The gray boxes leave a space between them through which the filter’s response curve must pass. The borders of the gray boxes establish the required performance for the filter. The gray box defining the stopband is bounded on the bottom by the stopband depth. The filter’s transmission in the stopband must be equal to or below the stopband depth. The gray box defining the passband is bounded on the top by the passband ripple. The filter’s transmission in the passband must be equal to or greater than the passband ripple. Between  $F_s$  and  $F_c$  is the transition region in which the response curve passes between the stopband and pass-

### 10.2:3 Filter Families

There is no single "best" way to design a filter. Instead we have to decide on some traits and then choose the most appropriate family for our design. Different families have different traits, and filter families are commonly named after the mathematician or engineer responsible for defining their behavior mathematically. Each filter family is represented by a specific type of equation that describes the filter's behavior.

Two primary traits of the most importance to amateurs are used to describe the behavior of filter families: ripple (variations in the magnitude response within the passband and stopband) and rolloff. Different families of filters have different degrees of ripple and rolloff (and

other characteristics, such as phase response).

With a flat magnitude response (and so no ripples in the passband) we have what is known as a *Butterworth* family design. This family also goes by the name of *Maximally Flat Magnitude* or *Maximally Flat Gain*. An example of the magnitude response of a filter from the Butterworth family is shown in **Figure 10.8**. (Most filter discussions are based on low-pass filters because the same concepts are easily extended to other types of filters and much of the mathematics behind filters is equivalent for the various types of frequency responses.)

By allowing magnitude response ripples in the passband, we can get a somewhat steeper rolloff from the passband into the stopband, particularly just beyond the cutoff frequency. A family that does this is the *Chebyshev* family. **Figure 10.9** illustrates how allowing magnitude ripple in the passband provides a sharper filter rolloff. This plot compares the 1-dB ripple Chebyshev with the no-ripple Butterworth filter down to 12 dB of attenuation.

Figure 10.9 also illustrates the usual definition of bandwidth for a low-pass Butterworth filter — the filter's 3-dB or cutoff frequency. For a low-pass Chebyshev filter, *ripple bandwidth* is used — the frequency range over which the filter's passband ripple is no greater than the specified limit. For example, the ripple bandwidth of a low-pass Chebyshev filter designed to have 1 dB of passband ripple is the highest frequency at which attenuation is 1 dB or less. The 3-dB bandwidth of the frequency of the filter will be somewhat greater.

A Butterworth filter is defined by specifying the order and bandwidth. The Chebyshev filter is defined by specifying the order, the ripple bandwidth, and the amount of passband ripple. In Figure 10.9, the Chebyshev filter has 1 dB of ripple; its ripple bandwidth is 1000 Hz. The Butterworth filter has a 3-dB bandwidth also of 1000 Hz. Some filter textbooks use the 3-dB point to define Chebyshev filters; most use the ripple bandwidth as illustrated here. The schematics (if you ignore parts values) of those two families are identical.

Even small amounts of ripple can be beneficial in terms of increasing a filter's rolloff. **Figure 10.10** compares a Butterworth filter (with the narrow line plot, no ripple in the passband) with a Chebyshev filter (wide line plot, 0.2 dB of ripple in the passband) down to 60 dB of attenuation. (For this comparison the cutoff frequencies at 3 dB of attenuation are the same for each filter.) Even that small amount of ripple in the Chebyshev filter passband allows a noticeably steeper rolloff between the passband and the stopband. As the passband ripple specification is increased, the steepness of the transition from passband to stopband increases, compared to the Butterworth family although the rolloff of the two families eventually becomes equal.

For Chebyshev filters, when the value of the passband ripple is changed, the magnitude response in the stopband region also changes. **Figure 10.11** compares the stopband response of Chebyshev filters with passband ripple ranging from 0.01 to 1 dB.

Figure 10.8 — Filters from the Butterworth family exhibit flat magnitude response in the passband.

Figure 10.9 — This plot compares the response of a Chebyshev filter with a 1-dB ripple bandwidth of 1000 Hz and a Butterworth filter 3-dB bandwidth of 1000 Hz.

Figure 10.10 — A Chebyshev filter (0.2 dB passband ripple) allows a sharper cutoff than a Butterworth design with no passband ripple.

Figure 10.11 — These stop band response plots illustrate the Chebyshev family with various values of passband ripple. These plots are for a seventh-order low-pass design with ripple values from 0.01 to 1 dB. Ignoring the effects in the passband of high ripple values, increasing the ripple will allow somewhat steeper rolloff into the stop band area, and better ultimate attenuation in the stop band.

It is possible to obtain even steeper rolloff into the stopband by adding “traps” whose frequencies are carefully calculated. The resonant frequencies of those traps are in the stopband region and are set to yield best performance. When this is done, we have a *Cauer* family design (also called the *elliptic-function* design). The rolloff of the Cauer filter from the passband into the stopband is the steepest of all analog filter types provided that the behavior in the passband is uniform (either no ripple or a uniform amount of ripple). **Figure 10.12** shows the response of the Chebyshev and Cauer designs for comparison.

The Cauer filter is defined by specifying the order, the ripple bandwidth, and the passband ripple, just as for the Chebyshev. Again, an alternative bandwidth definition is to use the 3-dB frequency instead of the ripple bandwidth. The Cauer family requires one more specification: the *stopband frequency* and/or the *stopband depth*. The stopband frequency is the lowest frequency of a null or notch in the stopband. The stopband depth is the minimum amount of attenuation allowed in the stopband. In **Figure 10.12**, the stopband frequency is about 3.5 MHz and the stopband depth is 50 dB. For this comparison both designs have the same passband ripple value of 0.2 dB.

A downside to the Cauer filter is that the ultimate attenuation is some chosen value rather than ever increasing, as is the case with the other families. In the far stopband region (where frequency is much greater than the cutoff frequency) the rolloff of Cauer filters ultimately reaches 6 or 12 dB per octave, depending on the order. Odd-ordered Cauer filters have an ultimate rolloff rate of about 6 dB per octave while the even-ordered versions have an ultimate rolloff rate of about 12 dB per octave.

### 10.2.4 Group Delay

Another trait that can influence the choice of which filter family to use is the way the transit time of signals through the filter varies with frequency. This is known as *group delay*. (“Group” refers to a group of waves of similar frequency and phase moving through a media, in this case, the filter.) The wide line (lower plot) in **Figure 10.13** illustrates the group delay characteristics of a Chebyshev low-pass filter, while the upper plot (narrow line) shows the magnitude response. As shown in **Figure 10.13**, the group delay of components near the cutoff frequency becomes quite large when compared to that of components at lower and higher frequencies. This is a result of the phase shift of the filter’s transmission being nonlinear with frequency; it is usually greater near the cutoff frequency. By delaying signals at different frequencies different amounts, the signal components are “smeared” in time. This

**Figure 10.12** — The Cauer family has an even steeper rolloff from the passband into the stop band than the Chebyshev family. Note that the ultimate attenuation in the stop band is a design parameter rather than ever-increasing as is the case with other families.

**Figure 10.13** — Magnitude response and group delay of a Chebyshev low-pass filter.

**Figure 10.14** — Magnitude response and group delay of a Bessel low-pass filter.

**Figure 10.15** — Transient response of a Chebyshev low-pass filter.

causes distortion of the signal and can seriously disrupt high-speed data signals.

If a uniform group delay for signals throughout the passband is needed, then the *Bessel* filter family should be selected. The Bessel filter can be used as a delay-line or time-delay element although the gentle rolloff of the magnitude response may need to be taken into account. The magnitude and delay characteristics for the Bessel family are shown in **Figure 10.14**. Comparing the Bessel filter’s response to that of the Butterworth in **Figure 10.8** shows the difference in roll off.

A downside of Bessel family filters is that the rolloff characteristic is quite poor; they are not very good as a magnitude-response-shaping filter. The Bessel family is characterized largely by its constant group delay in the passband (for a low- or high-pass filter) shown as the bottom plot in **Figure 10.14**. The *constant-delay* characteristic of the Bessel extends into the stopband. The Bessel filter bandwidth is commonly defined by its 3-dB point (as with the Butterworth).

Because the Bessel filter is used when phase response is important, it is often characterized by the frequency at which a specific amount of phase shift occurs, usually one radian. (One radian is equal to  $360 / 2\pi = 57.3^\circ$ .) Since the delay causes the output signal to lag behind the input signal, the filter is specified by its *one-radian lag frequency*.

### 10.2.5 Transient Response

Some applications require that a signal with sharp rising and falling edges (such as a digital data waveform) applied to the input of a low-pass design have a minimum *overshoot* or *ringing* as seen at the filter’s output. Overshoot (and undershoot) occurs when a signal exceeds (falls below) the final amplitude temporarily before settling at its final value. Ringing is a repeated sequence of overshoot and undershoot.

If a sharp-cutoff analog filter is used in such an application, overshoot or ringing will occur. The appearance of a signal such as a square wave with sharp rising and falling edges as it exits from the filter may be as shown in **Figure 10.15**. The scales for both the X- and the Y-axes would depend on the frequency and magnitude of the waveform. (As described later in this chapter, digital filters can be designed not to exhibit this ringing, although they are much more complex than simple analog filters and have other tradeoffs.)

The sharp edge of the square wave is a type of *transient*, an abrupt change in a signal. When a signal at a constant level and changes to another level very rapidly where it remains constant, that type of transient is a *step*. If the signal abruptly changes levels and immediately changes back again, that type of transient is a *pulse*. If the pulse is infinitely narrow, it is

called an *impulse* and has interesting mathematical characteristics as discussed below. The output of a circuit a transient occurs at its input is the circuit's *transient response*.

The square wave used in this discussion as a test waveform is composed of a fundamental and an endless series of odd harmonics. If harmonics only up to a certain order are used to create the square wave — that is, if the square wave is passed through a sharp-cutoff low-pass filter that attenuates higher frequencies — then that waveform will have the overshoot or ringing as shown as it exits from the filter. This is the filter's *step response*.

Transients can be repetitive, such as the edges of the square wave, but even a non-periodic waveform can be decomposed into sine waves, although in this case they are not harmonically-related. For example a single pulse of width  $\tau$  seconds has a frequency spectrum proportional to  $\text{sinc}(f\tau) = \sin(\pi f\tau)/(\pi f\tau)$ . You can think of this as an infinite number of sine waves spaced infinitely closely together with amplitudes that trace out that spectral shape. It is interesting to note that if  $\tau$  is decreased, the value of  $f$  must increase by the same factor for any given value of  $\sin(\pi f\tau)/(\pi f\tau)$ . In other words, the narrower the pulse the wider the spectrum. Of course that applies to sine waves and other periodic waveforms as well — the smaller the wavelength the higher the frequency. In general, anything that makes the signal “skinnier” in the time domain makes it “fatter” in the frequency domain and vice versa.

As the pulse becomes narrower and narrower, the frequency spectrum spreads out more and more. In the limit, if the pulse is made infinitely narrow (an impulse), the spectrum becomes flat from zero hertz to infinity.

The impulse is a very useful concept because of its flat frequency spectrum. The filter's *impulse response* has a frequency spectrum equal to the frequency response of the filter.

### 10.2.6 Filter Family Selection

Selecting a filter family is one of the first steps in filter design. To make that choice easier, the following list of filter family attributes is provided:

- Butterworth — No ripple in passband, smooth transition region, shallow rolloff for a given filter order, high ultimate attenuation, smooth group delay change across transition region. The smoothness of the response is particularly apparent near dc for the low-pass response, at the center frequency for a band-pass response, and at infinity for the high-pass response. The resulting magnitude response will also have a relatively gentle transition from the passband into the stop band.

- Chebyshev — Some passband ripple, abrupt transition region, steep rolloff for a given filter order, peak in group delay near cutoff frequency, high ultimate attenuation. The Chebyshev family is used when a sharper cutoff is desired for a given number of components and where at least a small amount of ripple is allowable in the passband.

- Cauer (or Elliptical-function) — Some passband ripple, abrupt transition region, steepest roll off, ripple in stopband due to traps, ultimate attenuation smaller than Butterworth and Chebyshev, group delay peaks near cutoff frequency and in stopband. When steepness of rolloff from passband into stop band is the item of greatest importance, then the Cauer filter family is used. Cauer filters involve a more complicated set of choices. In addition to

selecting a passband ripple, the designer must also assign a stop band depth (or stop band frequency). Some of the items interact; they can't all be selected arbitrarily.

- Bessel — No ripple in passband, smooth transition region, constant group delay in passband, shallow rolloff for a given filter order, smooth changes in group delay, high ultimate attenuation

All characterizations such as “steep” and “abrupt” are relative with respect to filter designs from other families with similar orders. Other factors, such as number of components, sensitivity to component value and so on may need to be considered when selecting a filter family for a specific application.

All of the traits mentioned so far in this chapter apply to a filter regardless of how it is implemented, whether it is fabricated using *passive* lumped-element inductors and capacitors or using op amps with resistors and capacitors (an *active* filter) or in software as a digital filter. The traits are general descriptions of filter behavior and can be applied to any type of filter technology. Each type of technology (passive, active, digital) has strong points and tradeoffs.

These four families are the most common, but other families are used as well: for example, Gaussian, Constant-k, and M-derived are all supported by the *ELSIE* filter design package provided with this book's downloadable supplemental information

Digital filters also implement these filter families and others, as well. They also have other classes, such as FIR and IIR, as described in this chapter's section on digital filters. For more information about analog and digital filter design, a list of references and articles is provided at the end of this chapter.

## 10.3 Passive LC Filters

This part of the chapter deals with passive LC filters fabricated using discrete inductors and capacitors (which gives rise to their name, *lumped-element*). We will begin with a discussion of basic low-pass filters and then generalize to other types of filters.

### 10.3.1 Low-Pass Filters

A very basic LC filter built using inductors and capacitors is shown in **Figure 10.16**. In the first case (**Figure 10.16A**), less power is delivered to the load at higher frequencies because the reactance of the inductor in series with the load increases as the test frequency increases. The voltage appearing at the load goes down as the frequency increases. This configuration would pass direct current (dc) and reject higher frequencies, and so it would

be a low-pass filter.

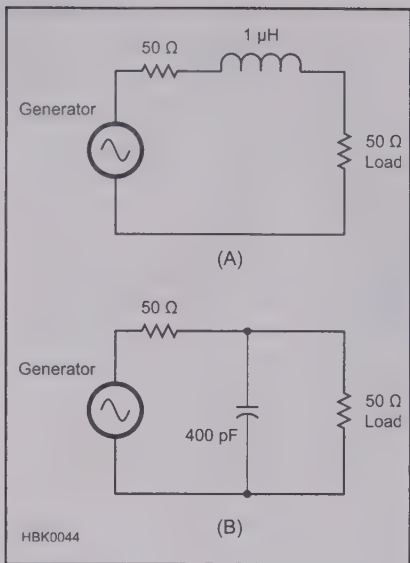

With the second case (**Figure 10.16B**), less power is delivered to the load at higher frequencies because the reactance of the capacitor in parallel with the load decreases as the test frequency increases. Again, the voltage appearing at the load goes down as the frequency increases and so this, too, would be called a low-pass filter. In the real world, combinations of both series and parallel components are used to form a low-pass filter.

A high-pass filter can be made using the opposite configuration — series capacitors and shunt inductors. And a band-pass (or band-stop) filter can be made using pairs of series and parallel tuned circuits. These filters, made from alternating LC elements or LC tuned

circuits, are called *ladder filters*.

We spoke of filter order, or complexity, earlier in this chapter. **Figure 10.17** illustrates *capacitor-input* low-pass filters with orders of 3, 4 and 5. Remember that the order corresponds to the number of energy-storing elements. For example, the third-order filter in **Figure 10.17A** has three energy-storing elements (two capacitors and one inductor), while the fifth-order design in **Figure 10.17C** has five elements total (three capacitors, two inductors). For comparison, a third-order filter is illustrated in **Figure 10.18**. The filters in **Figure 10.17** are *capacitor-input* filters because a capacitor is connected directly across the input source. The filter in **Figure 10.18** is an *inductor-input* filter.

As mentioned previously, the Cauer family

**Figure 10.16** — A basic low-pass filter can be formed using a series inductor (A) or a shunt capacitor (B).

**Figure 10.18** — A third-order inductor-input low-pass filter.

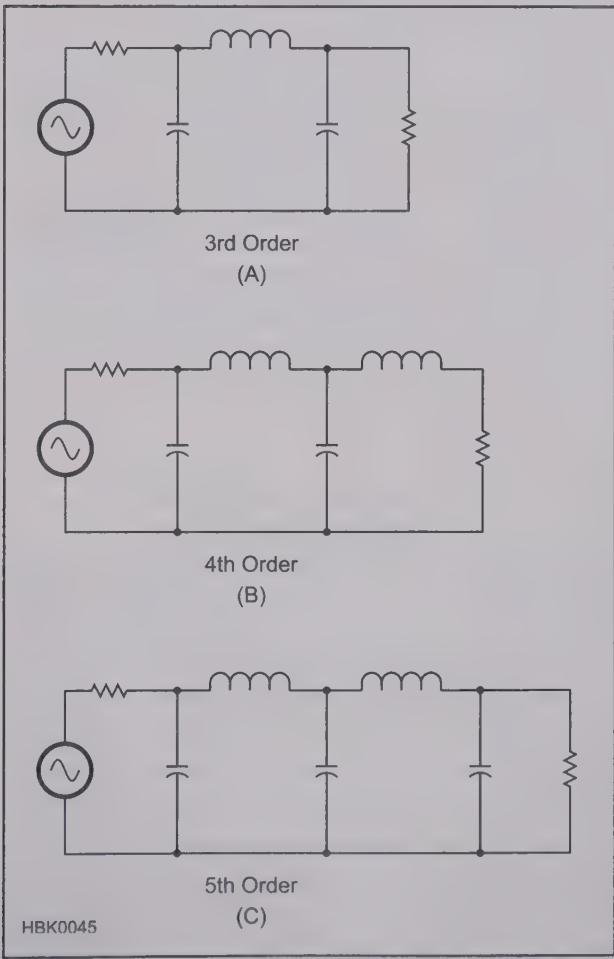

has traps (series or parallel tuned circuits) carefully added to produce dips or notches (properly called *zeros*) in the stop band. Schematics for the Cauer versions of capacitor-input low-pass filters with orders of 3, 4 and 5 are shown in **Figure 10.19**. The capacitors in parallel with the series inductors create the notches at calculated frequencies to allow the Cauer filter to be implemented.

The capacitor-input and the inductor-input

versions of a given low-pass design have identical characteristics for their magnitude, phase and time responses, but they differ in the impedance seen looking into the filter. The capacitor-input filter has low impedance in the stop band while the inductor-input filter has high impedance in the stop band.

**10.3.2 Low-Pass to Band-Pass Transformation**

A band-pass filter is defined in part by a *bandwidth* and a *center frequency*. (An alternative method is to specify a lower and an upper cutoff frequency.) A low-pass design such as the one shown in **Figure 10.17A** can be converted to a band-pass filter by resonating each of the elements at the center frequency. **Figure 10.20** shows a third-order low-pass filter with a design bandwidth of 2 MHz for use in a 50 Ω system. If the shunt elements are now resonated with a parallel component, and if the series elements are resonated with a series component, the result

**Figure 10.17** — Low-pass, capacitor-input filters for the Butterworth and Chebyshev families with orders 3, 4 and 5.

**Figure 10.19** — Low-pass topologies for the Cauer family with orders 3, 4 and 5.

Figure 10.20 — Third-order low-pass filter with a bandwidth of 2 MHz in a 50 Ω system.

Figure 10.21 — The low-pass filter of Figure 10.20 can be transformed to a band-pass filter by resonating the shunt capacitors with a parallel inductor and resonating the series inductor with a series capacitor. Bandwidth is 2 MHz and the center frequency is 2.828 MHz.

is a band-pass filter as shown in Figure 10.21. The series inductor value and the shunt capacitor values are the same as those for the original low-pass design.

### 10.3.3 High-Pass Filters

A high-pass filter passes signals above its cutoff frequency and attenuates those below. Simple high-pass equivalents of the filters in Figure 10.16 are shown in Figure 10.22.

The reactance of the series capacitor in Figure 10.22A increases as the test frequency is lowered and so at lower frequencies there will be less power delivered to the load. Similarly, the reactance of the shunt inductor in Figure 10.22B decreases at lower frequency, with the same effect. Similarly to the low-pass filter designs presented in Figure 10.17, a high-pass filter in a real world design would typically use both series and shunt components but with the positions of inductors and capacitors exchanged.

An example of a high-pass filter application would be a broadcast-reject filter designed to pass amateur-band signals in the range of 3.5 MHz and above while rejecting broadcast signals at 1.7 MHz and below. A high-pass filter with a design cutoff of 2 MHz is illustrated in Figure 10.23. It can be implemented as a capacitor-input (Figure 10.23A) or inductor-input (Figure 10.23B) design. In each case, signals above the cutoff are passed with minimum attenuation while signals below the cutoff are attenuated, in a manner similar to the action of a low-pass filter.

### 10.3.4 High-Pass to Band-Stop Transformation

Just as a low-pass filter can be transformed to a band-pass type, a high-pass filter can be transformed into a band-stop (also called a *band-reject*) filter. The procedures for doing this are similar in nature to those of the transformation from low-pass to band-pass. As with the band-pass filter example, to transform a high-pass to a band-stop we need to specify a center frequency. The bandwidth of a band-

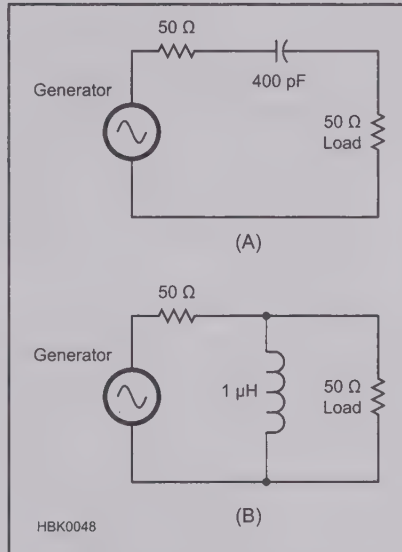

Figure 10.22 — A basic high-pass filter can be formed using a series capacitor (A) or a shunt inductor (B).

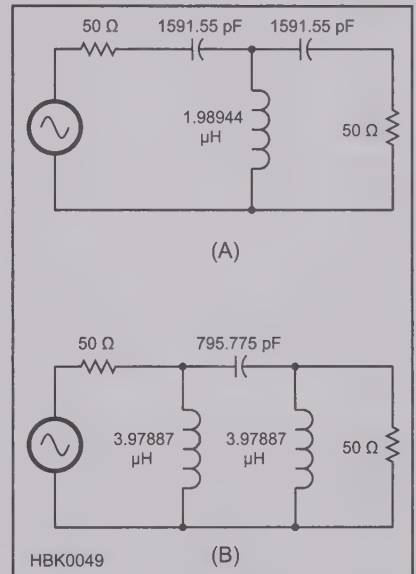

Figure 10.23 — Capacitor-input (A) and inductor-input (B) high-pass filters. Both designs have a 2 MHz cutoff.

Figure 10.24 — The high-pass filter of Figure 10.23A can be converted to a band-stop filter with a bandwidth of 2 MHz, centered at 2.828 MHz.

stop filter is measured between the frequencies at which the magnitude response drops 3 dB in the transition region into the stop band.

Figure 10.24 shows how to convert the 2 MHz capacitor-input high-pass filter of Figure 10.20A to a band-stop filter centered at

2.828 MHz. The original high-pass components are resonated at the chosen center frequency to form a band-stop filter. Either a capacitor-input high-pass or an inductor-input high-pass may be transformed in this manner. In this case the series capacitor values and the

shunt inductor values for the band-stop are the same as those for the high-pass. The series elements are resonated with an element in parallel with them. Similarly, the shunt elements are also resonated with an element in series with them. In each case the pair resonate at the center frequency of the band-stop.

### 10.3.5 Effect of Component Q

When components with less-than-ideal characteristics are used to fabricate a filter, the performance will also be less than ideal. One such item to be concerned about is component “Q.” As described in the **Radio Fundamentals** chapter, Q is a measure of the loss in an inductor or capacitor, as determined by its resistive component. Q is the ratio of component’s reactance to the loss resistance and is specified at a given test frequency. The loss resistance referred to here includes not only the value as measured by an ohmmeter but includes all sources of loss, such as skin effect, dielectric heating and so on.

The Q values for capacitors are usually greater than 500 and may reach a few thousand. Q values for inductors seldom reach 500 and may be as low as 20 or even worse for miniaturized parts. A good toroidal inductor can have a Q value in the vicinity of 250 to 400.

