg)** — Chaotic or random jumps in an oscillator's amplitude and/or frequency.

**Static (synthesizer)** — A synthesizer designed to output a signal whose frequency does not change or that is not changed frequently.

**Synthesis (frequency)** — The generation of variable-frequency signals by means of nonlinear combination and filtering (direct synthesis) or by using phase-lock or phase-control techniques (indirect synthesis).

**TCXO** — Temperature-compensated crystal oscillator. A **digitally temperature-compensated oscillator (DTCXO)** is controlled by a microcontroller or computer to maintain a constant frequency. **Oven-controlled crystal oscillators (OCXO)** are placed in a heated enclosure to maintain a constant temperature and frequency.

**Temperature coefficient (tempco)** — The amount of change in a component's value per degree of change in temperature.

**Temperature compensation** — Causing a circuit's behavior to change with temperature in such a way as to oppose and cancel the change with temperature of some temperature-sensitive component, such as a crystal.

**Varactor (Varicap)** — Reverse-biased diode used as a tunable capacitor.

**VCO** — Voltage-controlled oscillator (also called **voltage-tuned oscillator**).

**VFO** — Variable-frequency oscillator.

**VXO** — Variable crystal oscillator, whose frequency is adjustable around that of the crystal.

### Design Software

The following *Windows* software by Jim Tonne, W4ENE, is available with the downloadable supplemental content.

- *Diplexer* for design and analysis of diplexer filters
- *Elsie* for design and analysis of lumped-element LC filters
- *Helical* for design and analysis of helical-resonator bandpass filters
- *SVC Filter Designer* for design and analysis of lumped-element high-pass and low-pass filters
- *QuadNet* for design and analysis of active all-pass networks for SSB operation

# Analog and Digital Filtering

This chapter discusses the most common types of filters used by radio amateurs, both analog and digital. Design information is supplied where appropriate or references to software or detailed design procedures are supplied.

The sections describing basic concepts, lumped element filters and some design examples were initially prepared by Jim Tonne, W4ENE, and updated by Ward Silver, NØAX. Digital filter material was updated by Doug Grant, K1DG, based on material originally developed by Alan Bloom, N1AL. Additional digital filter material was based on the SDR: Simplified column in *QEX* by Ray Mack, W5IFS.

The downloadable supplemental information's design example for active filters was provided by Dan Tayloe, N7VE. The downloadable supplemental information's design example for crystal filters was developed by Dave Gordon-Smith, G3UUR.

## 10.1 Introduction

Electrical filters are circuits used to process signals based on their frequency. For example, most filters are used to pass signals of certain frequencies and reject others. The electronics industry has advanced to its current level in large part because of the successful use of filters. Filters are used in receivers so that the listener can hear only the desired signal; other signals are rejected. Filters are used in transmitters to pass only one signal and reject those that might interfere with other spectrum users. **Table 10.1** shows the usual signal bandwidths for several signal types.

The simplified receivers in **Figure 10.1** show filter use in both an analog, superheterodyne receiver (Figure 10.1A) and a simplified SDR receiver (Figure 10.1B). A *preselector* filter is placed between the antenna and the receiver's front end to pass all frequencies within a given amateur band with low loss. Strong out-of-band signals from broadcast, commercial, or military stations are rejected to prevent them from overloading the receiver input. The preselector filter is almost always built with *lumped-element* or "LC" technology.

In an analog receiver, there are one or more intermediate frequency (IF) filters to select only the desired signal. The IF filter closest to the antenna may be a relatively wide "roofing" filter with a bandwidth of several kHz to reject strong in-band signals not close to the desired signal frequency. Following detection or demodulation, an audio filter is placed somewhere ahead of the AF amplifier and speaker to reject unwanted products from the noise. The audio filter is often implemented with *active filter* technology. For an SDR receiver, similar preselector and audio filters may be used but the filters which select a single signal are implemented as *digital filters* in the I/Q Processing block.

The complementary transmitter block diagrams are shown in **Figure 10.2** in which a similar array of filters appears in reverse order. In the analog transmitter, an audio filter between the microphone and the balanced mixer rejects noise and unwanted speech components. Since the balanced mixer generates both lower and upper sidebands, an IF filter is placed at the mixer output to pass only the desired lower (or upper) sideband. In the SDR version, the input signals are digitized and processed before the I/Q signals are filtered for transmission.