Q values can affect both the *insertion loss* of signals passing through the filter and the steepness of the filter’s rolloff. Band-pass filters (and especially narrowband band-pass filters) are more vulnerable to this problem than low-pass and high-pass filters. **Figure 10.25** shows the effect of finite values of inductor Q values on the response of a low-pass filter. The Q values for each plot are as shown.

Inadequate component Q values introduce loss and more importantly they compromise the filter’s response at cutoff, especially problematic in the case of narrowband band-pass filters. **Figure 10.26** illustrates the effect of finite inductor Q values on a narrowband band-pass filter. In the case of a band-pass filter, the Q values required to support a given response shape are much higher than those required for the low-pass or high-pass filter (by the ratio of center to width). Capacitor Q values are generally much higher than inductor Q values and so contribute far less to this effect.

In general, component-value adjustment will not be able to fully compensate for inadequate component Q values. However, if the filter is deliberately mismatched (by changing the input and/or output terminations) then a limited amount of *response-shape* correction can sometimes be achieved by network component value optimization (“tweaking”). The loss caused by Q problems (at dc in the case of a low-pass or at the center frequency

Figure 10.25 — Effect of inductor Q values on a low-pass filter.

Figure 10.26 — Effect of inductor Q values on a narrowband band-pass filter.

in the case of a band-pass) may increase if such correction is attempted.

### 10.3.6 Side Effects of Passband Ripple

Especially in RF applications it is desirable to design a filter such that the impedance seen looking into the input side remains fairly constant over the passband. Increasing the value of passband ripple increases the rate of descent from the passband into the stop band, giving

a sharper cutoff. But it also degrades the uniformity of the impedance across the passband as seen looking into the input of the filter. This may be shown in terms of VSWR or return loss; those are simply different ways of stating the same effect. (*Return loss* is explained in the **RF Techniques** chapter.)

Designs using a low value of passband ripple are preferred for RF work. Audio-frequency applications are generally not as critical, and so higher ripple values (up to about 0.2 dB) may be used in audio work.

**Table 10.2**  
**Passband Ripple, VSWR and**  
**Return Loss**

Passband Ripple (dB)	VSWR	Return Loss (dB)
0.0005	1.022	39.38
0.001	1.031	36.37
0.002	1.044	33.36
0.005	1.07	29.39
0.01	1.101	26.38
0.02	1.145	23.37
0.05	1.24	19.41
0.1	1.355	16.42
0.2	1.539	13.46
0.5	1.984	9.636
1	2.66	6.868

Note: As the passband ripple specification is changed so do the other items. Conversely, to limit VSWR to a maximum value or return loss to at least some minimum value, use this table to find the passband ripple that should be used to design the filter.

Table 10.2 shows the maximum value of VSWR and minimum value of return loss for various values of passband ripple. Note that lower values for passband ripple yield better values for VSWR and return loss. Specifying a filter to have a passband ripple value of 0.01 dB will result in that filter's VSWR figure to be about 1.1:1. Or restated, the return loss will be about 26 dB. These values will be a function of frequency and at some test frequencies may be much better.

### 10.3.7 Use of Filters at VHF and UHF

Even when filters are designed and built properly, they may be rendered totally ineffec-

tive if not installed properly. Leakage around a filter can be quite high at VHF and UHF, where wavelengths are short. Proper attention to shielding and good grounding is mandatory for minimum leakage. Poor coaxial cable shield connection into and out of the filter is one of the greatest offenders with regard to filter leakage. Proper dc-lead bypassing throughout the receiving system is good practice, especially at VHF and above. Ferrite beads placed over the dc leads may help to reduce leakage. Proper filter termination is required to minimize loss.

Most VHF RF amplifiers optimized for noise figure do not have a 50 Ω input impedance. As a result, any filter attached to the input of an RF amplifier optimized for noise figure will not be properly terminated and filter loss may rise substantially. As this loss is directly added to the RF amplifier noise figure, carefully choose and place filters in the receiver.

### 10.3.8 Design Software for LC Filters

Previous editions of this book included an extensive set of design tables and formulas for manual calculation of filter component values. While this method was certainly instructive, it was tedious and error-prone, particularly for higher-order designs. The sections that described this method in previous editions have been extracted as a PDF document that is provided with the downloadable supplemental information for this book.

Filter design is almost universally performed with software today and the *ARRL Handbook* is fortunate to include such a package. Jim Tonne, W4ENE, has made available a version of *ELSIE*, a filter design program, to

amateurs at no charge. The latest version of *ELSIE* and related programs are available for downloading with the downloadable supplemental content. The list of software is presented at the beginning of this chapter and the program capabilities are listed below.

Users unfamiliar with *ELSIE* will benefit from following the “walkthrough” accessible from the program’s ABOUT menu tab. A presentation by W4ENE explaining *ELSIE* is available at [www.tonnesoftware.com/downloads/FilterTutorial.pdf](http://www.tonnesoftware.com/downloads/FilterTutorial.pdf). Numerous design examples and tutorials are available as online videos hosted on YouTube.com — search for “elsie filter design tutorial” to locate a good starting set. A two-part step-by-step tutorial for using *ELSIE* from the Hands-On Radio series of columns is available in the downloadable supplemental material for this book as well.

- *ELSIE* — design and analysis of lumped-element LC filters. In addition to providing parts values for filters with various topologies from various families, tools are included to assist with practical construction.

- *SVC Filter Designer* — design of lumped-element high-pass and low-pass filters. The software shows ideal values and also the nearest 5% values for capacitors and inductors. It also analyzes those filters and shows the deviation of key responses from ideal when those 5% values are used.

- *QuadNet* — design and analysis of active quadrature (“90-degree”) networks for use in SSB transmitters and receivers. It handles networks with orders from 2 to 10, odd and even, with tuning modes and analysis.

- *Helical* — design and analysis of helical-resonator bandpass filters usually used in the VHF and UHF frequency ranges.

- *Diplexer* — design and analysis of diplexer filters.

## 10.4 Active Audio Filters

Below RF, in what is broadly referred to as the “audio” range between a few Hz and a few hundred kHz, designers have several choices of filter technology.

- Passive LC
- DSP Digital Filters
- Switched-Capacitor Audio Filter (SCAF)
- Active RC

LC audio filters are not used much in current designs except in high-power audio applications, such as speaker crossover networks, and are not covered here. LC filters were once popular as external audio filters for CW reception. These designs tended to be large and bulky, often using large surplus 44 or 88 mH core inductors. (A classic *ARRL Handbook* project to construct a passive LC

CW filter can be found in the downloadable supplemental material for this book.) LC filters used in very low-level receiver applications can be very compact, but these tend to suffer from relatively high insertion loss, which reduces the receiver sensitivity (if no preamp is used ahead of the filter) or its large-signal dynamic range (if a loss-compensating preamp is used ahead of the filter). In addition, LC filters used in low-level receiver applications tend to pick up 60/120 Hz hum from stray magnetic fields from ac power transformers. Even “self shielded” inductors can produce noticeable ac hum pick up when followed by 90 to 120 dB of audio gain!

Digital filtering (see the following section of this chapter) can yield filters that are supe-

rior to analog filters. High signal-level DSP-based external audio filters such as the popular Timewave DSP-599 ([www.timewave.com](http://www.timewave.com)) and MFJ Enterprises MFJ-784B ([www.mfjenterprises.com](http://www.mfjenterprises.com)) have been available for some time. In addition, if the filter is coupled to a high-performance audio A/D converter, digital filtering can provide excellent filtering for even very low-level audio signals.

The main drawback to standalone digital filters is that of expense. A low-end DSP external audio filter costs at least \$100, while a DSP with a high-end A/D converter (such as an audio sound card front-end to a PC) can run in the \$150 to \$400+ price range, which does not include the cost of the host PC.

### 10.4.1 SCAF Filters

Simple SCAF filter designs can produce extremely effective low-power audio filters. The implementation of these filters in practical IC form usually involves small-value capacitors and high-value resistors. The use of high-value resistors tends to generate enough noise to make these filters unsuitable for very low-level audio processing such as the front end of a receiver audio chain. Thus, SCAF filters tend to be limited to filtering at the output end of the audio chain — headphone or speaker level audio applications, an area in which they very much excel. The cutoff frequency of a SCAF filter is set by an external clock signal. Thus, this class of filter naturally lends itself to use in variable frequency filters. For simplicity,

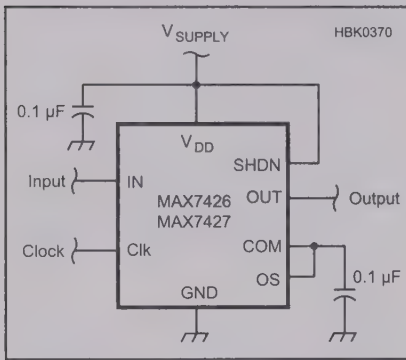

Figure 10.27 — Simple SCAF low pass filter, taken from the MAX7426 data sheet.

excellent frequency selectivity and relatively low cost, SCAF filters are highly recommended when additional audio filtering is desired on the output of an existing receiver.

An example of a very simple, but highly effective SCAF low-pass filter IC is the Maxim MAX7426 (5 V supply) or MAX7427 (3 V supply) in **Figure 10.27**. The filter's cutoff frequency can be set by placing an appropriately sized capacitor across the clock oscillator inputs because the part can generate its own internal clock signal. For example, connecting a 180 pF capacitor across the MAX7426's clock inputs will produce a 1 kHz low-pass filter. The MAX7427 (3-V version) was used in the NC2030 QRP transceiver along with a MVAM108 varactor diode to create a low-pass filter that was tunable from 300 Hz to 1 kHz.

A portion of that schematic is shown in **Figure 10.28**. The SCAF low-pass filter is followed by a 3-V unity-gain headphone amplifier (U14C and U14D) as the filter IC itself cannot directly drive headphones. The low-pass cutoff frequency is tuned by using R83 to vary the voltage applied across the MVAM108 varactor diode D10, thus changing the capacitance across the clock input (pin 8) of the chip. C116 was used to isolate the dc voltage across the varactor diode from the bias voltage on the clock input line. The frequency response of such a filter is shown in **Figure 10.29**.

As can be seen, this is an extremely sharp filter, producing almost 40 dB of attenuation very close to the cut off frequency — not too bad for an inexpensive part. The slightly more

expensive MAX7403 gives an even steeper 80 dB cutoff. Both parts are specified for an 80 dB signal-to-noise ratio based on an assumed 4-V<sub>P-P</sub> signal. Sensitive modern in-ear type headphones require only 20 mV<sub>P-P</sub> to produce a fairly loud signal. A 20 mV signal is 46 dB below 4 V<sub>P-P</sub>, so at such headphone levels, the noise floor is actually only 34 dB below the 4 V<sub>P-P</sub> signal — fairly quiet, but is a lot less noise margin than one would tend to think given the 80 dB specification.

Again, with a noise floor only 34 dB below typical headphone levels, SCAF filters such as these are fine at the end of the receiver chain,

Figure 10.29 — Frequency response of a low-pass filter using the MAX7426 set to a 1 kHz cutoff frequency.

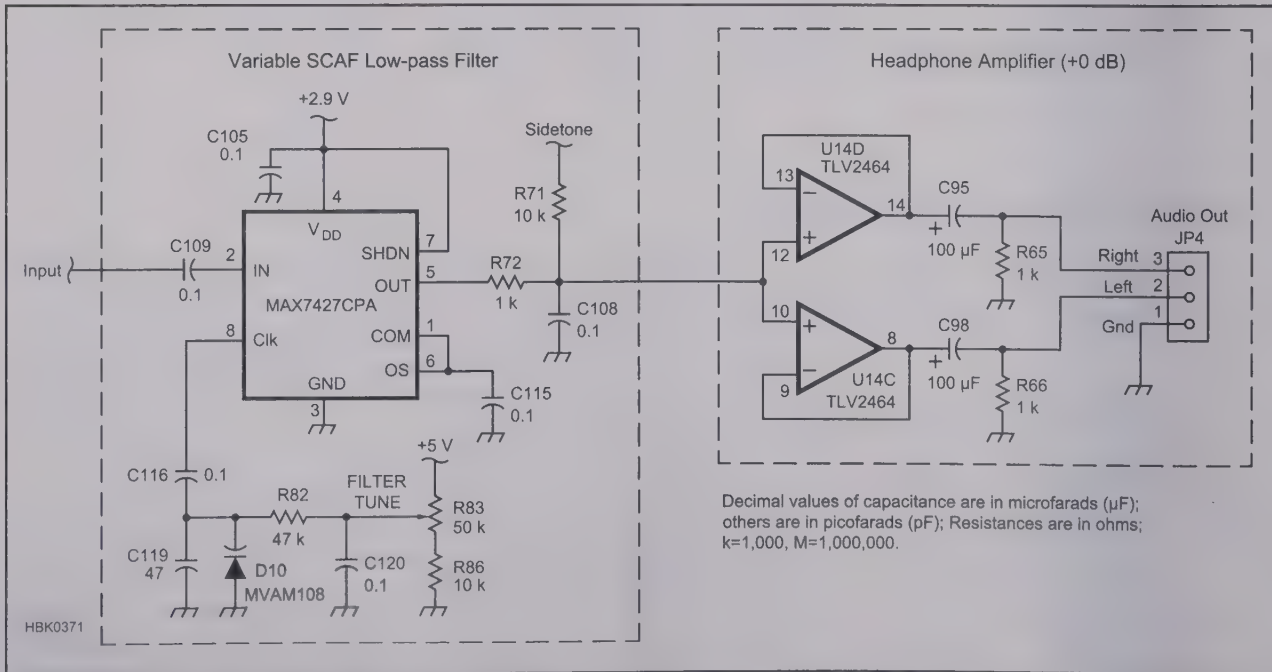

Figure 10.28 — SCAF with variable 300 to 1000 Hz low-pass cutoff and unity-gain headphone amplifier.

but are not useful as an audio filter at very low signal levels early on in a receiver.

**Figure 10.30** is an example of a slightly more complex SCAF band-pass filter. This filter features both a variable center frequency (450 Hz to 1000 Hz) and a variable bandwidth (90 Hz to 1500 Hz). This very popular filter, the NESCAF, was designed by the New England QRP Club ([www.newenglandqrp.org](http://www.newenglandqrp.org)) and is currently offered in kit form in batches. Contact the club if you wish to purchase the kit. The design is included here and is well within the range of a home-builder with intermediate construction skills. There are number of online websites that discuss the filter and how to build it.

The NESCAF filter features both sections of the SCAF10 IC configured as identical band-pass filters. The bandwidth (Q) is adjustable via R7A and R7B, while the center frequency is adjustable by R10 and the trimmer R9 as these resistors set the frequency of the LM555 clock generator.

As in the previous SCAF filter example, this filter also includes an audio amplifier (LM386) for driving either an external speaker or headphones as none of the SCAF filter ICs are capable of driving headphones directly.

### 10.4.2 Active RC Filters

Active RC filters based on op amp circuits can be used in either high-level audio output or very low-level direct-conversion receiver front-end filtering applications and thus are extremely flexible. Unlike LC filters, active RC filters can provide both filtering and gain at the same time, eliminating the relatively high insertion loss of a physically small, sharp LC filter. In addition, an active RC filter is not susceptible to the same ac hum pickup in low signal level applications as LC filters.

Active filters can be designed for gain and they offer excellent stage-to-stage isolation. The circuits require only resistors and capacitors, avoiding the limitations associated with inductors. By using gain and feedback, filter Q is controllable to a degree unavailable to passive LC filters. Despite the advantages, there are also some limitations. They require power, and performance may be limited by the op amp's finite input and output levels, gain and bandwidth. Active filters that drive speakers or other heavy loads usually employ an audio output amplifier circuit to boost the output power after a low-power filter stage.

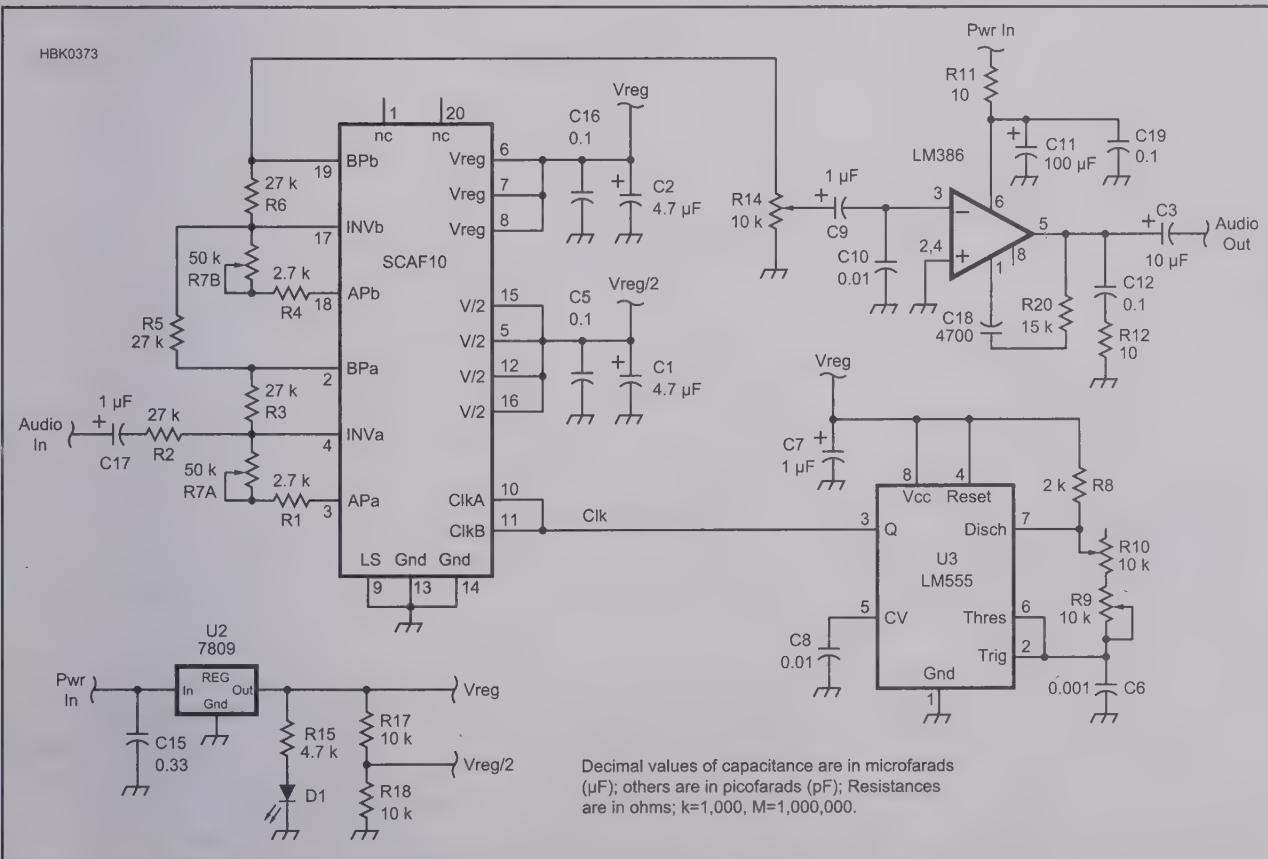

A particular advantage of active RC filters for use in receivers is that they can be capable

of extremely low noise operation, allowing the filtering of extremely small signals. At the same time they are capable of handling extremely large signals. Op amps are often capable of using  $\pm 18\text{-V}$  dual supply voltages or 36-V single supply voltages allowing the construction of a very high performance audio filter/amplifier chain that can handle signals up to 33  $V_{P-P}$ . The ability to provide gain while also providing filtering provides a lot of flexibility in managing the sensitivity of a receiver audio chain.

The main disadvantage of active RC filters is their relatively high parts count compared to other filter types. In addition, active RC filters tend to be fixed-frequency designs unlike SCAF filters whose frequency can be moved simply by changing the clock frequency that drives the SCAF IC.

### 10.4.3 Active Filter Responses

Active filters can implement any of the passive LC filter responses described in the preceding section: low-pass, high-pass, band-pass, band-stop and all-pass. Filter family responses such as Butterworth, Chebyshev, Bessel and

**Figure 10.30** — Example of a simple SCAF band-pass filter from a New England QRP Club kit.

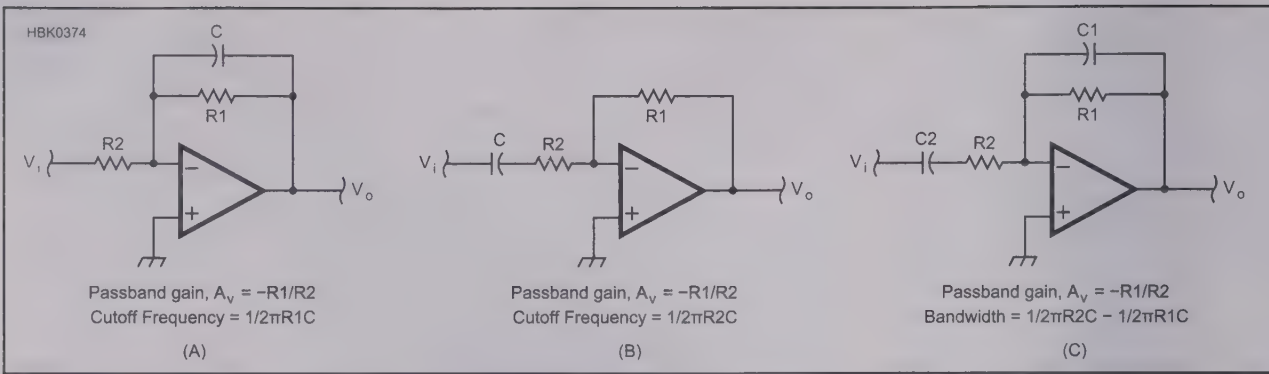

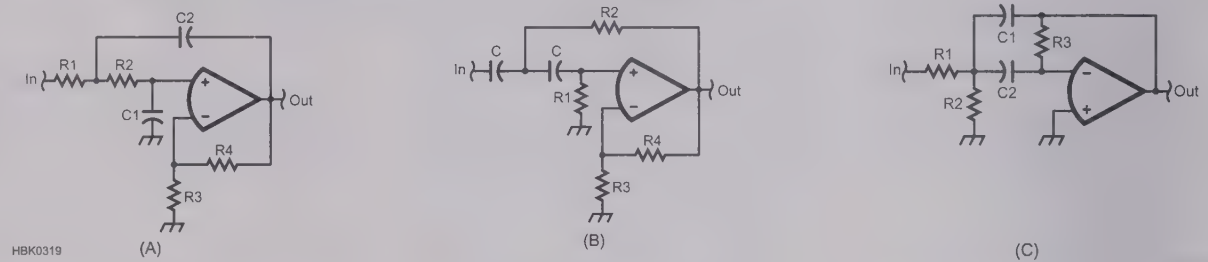

Figure 10.31 — Simple active filters. A low-pass filter is shown at A; B is a high-pass filter. The circuit at C combines the low- and high-pass filters into a wide band-pass filter.

Unless otherwise specified, values of R are in ohms, C is in farads, F in hertz and  $\omega$  in radians per second. Calculations shown here were performed on a scientific calculator.

### Low-Pass Filter

$$C_1 \leq \frac{[a^2 + 4(K-1)]C_2}{4}$$

$$R_1 = \frac{2}{[aC_2 + \sqrt{[a^2 + 4(K-1)]C_2^2 - 4C_1C_2}] \omega_c}$$

$$R_2 = \frac{1}{C_1C_2R_1\omega_c^2}$$

$$R_3 = \frac{K(R_1 + R_2)}{K-1} \quad (K > 1)$$

$$R_4 = K(R_1 + R_2)$$

where

K = gain

$f_c = -3$  dB cutoff frequency

$\omega_c = 2\pi f_c$

$C_2 =$  a standard value near  $10/f_c$  (in  $\mu\text{F}$ )

Note: For unity gain, short R4 and omit R3.

Example:

$a = 1.414$  (see table, one stage)

$K = 2$

$f = 2700$  Hz

$\omega_c = 16,964.6$  rad/sec

$C_2 = 0.0033$   $\mu\text{F}$

$C_1 \leq 0.00495$   $\mu\text{F}$  (use  $0.0050$   $\mu\text{F}$ )

$R_1 \leq 25,265.2$   $\Omega$  (use  $24$  k $\Omega$ )

$R_2 = 8,420.1$   $\Omega$  (use  $8.2$  k $\Omega$ )

$R_3 = 67,370.6$   $\Omega$  (use  $68$  k $\Omega$ )

$R_4 = 67,370.6$   $\Omega$  (use  $68$  k $\Omega$ )

### High-Pass Filter

$$R_1 = \frac{4}{[a + \sqrt{a^2 + 8(K-1)}] \omega_c C}$$

$$R_2 = \frac{1}{\omega_c^2 C^2 R_1}$$

$$R_3 = \frac{KR_1}{K-1} \quad (K > 1)$$

$$R_4 = KR_1$$

where

K = gain

$f_c = -3$  dB cutoff frequency

$\omega_c = 2\pi f_c$

C = a standard value near  $10/f_c$

(in  $\mu\text{F}$ )

Note: For unity gain, short R4 and omit R3.

Example:

$a = 0.765$  (see table, first of two stages)

$K = 4$

$f = 250$  Hz

$\omega_c = 1570.8$  rad/sec

$C = 0.04$   $\mu\text{F}$  (use  $0.039$   $\mu\text{F}$ )

$R_1 = 11,123.2$   $\Omega$  (use  $11$  k $\Omega$ )

$R_2 = 22,722$   $\Omega$  (use  $22$  k $\Omega$ )

$R_3 = 14,830.9$   $\Omega$  (use  $15$  k $\Omega$ )

$R_4 = 44,492.8$   $\Omega$  (use  $47$  k $\Omega$ )

### Band-Pass Filter

Pick K, Q,  $\omega_0 = 2\pi f_c$   
where  $f_c =$  center freq.

Choose C

Then

$$R_1 = \frac{Q}{K_0 \omega_0 C}$$

$$R_2 = \frac{Q}{(2Q^2 - K_0) \omega_0 C}$$

$$R_3 = \frac{2Q}{\omega_0 C}$$

Example:

$K = 2$ ,  $f_0 = 800$  Hz,  $Q = 5$  and  $C = 0.022$   $\mu\text{F}$

$R_1 = 22.6$  k $\Omega$  (use  $22$  k $\Omega$ )

$R_2 = 942$   $\Omega$  (use  $910$   $\Omega$ )

$R_3 = 90.4$  k $\Omega$  (use  $91$  k $\Omega$ )

Figure 10.32 — Equations for designing a low-pass RC active audio filter are given at A, B, C and D show design information for high-pass, band-pass and band-reject filters, respectively. All of these filters will exhibit a Butterworth response. Values of K and Q should be less than 10. See Table 10.3 for values of "a".

Cauer (elliptic) can be realized. All of the same family characteristics apply equally to passive and active filters and will not be repeated here. (Op amps are discussed in the **Circuits and Components** chapter.)

**Figure 10.31** presents circuits for first-order low-pass (Figure 10.31A) and high-pass (Figure 10.31B) active filters. The frequency response of these two circuits is the same as a parallel and series RC circuit, respectively, except that these two circuits can have a passband gain greater than unity. Rolloff is shallow at 6 dB/octave. The two responses can be combined to form a simple band-pass filter (Figure 10.31C). This combination cannot produce sharp band-pass filters because of the shallow rolloff.

HBK0319

(D)

### Band-Reject Filter

$$F_0 = \frac{1}{2\pi R1C1}$$

$$K = 1 - \frac{1}{4Q}$$

$$R \gg (1 - K)R1$$

where

$$C1 = C2 = \frac{C3}{2} = \frac{10 \mu F}{f_0}$$

$$R1 = R2 = 2R3$$

$$R4 = (1 - K)R$$

$$R5 = K \times R$$

Example:

$$f_0 = 500 \text{ Hz}, Q = 10$$

$$K = 0.975$$

$$C1 = C2 = 0.02 \mu F \text{ (or use } 0.022 \mu F)$$

$$C3 = 0.04 \mu F \text{ (or use } 0.044 \mu F)$$

$$R1 = R2 = 15.92 \text{ k}\Omega \text{ (use } 15 \text{ k}\Omega)$$

$$R3 = 7.96 \text{ k}\Omega \text{ (use } 8.2 \text{ k}\Omega)$$

$$R \gg 1 \text{ k}\Omega$$

$$R4 = 25 \Omega \text{ (use } 24 \Omega)$$

$$R5 = 975 \Omega \text{ (use } 910 \Omega)$$

To achieve high-order responses with steeper rolloff and narrower bandwidths, more complex circuits are required in which combinations of capacitors and resistors create *poles* and *zeros* in the frequency response. (Poles and zeros are described in the **Radio Fundamentals** chapter.) The various filter response families are created by different combinations of additional poles and zeroes. There are a variety of circuits that can be configured to implement the equations that describe the various families of filter responses. The most common circuits are *Sallen-Key* and *multiple-feedback*, but there are numerous other choices.

There are many types of active filters — this section presents some commonly used circuits as examples. A book on filter design (see the References section) will present more choices and how to develop designs based on the different circuit and filter family types. In addition, op amp manufacturer's publish numerous application notes and tutorials on active filter design. Several are listed in the References section of this chapter. The set of tutorials published by Analog Devices is particularly good.

### SECOND-ORDER ACTIVE FILTERS

**Figure 10.32** shows circuits for four second-order filters: low-pass (Figure 10.32A), high-pass (Figure 10.32B), band-pass (Figure 10.32C) and band-reject or notch (Figure 10.32D). Sequences of these filters are used to create higher-order circuits by connecting them in series. Two second-order filter stages create a fourth-order filter, and so forth.

The low-pass and high-pass filters use the Sallen-Key circuit. Note that the high-pass circuit is just the low-pass circuit with the positions of R1-R2 and C1-C2 exchanged. R3 and R4 are used to control gain in the low- and high-pass configurations. The band-pass filter is a multiple-feedback design. The notch filter is based on the twin-T circuit. All of the filter design equations and tables will result in a Butterworth family response. (For the Chebyshev and other filter responses, consult the references listed at the end of the chapter.)

The circuits in Figure 10.32 assume the op amp is operating from a balanced, bipolar power supply, such as  $\pm 12 \text{ V}$ . If a single supply is used (such as  $+12 \text{ V}$  and ground), the circuit must have a dc offset added and blocking

capacitors between filter sections to prevent the dc offset from causing the op amp to saturate. The references listed at the end of the chapter provide more detailed information on single-supply circuit design.

Avoid electrolytic or tantalum capacitors as frequency-determining components in active filter design. These capacitors are best used for bypassing and power filtering as their tolerance is generally quite low, they have significant parasitic effects, and are usually polarized. Very small values of capacitance (less than 100 pF) can be affected by stray capacitance to other circuit components and wiring. High-order and high-Q filters require close attention to component tolerance and temperature coefficients, as well.

### SECOND-ORDER ACTIVE FILTER DESIGN PROCEDURES

The following simple procedures are used to design filters based on the schematics in Figure 10.32. Equations and a design example are provided in the figure.

#### Low- and High-Pass Filter Design

To design a low- or high-pass filter using the circuits in Figure 10.32, start by determining your performance requirements for filter order (2, 4, 6, or 8), gain (K) and cutoff frequency ( $f_c$ ). Calculate  $\omega_c = 2\pi f_c$  and  $C_2$  or C as required.

**Table 10.3** provides design coefficients to create the Butterworth response from successive Sallen-Key low- and high-pass stages. A different coefficient is used for each stage. Obtain design coefficient "a" from Table 10.3. Calculate the remaining component values from the equations provided.

#### Band-Pass Filter Design

To design a band-pass filter as shown in Figure 10.32C, begin by determining the filter's required Q, gain, and center frequency,  $f_0$ . Choose a value for C and solve for the resistor values. Very high or very low values of resistance (above 1 M $\Omega$  or lower than 10  $\Omega$ ) should be avoided. Change the value of C until suitable values are obtained. High gain and Q may be difficult to obtain in the same stage with reasonable component values. Consider a separate stage for additional gain or to

**Table 10.3**  
Factor "a" for Low- and High-Pass Filters in Figure 10.32

No. of Stages	Stage 1	Stage 2	Stage 3	Stage 4
1	1.414	—	—	—
2	0.765	1.848	—	—
3	0.518	1.414	1.932	—
4	0.390	1.111	1.663	1.962

These values are truncated from those of Appendix C of Williams, *Electronic Filter Design Handbook*, for even-order Butterworth filters

narrow the filter bandwidth.

### Band-Reject (Notch) Filter Design

Band-reject filter design begins with the selection of center frequency,  $f_0$ , and  $Q$ . Calculate the value of  $K$ . Choose a value for  $C1$  that is approximately  $10 \mu\text{F} / f_0$ . This determines the values of  $C2$  and  $C3$  as shown. Calculate the value for  $R1$  that results in the desired value for  $f_0$ . This determines the values of  $R2$  and  $R3$  as shown. Select a convenient value for  $R4 + R5$  that does not load the output amplifier. Calculate  $R4$  and  $R5$  from the value of  $K$ .

The depth of the notch depends on how closely the values of the components match the design values. The use of 1%-tolerance resistors is recommended and, if possible, matched values of capacitance. If all identical components are used, two capacitors can be paralleled to create  $C3$  and two resistors in parallel create  $R3$ . This helps to minimize thermal drift.

### 10.4.4 Active Filter Design Tools

While the simple active filter examples presented above can be designed manually, more

sophisticated circuits are more easily designed using filter-design software. Follow the same general approach to determining the filter's performance requirements and then the filter family as was presented in the section on LC filters. You can then enter the values or make the necessary selections for the design software. Once a basic design has been calculated, you can then "tweak" the design performance, use standard value components and make other adjustments. The design example presented below shows how a real analog design is assembled by understanding the performance requirements and then using design software to experiment for a "best" configuration.

Op amp manufacturers such as Texas Instruments and National Semiconductor (originally separate companies but now merged) have made available sophisticated "freeware" filter design software. These packages are extremely useful in designing active RC filters. They begin by collecting specifications from the user and then creating a basic circuit. Once the initial circuit has been designed, the user can adjust specifications, component values, and op amp types until satisfied with the final design.

Free online filter design software is available from the following sources:

- Analog Devices — *Analog Filter Wizard 2.0* ([tools.analog.com/en/filterwizard/](http://tools.analog.com/en/filterwizard/))
- Texas Instruments — *FilterPro 3.1* ([www.ti.com](http://www.ti.com), search for "FilterPro")

Even if a manual design process is followed, using a software tool to double-check the results is a good way to verify the design before building the circuit. A circuit simulator such as *LTSpice* (see the **Computer-Aided Circuit Design** chapter) can also verify a design before building the actual circuit.

An extended design example using the Texas Instruments *FilterPro* software is included in this book's downloadable supplemental information. In the example, Dan Taylor, N7VE explains the process of designing a high-performance 750 Hz low-pass filter, illustrating the power of using sophisticated interactive tools that enable design changes on-the-fly. The reader is encouraged to follow along and experiment with *FilterPro* as a means of becoming familiar with the software so that it can be used for other filter design tasks. Similar processes apply to other filter design software tools.

## 10.5 Digital Filters

Where an analog filter operates on a continuous signal in the time domain, digital filters operate on signals that have been converted to a digital stream of data. (See the discussion of digital signals in the **DSP and SDR Fundamentals** chapter.) The usual method of constructing a digital filter is as a series of registers with the stream of samples moving through them in a series of steps called *delays*. At each register (called a *tap*) the amplitude of the signal is modified (by an amount referred to as a *coefficient*) and the result added to the results from other taps. The signal stream is shifted to the next register and the process is repeated. The sum of the results from the taps constitutes the output of the filter.

The value of each coefficient and the configuration of how the filter's taps are added together determine the filter's response to the input signal. This section will discuss two basic filter types, the finite impulse response or FIR, the infinite impulse response or IIR.

The purpose of this section is not to give a tutorial in how each type of filter is designed but explain the characteristics of each type of filter. As with analog filters, the design of digital filter is mostly done by software using validated algorithms that accept performance requirements as inputs and generate design information, in many cases as a data file that can be loaded directly into a DSP processor or subsystem. (The GNU Radio ([gnuradio.org](http://gnuradio.org))

toolkit, for example, treats digital filters as one of many functional blocks. The user configures the filter parameters and the software manages the organization of the actual computing elements in the DSP or SDR system.) For the reader interested in a deeper discussion of digital filter theory and design, several excellent references are listed at the end of the chapter.

### 10.5.1 FIR Filters

The earlier discussion of transient response introduced the impulse, an infinitely narrow pulse. The spectrum of an impulse is infinitely wide, containing all frequencies. If you feed an impulse into the input of a filter (analog or digital), the output of the filter is the filter's impulse response. Because the impulse is made up of all frequencies, it excites the filter at all frequencies. As a result, the impulse response has a frequency spectrum equal to the frequency response of the filter.

One way to design a filter is to determine the impulse response that corresponds to the desired frequency spectrum and then design the filter to have that impulse response. That method is the basis for designing *finite impulse response* (FIR) filters. (Finite refers to time, not amplitude.)

An FIR filter is a filter whose impulse response is finite, ending in some fixed time.

Note that analog filters have an infinite impulse response — the output theoretically rings forever. Even a simple R-C low-pass filter's output decays exponentially toward zero but theoretically never quite reaches it. In contrast, an FIR filter's impulse response becomes exactly zero at some time after receiving the impulse and stays zero forever (or at least until another impulse comes along).

Given that you have somehow figured out the desired impulse response, how would you design a digital filter to have that response? The obvious method would be to pre-calculate a table of impulse response values, sampled at the sample rate. These are called the filter *coefficients*. When an impulse of a certain amplitude is received, you multiply that amplitude by the first entry in the coefficient table and send the result to the output. At the next sample time, multiply the impulse by the second entry, and so on until you have used up all the entries in the table.

A circuit to do that is shown in **Figure 10.33**. The input signal is stored in a shift register. Each block labeled "Delay" represents a delay of one sample time. At each sample time, the signal is shifted one register to the right. Each register feeds a multiplier and the other input to the multiplier comes from one of the coefficient table entries. All the multiplier outputs are added together. Since the input is assumed to be a single impulse, at any given time all

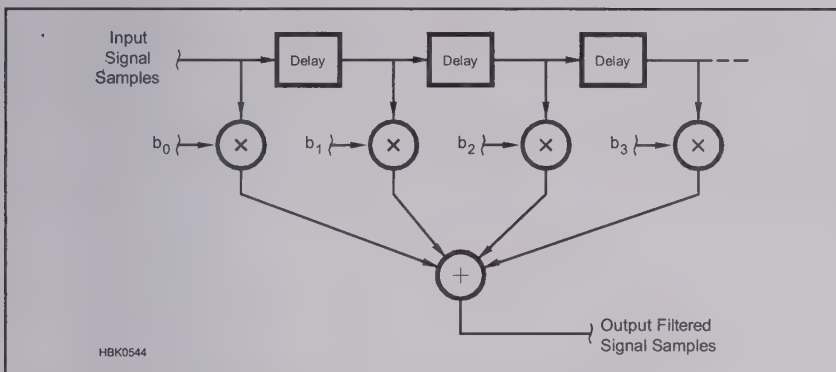

Figure 10.33 — A 4-tap FIR filter. The  $b_n$  values are the filter coefficients.

the shift registers contain zero except one, which is multiplied by the appropriate table entry and sent to the output.

We've just designed an FIR filter! By using a shift register with a separate multiplier for each tap, the filter works for continuous signals as well as for impulses. Since this is a linear system, the continuing signal is affected by the filter the same as an individual impulse.

It should be obvious from the diagram how to implement an FIR filter in software. You set up two buffers in memory, one for the filter coefficients and one for the data. The length of each buffer is the number of filter taps. (A  $tap$  is the combination of one filter coefficient, one shift register and one multiplier/accumulator.) Each time a new data value is received, it is stored in the next available position in the data buffer and the accumulator is set to zero. Next, a software loop is executed a number of times equal to the number of taps. During each loop, pointers to the two buffers are incremented, the next coefficient is multiplied by the next data value and the result is added to the current accumulator value. After the last loop, the accumulator contents are the output value. Normally the buffers are implemented as *circular buffers*—when the address pointer gets to the end it is reset back to the beginning.

Now you can see why a hardware multiplier-accumulator (MAC) is such an important feature of a DSP chip. Each tap of the FIR filter involves one multiplication and one addition. With a 1000-tap FIR filter, 1000 multiplications and 1000 additions must be performed during each sample time. The ability to do each MAC operation in a single clock cycle saves a lot of processing time compared to a CPU-type processor.

An FIR filter is a hardware or software implementation of the mathematical operation called *convolution*. We say that the filter *convolves* the input signal with the impulse response of the filter. It turns out that convolution in the time domain is mathematically equivalent to multiplication in the frequency domain. That means that the frequency spec-

trum of the output equals the frequency spectrum of the input times the frequency spectrum of the filter. Expressed in decibels, the output spectrum equals the input spectrum plus the filter frequency response, all in dB. If at some frequency the input signal is +3 dB and the filter is -10 dB compared to some reference, then the output signal will be  $3 - 10 = -7$  dB at that frequency.

An FIR filter whose bandwidth is very small compared to the sample rate requires a long impulse response with lot of taps. This is another consequence of the “skinny” versus “fat” relationship between the frequency and time domains. If the filter is narrow in the frequency domain, then its impulse response is wide. Actually, if you want the frequency response to go all the way to zero (minus infinity dB) throughout the stopband, then the impulse response theoretically becomes infinitely wide. Since we're designing a *finite* impulse response filter we have to truncate the impulse response at some point to get it to fit in the coefficient table. When you do that, however, you no longer have infinite attenuation in the stopband. The more heavily you truncate (the narrower the impulse response) the worse the stopband attenuation and the more ripple you get in the passband. Assuming optimum design techniques for selecting coefficients, you can estimate the minimum length  $L$  of the impulse response from the following equation:

$$L = 1 - \frac{10 \log(\delta_1 \delta_2) - 15}{14 \left( \frac{f_T}{f_s} \right)} \text{ taps}$$

where

- $\delta_1$  and  $\delta_2$  = the passband and stopband ripple expressed as a fraction
- $f_T$  = the transition bandwidth (frequency difference between passband and stopband edges)
- $f_s$  = the sample rate.

For example, for a low-pass filter with a passband that extends up to 3 kHz, a stopband

that starts at 4 kHz ( $f_T = 4 - 3 = 1$  kHz),  $f_s = 10$  kHz sample rate,  $\pm 0.1$  dB passband ripple ( $d_1 = 10^{0.1/20} - 1 = 0.0116$ ), and 60 dB stopband rejection ( $d_2 = 10^{-60/20} = 0.001$ ), we get

$$L = 1 - \frac{10 \log(0.0116 \times 0.001) - 15}{14 \left( \frac{1}{10} \right)}$$

$$= 1 - \frac{-49.4 - 15}{1.4} = 47 \text{ taps}$$

Overflow is a potential problem when doing the calculations for an FIR filter. Multiplying two  $N$ -bit numbers results in a product with  $2N$  bits, so space must be provided in the accumulator to accommodate that. Although the final result normally will be scaled and truncated back to  $N$  bits, it is best to carry through all the intermediate results with full resolution in order not to lose any dynamic range. In addition, the sum of all the taps can be a number with more than  $2N$  bits. For example, if the filter width is 256 taps, then if all coefficients and data are at full scale, the final result could theoretically be 256 times larger, requiring an extra 8 bits in the accumulator. We say “theoretically” because normally most of the filter coefficients are much less than full scale and it is highly unlikely that all 256 data values would ever simultaneously be full-scale values of the correct polarity to cause overflow. The dsPIC processors use 16-bit multipliers with 32-bit results and a 40-bit accumulator, which should handle any reasonable circumstances.

After all taps have been calculated, the final result must be retrieved from the accumulator. Since the accumulator has much more resolution than the processor's data words, normally the result is truncated and scaled to fit. It is up to the circuit designer or programmer to scale by the correct value to avoid overflow. The worst case is when each data value in the shift register is full-scale—positive when it is multiplying a positive coefficient and negative for negative coefficients. That way, all taps add to the maximum value. To calculate the worst-case accumulator amplitude, simply add the absolute values of all the coefficients. However, that normally gives an unrealistically pessimistic value because statistically it is extremely unlikely that such a high peak will ever be reached. For a low-pass filter, a better estimate is to calculate the gain for a dc signal and add a few percent safety margin. The dc gain is just the sum of all the coefficients (not the absolute values). For a band-pass filter, add the sum of all the coefficients multiplied by a sine wave at the center frequency.

### Calculating FIR Filter Coefficients

So far we have ignored the question of how to determine the filter coefficients. For an ideal “brick-wall” low-pass filter, the answer turns out to be pretty simple. A “brick-wall” low-

pass filter is one that has a constant response from zero hertz up to the cutoff frequency and zero response above. Its impulse response is proportional to the sinc function:

$$C(n) = C_0 \operatorname{sinc}(2Bn) = \frac{\sin(2\pi Bn)}{2\pi Bn}$$

where  $C(n)$  are the filter coefficients,  $n$  is the sample number with  $n = 0$  at the center of the impulse response,  $C_0$  is a constant, and  $B$  is the single-sided bandwidth normalized to the sample rate,  $B = \text{bandwidth} / \text{sample rate}$ .

It is interesting that this has the same form as the frequency response of a pulse, as was shown in Figure 10.33. That is because a brick-wall response in the frequency domain has the same shape as a pulse in the time domain. A pulse in one domain transforms to a sinc function in the other. This is an example of the general principle that the transformation between time and frequency domains is symmetrical. This is discussed in more detail in the section on Fourier transforms in the **DSP and SDR Fundamentals** chapter.

Normally, the filter coefficients are set up with the peak of the sinc function,  $\operatorname{sinc}(0)$ , at the center of the coefficient table so that there is an equal amount of “tail” on both sides. That points up the principle problem with this method of determining filter coefficients. Theoretically, the sinc function extends from minus infinity to plus infinity. Abruptly terminating the tails causes the frequency response to differ from an ideal brick-wall filter. There is ripple in the passband and non-zero response in the stopband, as shown in the graph in the upper right of Figure 10.34. This is mainly caused by the abruptness of the truncation. In effect, all the coefficients outside the limits of the coefficient table have been set to zero. The passband and stopband response can be improved by tapering the edges of the impulse response instead of abruptly transitioning to zero.

The process of tapering the edges of the impulse response is called *windowing*. The impulse response is multiplied by a window, a series of coefficients that smoothly taper to zero at the edges. For example, a rectangular window is equivalent to no window at all. Many different window shapes have been developed over the years — at one time it seemed that every doctoral candidate in the field of signal processing did their dissertation on some new window. Each window has its advantages and disadvantages. A window that transitions slowly and smoothly to zero has excellent passband and stopband response but a wide transition band. A window that has a wider center portion and then transitions more abruptly to zero at the edges has a narrower transition band but poorer passband and stopband response. The equations for the windows in Figure 10.34 are included in a sidebar.

The routine shown in **Table 10.4** is written

for a dsPIC processor so it can be used to calculate filter coefficients “on the fly” as the operator adjusts a bandwidth control. The same code should also work using a generic C compiler on a PC so the coefficients could be downloaded into an FIR filter implemented in hardware.

The windowed-sinc method works pretty

well for a simple low-pass filter, but what if some more-complicated spectral shape is desired? The same general design approach still applies. You determine the desired spectral shape, transform it to the time domain using an inverse Fourier transform, and apply a window. There is lots of (often free) software available that can calculate the fast Fourier transform

**Table 10.4**  
**Routine for dsPIC Processor to Calculate Filter Coefficients**

```
// Calculate FIR filter coefficients
// using the windowed-sinc method
void set_coef (
    double sample_rate;
    double bandwidth;)
{
    extern int c[FIR_LEN]; // Coefficient array
    int i; // Coefficient index
    double ph; // Phase in radians
    double coef; // Filter coefficient
    int coef_int; // Digitized coefficient
    double bw_ratio; // Normalized bandwidth

    bw_ratio = 2 * bandwidth / sample_rate;
    for (i = 0; i < (FIR_LEN/2); i++) {
        // Brick-wall filter:
        ph = PI * (i + 0.5) * bw_ratio;
        coef = sin(ph) / ph;
        // Hann window:
        ph = PI * (i + 0.5) / (FIR_LEN/2);
        coef *= (1 + cos(ph)) / 2;
        // Convert from floating point to int:
        coef *= 1 << (COEF_WIDTH - 1);
        coef_int = (int)coef;
        // Symmetrical impulse response:
        c[i + FIR_LEN/2] = coef_int;
        c[FIR_LEN/2 - 1 - i] = coef_int;
    }
}
```

## Equations for Window Functions

For each window function, the center of the response is considered to be at time  $t = 0$  and the width of the impulse is  $L$ . Each window is 1.0 when  $t = 0$  and 0.0 when the  $|t| > L/2$ .

### Rectangular:

$$w(t) = 1.0$$

### Triangular (Bartlett):

$$w(t) = 2 \left( \frac{L/2 - |t|}{L} \right)$$

### Blackman:

$$w(t) = 0.42 + 0.5 \cos\left(\frac{2\pi t}{L}\right) + 0.08 \cos\left(\frac{4\pi t}{L}\right)$$

### Hamming:

$$w(t) = 0.54 + 0.46 \cos\left(\frac{2\pi t}{L}\right)$$

### Hanning (Hann):

$$w(t) = 0.5 + 0.5 \cos\left(\frac{2\pi t}{L}\right)$$

(FFT) and inverse fast Fourier transform (IFFT). So the technique is to generate the desired spectral shape, transform to the time domain with the IFFT, and multiply the resulting impulse response by the desired window. Then you can transform back to the frequency domain with the FFT to see how the window affected the result. If the result is not satisfactory, you can either choose a different window or modify the original spectral shape and go through the process again.