Finally, a filter at the output of the transmit mixer passes only signals within the amateur band in use rejects unwanted frequencies generated by the mixer to prevent them from being amplified and transmitted. Filters at the transmitter output attenuate the harmonics of the transmitted signals.

**Table 10.1**

### Typical Filter Bandwidths for Typical Signals

Source	Required Bandwidth
Fast-scan analog television (ATV)	4.5 MHz
Broadcast-quality speech and music	15 kHz (from 20 Hz to 15 kHz)
Communications-quality speech	3 kHz (from 300 Hz to 3 kHz)
Slow-scan television (SSTV)	3 kHz (from 300 Hz to 3 kHz)
HF Digital (general)	100 to 1500 Hz (depends on modulation and bit rate)
HF RTTY (standard shift)	250 to 500 Hz
Radiotelegraphy (Morse code, CW)	200 to 500 Hz
PSK31 digital modulation	100 Hz

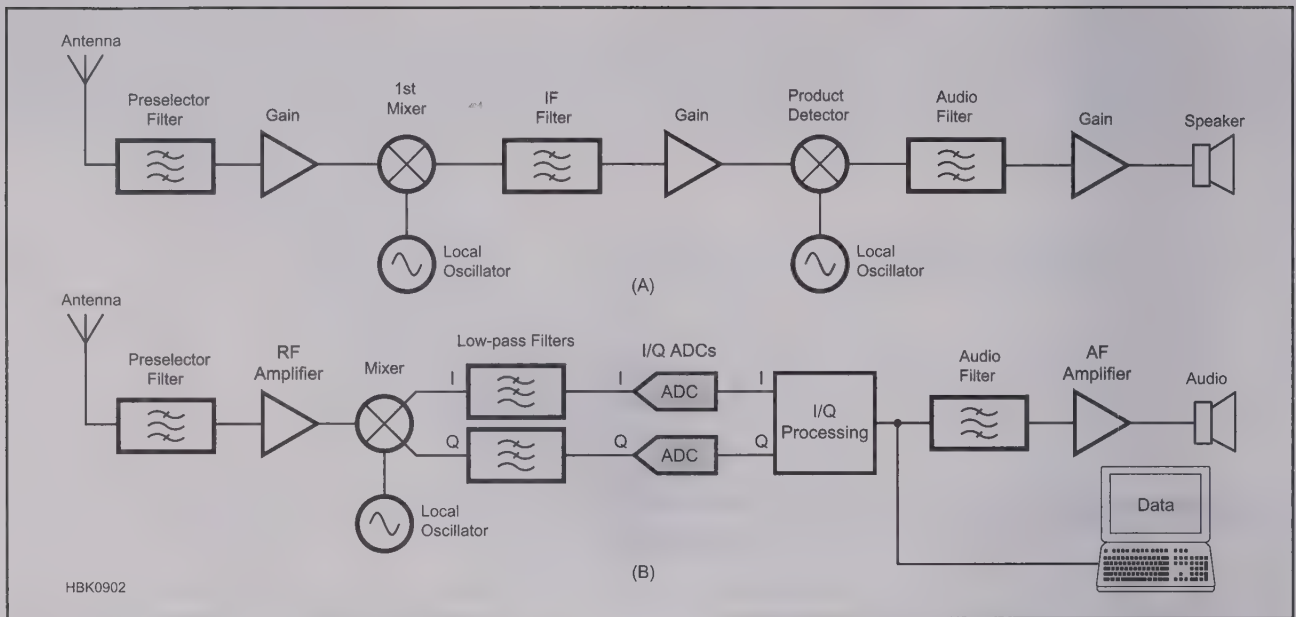

Figure 10.1 — Single-band SSB superheterodyne receiver (A) and SDR SSB/Data receiver (B) showing the filters typically used by each.