Windowing methods are useful because they are simple to program and the resulting software routines execute quickly. For example, you can include a bandwidth knob on your DSP filter and calculate filter coefficients “on the fly” as the user turns the knob. However, while the filter performance that results is pretty good, it is not “optimum” in the sense that it does not have minimum passband ripple and maximum stopband attenuation for a given number of filter coefficients. For that, you need what is known as an *equal-ripple*, or *Chebyshev* filter. The calculations to determine Chebyshev filter coefficients are more complicated and time-consuming. For that reason, the coefficients are normally calculated in advance on a PC and stored in DSP program memory for retrieval as needed.

Engineers have not had much success in devising a mathematical algorithm to calculate the Chebyshev coefficients directly, but in 1972 Thomas Parks and James McClellan figured out a method to do it iteratively. The *Parks-McClellan algorithm* is supported in most modern filter-design software, including a number of programs available for free download on the Web. Typically you enter the sample rate, the passband and stopband frequency ranges, the passband ripple and the stopband attenuation. The software then determines the required number of filter coefficients, calculates them and displays a plot of the resulting filter frequency response.

Filter design software typically presents the filter coefficients as floating-point numbers to the full accuracy of the computer. You will need to scale the values and truncate the resolution to the word size of your filter implementation. Truncation of filter coefficients affects the frequency response of the filter but does not add noise in the same manner as truncating the signal data.

As you look at impulse responses for various FIR filters calculated by various methods you soon realize that most of them are symmetrical. If the center of the impulse response is considered to be at time zero, then the value at time  $t$  equals the value at time  $-t$  for all  $t$ . If you know in advance that the filter coefficients are symmetrical, you can take advantage of that in the filter design. By re-arranging the adders and multipliers, the number of multipliers can be reduced by a factor of two, as shown in **Figure 10.35**. This trick is less useful in a

**Figure 10.35** — A 6-tap FIR filter. Because the coefficients are symmetrical, the symmetrical taps may be combined before multiplication.

software implementation of an FIR filter because the number of additions is the same and many DSPs take the same amount of time to do an addition as a multiply-accumulate.

In addition to the computational benefit, a symmetrical impulse response also has the advantage that it is *linear phase*. The time delay through such a filter is one-half the length of the filter for all frequencies. For example, for a 1000-tap filter running at 10 kHz the delay is  $500/10,000 = 0.05$  second. Since the time delay is constant for all frequencies, the phase delay is directly proportional to the frequency. For example, if the phase delay at 20 Hz is one cycle (0.05 second) it is ten cycles at 200 Hz (still 0.05 second). Linear phase delay is important with digital modulation signals to avoid distortion and inter-symbol interference. It is also desirable with analog modulation where it can result in more natural-sounding audio. All analog filters are non-linear-phase; the phase distortion tends to be worse the more abrupt the transition between passband and stopband. That is why an SSB signal sounds unnatural after being filtered by a crystal filter with a small shape factor even though the passband ripple may be small and distortion minimal.

A band-pass filter can be constructed from a low-pass filter simply by multiplying the impulse response by a sine wave at the desired center frequency. This can be done before or after windowing. The linear-phase property is retained but with reference to the center frequency of the filter, that is, the phase shift is proportional to the difference in frequency from the center frequency. The frequency response is a double-sided version of the low-pass response with the zero-hertz point of the low-pass filter shifted to the frequency of the sine wave.

## 10.5.2 IIR Filters

An *infinite impulse response* (IIR) filter is a filter whose impulse response is infinite. After an impulse is applied to the input, theoretically the output never goes to zero and stays there. In practice, of course, the signal eventually does decay until it is below the noise level (analog filter) or less than one LSB (digital filter).

Unlike a symmetrical FIR filter, an IIR filter is not generally linear-phase. The delay through the filter is not the same for all frequencies. Also, IIR filters tend to be harder to design than FIR filters. On the other hand, many fewer adders and multipliers are typically required to achieve the same passband and stopband ripple in a given filter, so IIR filters are often used where computations must be minimized.

All analog filters have an infinite impulse response. For a digital filter to be IIR it must have feedback. That means a delayed copy of some internal computation is applied to an earlier stage in the computation. A simple but useful example of an IIR filter is the exponential decay circuit in **Figure 10.36**. In the absence of a signal at the input, the output on the next clock cycle is always  $(1-\delta)$  times the current output. The time constant (the time for the output to die to  $1/e = 36.8\%$  of the initial value) is very nearly

$$\tau = f_s \left( \frac{1}{\delta} - \frac{1}{2} \right)$$

where  $f_s$  is the sample rate. The circuit is the digital equivalent of a capacitor with a resistor in parallel and might be useful for example in a digital automatic gain control circuit.

One issue with IIR filters is resolution. Because of the feedback, the number of bits

of resolution required for intermediate computations can be much greater than at the input or output. In the previous example,  $\delta$  is very small for very long time constants. When the value in the register falls below a certain level the multiplication by  $(1-\delta)$  will no longer be accurate unless the bit width is increased. In practice, the increased resolution required with IIR filters often cancels out part of the savings in the number of circuit elements.

Another issue with IIR filters is stability. Because of the feedback it is possible for the filter to oscillate if care is not taken in the design. Stability can also be affected by non-linearity at low signal levels. A circuit that is stable with large signals may oscillate with small signals due to the round-off error in certain calculations, which causes faint tones to appear when strong signals are not present. This is known as an unstable *limit cycle*. These issues are part of the reason that IIR filters have a reputation for being hard to design.

Design techniques for IIR filters mostly involve first designing an analog filter using any of the standard techniques and then transforming the design from the analog to the digital domain. The *impulse-invariant* method attempts to duplicate the filter response directly by making the digital impulse response equal the impulse response of the equivalent analog filter. It works fairly well for low-pass filters with bandwidths much less than the sample rate. Its problem is that it tries to duplicate the frequency response all the way to infinity hertz, but that violates the Nyquist criterion resulting in a folding back of the high-frequency response down into low frequencies. It is similar to the aliasing that occurs in a DSP system when the input signal to be sampled is not band-limited below the Nyquist frequency.

The *bilinear transform* method gets around that problem by distorting the frequency axis such that infinity hertz in the analog domain becomes sample rate / 2 in the digital domain. Low frequencies are fairly accurate, but high frequencies are squeezed together more and more the closer you get to the Nyquist frequency. It avoids the aliasing problem at the expense of a change in the spectrum shape, especially at the high-frequency end. For

example, when designing a low-pass filter it may be necessary to change the cutoff frequency to compensate. Again, the method works best for filters with passband frequencies much less than the sample rate.

In general, the output of an IIR filter is a combination of the current and previous input values (feed-forward) and previous output values (feed-back). **Figure 10.37A** shows the so-called *direct form I* of an IIR filter. The  $b_i$  coefficients represent feed-forward and the  $a_i$  coefficients feed-back. For example the previous value of the  $y$  output is multiplied by  $a_1$ , the second previous value is multiplied by  $a_2$ , and so on. Because the filter is linear, it doesn't matter whether the feed forward or feed back stage is performed first. By reversing the order, the number of shift registers is reduced as in **Figure 10.37B**. There are other equivalent topologies as well. The mathematics for gen-

erating the  $a_i$  and  $b_i$  coefficients for both the impulse-invariant and bilinear transform methods is fairly involved, but fortunately some filter design programs can handle IIR as well as FIR filters.

### 10.5.3 CIC Filters

(This overview of CIC filters is taken from the 2011 Sep/Oct *QEX* column SDR: Simplified by Ray Mack, W5IFS. Additional background on CIC filters is available in the referenced articles by Donadio and by Lyons.)

The problem with both FIR and IIR filters is that they require a large number of multiply operations, which consume a large number of DSP processor cycles. Eugene Hogenaer (see references) developed a very useful simplification of the sample conversion/filter configuration called a cascaded integrator comb (CIC) filter. The important aspect of CIC filters is

Figure 10.36 — An exponential decay implementation.

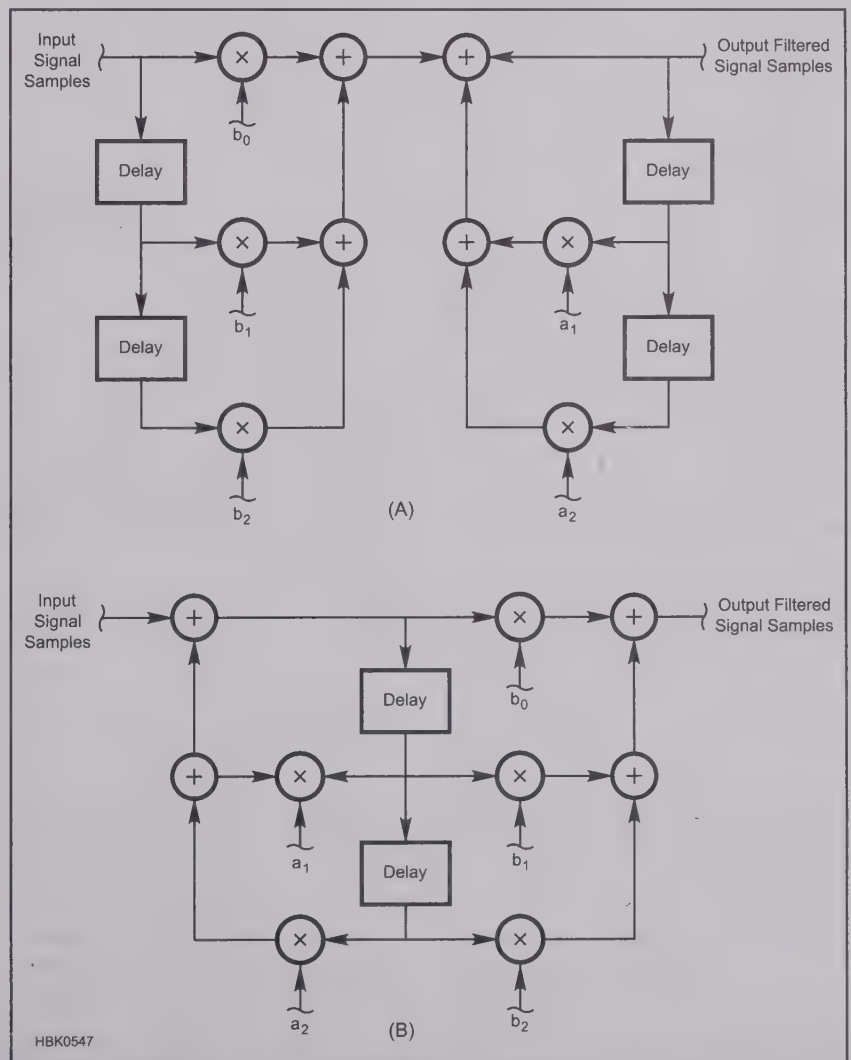

Figure 10.37 — An IIR filter with three feed-forward taps and two feed-back taps. Direct form I (A) and the equivalent direct form II (B).

Figure 10.38 — Z transform diagram of an integrator. The new output is the sum of the previous output (represented by  $Z^{-1}$ ) and the new sample. (The Z transform is explained at [en.wikipedia.org/wiki/Z-transform](http://en.wikipedia.org/wiki/Z-transform).)

Figure 10.39 — Z transform diagram of a comb. The new output is the difference of the present sample and a delayed sample. The number  $M$  designates how many steps happened during the delay.

that only addition, subtraction, and delay operations are required for implementation.

As with most things in life, improving one aspect of a system requires compromise in other aspects. This is also true of CIC filters where we trade the simplification of eliminating multipliers for restricting the filter response: A CIC filter can only have a low-pass response. Additionally, there is a limited subset of possible low-pass responses constrained by the sample rate change and number of stages in the comb and integrator stages. The most important property of a CIC filter is that it can be very easily implemented in hardware either in an FPGA or as part of the dedicated logic of an IC.

The integrator is an infinite impulse response filter. Figure 10.38 shows how it works and how simple it is. The integrator holds a running total of all previous samples. The integrator adds the last output value ( $z^{-1}$ ) to the current input value ( $x$ ). Ordinarily, we would worry about overflow in an integrator because a dc component in the signal will cause the integrator to overflow.

The combination of the comb and the integrator, however, cancels any problems with overflow. The integrator is a single pole low pass filter with infinite gain at dc. (The possibility of overflow doesn't matter as long as the integrators are implemented with

adders using two's complement addition ([en.wikipedia.org/wiki/Two's\\_complement](http://en.wikipedia.org/wiki/Two's_complement)) that allow wrap around when overflow occurs, and that the number of bits in the word is as big as the expected output word.)

The comb is a finite impulse response stage that subtracts a previous sample from the present sample. The amount of delay between the present sample and the delayed sample is called the differential delay and is denoted as  $M$  by most authors. Figure 10.39 shows the operation of the comb.

An actual CIC filter is composed of multiple integrator-comb sections that are cascaded. A CIC filter has exactly the same number of integrators as combs. According to the associative property you can rearrange the order of the additions in a sequence and the result of the sequence does not change ( $a + (-b) + c + d + (-e) + (-f)$  is identical to  $a + c + d - b - e - f$ ). A CIC filter with a sample rate change uses that property to group all of the integrators together and to group all of the combs together. We place either a downsample or upsample rate changer between the combs and integrators. (See the **DSP and SDR Fundamentals** chapter for a discussion of sample rate changing.)

Figure 10.40 shows that a decimator is an integrator section followed by a down rate change, which is then followed by a comb section. An interpolator turns the system

around and puts the comb section first, followed by an up rate changer, which is followed by an integrator section. It is very useful for a hardware implementation that the number of integrators and combs is independent (within reason) from the rate change and that, in general, you can rearrange the inputs, outputs, and rate change to create a decimator and interpolator with the same blocks.

There are three parameters that affect the implementation of a CIC filter. "R" is the up sample rate or down sample rate. "M" is the delay in the comb section and is almost always either one or two. "N" is the number of stages in the comb section (which is required to be the same as the number of integrator sections). The simplification of separating the combs into one section and the integrators into a second section is advantageous for the speed required of the storage elements for the combs. The combs always operate at the low frequency end of the system and the integrators work at the high speed side of the system.

Notice that the associative property would also allow a decimator with the comb first and the integrator after the down converter. Either configuration will give the same results. The reason we always put the comb on the low sample rate side of the system is pragmatic. The comb requires one additional storage element (for the usual  $M = 1$  situation) over what is required for an integrator. Each storage element consumes power when it is clocked. A faster clock and more storage registers translate directly into additional power dissipation. The additional power is an issue when implementing a CIC filter in hardware such as an FPGA.

### 10.5.4 Adaptive Filters

An *adaptive filter* is one that automatically adjusts its filter coefficients under the control of some algorithm. This is often done in situations where the filter characteristics are not known in advance. For example, an adaptive channel equalizer corrects for the non-flatness in the amplitude and phase spectrum of a com-

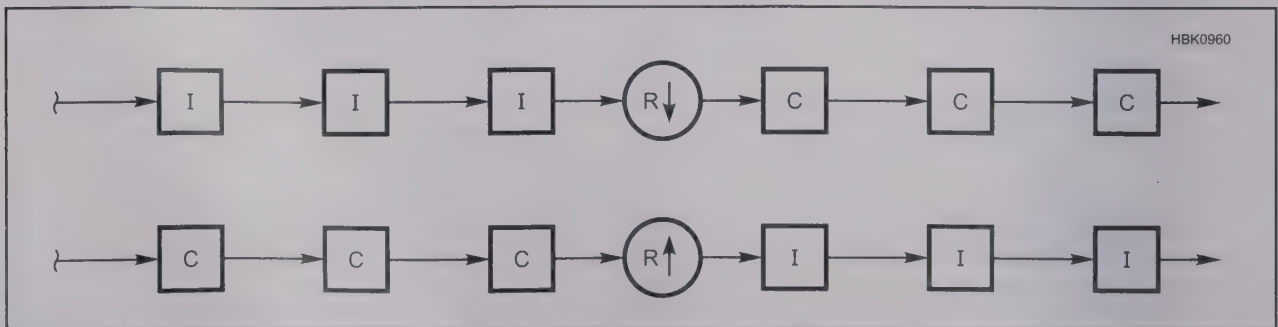

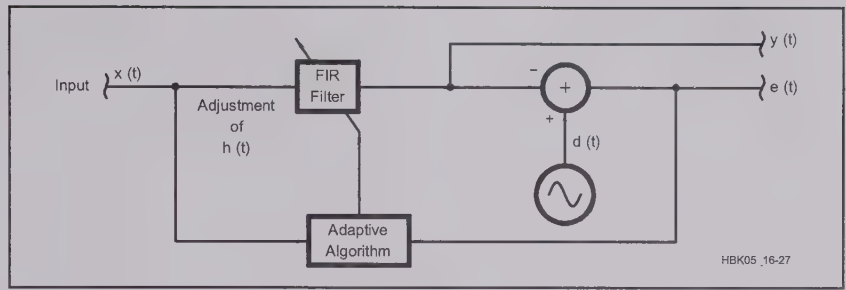

Figure 10.40 — The top CIC filter shows a decimator, where the sample rate is reduced by a value "R." The bottom CIC filter shows an interpolator where the sample rate is increased by a value "R." Note that the difference between the two is the order of the combs and integrators as well as the direction of the rate change. The combs are on the low sample rate side of both systems.

munications channel due to multipath propagation. Typically, the transmitting station periodically sends a known sequence of data, known as a *training sequence*, which is used by the receiver to determine the channel characteristics and adjust its filter coefficients accordingly.

Another example is an automatic notch filter. An algorithm determines the frequency of an interfering tone and automatically adjusts the notch frequency to remove the tone. Noise cancellation is another application. It can be thought of as the opposite of a notch filter. In this case, all the sine-wave tones in the input signal are considered to be desired and the filter coefficients are configured to enhance them. That method works not only for CW signals but for voice as well since the human voice consists largely of discrete frequencies.

A generic block diagram of an adaptive filter is shown in **Figure 10.41**. The variable filter is typically an FIR type with coefficients calculated by the update algorithm. By some means, an estimate of the desired, unimpaired signal,  $d$ , is generated and compared to the filter output  $y$ . The difference between  $y$  and  $d$  is the error,  $e$ , which is used by the update

**Figure 10.41** — An adaptive filter configuration.

algorithm to modify the filter coefficients to improve the accuracy of  $y$ . The algorithm is capable of acting as a noise-reduction filter and a notch filter simultaneously. Assuming  $d$  is in the form of a pure tone (sine wave), the tone is simultaneously optimized in the  $y$  output and minimized in the  $e$  output.

A common algorithm for minimizing the error signal is called *least mean squares* (LMS). The LMS algorithm includes a performance parameter,  $\mu$ , which can be adjusted

between 0 and 1 to control the tradeoff between adjustment speed and accuracy. A value near 1 results in fast convergence but the convergence is not very accurate. For better accuracy at the cost of slower adjustment, lower the value of  $\mu$ . Some implementations adjust  $\mu$  on the fly, using a large value at first to get faster lock-in when the error is large then a smaller value after convergence to reduce the error. That works as long as the signal characteristics are not changing too rapidly.

## 10.6 Quartz Crystal Filters

(The sections on designing and building crystal filters from previous editions are available as a PDF document in the this book's downloadable supplemental material.)

Inductor  $Q$  values effectively limit the minimum bandwidth that can be achieved with LC band-pass filters. Higher- $Q$  circuit elements, such as quartz crystal, PLZT ceramic and constant-modulus metal alloy resonators, are required to extend these limits. Quartz crystals offer the highest  $Q$  and best stability with time and temperature of all available resonators. They are manufactured for a wide range of frequencies from audio to VHF, using cuts (crystal orientations) that suit the frequency and application of the resonator. The AT cut is favored for HF fundamental and VHF overtone use, whereas other cuts (DT, SL and E) are more convenient for use at lower frequencies.

Each crystal plate has several modes of mechanical vibration. These can be excited

electrically thru the piezoelectric effect, but generally resonators are designed so as to maximize their response on a particular operating frequency using a crystal cut that provides low loss and a favorable temperature coefficient. Consequently, for filter design, quartz crystal resonators are modeled using the simplified equivalent circuit shown in **Figure 10.42**. Here  $L_m$ ,  $C_m$  and  $r_m$  represent the *motional* parameters of the resonator at the main operating frequency —  $r_m$  being the loss resistance, which is also known as the *equivalent series resistance*, or ESR.  $C_o$  is a combination of the static capacitance formed between the two metal electrodes with the quartz as dielectric ( $\epsilon_r = 4.54$  for AT-cut crystals) and some additional capacitance introduced by the metal case, base and mount. There is a physical relationship between  $C_m$  and the static capacitance formed by the resonator electrodes, but, unfortunately, the added holder capacitance masks this direct relationship causing  $C_o/C_m$  to vary from 200 to over 500. However, for modern fundamental AT-cut crystals between 1 and 30 MHz, their values of  $C_m$  are typically between 0.003 and 0.03 pF. Theoretically, the motional inductance of a quartz crystal should be the same whether it is operated on the fundamental or one of its overtones, making the motional capacitance at the  $n$ th overtone  $1/n^2$  of the value at the fundamental. However, this relationship is modified by the effect of the metal electrodes deposited on either side of the crystal plate and in practice

the motional inductance increases with the frequency of the overtone. This makes the motional capacitance at the overtone substantially less than  $C_m/n^2$ .

An important parameter for crystal filter design is the unloaded  $Q$  at  $f_s$ , the resonant frequency of the series arm. This is usually denoted by  $Q_U$ .

$$Q_u = 2 \pi f_s L_m / r_m$$

$Q_U$  is very high, often exceeding 100,000 in the lower HF region. Even VHF overtone crystals can have  $Q_U$  values over 20,000, making it possible to design quartz crystal band-pass filters with a tremendously wide range of bandwidths and center frequencies.

The basic filtering action of a crystal can be seen from **Figure 10.43**, which shows a plot of attenuation vs frequency for the test circuit shown in the inset. The series arm of the crystal equivalent circuit forms a series-tuned circuit, which passes signals with little attenuation at its resonant frequency,  $f_s$ , but appears inductive above this frequency and parallel resonates with  $C_o$  at  $f_p$  to produce a deep notch in transmission. The difference between  $f_s$  and  $f_p$  is known as the pole-zero separation, or PZ spacing, and is dependent on  $C_m/C_o$  as well as  $f_s$ . Further information on quartz crystal theory and operation can be found in the **Oscillators and Synthesizers** chapter and in the reference for Bottom.

A simple crystal filter developed in the 1930s

**Figure 10.42** — Equivalent circuit of a quartz crystal and its circuit symbol.

Figure 10.43 — Response of 10 MHz crystal ( $C_m = 0.0134$  pF,  $L_m = 18.92$  mH,  $ESR = 34$   $\Omega$ ) in a series test circuit (see inset) showing peak of transmission (lowest attenuation) at the series resonant frequency,  $f_s$ , and a null (maximum attenuation) caused by the parallel resonance due to  $C_o$  at  $f_p$ .

is shown in Figure 10.44. The voltage-reversing transformer T1 was usually an IF transformer, but nowadays could be a bifilar winding on a ferrite core. Voltages  $V_a$  and  $V_b$  have equal magnitude but  $180^\circ$  phase difference. When  $C_1 = C_o$ , the effect of  $C_o$  will disappear and a well-behaved single resonance will occur as indicated by the solid line in Figure 10.44B. However, if  $C_1$  is adjusted to unbalance the circuit, a transmission zero (notch) is produced well away from the pass band and by increasing the amount of imbalance this can be brought back toward the edge of the pass band to attenuate close-by interfering CW signals. If  $C_1$  is reduced in value from the balanced setting, the notch comes in from the high side and if  $C_1$  is increased, it comes in from the low side. The dotted curve in Figure 10.44B illustrates how the notch can be set with  $C_1$  less than  $C_o$  to suppress adjacent signals just above the pass band. In practice a notch depth of up to 60 dB can be achieved. This form of “crystal gate” filter, operating at 455 kHz, was present in many high-quality amateur communications receivers from the 1930s through the 1960s. When the filter was switched into the receiver IF amplifier the bandwidth was reduced to a few hundred Hz for CW reception. The close-in range of the notch was sometimes improved by making  $C_1$  part of a differential capacitor that could add extra capacitance to either the  $C_1$  or  $C_o$  side of the IF transformer. This design could also be used to

good effect at frequencies up to 1.7 MHz with an increased minimum bandwidth. However, any crystal gate requires considerable additional IF filtering to achieve a reasonable ultimate attenuation figure, so it should not be the only form of selectivity used in an IF amplifier.

The half-lattice filter shown in Figure 10.45 offers an improvement in performance over a single-crystal filter. The quartz crystal static capacitors,  $C_o$ , cancel each other. The remaining series-resonant arms, if offset in frequency and terminated properly, will produce an approximate 2-pole Butterworth or Chebyshev response. The crystal spacing for simple Chebyshev designs is usually around two-thirds of

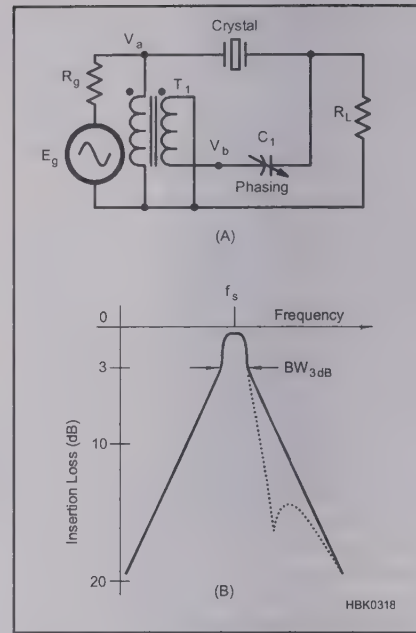

Figure 10.44 — Classic single-crystal filter in A has the response shown in B. The phasing capacitor can be adjusted to balance out  $C_o$  (solid line), or set to a lesser or greater value to create a movable null to one side, or other, of the passband (dotted line).

the bandwidth. Half-lattice filter sections can be cascaded to produce composite filters with multiple poles. Many of the older commercial filters are coupled half-lattice types using 4, 6 or 8 crystals, and this is still the favored technology for some crystal filters at lower frequencies. Very often extra capacitance was added across one crystal in each half lattice to unbalance  $C_o$  and provide deep transmission zeroes on either side of the pass band to sharpen up the close-in response at the expense of the attenuation further out. The reference for Steder and Harcastle discusses the computer design of half-lattice filters.

Most commercial HF and VHF crystal filters

Figure 10.45 — A half-lattice crystal filter. The  $C_o$  of one crystal can be made to balance the  $C_o$  of the other, or  $C_1$  across the higher crystal can be deliberately increased to create nulls on either side of the passband.

**Figure 10.46** — A dual monolithic crystal filter has two sets of electrodes acoustically coupled to provide a two-pole response in a single crystal unit. The center lead is connected to the case and grounded in normal operation.

produced today use dual monolithic structures as their resonant elements. These are a single quartz plate onto which two sets of metal electrodes have been deposited, physically separated to control the acoustic (mechanical) coupling between them. An example of a dual monolithic filter (2-pole) is shown in **Figure 10.46**. These are available with center frequencies from 9 MHz to well over 120 MHz. In effect, the dual monolithic structure behaves just like a pair of coupled crystal resonators. There is a subtle difference, however, because the static capacitance in duals appears across the input and output terminations and doesn't produce a null above the pass band, as it would for two electrically coupled crystal resonators. Multi-pole filters can be built by coupling duals together using external capacitors, the  $C_0$  from each dual input and output being absorbed in the coupling capacitors or terminations, or by including more acoustically coupled resonators in the electrode structure on a single quartz plate. Though not common, 3-pole and 4-pole monolithic filters housed in standard, single crystal holders are available from some manufacturers.

### 10.6.1 Filter Parameters

An ideal band-pass filter would pass the desired signal with no loss and completely attenuate everything else. Practically, it is not possible to achieve such a response with a finite number of resonators, and approximations to this ideal have to be accepted. Greater stop-band attenuation and steeper sides can be achieved if more and more crystals are used, and the response gets nearer to the ideal “brick-wall” one. This feature of a filter is expressed

as a *shape factor*, which specifies the ratio of the bandwidth at an attenuation of 60 dB to the bandwidth at 6 dB — both these levels being taken relative to the actual pass band peak to eliminate insertion loss from the calculation. An ideal brickwall filter would have a shape factor of 1, and practical filters have shape factors that depend on the number of crystals used in the design and the type of response chosen for the pass band. A 1 dB Chebyshev design, for example, can typically produce shape factors that vary from about 4.1 for a 4-pole to 1.5 for a 10-pole, but the actual figures obtained in practice are very much dependent on  $Q_u$  and how much greater it is than the filter  $Q$ , defined by  $f_0/BW$ , where  $f_0$  is the center frequency and  $BW$  the 3 dB bandwidth. The ratio of  $Q_u$  to  $f_0/BW$  is often quoted as  $Q_o$ , or  $q_o$ , and this, along with the order and type of response, determines the insertion loss of a crystal filter.  $Q_o$  also determines how closely the pass band follows the design response, and how much the passband ripple is smoothed out and the edges of the response rounded off by crystal loss.

Commercial filter manufacturers usually choose the Chebyshev equiripple design for SSB, AM and FM bandwidths because it gives the best compromise between passband response and the steepness of the sides, and 1 dB-ripple Chebyshev designs are pretty standard for speech bandwidths. Tolerances in component values and crystal frequencies can cause the ripple in the pass band to exceed 1 dB, so often the maximum ripple is specified as 2 dB even though the target ripple is lower. Insertion loss, the signal loss going thru the filter, also varies with the type of response and increases as the order of the filter increases. The insertion loss for a given order and bandwidth is higher for high-ripple Chebyshev designs than it is for low-ripple ones, and Butterworth designs have lower insertion loss than any Chebyshev type for a given bandwidth. Pass-band amplitude response and shape factor are important parameters for assessing the performance of filters used for speech communications.

However, group delay is also important for data and narrow bandwidth CW reception. Differential group delay can cause signal distortion on data signals if the variations are greater than the automatic equalizer can handle. Ringing can be an annoying problem when using very narrow CW filters, and the group delay differential across the pass band must be minimized to reduce this effect. When narrow bandwidth filters are being considered, shape factor has to be sacrificed to reduce differential group delay and its associ-

ated ringing problems. It's no good having a narrow Chebyshev design with a shape factor of 2 if the filter produces unacceptable ringing and is intolerable to use in practice.

Both Bessel and linear phase (equiripple 0.05°) responses have practically constant, low group delay across the entire pass band and well beyond on either side, making either a good choice for narrow CW or specialized data use. They also have the great advantage of offering the lowest possible insertion loss of all the types of response currently in use, which is important when  $Q_o$  is low, as it often is for very narrow bandwidth filters. The insertion loss of the Bessel design is marginally lower than that of the linear phase, but the latter has a superior shape factor giving it the best balance of low group delay and good selectivity. A 6-pole linear phase (equiripple 0.05°) design has a shape factor of 3.39, whereas a 6-pole Bessel has 3.96. The Gaussian-to-12 dB response has a better shape factor than that of either the linear phase or Bessel designs but the group delay across the pass band is not as flat and pronounced peaks (ears) are beginning to appear at the band edges with a 6-pole design. The Gaussian-to-6 dB group delay is reasonably flat for 3- and 4-pole filters, but significant ears appear toward the passband edges in designs with 5 poles or more.

### 10.6.2 Crystal Filter Evaluation

The simplest means of assessing the performance of a crystal filter is to temporarily install it in a finished transceiver, or receiver, and use a strong on-air signal, or locally generated carrier, to run thru the filter pass band and down either side to see if there are any anomalies. Provided that the filter crystals have been carefully characterized in the first instance, and computer modeling has shown that the design is close to what's required, this may be all that's required to confirm a successful project. However, more elaborate checks on both the pass band and stop band can be made if a DDS signal generator, or vector network analyzer (VNA), is available. A test set-up for evaluating the response of a filter using a DDS generator requires an oscilloscope to display the response, whereas a VNA controlled via the USB port of a PC can display the response on the PC screen with suitable software — see the **Test Equipment and Measurements** chapter. In addition, it can measure the phase and work out the group delay of the filter. VNAs can also be used to characterize the crystals prior to making the filter as well as evaluating filter performance after completion.

## 10.7 SAW Filters

The resonators in a monolithic crystal filter are coupled together by bulk acoustic waves. These acoustic waves are generated and propagated in the interior of a quartz plate. It is also possible to launch, by an appropriate transducer, acoustic waves that propagate only along the surface of the quartz plate. These are called “surface-acoustic-waves” because they do not appreciably penetrate the interior of the plate.

A *surface-acoustic-wave* (SAW) filter consists of thin aluminum electrodes, or fingers, deposited on the surface of a piezoelectric substrate as shown in **Figure 10.47**. Lithium Niobate ( $\text{LiNbO}_3$ ) is usually favored over quartz because it yields less insertion

loss. The electrodes make up the filter’s transducers. RF voltage is applied to the input transducer and generates electric fields between the fingers. The piezoelectric material vibrates in response, launching an acoustic wave along the surface. When the wave reaches the output transducer it produces an electric field between the fingers. This field generates a voltage across the load resistor.

Since both input and output transducers are not entirely unidirectional, some acoustic power is lost in the acoustic absorbers located behind each transducer. This lost acoustic power produces a mid-band electrical insertion loss typically greater than 10 dB. The SAW filter frequency response is determined by the choice of substrate material and finger pattern.

The finger spacing, (usually one-quarter wavelength) determines the filter center frequency. Center frequencies are available from 20 to 1000 MHz. The number and length of fingers determines the filter loaded  $Q$  and shape factor.

Loaded  $Q$ s are available from 2 to 100, with a shape factor of 1.5 (equivalent to a dozen poles). Thus the SAW filter can be made broadband much like the LC filters that it replaces. The advantage is substantially reduced volume and possibly lower cost. SAW filter research was driven by military needs for exotic amplitude-response and time-delay requirements. Low-cost SAW filters are presently found in television IF amplifiers where high mid-band loss can be tolerated.

Figure 10.47 — The *interdigitated* transducer, on the left, launches SAW energy to a similar transducer on the right (see text).

## 10.8 Transmission Line VHF/UHF/Microwave Filters

LC filter calculations are based on the assumption that the reactances are *lumped*—that the physical dimensions of the components are considerably less than the operating wavelength. In such cases the unavoidable inter-turn parasitic capacitance associated with inductors and the unavoidable series parasitic inductance associated with capacitors are neglected as being secondary effects. If careful attention is paid to circuit layout and miniature components are used, lumped LC filter technology can be used up to perhaps 1 GHz.

Replacing lumped reactances with selected short sections of *Transverse Electromagnetic Mode* (TEM) transmission lines results in transmission line filters. (In TEM the electric and magnetic fields associated with a transmission line are at right angles (transverse) to the direction of wave propagation.) Coaxial cable, stripline and microstrip are examples of TEM components. Waveguides and waveguide resonators are not TEM components.

Coaxial cable transmission line filters are often used at HF and VHF frequencies. Stripline and microstrip transmission-line filters predominate from 500 MHz to 10 GHz. In addition they are often used down to 50 MHz when narrowband ( $Q_L > 10$ ) band-pass filtering is required. In this application they exhibit considerably lower loss than their LC counterparts and are useful at frequencies where coaxial transmission lines are too lossy. A detailed treatment of the use of coaxial cable to form transmission line filters is presented in the **Transmission Lines** chapter. This section focuses on stripline and microstrip filters used at VHF and above.

### 10.8.1 Stripline and Microstrip Filters

Figure 10.48 shows three popular transmission lines used in transmission line filters. The circular coaxial transmission line (*coax*) shown

in Figure 10.48A consists of two concentric metal cylinders separated by dielectric (insulating) material. The first transmission-line filters were built from sections of coaxial line. Their mechanical fabrication is expensive and it is difficult to provide electrical coupling between line sections.

Fabrication difficulties are reduced by the use of shielded strip transmission line (*stripline*) shown in Figure 10.48B. The outer conductor of stripline consists of two flat parallel metal plates (ground planes) and the inner conductor is a thin metal strip. Sometimes the inner conductor is a round metal rod. The dielectric between ground planes and strip can be air or a low-loss plastic such as polyethylene. The outer conductors (ground planes or shields) are separated from each other by distance  $b$ .

Striplines can be easily coupled together by locating the strips near each other as shown in Figure 10.48B. Stripline  $Z_0$  vs width ( $w$ ) is

plotted in **Figure 10.49**. Air-dielectric stripline technology is best for low bandwidth ( $Q_L > 20$ ) band-pass filters.

The most popular transmission line at UHF and microwave is *microstrip* (unshielded strip-line), shown in **Figure 10.48C**. It can be fabricated with standard printed-circuit processes and is the least expensive configuration. In microstrip the outer conductor is a single flat metal ground-plane. The inner conductor is a thin metal strip separated from the ground-plane by a solid dielectric substrate. Typical substrates are 0.062 inch G-10 fiberglass ( $\epsilon = 4.5$ ) for the 50 MHz to 1 GHz frequency range and 0.031 inch Teflon ( $\epsilon = 2.3$ ) for frequencies above 1 GHz. Unfortunately, microstrip has the most loss of the three types of transmission line; therefore it is not suitable for narrow, high-Q, band-pass filters.

Conductor separation must be minimized or radiation from the line and unwanted coupling to adjacent circuits may become problems. Microstrip characteristic impedance and the effective dielectric constant ( $\epsilon$ ) are shown in **Figure 10.50**. Unlike coax and stripline, the effective dielectric constant is less than that of the substrate since a portion of the electromagnetic wave propagating along the microstrip travels in the air above the substrate.

The characteristic impedance for stripline

**Figure 10.48** — Transmission lines. A: Coaxial line. B: Coupled stripline, which has two ground planes. C: Microstrip has only one ground plane.

**Figure 10.49** — The  $Z_0$  of stripline varies with  $w$ ,  $b$  and  $t$  (conductor thickness). See **Figure 10.48B**. The conductor thickness is  $t$  and the plots are normalized in terms of  $t/b$ .

and microstrip-lines that results in the lowest loss is not  $75 \Omega$  as it is for coax. Loss decreases as line width increases, which leads to clumsy, large structures. Therefore, to conserve space, filter sections are often constructed from  $50 \Omega$  stripline or microstrip stubs even though the loss at that characteristic impedance is not a minimum for that type of transmission line.

### 10.8.2 Transmission Line Band-Pass Filters

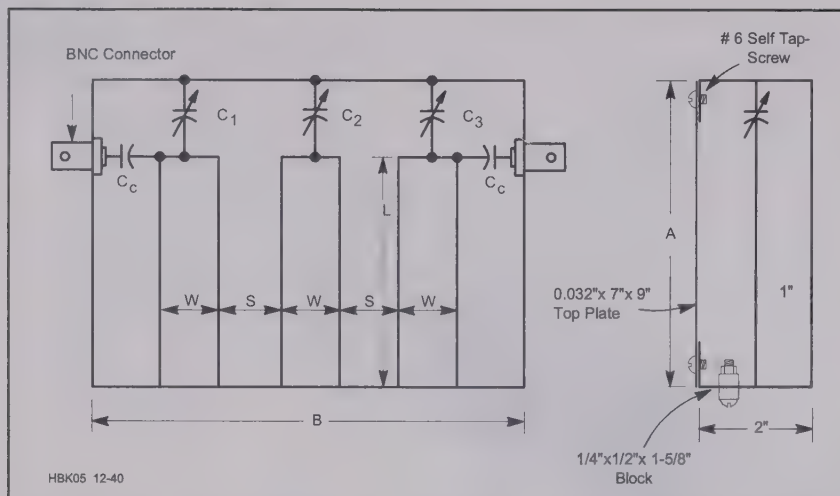

Band-pass filters can also be constructed from transmission line stubs. (See the **Transmission Lines** chapter for information on stub behavior and their use as filters at HF and VHF.) At VHF the stubs can be considerably shorter than a quarter-wavelength ( $1/4 \lambda$ ), yielding a compact filter structure with less mid-band loss than its LC counterpart. The single-stage 146 MHz stripline band-pass filter shown in **Figure 10.51** is an example.

$Z_0 \Omega$	$\epsilon = 1$ (AIR) $W/h$	$\epsilon = 2.3$ (RT/Duroid)		$\epsilon = 4.5$ (G-10)	
		$W/h$	$\sqrt{\epsilon_e}$	$W/h$	$\sqrt{\epsilon_e}$
25	12.5	7.6	1.4	4.9	2.0
50	5.0	3.1	1.36	1.8	1.85
75	2.7	1.6	1.35	0.78	1.8
100	1.7	0.84	1.35	0.39	1.75
	$\sqrt{\epsilon_e} = 1$				

**Figure 10.50** — Microstrip parameters (after H. Wheeler, *IEEE Transactions on MTT*, March 1965, p 132).  $\epsilon_e$  is the effective  $\epsilon$ .

**Figure 10.51** — This 146 MHz stripline band-pass filter has been measured to have a  $Q_L$  of 63 and a loss of approximately 1 dB.

**Figure 10.52** — This Butterworth filter is constructed in combine. It was originally discussed by R. Fisher in December 1968 *QST*.

This filter consists of a single inductive  $50\ \Omega$  strip-line stub mounted into a  $2 \times 5 \times 7$  inch aluminum box. The stub is resonated at 146 MHz with the “APC” variable capacitor, C1. Coupling to the  $50\ \Omega$  generator and load is provided by the coupling capacitors  $C_c$ . The measured performance of this filter is:  $f_o = 146$  MHz, BW = 2.3 MHz ( $Q_L = 63$ ) and mid-band loss = 1 dB.

Single-stage stripline filters can be coupled together to yield multistage filters. One method uses the capacitor coupled band-pass filter synthesis technique to design a 3-pole filter. Another method allows closely spaced inductive stubs to magnetically couple to each other. When the coupled stubs are grounded on the same side of the filter housing, the structure is called a “combine filter.” Three examples of combine band-pass filters are shown in **Figure 10.52** and a set of VHF/UHF filter designs by WIGHZ is included in the projects section of this chapter. These filters are constructed in  $2 \times 7 \times 9$  inch aluminum boxes. The article describing these filters by Reed Fisher, W2CQH, is available in this book’s downloadable supplemental information and is listed in the references, as well.

### 10.8.3 Quarter-Wave Transmission Line Filters

The reactance of a  $\frac{1}{4}\ \lambda$  shorted-stub is infinite, as discussed in the **Transmission Lines** chapter. Thus, a  $\frac{1}{4}\ \lambda$  shorted stub behaves like a parallel-resonant LC circuit. Proper input and output coupling to a  $\frac{1}{4}\ \lambda$  resonator yields a practical band-pass filter. Closely spaced  $\frac{1}{4}\ \lambda$  resonators will couple together to form a multistage band-pass filter. When the resonators are grounded on opposite walls of the filter housing, the structure is called an *interdigital filter* because the resonators look like

interlaced fingers. Two examples of 3-pole UHF interdigital filters are shown in **Figure 10.53**. Design graphs for round-rod interdigital filters are given in the reference for Metcalf. The  $\frac{1}{4}\ \lambda$  resonators may be tuned by physically changing their lengths or by tuning the screw opposite each rod.

If the short-circuited ends of two  $\frac{1}{4}\ \lambda$  resonators are connected to each other, the resulting  $\frac{1}{2}\ \lambda$  stub will remain in resonance, even when the connection to the ground-plane is removed. Such a floating  $\frac{1}{2}\ \lambda$  microstrip line, when bent into a U-shape, is called a *hairpin resonator*. Closely coupled hairpin resonators can be arranged to form multistage band-pass filters. Microstrip hairpin band-pass filters are popular above 1 GHz because they can be easily fabricated using photo-etching techniques. No connection to the ground-plane is required.

**Figure 10.53** — These 3-pole Butterworth filters for 432 MHz (shown at A, 8.6 MHz bandwidth, 1.4 dB passband loss) and 1296 MHz (shown at B, 110 MHz bandwidth, 0.4 dB passband loss) are constructed as interdigital filters. The material is from R. E. Fisher, March 1968 *QST*.

**Figure 10.54** — A microstrip 3-pole emulated-Butterworth low-pass filter with a cutoff frequency of 720 MHz. A: Microstrip version built with G-10 fiberglass board ( $\epsilon = 4.5$ ,  $h = 0.062$  inches). B: Lumped LC version of the same filter. To construct this filter with lumped elements very small values of  $L$  and  $C$  must be used and stray capacitance and inductance would have to be reduced to a tiny fraction of the component values.

### 10.8.4 Emulating LC Filters with Transmission Line Filters

Low-pass and high-pass transmission-line filters are usually built from short sections of transmission lines (stubs) that emulate lumped LC reactances. Sometimes low-loss lumped capacitors are mixed with transmission line inductors to form a hybrid component filter. For example, consider the 720 MHz, 3-pole microstrip low-pass filter shown in **Figure 10.54A** that emulates the LC filter shown in **Figure 10.54B**.  $C1$  and  $C3$  are replaced with 50  $\Omega$  open-circuit shunt stubs  $\ell_C$  long.  $L2$  is replaced with a short section of 100- $\Omega$  line  $\ell_L$  long. The LC filter, **Figure 10.54B**, was designed for  $f_c = 720$  MHz. Such a filter could be connected between a 432 MHz transmitter and antenna to reduce harmonic and spurious emissions. A reactance chart shows that  $X_C$  is 50  $\Omega$ , and the inductor reactance is 100  $\Omega$  at  $f_c$ . The microstrip version is constructed on G-10 fiberglass 0.062 inch thick, with  $\epsilon = 4.5$ . Then, from **Figure 10.50**,  $w$  is 0.11 inch and  $\ell_C = 0.125 l_g$  for the 50  $\Omega$  capacitive stubs. Also, from **Figure 10.50**,  $w$  is 0.024 inch and  $\ell_L$  is  $0.125 l_g$  for the 100- $\Omega$  inductive line. The inductive line length is approximate because the far end is not a short circuit.  $l_g$  is  $300/(720 \times 1.75) = 0.238$  m, or 9.37 inches. Thus  $\ell_C$  is 1.1 inch and  $\ell_L$  is 1.1 inches.

This microstrip filter exhibits about 20 dB of attenuation at 1296 MHz. Its response rises again, however, around 3 GHz. This is because the fixed-length transmission line stubs change in terms of wavelength as the frequency rises. This particular filter was designed to eliminate third-harmonic energy near 1296 MHz from a 432 MHz transmitter and does a better job in this application than the Butterworth filter in **Figure 10.53** which has spurious responses in the 1296 MHz band.

# 10.9 Helical Resonators

Ever-increasing occupancy of the radio spectrum brings with it a parade of receiver overload and spurious responses. Overload problems can be minimized by using high-dynamic-range receiving techniques, but spurious responses (such as the image frequency) must be filtered out before mixing

occurs. Conventional tuned circuits cannot provide the selectivity necessary to eliminate the plethora of signals found in most urban and many suburban environments. Other filtering techniques must be used.

Helical resonators are usually a better choice than  $\frac{1}{4} \lambda$  cavities on 50, 144 and 222 MHz to eliminate these unwanted inputs because they are smaller and easier to build than coaxial cavity resonators, although their Q is not as high as that of cavities. In the frequency range from 30 to 100 MHz it is difficult to build high-Q inductors, and coaxial cavities are very large. In this frequency range the helical resonator is an excellent choice. At 50 MHz for example, a capacitively tuned,  $\frac{1}{4} \lambda$  coaxial cavity with an unloaded Q of 3000 would be about 4 inches in diameter and nearly 5 ft long. On the other hand, a helical resonator with the same unloaded Q is about 8.5 inches in diameter and 11.3 inches long. Even at 432 MHz, where coaxial cavities are common, the use of helical resonators results in substantial size reductions.

The helical resonator was described by the late Jim Fisk, W1HR, in a June 1976 *QST* article. (see the Reference section) The resonator is described as a coil surrounded by a

shield, but it is actually a shielded, resonant section of helically wound transmission line with relatively high characteristic impedance and low propagation velocity along the axis of the helix. The electrical length is about 94% of an axial  $\frac{1}{4} \lambda$  or 84.6°. One lead of the helical winding is connected directly to the shield and the other end is open circuited as shown in Figure 10.55. Although the shield may be any shape, only round and square shields will be considered here.

## 10.9.1 Helical Resonator Design

The unloaded Q of a helical resonator is determined primarily by the size of the shield. For a round resonator with a copper coil on a low-loss form, mounted in a copper shield, the unloaded Q is given by

$$Q_U = 50D\sqrt{f_0}$$

where

D = inside diameter of the shield, in inches  
 $f_0$  = frequency, in MHz.

D is assumed to be 1.2 times the width of

Figure 10.55 — Dimensions of round and square helical resonators. The diameter, D (or side, S) is determined by the desired unloaded Q. Other dimensions are expressed in terms of D or S (see text).