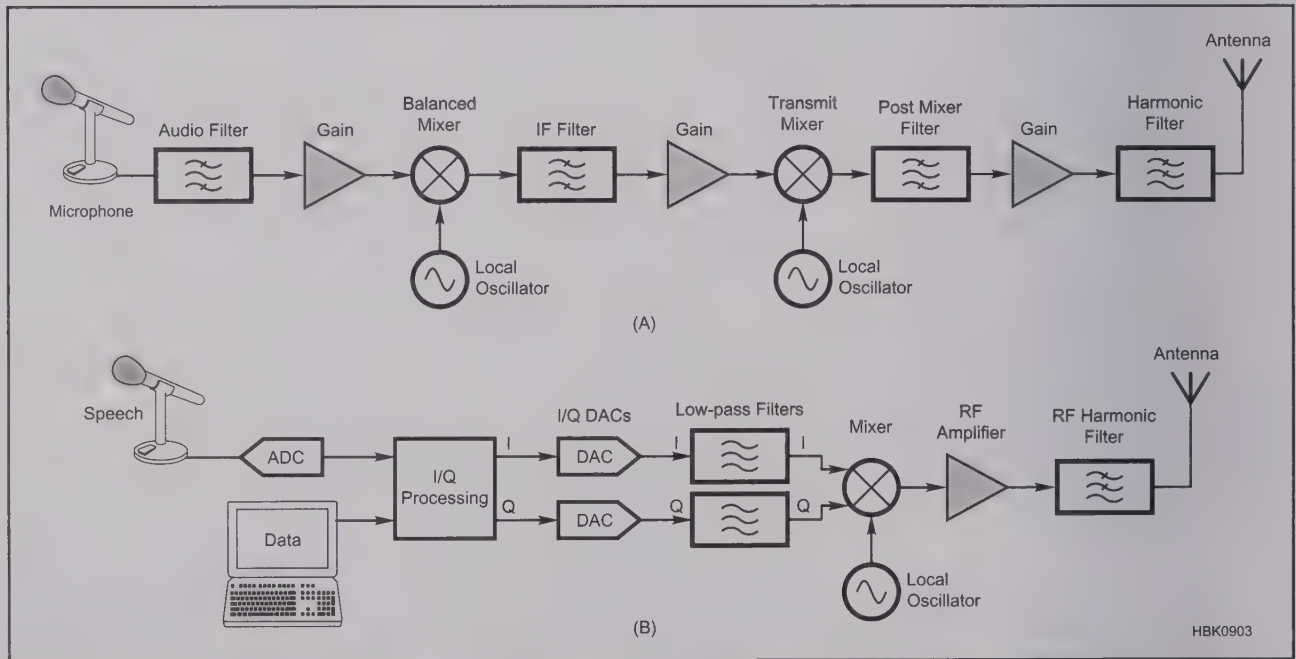

Figure 10.2 — Single-band SSB superheterodyne transmitter (A) and SDR SSB/Data transmitter (B) showing the filters typically used by each.

# 10.2 Filter Basics

## 10.2.1 Filter Magnitude Responses

A common type of filter, the *band-pass*, passes signals in a range of frequencies — the *passband* — while rejecting signals outside that range — the *stopband*. To pass signals from dc up to some *cutoff frequency* at which output power is halved (reduced by 3 dB) we would use a *low-pass* filter. To pass signals above a cutoff frequency (also called the “3-dB frequency”) we would use a *high-pass* filter. Similarly, to pass signals within a range of frequencies we would use a *band-pass* filter. To pass signals at all frequencies *except* those within a specified range requires a *band-stop* or *notch filter*.

Figure 10.3A illustrates the *magnitude response* of a low-pass filter. Signals lower than the cutoff frequency (3 MHz in this case) are passed with some small amount of attenuation while signals higher than that frequency are attenuated. The degree of attenuation is dependent on several variables, filter complexity being a major factor.

Of the graphs in this chapter that show a filter’s magnitude response, the vertical axes are labeled “Transmission (dB)” with 0 dB at the top of the axis and negative values increasing toward the X-axis. Increasingly negative values of transmission in dB are the same as increasingly positive values of attenuation in dB. For example, -40 dB transmission is the same as 40 dB of attenuation.

Figure 10.3B illustrates the magnitude response of a high-pass filter. Signals above the 3 MHz cutoff frequency are passed with minimum attenuation while signals below that frequency are attenuated. Again, the degree of attenuation is dependent on several variables.