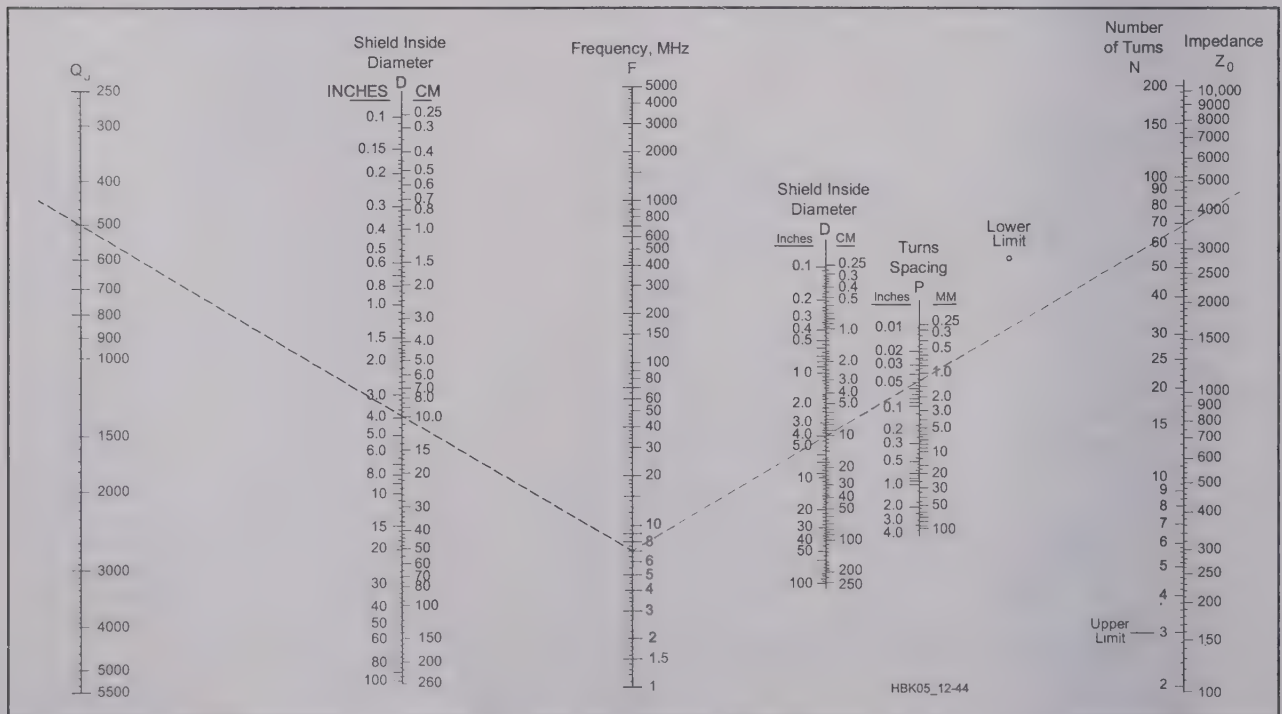

Figure 10.56 — The design nomograph for round helical resonators starts by selecting  $Q_U$  and the required shield diameter. A line is drawn connecting these two values and extended to the frequency scale (example here is for a shield of about 3.8 inches and  $Q_U$  of 500 at 7 MHz). Finally the number of turns, N, winding pitch, P, and characteristic impedance,  $Z_0$ , are determined by drawing a line from the frequency scale through selected shield diameter (but this time to the scale on the right-hand side. For the example shown, the dashed line shows  $P \approx 0.047$  inch,  $N = 70$  turns, and  $Z_n = 3600 \Omega$ ).

one side for square shield cans. This formula includes the effects of losses and imperfections in practical materials. It yields values of unloaded Q that are easily attained in practice. Silver plating the shield and coil increases the unloaded Q by about 3% over that predicted by the equation. At VHF and UHF, however, it is more practical to increase the shield size slightly (that is, increase the selected QU by about 3% before making the calculation). The fringing capacitance at the open-circuit end of the helix is about 0.15D pF (that is, approximately 0.3 pF for a shield 2 inches in diameter). Once the required shield size has been determined, the total number of turns, N, winding pitch, P and characteristic impedance, Z<sub>0</sub>, for round and square helical resonators with air dielectric between the helix and shield, are given by:

$$N = \frac{1908}{f_0 D}$$

$$P = \frac{f_0 D^2}{2312}$$

$$Z_0 = \frac{99,000}{f_0 D}$$

$$N = \frac{1590}{f_0 S}$$

$$P = \frac{f_0 S^2}{1606}$$

$$Z_0 = \frac{82,500}{f_0 S}$$

In these equations, dimensions D and S are in inches and f<sub>0</sub> is in megahertz. The design nomograph for round helical resonators in **Figure 10.56** is based on these formulas.

Although there are many variables to consider when designing helical resonators, certain ratios of shield size to length and coil diameter to length, provide optimum results. For helix diameter, d = 0.55 D or d = 0.66 S. For helix length, b = 0.825D or b = 0.99S. For helix length, B = 1.325 D and H = 1.60 S.

Design of filter dimensions can be done using the nomographs in this section or with computer software. The program *Helical* for designing and analyzing helical filters is available with the downloadable supplemental content. Use of the nomographs is described in the following paragraphs.

**Figure 10.57** simplifies calculation of these dimensions. Note that these ratios result in a

helix with a length 1.5 times its diameter, the condition for maximum Q. The shield is about 60% longer than the helix — although it can be made longer — to completely contain the electric field at the top of the helix and the magnetic field at the bottom.

The winding pitch, P, is used primarily to determine the required conductor size. Adjust the length of the coil to that given by the equations during construction. Conductor size ranges from 0.4 P to 0.6 P for both round and square resonators and are plotted graphically in **Figure 10.58**.

Obviously, an area exists (in terms of frequency and unloaded Q) where the designer must make a choice between a conventional cavity (or lumped LC circuit) and a helical resonator. The choice is affected by physical shape at higher frequencies. Cavities are long and relatively small in diameter, while the length of a helical resonator is not much greater than its diameter. A second consideration is that point where the winding pitch, P, is less than the radius of the helix (otherwise the structure tends to be non-helical). This condition occurs when the helix has fewer than three turns (the “upper limit” on the design nomograph of Figure 10.56).

## 10.9.2 Helical Filter Construction

The shield should not have any seams parallel to the helix axis to obtain as high an unloaded Q as possible. This is usually not a problem with round resonators because large-diameter copper tubing is used for the shield, but square resonators require at least one seam

**Figure 10.57** — The helical resonator is scaled from this design nomograph. Starting with the shield diameter, the helix diameter, d, helix length, b, and shield length, B, can be determined with this graph. The example shown has a shield diameter of 3.8 inches. This requires a helix mean diameter of 2.1 inches, helix length of 3.1 inches, and shield length of 5 inches.

**Figure 10.58** — This chart provides the design information of helix conductor size vs winding pitch, P. For example, a winding pitch of 0.047 inch results in a conductor diameter between 0.019 and 0.028 inch (#22 or #24 AWG).

and usually more. The effect on unloaded  $Q$  is minimized if the seam is silver soldered carefully from one end to the other.

Results are best when little or no dielectric is used inside the shield. This is usually no problem at VHF and UHF because the conductors are large enough that a supporting coil form is not required. The lower end of the helix should be soldered to the nearest point on the inside of the shield.

Although the external field is minimized by the use of top and bottom shield covers, the top and bottom of the shield may be left open with negligible effect on frequency or unloaded  $Q$ . Covers, if provided, should make electrical contact with the shield. In those resonators where the helix is connected to the bottom cover, that cover must be soldered solidly to the shield to minimize losses.

### 10.9.3 Helical Resonator Tuning

A carefully built helical resonator designed from the nomograph of Figure 10.56 will resonate very close to the design frequency. Slightly compress or expand the helix to adjust resonance over a small range. If the helix is made slightly longer than that called for in Figure 10.57, the resonator can be tuned by pruning the open end of the coil. However, neither of these methods is recommended for wide frequency excursions because any major deviation in helix length will degrade the unloaded  $Q$  of the resonator.

Most helical resonators are tuned by means of a brass tuning screw or high-quality air-variable capacitor across the open end of the helix. Piston capacitors also work well, but the  $Q$  of the tuning capacitor should ideally be several times the unloaded  $Q$  of the resonator. Varactor diodes have sometimes been used where remote tuning is required, but varactors can generate unwanted harmonics and other spurious signals if they are excited by strong, nearby signals.

When a helical resonator is to be tuned by a variable capacitor, the shield size is based on the chosen unloaded  $Q$  at the operating frequency. Then the number of turns,  $N$  and the winding pitch,  $P$ , are based on resonance at  $1.5 f_0$ . Tune the resonator to the desired operating frequency,  $f_0$ .

### 10.9.4 Helical Resonator Insertion Loss

The insertion loss (dissipation loss),  $I_L$ , in

Figure 10.59 — The ratio of loaded ( $Q_L$ ) to unloaded ( $Q_U$ )  $Q$  determines the insertion loss of a tuned resonant circuit.

decibels, of all single-resonator circuits is given by

$$I_L = 20 \log_{10} \left( \frac{1}{1 - \frac{Q_L}{Q_U}} \right)$$

where

$$\begin{aligned} Q_L &= \text{loaded } Q \\ Q_U &= \text{unloaded } Q \end{aligned}$$

This is plotted in Figure 10.59. For the most practical cases ( $Q_L > 5$ ), this can be closely approximated by  $I_L \approx 9.0 (Q_L/Q_U)$  dB. The selection of  $Q_L$  for a tuned circuit is dictated primarily by the required selectivity of the circuit. However, to keep dissipation loss to 0.5 dB or less (as is the case for low-noise VHF receivers), the unloaded  $Q$  must be at least 18 times the  $Q_L$ .

### 10.9.5 Coupling Helical Resonators

Signals are coupled into and out of helical resonators with inductive loops at the bottom of the helix, direct taps on the coil or a combination of both. Although the correct tap point can be calculated easily, coupling by loops and probes must be determined experimentally.

The input and output coupling is often provided by probes when only one resonator is used. The probes are positioned on opposite sides of the resonator for maximum isolation. When coupling loops are used, the plane of the loop should be perpendicular to the axis of the helix and separated a small distance from the bottom of the coil. For resonators

Figure 10.60 — This response curve for a single-resonator 432 MHz filter shows the effects of capacitive and inductive input/output coupling. The response curve can be made symmetrical on each side of resonance by combining the two methods (inductive input and capacitive output, or vice versa).

with only a few turns, the plane of the loop can be tilted slightly so it is parallel with the slope of the adjacent conductor.

Helical resonators with inductive coupling (loops) exhibit more attenuation to signals above the resonant frequency (as compared to attenuation below resonance), whereas resonators with capacitive coupling (probes) exhibit more attenuation below the passband, as shown for a typical 432 MHz resonator in Figure 10.60. Consider this characteristic when choosing a coupling method. The passband can be made more symmetrical by using a combination of coupling methods (inductive input and capacitive output, for example).

If more than one helical resonator is required to obtain a desired band-pass characteristic, adjacent resonators may be coupled through apertures in the shield wall between the two resonators. Unfortunately, the size and location of the aperture must be found empirically, so this method of coupling is not very practical unless you're building a large number of identical units.

Since the loaded  $Q$  of a resonator is determined by the external loading, this must be considered when selecting a tap (or position of a loop or probe). The ratio of this external loading,  $R_b$ , to the characteristic impedance,  $Z_0$ , for a  $1/4 \lambda$  resonator is calculated from:

$$K = \frac{R_b}{Z_0} = 0.785 \left( \frac{1}{Q_L} - \frac{1}{Q_U} \right)$$

# 10.10 Filter Projects

The filter projects to follow are by no means the only filter projects in this book. Filters for specific applications may be found in other chapters of this *Handbook* and in the downloadable supplemental material. Receiver input filters, transmitter filters, inter-stage filters and others can be extracted from the various projects and built for other applications. Since filters are a first line of defense against *electromagnetic interference* (EMI) problems, additional filter methods appear in the **RF Interference** chapter.

## 10.10.1 Audio Waveshaping Filter for CW Reception

This project is condensed from the Mar/Apr 2017 *QEX* article, “An Improved Audio-Frequency Bandpass Filter for Morse Code Reception,” by Jim Tonne, W4ENE. That article is included in the downloadable supplemental information for this book.

The IF response of the superheterodyne receiver used by a typical CW operator has a flat top with a width of typically 400 Hz. If the center frequency is set to 500 Hz, the filter bandwidth extends from about 300 to 700 Hz, dropping off abruptly beyond those limits. In most of these receivers, the filter characteristics result in distortion of the leading and trailing edge of the CW audio. The distortion (primarily ringing) is strong enough to become objectionable at sending speeds beginning above 20 WPM. The cause is the group delay char-

acteristics typical of filters with sharp bandpass edges or “skirts”. (The original article contains several measured and simulated waveforms showing the cause and effect relationship.)

Short of replacing the filter circuit in the receiver, one way to improve the situation is to modify the entire system response of the receiver by adding a waveshaping filter. (SDR receiver filters can be redesigned or modified to eliminate these effects without hardware circuit changes.) The author has designed this add-on filter to have a slightly narrower bandwidth than the IF filter and has a smoother (“more gentle”) response at the band edges, both in magnitude and phase. As a result, the original filter’s overshoot and ringing are greatly reduced in the final audio output. Field testers report that the filter “sounds better” which is the ultimate goal for CW reception by ear.

The filter can be constructed either from passive components (**Figure 10.61**) or an equivalent active design (**Figure 10.62**). The passive filter has a center frequency of about 500 Hz and shows optional input and output matching transformers for 8 Ω to the filter’s input and output 125Ω impedance. (That value was chosen to use the 77.5 mH inductors available as surplus from Ed Wetherhold, W3NQN, [w3nqn@comcast.net](mailto:w3nqn@comcast.net) and other sources.) All inductor values are the same to ease construction. Components with 5% tolerance can be used with some loss of performance or components could be selected from a batch by using

an L-C meter. Transformers are optional (performance degrades somewhat if connected directly to 8 Ω inputs or loads) but should be high-quality and able to handle the expected signal levels. If driven into saturation, the signal will be distorted, eliminating any benefit provided by the filter. The active version does not require transformers but the high-impedance input should be shielded from RF pickup. The output op-amp may not be able to drive larger headphones, so an audio output amplifier IC may need to be added.

## 10.10.2 Comblne Filters for 50 – 432 MHz

(This project description is condensed from the paper “Comblne Filters for VHF and UHF” by Paul Wade, W1GHZ, at the 41st Eastern VHF Conference in 2015. The full paper is available in the downloadable supplemental information for this book.)

RF pollution is rampant at good portable locations on mountaintops and other high places — anywhere accessible is populated with cell phone towers, TV and FM broadcast stations, two-way radio and pager transmitters, and even amateur repeaters. Most of these are high power, producing signals strong enough to seriously overload the VHF and UHF transceivers we use for contest operation or microphone liaison. The advent of broadband MMIC preamps acerbates the problem. The problem often manifests itself as a very high noise level.

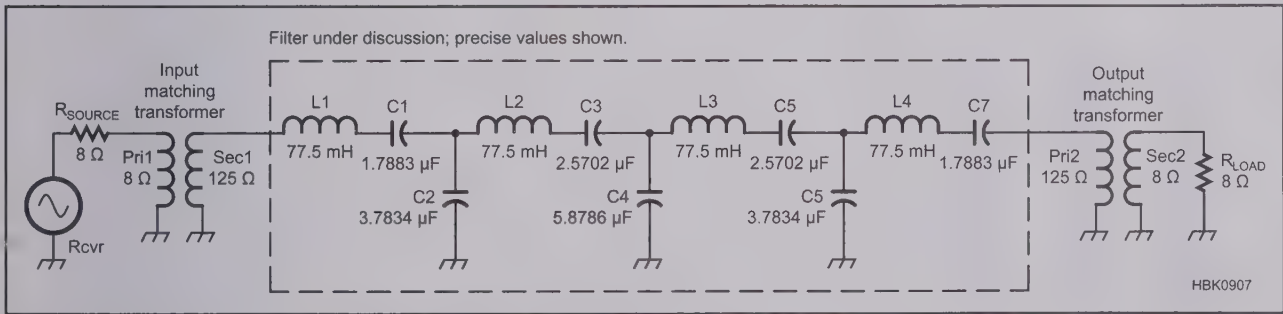

Figure 10.61 — Schematic of the passive waveshaping add-on filter.

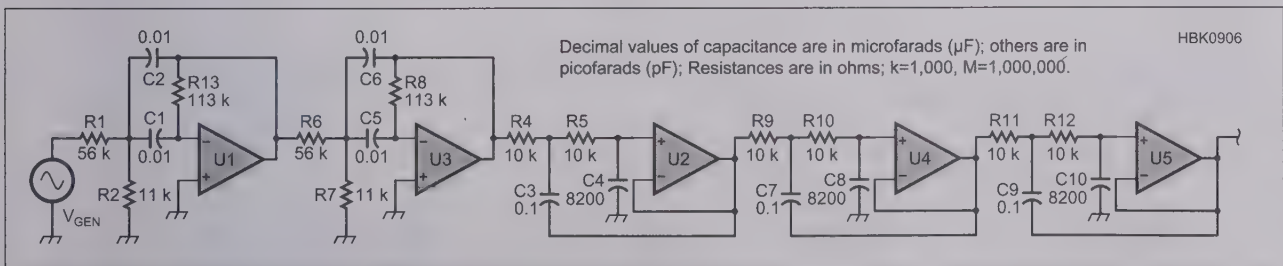

Figure 10.62 — Schematic of the active waveshaping add-on filter.

A combline filter uses parallel transmission line resonators less than a quarter-wave long, loaded by capacitance at the open end. This allows tuning over a range of frequencies by varying the capacitance. Typical electrical length of the resonators is between 30 and 60 electrical degrees; a quarter-wavelength is 90 degrees. These filters use stripline construction with tapped input and output coupling, as sketched in **Figure 10.63**, and the design procedure is given in the full paper.

A good, sharp filter must be mechanically robust to stay on frequency, especially for rover work. For low loss, high Q is important, requiring wide striplines with good contact to ground at the bottom, the high-current point. The filter uses all-aluminum construction to prevent dissimilar metal corrosion. All connections are made with #4 tinned solder lugs and stainless-steel hardware, metals that are least likely to interact with aluminum. An inexpensive aluminum enclosure of 220 × 145 × 60 mm was used for the 144 MHz filter in **Figure 10.64**. Dimensions for all of the filters are included in **Table 10.5**. Enclosure model numbers can be searched online to find sources for the boxes. A close match is sufficient.

The full paper includes construction guidelines, including selecting parts, metalworking, and assembly details. Tuning instructions are given and require the use of a sweep generator or a vector network analyzer can be used. The performance curves in **Figure 10.65** are indic-

**Figure 10.64** — Combline filter for 144 MHz

ative of completed filter performance. If that equipment is not available, the filters can be optimized at one frequency and used as narrowband filters.

### 10.10.3 Broadcast-Band Rejection Filters

Inadequate front-end selectivity or poorly performing RF amplifier and mixer stages often result in unwanted cross-talk and overloading from adjacent commercial or amateur stations. Two passive receive-only filters are described here — a high-pass, multi-section filter and a simple series wave trap.

#### BROADCAST-BAND REJECTION HIGH-PASS FILTER

The filter shown is inserted between the antenna and receiver. It attenuates the out-of-band signals from broadcast stations but passes signals of interest (1.8 to 30 MHz) with little or no attenuation.

The high signal strength of local broadcast stations requires that the stop-band attenuation of the high-pass filter also be high. This filter provides about 60 dB of stop-band attenuation with less than 1 dB of attenuation above 1.8 MHz. The filter input and output ports match 50 Ω with a maximum SWR of 1.353:1 (reflection coefficient = 0.15). A 10-element filter yields adequate stop-band attenuation and a reasonable rate of attenuation rise. The design uses only standard-value capacitors.

The filter parts layout, schematic diagram, response curve and component values are shown in **Figure 10.66**. The standard capacitor values listed are within 2.8% of the design values. If the attenuation peaks (f2, f4 and f6) do not fall at 0.677, 1.293 and 1.111 MHz, tune the series-resonant circuits by slightly squeezing or separating the inductor windings.

Construction of the filter is shown in **Figure 10.67**. Use polypropylene film-type capacitors. These capacitors are available through Digi-Key and other suppliers. The powdered-iron T50-2 toroidal cores are available through Amidon, Palomar Engineers and others.

For a 3.4 MHz cutoff frequency, divide the L and C values by 2. (This effectively doubles the frequency-label values in Figure 10.66.)

**Figure 10.67** — The filter fits easily in a 2 × 2 × 5 inch enclosure. The version in the photo was built on a piece of perfbord.

**Figure 10.66** — Schematic, layout and response curve of the broadcast band rejection filter.

For the 80 meter version, L2 through L6 should be 20 to 25 turns each, wound on T50-6 cores. The actual turns required may vary one or two from the calculated values. Parallel-connect capacitors as needed to achieve the nonstandard capacitor values required for this filter.

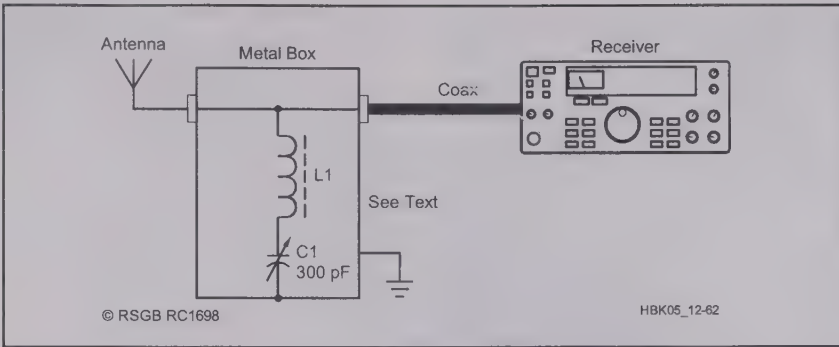

The measured filter performance is shown in Figure 10.66. The stop-band attenuation is more than 58 dB. The measured cutoff frequency (less than 1 dB attenuation) is under 1.8 MHz. The measured passband loss is less than 0.8 dB from 1.8 to 10 MHz. Between 10 and 100 MHz, the insertion loss of the filter gradually increases to 2 dB. Input impedance was measured between 1.7 and 4.2 MHz. Over the range tested, the input impedance of the filter remained within the 37- to 67.7-Ω input-impedance window (equivalent to a maximum SWR of 1.353:1).

#### WAVE TRAP FOR BROADCAST STATIONS

Nearby medium-wave broadcast stations can sometimes cause interference to HF receivers over a broad range of frequencies. A wave trap can catch the unwanted frequencies and keep them out of your receiver.

The way the circuit works is quite simple. Referring to **Figure 10.68**, you can see that it consists essentially of only two components, a coil L1 and a variable capacitor C1. This series-tuned circuit is connected in parallel with the antenna circuit of the receiver. The characteristic of a series-tuned circuit is that the coil and capacitor have a very low impedance (resistance) to frequencies very close to the frequency to which the circuit is tuned. All other frequencies are almost unaffected. If the circuit is tuned to 1530 kHz, for example, the signals from a broadcast station on that frequency will flow through the filter to ground, rather than go on into the receiver. All other frequencies will pass straight into the receiver. In this way, any interference caused in the receiver by the station on 1530 kHz is significantly reduced.

This is a series-tuned circuit that is adjustable from about 540 kHz to 1600 kHz. It is built into a metal box, **Figure 10.69**, to shield it from other unwanted signals and is connected as shown in Figure 10.68. To make the inductor, first make a former by winding two layers of paper on the ferrite rod. Fix this in place with black electrical tape. Next, lay one end of the wire for the coil on top of the former, leaving about an inch of wire protruding beyond the end of the ferrite rod. Use several turns of electrical tape to secure the wire to the former. Now, wind the coil along the former, making sure the turns are in a single layer and close together. Leave an inch or so of wire free at the end of the coil. Once again, use a couple of turns of electrical tape

**Figure 10.68** — The wave trap consists of a series tuned circuit, which ‘shunts’ signals on an unwanted frequency to ground.

**Figure 10.70** — Wiring of the wave trap. The ferrite rod is held in place with cable clips. C1 — 300 pF polyvaricon variable. L1 — 80 turns of 30 SWG enameled wire, wound on a ferrite rod.

Associated items: Case (die-cast box), knobs to suit, connectors to suit, nuts and bolts, plastic cable clips.

to secure the wire to the former. Finally, remove half an inch of enamel from each end of the wire.

Alternatively, if you have an old AM transistor radio, a suitable coil can usually be recovered already wound on a ferrite rod. Ignore any small coupling coils. Drill the box to take the components, then fit them in and solder together as shown in **Figure 10.70**. Make sure the lid of the box is fixed securely in place, or the wave trap’s performance will be adversely affected by pick-up on the components.