Figure 10.3C illustrates the magnitude response of a band-pass filter. Signals within the band-pass range (between the lower and upper cutoff frequencies) are passed with minimum attenuation while signals outside that range are attenuated. In this example the filter was designed with cutoff frequencies of 2 MHz and 4 MHz, for a passband width of 2 MHz.

Figure 10.3D illustrates the magnitude response of a band-stop filter. Signals within the band-stop range are attenuated while all other signals are passed with minimum attenuation. A notch filter is a type of band-stop filter with a narrow stop-band in which the attenuation is a maximum at a single frequency.

An *ideal filter* — a low-pass filter, for example — would pass all frequencies up to some point with no attenuation at all and totally reject everything beyond that point. This is known as a *brick wall* response because the filter’s passband and stopband are *flat*, meaning no attenuation, and the rolloff in the transition

region is infinitely steep. The magnitude response of such a filter would be drawn as a flat line representing 0 dB attenuation up to the cutoff frequency that then abruptly changes

at the cutoff frequency to a flat line at infinite attenuation throughout the stopband to infinite frequency.

Figure 10.4 shows all of the basic para-

Figure 10.3 — Examples of a low-pass magnitude response (A), high-pass magnitude response (B), band-pass magnitude response (C), and band-stop magnitude response (D).

Figure 10.4 — Low-pass filter characteristics showing the passband and stopband, bandwidth, 3 dB cutoff, passband ripple, and insertion loss (IL). This filter has approximately 0.5 dB IL at the frequency of peak response while passband ripple is also 0.5 dB. The vertical axis shows gain (or loss) through the filter, assuming both the input and output are properly terminated. The horizontal axis represents frequency.

**Figure 10.5 — The key specifications for a filter’s amplitude response. As long as the filter response curve stays between the light gray boxes, the filter meets the design specification.**

band. Any response curve that passes through the space between the gray boxes meets the performance requirements for the filter.

As frequency increases through the transition region from the passband into the stopband, the attenuation increases. *Rolloff*, the rate of change of the attenuation for frequencies above cutoff, is expressed in terms of dB of change per octave of frequency. A filter’s response with high values of rolloff is called “sharp” or “steep” and “soft” or “shallow” if rolloff is low.

### 10.2.2 Filter Order

The steepness of the descent from the passband to the region of attenuation — the stopband — is dependent on the complexity of the filter, called the *order*. In a lumped-element filter made from inductors and capacitors, the order is determined by the number of separate energy-storing elements (either L or C) in the filter. For example, an RC filter with one resistor and one capacitor has an order of 1. A notch filter made of a single series-LC circuit has an order of 2. The definition of order for active and digital signal processing filters can be more complex, but the general understanding remains valid that the order of a filter determines how rapidly its response can change with frequency.

For example, **Figures 10.6 and 10.7** shows the magnitude response of one type of low-pass filter (Butterworth family) with orders varying from very simple (“N=2”) to the more complex (“N=20”). For each order, frequency has been *normalized* to the ratio of frequency,  $f$ , to cutoff frequency,  $f_c$ . (i.e. Normalized cutoff frequency is always 1.0.) As the order increases, the rolloff also increases. Figure 10.6 has an expanded vertical scale to show the filter’s behavior in the passband more clearly.

eters for a low-pass filter. Variations in amplitude of the response curve in the passband are called *ripple*. (Filters can also have ripple in the stopband for some design families as discussed later.) If the filter is made from passive components, there will be some losses in those components — the amount of loss is called *insertion loss* (IL). The attenuation for signal frequencies in the stopband far from the cutoff frequency is the filter’s *ultimate attenuation*.

### SPECIFYING A FILTER RESPONSE

**Figure 10.5** shows a high-pass filter’s *response curve* and some of the terms used to specify the filter’s design. On the frequency axis,  $F_c$  is the cutoff frequency and  $F_s$  defines the *stopband width*. The passband for a high-pass filter consists of all frequencies above  $F_c$ . The stopband for a high-pass filter consists of

all frequencies below  $F_s$ . The *transition region* is the range of frequencies between the stopband and passband. (For a low-pass filter,  $F_s$  and  $F_c$  are reversed along with the gray boxes they bound.)