Connect the wave trap between the antenna and the receiver, then tune C1 until the interference from the offending broadcast station is a minimum. You may not be able to elim-

**Figure 10.69** — The wave trap can be roughly calibrated to indicate the frequency to which it is tuned.

inate interference completely, but this handy little device should reduce it enough to listen to the amateur bands. Let’s say you live near an AM transmitter on 1530 kHz, and the signals break through on your 1.8 MHz receiver. By tuning the trap to 1530 kHz, the problem is greatly reduced. If you have problems from more than one broadcast station, the problem needs a more complex solution.

### 10.10.4 Optimized Harmonic Transmitting Filters

Low-pass filters should be placed at the output of transmitters to ensure that they meet the various regulatory agency requirements for harmonic suppression. These are commonly designed to pass a single amateur band and provide attenuation at harmonics of that band sufficient to meet the requirements. The material presented here by Jim Tonne, W4ENE, is based on material originally published in the September/October 1998 issue of *QEX*. The basic approach is to use a computer to optimize the performance in the passband (a single amateur band) while simultaneously maximizing the attenuation at the second and third harmonic of that same band. When this is done, the higher harmonics will also be well within spec.

The schematic of this filter along with parts values for the 3.5 to 4.0 MHz amateur band

**Table 10.6**  
Values for the Optimized Harmonic Filters

Band (meters)	C1 (pF)	L2, 5% (μH)	L2, Exact (μH)	C2 (pF)	C3 (pF)	L4, 5% (μH)	L4, Exact (μH)	C4 (pF)	C5 (pF)
160	2400	3.0	2.88	360	4700	2.4	2.46	820	2200
80	1300	1.5	1.437	180	2400	1.3	1.29	390	1100
60	910	1.0	1.029	120	1600	0.91	0.8897	270	750
40	680	0.75	0.7834	91	1300	0.62	0.6305	220	560
30	470	0.56	0.5626	68	910	0.47	0.4652	160	430
20	330	0.39	0.3805	47	620	0.33	0.3163	110	300
17	270	0.30	0.3063	36	510	0.27	0.2617	82	240
15	220	0.27	0.2615	30	430	0.22	0.2245	68	200
12	200	0.24	0.241	27	390	0.20	0.2042	62	180
10	180	0.20	0.2063	24	330	0.18	0.1721	56	150
6	91	0.11	0.108	13	180	0.091	0.0911	30	82

is shown in **Figure 10.71**. The responses of that filter are shown in **Figure 10.72**.

Component values for the 160 meter through the 6 meter amateur bands are shown in **Table 10.6**. The capacitors are shown in pF and the inductors in  $\mu\text{H}$ . The capacitors are the nearest 5% values; both the nearest 5% and the exact inductor values are shown.

Using the nearest-5% inductor values will result in satisfactory operation. If the con-

struction method is such that exact-value (adjustable) inductors can be used then the "Exact" values are preferred. These values were obtained from the program *SVC Filter Designer* which is available with the downloadable supplemental content.

An example of how to construct 100-W class transmitting filters using simple PC techniques is provided in the downloadable supplemental information. See the article

"Band-Pass Filters for HF Transceivers," by Lew Gordon, K4VX which includes a series of alternate designs for the 1.8, 3.5, 7, 14, 21, and 28 MHz bands. Construction of high-power filters involves higher voltages and currents as discussed in the article "High-Power HF Band-Pass Filter Design" by KØZR, which is included in the downloadable supplemental information.

### 10.10.5 Diplexer Filter

This section, covering diplexer filters, was written by William E. Sabin, WØIYH. The diplexer is helpful in certain applications, such as frequency mixer terminations.

The terms "diplexer" and "duplexer" are often confused. A diplexer is a device that allows transmitters and receivers to share a common antenna on a single band. A diplexer can be a device such as a circulator or isolator (types of waveguide components that allow power to flow in only one direction) or filters (cavity or lumped-circuit). Diplexers are filters that enable antennas on different bands to be used by a transceiver through a common feed line. Diplexers can also be used to allow transceivers on different bands to share a multiband antenna. A triplexer extends the diplexer to three bands.

It is important that a diplexer or triplexer have a constant filter-input resistance that extends to the stop band as well as the pass-band. Ordinary filters that become highly reactive or have an open or short-circuit input impedance outside the passband may degrade performance of the devices to which they are attached. For example, impedances far from  $50\ \Omega$  outside the operating frequency range may cause an amplifier to become unstable and generate spurious emissions or oscillate.

**Figure 10.73** shows a normalized prototype 5-element, 0.1-dB Chebyshev low-pass/high-pass (LP/HP) filter. This idealized filter is driven by a voltage generator with zero internal resistance, has load resistors of  $1.0\ \Omega$  and a cut-off frequency of 1.0 radian per second (0.1592 Hz). The LP prototype values are taken from standard filter tables.<sup>1</sup> The first element is a series inductor. The HP prototype is found by:

- replacing the series L (LP) with a series C (HP) whose value is  $1/L$ , and
- replacing the shunt C (LP) with a shunt L (HP) whose value is  $1/C$ .

For the Chebyshev filter, the return loss is improved several dB by multiplying the prototype LP values by an experimentally derived number,  $K$ , and dividing the HP values by the same  $K$ . You can calculate the LP values in henrys and farads for a  $50\ \Omega$  RF application with the following formulas:

$$L_{LP} = \frac{KL_{P(LP)}R}{2\pi f_{CO}}; C_{LP} = \frac{KC_{P(LP)}}{2\pi f_{CO}R}$$

**Figure 10.71** — Optimized low-pass filter. This design is for the 80 meter amateur band. It is similar to a Cauer design but the parts values have been optimized as described in the text and in the Sep/Oct 1998 issue of *QEX*.

**Figure 10.72** — Responses of the filter shown in **Figure 10.71**. Note the low values of SWR from 3.5 to 4 MHz. At the same time the harmonics are attenuated to meet regulations. Responses for the other amateur bands are very similar except for the frequency scaling.

**Figure 10.73** — Low-pass and high-pass prototype diplexer filter design. The low-pass portion is at the top, and the high-pass at the bottom of the drawing. See text.

**Figure 10.74** — Response for the low-pass and high-pass portions of the 80 meter diplexer filter. Also shown is the return loss of the filter.

where

$L_{P(LP)}$  and  $C_{P(LP)}$  are LP prototype values

$K = 1.005$  (in this specific example)

$R = 50 \Omega$

$f_{CO}$  = the cutoff ( $-3$  dB response) frequency in Hz.

For the HP segment:

$$L_{HP} = \frac{L_{P(HP)}R}{2\pi f_{CO}K}; C_{HP} = \frac{C_{P(HP)}}{2\pi f_{CO}KR}$$

where  $L_{P(HP)}$  and  $C_{P(HP)}$  are HP prototype values.

**Figure 10.74** shows the LP and HP responses of a diplexer filter for the 80 meter band. The following items are to be noted:

- The 3 dB responses of the LP and HP meet at 5.45 MHz.
- The input impedance is close to  $50 \Omega$  at all frequencies, as indicated by the high value of return loss (SWR  $< 1.07:1$ ).
- At and near 5.45 MHz, the LP input reactance and the HP input reactance are conjugates; therefore, they cancel and produce an almost perfect  $50 \Omega$  input resistance in that region.
- Because of the way the diplexer filter is derived from synthesis procedures, the transfer characteristic of the filter is mostly independent of the actual value of the amplifier dynamic output impedance.<sup>2</sup> This is a useful feature, since the RF power amplifier output impedance is usually not known or specified.
- The 80 meter band is well within the LP response.
- The HP response is down more than 20 dB at 4 MHz.
- The second harmonic of 3.5 MHz is down only 18 dB at 7.0 MHz. Because the second harmonic attenuation of the LP is not great, it is necessary that the amplifier itself be a well-balanced push-pull design that greatly rejects the second harmonic. In practice this is not a

difficult task.

- The third harmonic of 3.5 MHz is down almost 40 dB at 10.5 MHz.

**Figure 10.75A** shows the unfiltered output of a solid-state push-pull power amplifier for the 80 meter band. In the figure you can see that:

- The second harmonic has been suppressed by a proper push-pull design.
- The third harmonic is typically only 15 dB or less below the fundamental.

The amplifier output goes through our diplexer filter. The desired output comes from the LP side, and is shown in **Figure 10.75B**. In it we see that:

- The fundamental is attenuated only about 0.2 dB.
- The LP has some harmonic content; however, the attenuation exceeds FCC requirements for a 100 W amplifier.

**Figure 10.75C** shows the HP output of the diplexer that terminates in the HP load or *dump* resistor. A small amount of the fundamental frequency (about 1%) is also lost in this resistor. Within the 3.5 to 4.0 MHz band, the filter input resistance is almost exactly the correct  $50 \Omega$  load resistance value. This is because power that would otherwise be *reflected* back to the amplifier is absorbed in the dump resistor.

Solid state power amplifiers tend to have stability problems that can be difficult to debug.<sup>3</sup> These problems may be evidenced by level changes in: load impedance, drive, gate or base bias, supply voltage, etc. Problems may arise from:

- The reactance of the low-pass filter outside the desired passband. This is especially true for transistors that are designed for high-frequency operation.
- Self-resonance of a series inductor at some high frequency.
- A stop band impedance that causes voltage, current and impedance reflections back to the amplifier, creating instabilities within

(A)

(B)

(C)

**Figure 10.75** — At A, the output spectrum of a push-pull 80 meter amplifier. At B, the spectrum after passing through the low-pass filter. At C, the spectrum after passing through the high-pass filter.

the output transistors.

Intermodulation performance can also be degraded by these reflections. The strong third harmonic is especially bothersome for these problems.

The diplexer filter is an approach that can greatly simplify the design process, especially for the amateur with limited PA-design experience and with limited home-lab facilities. For these reasons, the amateur homebrew enthusiast may want to consider this solution, despite its slightly greater parts count and expense.

The diplexer is a good technique for narrowband applications such as the HF amateur bands.<sup>4</sup> From **Figure 10.74**, we see that if the signal frequency is moved beyond 4.0 MHz the amount of desired signal lost in the dump resistor becomes large. For signal frequencies

below 3.5 MHz the harmonic reduction may be inadequate. A single filter will not suffice for all the HF amateur bands.

This treatment provides you with the information to calculate your own filters. A *QEX* article has detailed instructions for building and testing a set of six filters for a 120 W amplifier. These filters cover all nine of the MF/HF amateur bands.<sup>5</sup>

You can use this technique for other filters such as Bessel, Butterworth, linear phase, Chebyshev 0.5, 1.0, etc.<sup>6</sup> However, the diplexer idea does *not* apply to the elliptical function types.

The diplexer approach is a resource that can be used in any application where a constant value of filter input resistance over a wide range of passband and stop band frequencies is desirable for some reason. Computer modeling is an ideal way to finalize the design before the actual construction. The coil dimensions and the dump resistor wattage need to be determined from a consideration of the power levels involved.

Another significant application of the diplexer is for elimination of EMI, RFI and TVI energy. Instead of being reflected and very possibly escaping by some other route, the unwanted energy is dissipated in the dump resistor.<sup>7</sup>

See the discussion “Design Software for LC Filters” at the end of the Passive LC Filters section of this chapter. The software package provided by Jim Tonne, W4ENE, of Tonne Software ([www.tonnesoftware.com](http://www.tonnesoftware.com)) includes *Diplexer* which greatly simplifies the process of designing diplexer filters. The software is part of the downloadable supplemental information for this book.

### Low-Pass Filter Parts List

Qty	Description
1	Miniature brass strip, 1 × 12 in., 0.032 in. thick (C3)
1	Miniature brass strip, 2 × 12 in., 0.064 in. thick (C1, C2)
5 ft	¼ inch diameter soft copper tubing
4	¼ × 20 × ½ in. long hex head bolt
4	Plastic spacer or washer, 0.5 in. OD, 0.25 in. ID, 0.0625 in. thick
6	¼ × 20 hex nut with integral tooth lock washer
1	¼ × 20 × 4 in. long bolt
1	¼ × 20 threaded nut insert, PEM nut, or “Nutsert”
1	1 × 0.375 in. diameter nylon spacer. ID smaller than 0.25 in. (used for C3 plunger).
4	Nylon spacer, 0.875 in. OD, 0.25 to 0.34 in. ID, approx. 0.065 in. or greater thickness (used to attach brass capacitor plates).

Aluminum diecast enclosure is available from Jameco Electronics ([www.jameco.com](http://www.jameco.com)) part no. 11973. The box dimensions are 7.5 × 4.3 × 2.4 in. The 0.03125 in. thick Teflon sheet is available from McMaster-Carr Supply Co ([www.mcmaster.com](http://www.mcmaster.com)), item #8545K21 is available as a 12 × 12 in. sheet.

### 10.10.6 High-Performance, Low-Cost 1.8 to 54 MHz Low-Pass Filter

The low-pass filter shown in **Figure 10.76** offers low insertion loss, mechanical simplicity, easy construction and operation on all amateur bands from 160 through 6 meters. Originally built as an accessory filter for a 1500 W 6 meter amplifier, the filter easily handles legal limit power. No complicated test equipment is necessary for alignment. It was originally described by Bill Jones, K8CU, in November 2002 *QST*. The complete original *QST* article for this project is included with the downloadable supplemental content. The article supplies complete assembly and alignment drawings.

Although primarily intended for coverage of the 6 meter band, this filter has low insertion loss and presents excellent SWR characteristics

for all HF bands. Although harmonic attenuation at low VHF frequencies near TV channels 2, 3 and 4 does not compare to filters designed only for HF operation, the use of this filter on HF is a bonus to 6 meter operators who also use the HF bands. Six meter operators may easily tune this filter for low insertion loss and SWR in any favorite band segment, including the higher frequency FM portion of the band.

## ELECTRICAL DESIGN

The software tool used to design this low-pass filter is *Elsie* by Jim Tonne, W4ENE, which is available with the downloadable supplemental content. The *Elsie* format data file for this filter, DC54.lct, may be downloaded for your own evaluation from the author’s website at [www.realhamradio.com](http://www.realhamradio.com).

**Figure 10.77** is a schematic diagram of the filter. The use of low self-inductance capacitors with Teflon dielectric easily allows legal limit

**Figure 10.76** — The 1.8 to 54 MHz low-pass filter is housed in a die-cast box.

**Figure 10.77** — The low-pass filter schematic. See construction details in the article with the downloadable supplemental content.

**C1, C2** — 74.1 pF. 2 × 2.65 inch brass plate sandwiched with 0.03125 inch thick Teflon sheet. The metal enclosure is the remaining grounded terminal of this capacitor.

**C3** — Homemade variable using brass and Teflon.

**L1, L3** — 178.9 nH. Wind with 1/8 inch OD soft copper tubing, 3.5 turns, 0.75 inch diameter form, 0.625 inch long, 1/4 inch lead length for soldering to brass plate. The length of the other lead to RF connector as required.

**L2** — 235.68 nH. Wind with 1/8 inch OD soft copper tubing, 5 turns, 0.75 inch diameter form, 1.75 inches long. Leave 1/4 inch lead length for soldering.

high power operation and aids in the ultimate stop band attenuation of this filter. Capacitors with essentially zero lead length will not introduce significant series inductance that upsets filter operation. This filter also uses a trap that greatly attenuates second harmonic frequencies of the 6 meter band. The parts list for the filter is given in **Table 10.7**.

## PERFORMANCE DISCUSSION

Assuming the 6 meter SWR is set to a low value for a favorite part of the band, the worst case calculated forward filter loss is about 0.18 dB. The forward loss is better in the HF bands, with a calculated loss of only 0.05 dB from 1.8 through 30 MHz. The filter cutoff frequency is about 56 MHz, and the filter response drops sharply above this.

**Figure 10.78** shows the calculated filter response from 1 to 1000 MHz. The impressive notch near 365 MHz is because of these inherent stray capacitances across each of the coils. Slight variations in each coil will make slightly different tuned traps. This will introduce a stagger-tuned effect that results in a broader notch.

**Figure 10.78** — Modeled filter response from 1 to 1000 MHz.

## 10.10.7 Band-Pass Filter for 145 MHz

The following project is based on a design from the RSGB *Radio Communication Handbook, 11th edition*. This filter is intended to reduce harmonics and other out-of-band spurious emissions when transmitting and suppress strong out-of-band incoming signals which could overload the receiver. The filter's schematic and response curve are shown in **Figure 10.79**. This filter design is not suitable for use as a repeater duplexer for in-band signals sharing a common antenna — a high-Q cavity resonator is required.

Direct inductive coupling from the proximity of the coils is used between the first two and the last two resonant circuits.  $C_C$  performs "top coupling" between the center two sections where a shield prevents stray coupling. The input and output connections are tapped down on their respective coils to transform the 50  $\Omega$  source and load into the proper impedances for terminating the filter.

At VHF, self-supporting coils and mica, ceramic or air-dielectric trimmer capacitors give adequate results for most applications. Piston ceramic trimmers can be used for receiving or for low-power signals of a few watts. At higher power, use an air-variable capacitor. The filter is assembled in a 4 × 2½ × 1½ inch die-cast aluminum box so there is room for

either piston or air-variable capacitors.

The band-pass filter is made from four parallel resonant circuits formed by the inductance of the coils and their associated parasitic inter-turn capacitance described in the **RF Techniques** chapter. A 1-6 pF series capacitor ( $C$  in **Figure 10.79**) connected to ground adjusts the resonant frequency of each coil. A ceramic capacitor should be used for  $C_C$  which has a value of 0.5 pF.

The dimensions of the coils are important to control the self-resonant frequency. Each coil is constructed from 6-½ turns of #17 AWG solid, bare wire (1.15 mm dia), 3/8 inch (9.5 mm) in diameter. Each turn is spaced 1 wire diameter apart. The original design used British #18 SWG wire which is slightly thicker (1.22 mm) so coils made with #17 AWG wire will have a slightly higher resonant frequency. The taps for the coils are made 1 turn from the grounded end of the coil as shown in the figure.

Adjustment will be required after assembly to tune out the stray capacitances and inductances. A sweep generator and oscilloscope (see the **Test Equipment and Measurements** chapter) provide the most practical adjustment method. A variable oscillator with frequency counter and a voltmeter with RF probe, plus a good deal of patience, can also do the job.

Figure 10.79 — A four-section band-pass filter for 145 MHz for attenuating strong out-of-band signals and reducing harmonics or other out-of-band spurious emissions.

# 10.11 Filter Glossary

**Active filter** — A filter that uses active (powered) devices to implement its function.

**Adaptive filter** — A filter whose coefficients can be changed automatically.

**All-pass** — Filter response in which the magnitude response does not change with frequency, but the phase response does change with frequency.

**Amplitude response** — see **magnitude response**

**Band-pass** — Filter response in which signals are passed in a range of frequencies and rejected outside that range.

**Band-stop** — Filter response in which signals are rejected in a range of frequencies and passed outside that range (also called *band-reject* or *notch* filter).

**Bandwidth** — Range of frequencies over which signals are passed (low-pass, high-pass, band-pass) or rejected (band-stop).

**Brick wall response** — An ideal filter response in which signals are either passed with no attenuation or attenuated completely.

**Chebyshev filter** — A filter with equal ripple in the passband, stopband or both.

**Cutoff frequency** — Frequency at which a filter's output is 3 dB below its passband output (also called *corner frequency* or *3 dB frequency*).

**Decade** — A ratio of 10 in frequency.

**Decimation** — Reduction of sample rate by an integer factor.

**Duplexer** — A device, typically a pair of filters, that allows antennas or transceivers for two different bands to share a single feed line.

**Duplexer** — A device that allows transceivers, transmitters, or receivers operating on different frequencies within a single band to share a common antenna. The duplexer may be implemented with filters or other feed line components, such as a circulator or isolator.

**Equiripple** — Equalized ripple in a filter's magnitude response across the passband, stopband, or both.

**Filter coefficient** — One of a series of numbers that define the transfer function of a filter.

**Finite impulse response (FIR)** — An impulse response that is zero for all time that is greater than some finite amount from the time of the impulse.

**Flat** — Refers to a filter's magnitude response that is constant across a range of frequencies.

**Group delay** — The transit time of signals through a filter.

**High-pass** — Filter response in which signals above the cutoff frequency are passed and rejected at lower frequencies.

**Ideal filter** — Filter that passes signals without loss or attenuates them completely. An ideal filter has no transition regions. (See also **brick wall response**).

**Impulse** — A pulse of finite energy with a width that approaches zero.

**Impulse-invariant** — A design technique for IIR filters in which the impulse response is the same as the impulse response of a certain analog filter.

**Impulse response** — The response versus time of a filter to an impulse.

**Infinite impulse response (IIR)** — An impulse response that theoretically never goes to and remains at zero.

**Insertion loss** — The loss incurred by signals in a filter's passband.

**Interpolation** — Increasing the sample rate by an integer factor.

**Low-pass** — Filter response in which signals below the cutoff frequency are passed and rejected at higher frequencies.

**Lumped elements** — Discrete inductors and capacitors; a lumped-element filter made from discrete inductors and capacitors.

**Magnitude response** — Graph of a filter's output amplitude versus frequency.

**Microstrip** — A type of transmission line made from a strip of metal separated from a ground plane by a layer of insulating material, such as on a printed-circuit board.

**Normalize** — The technique of converting numeric values to their ratio with respect to some reference value. (To denormalize is to reverse the normalization, converting the ratios back to the original values.)

**Notch filter** — see **band-stop filter**.

**Octave** — A ratio of two in frequency (see also **decade**).

**Overshoot** — The condition in which the output of a circuit, in responding to a change in its input, temporarily exceeds the steady-state value that the input should cause.

**Overtone** — Vibration mode at a higher frequency than the fundamental mode, usually harmonically related.

**Passband** — The range of frequencies passed by a filter.

**Passive filter** — A filter that does not require power to perform its function (see also **lumped element**).

**Phase response** — Graph of the difference in angular units (degrees or radians) between a filter's input and output versus frequency.

**Radian** — Unit of angular measurement equal to  $1/2\pi$  of a circle, equal to  $360 / 2\pi$  degrees

**Ringling** — The condition in which the output of a circuit, in responding to a change in its input, exhibits a damped alternating sequence of exceeding and falling below the steady-state value that the input should cause before settling at the steady-state value.

**Ripple** — A regular variation with frequency in a filter's magnitude response.

**Rolloff** — The rate of change in a filter's magnitude response in the transition region and stopband.

**Scaling** — Changing a filter's impedance or frequency characteristics through multiplication or division by a constant.

**Shape factor** — The ratio of a filter's bandwidth between the points at which its magnitude response is 6 dB and 60 dB below the response in the filter's passband.

**Stopband** — The range of frequencies that are rejected by a filter.

**Stripline** — A transmission line consisting of a metal strip suspended between two ground planes.

**Tap** — One processing block, consisting of a coefficient memory, signal register, multiplier and adder, of an FIR filter.

**TEM** — Transverse electromagnetic mode in which the electric and magnetic fields of electromagnetic energy are aligned perpendicularly to the direction of motion.

**Topology** — The arrangement of connections of components in the filter. For example, "capacitor-input" and "inductor-input" are two different topologies.

**Transition region** — Range of frequencies between a filter's passband and stopband.

**Triplexer** — See **duplexer**. The triplexer operates on three different bands.

# Modulation

Radio amateurs use a wide variety of modulations to convey information. This chapter, updated from Alan Bloom, N1AL's original material by Doug Grant, K1DG, explores various characteristics of modulation commonly used by amateurs. Traditional modulation types used for analog signals are discussed, as well as techniques suited for digital transmissions. Pulse and image modulations are also included. Methods of modulating and demodulating these signals are presented in the chapters on **Receiving** and **Transmitting**. The chapter concludes with a discussion of modulation impairments and a glossary of terms and suggestions for additional reading.

## 11.1 Introduction

The purpose of Amateur Radio transmissions is to send information via radio. The one possible exception to that is a beacon station that transmits an unmodulated carrier for propagation testing. In that case the only information being sent is, "I am transmitting (or not) from this location." One can think of it as a single data bit with two states, *on* or *off*. However, in reality even a beacon station or test transmission must periodically identify with the station call sign! Modulation is what allows the signal to carry the information, no matter how much or little.

To represent the information being sent, the radio signal must periodically change its characteristics (or *state*) in some way that can be detected by the receiver. In the early days of radio, the only way to do that was on-off keying using Morse code. By alternating the on and off states with the proper sequence and rhythm, a pair of highly-skilled operators can exchange textual data at rates up to perhaps 60 WPM.

Later, engineers figured out how to amplify the signal from a microphone and use it to vary the power of the radio signal continuously. Thus was born amplitude modulation, which allowed transmitting voices at full speaking speeds, that is, up to about 200 WPM. That led to analog modes such as television with even faster information rates. Today's digital radio systems are capable of transferring tens of megabits of information per second, equivalent to tens of millions of words per minute.

Modulation is but one component of any transmission mode. For example AM voice and NTSC television (the old analog TV system) both use amplitude modulation, but the transmission protocol and type of information sent are very different. Digital modes also are generally defined not only by the modulation but also by multiple layers of protocol and data coding. Of the three components of a mode (modulation, protocol and information), this chapter will concentrate on the first. The **Digital Protocols and Modes** chapter covers digital transmission protocols and the **Digital Communications** operating chapter with the downloadable supplemental content covers practical aspects of operating using the various digital modes.

Types of modulation are often referred to as "analog" or "digital." There is really no distinction between the two. What is usually meant is whether the modulating signal itself is an analog (continuously varying) or digital (some number of fixed states) signal.

The type of modulation is the choice of the radio system designer. The combination of modulation and a protocol create a mode. Modes can be analog or digital, again referring to whether they carry a continuously varying signal or not.

As an example of the difference between mode and modulation, consider HF and VHF packet radio. Both modes use the same AX.25 protocol to control how the data packets are formed and how the stations establish, conduct, and terminate the contact. Both modes also encode data as a pair of audio tones. On HF, however, the audio tones modulate an SSB transceiver to create an AFSK signal. On VHF, the tones modulate an FM transceiver, creating a very different type of signal. Both transceivers (SSB and FM) don't "know" whether the audio tones represent speech or data. If the audio is speech, the result is an "analog" mode. If the audio tones represent data, the result a "digital" mode.

### 11.1.1 Emission Designators

We tend to think of a radio signal as being “on” a particular frequency. In reality, any modulated signal occupies a band of frequencies. The bandwidth depends on the type of modulation and the data rate. A Morse code signal can be sent within a bandwidth of a couple hundred Hz at 60 WPM, or less at lower speeds. An AM voice signal requires about 6 kHz. For high-fidelity music, more bandwidth is needed; in the United States, an FM broadcast signal occupies a 200-kHz channel. Television signals need about 6 MHz, while 802.11ad, the latest generation of “WiFi” wireless LAN, uses up to 2 GHz for data transmission at its maximum transfer rate.

The International Telecommunication Union (ITU) has specified a system for designating radio emissions based on the bandwidth, modulation type and information to be transmitted. The emission designator begins with the bandwidth, expressed as a maximum of five numerals and one letter. The letter occupies the position of the decimal point and represents the unit of bandwidth, as follows: H=hertz, K=kilohertz, M=megahertz and G = gigahertz. The bandwidth is followed by three to five emission classification symbols, as defined in the table of emission designators available with the downloadable supplemental content. The first three symbols are mandatory; the fourth and fifth symbols are supplemental. These designators are found in Appendix 1 of the ITU Radio Regulations, ITU-R Recommendation SM.1138 and in the FCC rules §2.201. More information on

emissions designators is also available online at [fccid.io/Emissions-Designer](http://fccid.io/Emissions-Designer).

For example, the designator for a CW signal might be 150H0A1A, which means 150 Hz bandwidth, double sideband, digital information without subcarrier, and telegraphy for aural reception. SSB would be 2K5J3E, or 2.5 kHz bandwidth, single sideband with suppressed carrier, analog information, and telephony. The designator for a PSK31 digital signal is 60H0J2B, which means 60 Hz bandwidth, single sideband with suppressed carrier, digital information using a modulating subcarrier, and telegraphy for automatic reception.

Authorized modulation modes for Amateur Radio operators depend on frequency, license class, and geographical location, as specified in the FCC regulations §97.305. Technical standards for amateur emissions are specified in §97.307. Among other things, they require that no amateur station transmission shall occupy more bandwidth than necessary for the information rate and emission type being transmitted, in accordance with good amateur practice. We will discuss the necessary bandwidth for each type of modulation as it is covered in the following sections.

### 11.1.2 Bandwidth Definition

The general definition of bandwidth for a tuned circuit or filter are not used for the legal definition of signal bandwidth. The FCC regulations are more concerned with the amount of spectrum a signal consumes. This leads to the concept of *occupied bandwidth*.

Figure 11.1 — The FCC definition of bandwidth (see text).

This is the range of frequencies within which a specified percentage of the total power occurs. A common percentage used is 99%. This means that the total signal power outside the occupied bandwidth must be less than 20 dB less than the total signal power. For a properly-adjusted, low-distortion transmitting system, the occupied bandwidth is determined mainly by the modulation type and filtering and, in the case of digital modulation, the symbol rate.

FCC Rule §97.3(a)(8) provides the legal definition of a signal’s bandwidth as “The width of a frequency band outside of which the mean power of the transmitted signal is attenuated at least 26 dB below the mean power of the transmitted signal with the band.” The 26 dB limit is equivalent to 1/400th of the signal’s power. Figure 11.1 illustrates this relationship.

## 11.2 Amplitude Modulation (AM)

Of the various properties of a signal that can be modulated to transmit voice information, amplitude was the first to be used. Not only are modulation and demodulation of AM signals simple in concept, but they are simple to implement as well.

### 11.2.1 Double-Sideband, Full-Carrier AM

An AM signal is created from two signals; the RF signal that can be transmitted and the modulating signal that will be combined with the RF signal. The RF signal is called the *carrier*,  $c(t)$ , which is a single-frequency sinusoid at a frequency of  $f_C$ .

$$c(t) = C \sin(2\pi f_C t)$$

The modulating signal is represented by  $m(t)$  and may be a sine wave or a complex signal like speech. The modulating signal is also referred to as *baseband modulation*.

$$m(t) = M \cos(2\pi f_M t)$$

(The use of sine and cosine are to help identify which signal is which — there is no requirement for the carrier and modulating signal to have a specific phase relationship.)

Amplitude modulation is performed when  $c(t)$  is multiplied by  $m(t)$ . Mathematically, the process of amplitude modulation is easiest to envision if the modulating signal,  $m(t)$  is

Figure 11.2 — Graphical representation of amplitude modulation. In the unmodulated carrier (A) each RF cycle has the same amplitude. When the modulating signal (B) is applied, the RF amplitude is increased or decreased according to the amplitude of the modulating signal (C). A modulation index of approximately 75% is shown. With 100% modulation the RF power would just reach zero on negative peaks of the modulating signal.

**Figure 11.3** — AM with a single 1 kHz tone modulating a 10 MHz carrier (A) and a speech waveform (B) modulating the same carrier in (C).

a single audio tone with a frequency of  $f_M$ .

$$c(t) \times [1 + m(t)] = [1 + M \cos(2\pi f_M t)] \times C \sin(2\pi f_C t)$$

The constant 1 represents a dc component which is necessary to allow the *envelope* of the AM signal to both increase and decrease as in **Figure 11.2**. Note that if the modulating signal is zero (such as when there is no speech or tone) then the result is just the original carrier,  $c(t)$ . If  $M=1$ , the value of  $1 + m(t)$

**Figure 11.4** — AM waveforms showing 50% modulation (A) and 100% modulation (B). Overmodulation (C) causes distortion of the envelope and reversal of the RF carrier's phase, creating spurious emissions and interference on adjacent channels.

can vary from zero to 2 and the signal would just go to zero on the peaks of the modulating signal. Figure 11.2C shows a case very similar to this where the signal's envelope almost goes to zero but not quite.

Mathematically, the resulting AM signal is:

$$C \sin(2\pi f_C t) + \frac{C \times M}{2} \sin(2\pi(f_C + f_M)t) + \frac{C \times M}{2} \sin(2\pi(f_C - f_M)t)$$

This expression describes a signal with three components represented by the three terms: first, the carrier; second, an *upper sideband* with a frequency of  $f_C + f_M$ ; and third, a *lower sideband* with a frequency of  $f_C - f_M$ . This is *double-sideband, full-carrier (DSB-FC) AM*.

If  $M=1$ , each sideband's amplitude ( $C/2$ ) has half the amplitude of the carrier ( $C$ ). This means each sideband has one-quarter of the carrier's power level or is 6 dB weaker than the carrier. Adding the two sidebands together means that  $1/3$  of the total signal power is in

the sidebands and  $2/3$  in the carrier. For example, if the carrier power is 100 watts, each sideband will have  $100 \times 1/4 = 25$  watts. The total signal power is  $100 + 2 \times 25 = 150$  watts.

### AM SPECTRUM

**Figure 11.3A** shows the spectrum of a 10-MHz signal modulated with a 1-kHz sine wave. The upper sideband is a single frequency at  $10 \text{ MHz} + 1 \text{ kHz} = 10.001 \text{ MHz}$ . The spectrum of the lower sideband is inverted, so it is at  $10 \text{ MHz} - 1 \text{ kHz} = 9.999 \text{ MHz}$ .

When the modulating signal is speech, instead of a single tone, the result is shown in **Figure 11.3B** and **11.3C**. The speech signal is represented by the shaded region in **Figure 11.3B** extending from 300 Hz to 3 kHz with the higher frequency speech components having a slightly higher amplitude. When the 10 MHz carrier is modulated with the speech signal, the resulting sidebands are shown in **Figure 11.3C**. Each speech component behaves like a separate tone, creating its

own sideband. The set of components in speech create the set of sidebands shown by the shaded regions. Note that the upper and lower sideband spectra are “mirror images” of each other with the lower components closest to the carrier.

With both sidebands and the carrier, the AM signal’s total bandwidth is twice the bandwidth of the baseband modulation signal. (A single tone’s bandwidth is considered to be the frequency of the tone.) The bandwidth of an AM signal modulated by communications-quality speech with a frequency range of 300 Hz to 3 kHz is  $2 \times 3 \text{ kHz} = 6 \text{ kHz}$ . Note that the AM signal’s bandwidth does not depend on the lower limit of the baseband modulation signal.

### AM MODULATION INDEX

If the AM signal’s envelope is zero on negative peaks of the modulating signal, that corresponds to 100% modulation. For the case where the modulation signal is zero leaving just the steady carrier signal, that is 0% modulation. Expressed as a value from 0 to 1, this is the *modulation index*:

$$\text{Modulation index} = M / C$$

$$\text{Modulation percentage} = (M / C) \times 100\%$$

**Figure 11.4A** and **11.4B** show the AM signal waveform when  $M = C/2$  (50% modulation or a modulation index of 0.5) and when  $M = C$  (100% modulation or a modulation index of 1.0). If  $M$  is greater than  $C$ , the envelope of the AM signal can go “below zero” as shown in **Figure 11.4C**, causing the envelope of the signal to be distorted on negative peaks (and possibly positive peaks depending on the design of the modulator circuit). This is the condition of *overmodulation* and the distortion is known as “flat-topping” because of the shape of the envelope which often exhibits a flattening of peaks during overmodulation. This also results in spurious emissions that extend beyond the upper and lower sideband, causing interference on adjacent channels.

### 11.2.2 Double-Sideband, Suppressed Carrier (DSB-SC) AM

Another way of seeing how an AM signal is constructed is illustrated in **Figure 11.5**. **Figure 11.5A** shows the carrier and the sidebands

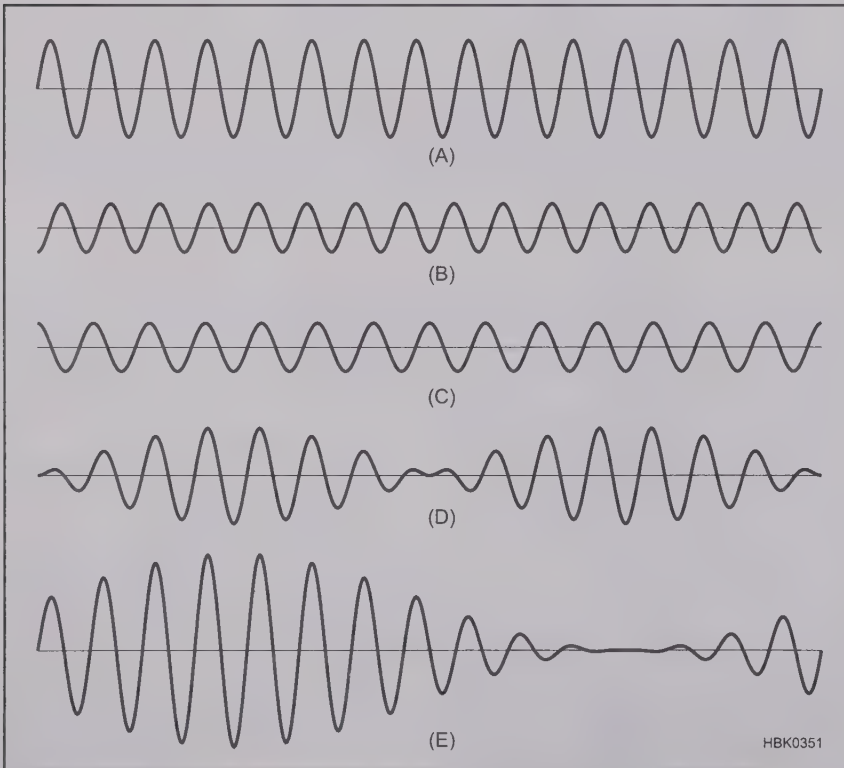

from a modulating tone are shown in **11.5B** and **11.5C**. If you look closely, you can see that the waveforms in **Figure 11.5B** and **11.5C** have slightly different frequencies than the carrier. If the two sidebands are added together, the signal of **Figure 11.5D** is produced. This is a *double-sideband, suppressed carrier (DSB-SC)* signal and its spectrum is shown in **Figure 11.6**, assuming the same 10 MHz carrier and 300-3000 Hz sidebands.

When the carrier signal is added, the full AM signal is produced in **Figure 11.5D**. When all of the signals are in-phase, the resulting signal has its maximum amplitude. When all of the signals are out of phase, the resulting signal goes to zero. If the carrier’s phase is used as our reference, the phase of each sideband can be viewed as slipping behind (lower sideband) or moving ahead (upper sideband) of the carrier. The sidebands are out of phase with each other at the frequency of the tone so the resulting envelope reproduces the modulating tone’s sine wave.

### 11.2.3 Single-Sideband (SSB-SC)

As we have seen, since the carrier itself contains no modulation, it does not need to be transmitted, which saves at least 67% of the transmitted power. Since the two sidebands carry identical information, one of them may be eliminated as well, saving half the bandwidth. The result is *single sideband, suppressed carrier (SSB-SC)*, which is commonly referred to simply as “SSB.” If the lower sideband is eliminated, the result is called *upper sideband (USB)*. If the upper sideband is eliminated, you’re left with *lower sideband (LSB)*. **Figure 11.7** shows the result of removing one of the sidebands in **Figure 11.6**.

The effect of SSB modulation is that

**Figure 11.5** — At **A** is an unmodulated carrier. If the upper (**B**) and lower (**C**) sidebands are added together a double-sideband suppressed carrier (DSB-SC) signal results (**D**). If each sideband has half the amplitude of the carrier, then the combination of the carrier with the two sidebands results in a 100%-modulated AM signal (**E**). Whenever the two sidebands are out of phase with the carrier, the three signals sum to zero. Whenever the two sidebands are in phase with the carrier, the resulting signal has twice the amplitude of the unmodulated carrier.

**Figure 11.6** — The spectrum of a double-sideband, suppressed-carrier (DSB-SC) signal created from the signal shown in **Figure 11.3**.

the baseband modulation signal is simply frequency-shifted to the RF carrier frequency (whether the carrier is transmitted or not.) The spectrum of the modulation may be inverted during the shifting process, requiring the demodulation process to re-invert the signal as it is translated back to the baseband frequency range. Aside from that technical consideration, there is no difference between the information in the LSB and USB signals.

The bandwidth of an SSB signal is a little less than half that of an equivalent AM signal. Using the same 300 Hz to 3 kHz speech bandwidth, the SSB signal has a bandwidth of  $3000 - 300 = 2700$  Hz = 2.7 kHz. In practice, SSB transmitters have an overall audio response from 300 Hz to 2.8 kHz, resulting in 2.5 kHz bandwidth.

Compared to most other analog modulation modes, SSB has excellent power efficiency because the transmitted power is proportional to the modulating signal and no power at all is transmitted during pauses in speech. Another advantage is that the lack of a carrier results in less interference to other stations.

SSB transceivers also are well-suited for the narrowband digital modes. Because an SSB transceiver simply frequency-translates the baseband audio signal to RF in the transmitter and back to audio again in the receiver, digital modulation may be generated and detected at audio frequencies using the sound card in a personal computer.

### 11.2.4 Amplitude-Modulated On-Off Keying (OOK)

*On-off keying* (OOK) is a special case of *amplitude-shift keying* (ASK) and is normally used for sending Morse code. For historical reasons dating from the days of spark transmitters, amateurs often refer to this as *continuous wave* (CW) even though the signal is actually keyed on and off.

You can think of OOK as being the same as analog AM that is modulated with a two-level signal that switches between full power and zero power. For example, imagine that the modulation is a 10 Hz square wave, equivalent to sending a series of dits at 24 WPM. A square wave may be decomposed into a sine wave of the same frequency and a theoretically infinite succession of odd harmonics. Recall that the lower and upper sidebands of an AM signal are simply the inverted and non-inverted spectra of the baseband modulation. The RF spectrum therefore contains sidebands at the carrier frequency  $\pm 10$  Hz,  $\pm 30$  Hz,  $\pm 50$  Hz, and so on to plus and minus infinity. This phenomenon is called *key clicks*. Stations listening on nearby frequencies hear a click upon every key closure and opening.

To prevent interference to other stations, the modulation must be low-pass filtered, which

slows down the transition times between the on and off states. See **Figure 11.8**. If the transitions are too fast, then excessive key clicks occur. If the transitions are too slow, then at high speeds the previous transition may not have finished before the next one starts, which makes the signal sound mushy and hard to read. Traditionally, filtering was done with a simple resistor-capacitor low-pass filter on the keying line, but using a transition with a raised-cosine shape allows faster transition times without excessive key

clicks. Some modern transceivers use DSP techniques to generate such a controlled transition shape.

The optimum transition time, and thus bandwidth, depends on keying speed. It also depends on propagation conditions. When the signal is fading, the transitions must be sharper to allow good copy. **Figure 11.9** gives recommended keying characteristics based on sending speed and propagation. As a compromise, many transmitters use a 5 ms rise and fall time. That limits the bandwidth

Figure 11.7 — The spectrum of the two single sideband (SSB) signals that could be created from the signal shown in Figure 11.6.

Figure 11.8 — A filtered CW keying waveform. The on-off transitions of the RF envelope should be as smooth as possible while transitioning as quickly as possible. The shape of the RF Output waveform is nearly optimum in that respect.

Figure 11.9 — Keying speed vs rise and fall times vs bandwidth for fading and non-fading communications circuits. For example, to optimize transmitter timing for 20 WPM on a non-fading circuit, draw a vertical line from the WPM axis to the  $K = 3$  line. From there draw a horizontal line to the rise/fall axis (approximately 15 ms). Draw a vertical line from where the horizontal line crosses the bandwidth line and see that the bandwidth is about 50 Hz. Harder (more abrupt) keying is required to maintain copying ability in the presence of fading.

to approximately 150 Hz while allowing good copy up to 60 WPM on non-fading channels and 35 WPM on fading channels, which covers most requirements.

With any digital system, the number of changes of state per second is called the *baud rate* or the *symbol rate*, measured in *bauds* or *symbols per second*. Sending a single Morse code dit requires two equal-length states, or symbols: *on* for the length of the dit and *off* for the space between dits. Thus, a string of dits sent at a rate of 10 dits per second has a symbol rate of 20 bauds.

Refer to **Figure 11.10**. A Morse code dash is on for three times the length of a dit. Including one symbol for the off time, the total time to send a dash is four symbols, twice the time to send a dit. For example, at a baud rate of 20 bauds, there are 10 dits per second or 5 dashes per second. The spacing between characters within a word is three symbols, two more than the normal space between dits and dashes. The spacing between words is seven symbols.

For purposes of computing sending speed, a standard word is considered to have five characters, plus the inter-word spacing. On average, that results in 50 symbols per word. From that, the speed in words per minute may be computed from the baud rate:

$$\text{WPM} = \frac{60 \text{ (sec / min)}}{50 \text{ (symbols / word)}} \times \text{bauds}$$

$$= 1.2 \times \text{bauds} = 2.4 \times \text{dits / sec}$$

Characters in Morse code do not all have the same length. Longer codes are used for characters that are used less frequently while the shortest codes are reserved for the most common characters. For example, the most common letter in the English language, E, is sent as a single dit. In that way, the average character length is reduced, resulting in a faster sending speed for a given baud rate. Such a variable-length code is known as *varicode*, a technique that has been copied in some modern digital modes (see the **Digital Protocols and Modes** chapter).

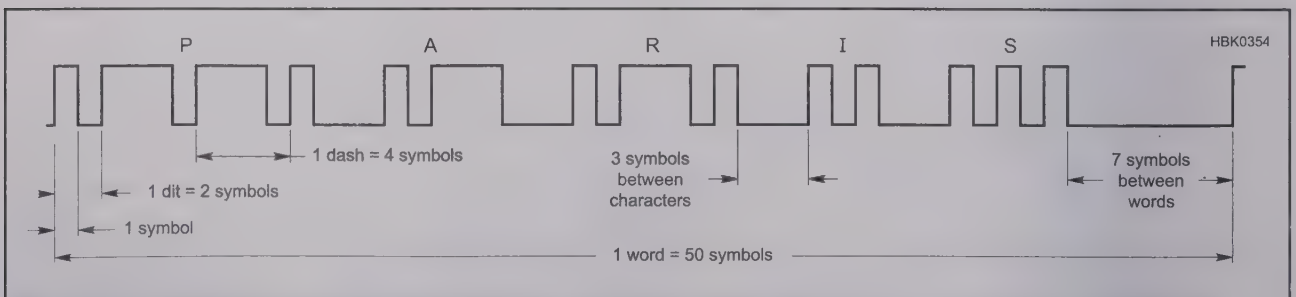

Figure 11.10 — CW timing of the word PARIS, which happens to have a length equal to the standard 50 symbols per word. By programming it multiple times into a memory keyer, the speed may be calibrated simply by counting the number of times the word is completed in one minute.

# 11.3 Angle Modulation

Angle modulation varies the phase angle of an RF signal in response to the modulating signal. In this context, “phase” means the phase of the modulated RF sine wave with respect to the unmodulated carrier. Angle modulation includes both frequency modulation and phase modulation because any change in frequency results in a change in phase. For example, the way to smoothly ramp the phase from one value to another is to change the frequency and wait. If the frequency is changed by +1 Hz, then after 1 second the phase will have changed by +360°. After 2 seconds, the phase will have changed by +720°, and so on. Change the frequency in the other direction and the phase moves in the opposite direction as well. With sine-wave modulation, the frequency and phase both vary in a sinusoidal fashion. See **Figure 11.11**.

For angle modulation, the modulation signal,  $m(t)$  is applied to the frequency or phase of the carrier, not its amplitude:

$$\sin(2\pi f_c t + k_p m(t)) \text{ or } \sin(2\pi f_c t + f_d m(t))$$

Mathematically, these are equivalent and most texts work with the second form. The constants  $k_p$  and  $f_d$  are described below in the discussion on modulation index.

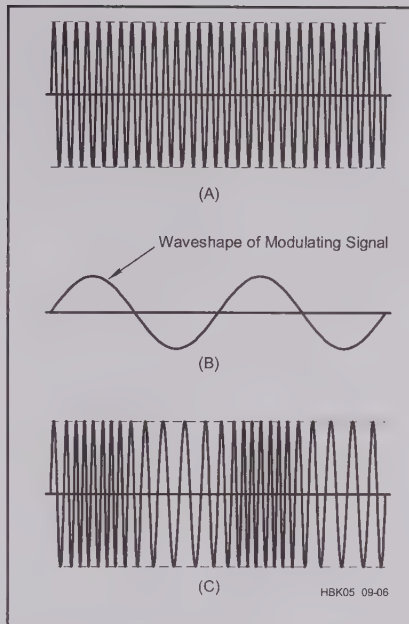

Since any change in frequency results in a change in phase and vice versa, *frequency modulation* (FM) and *phase modulation* (PM) are fundamentally the same. The term *frequency deviation* means the amount the RF frequency deviates from the center (carrier) frequency with a given modulating signal. The instantaneous deviation of an FM signal is proportional to the instantaneous amplitude of the modulating signal. The instantaneous deviation of a PM signal is proportional to the instantaneous *rate of change* of the modulating signal. Since the rate of change of a sine wave is proportional to its frequency as well as its amplitude, the deviation of a PM signal is proportional to both the amplitude and the frequency of the modulating signal.

## 11.3.1 Angle-Modulated Modulation Index

The *modulation index* is the ratio of the peak deviation to the highest audio frequency. The *deviation ratio* is the ratio of maximum permitted peak deviation to the maximum permitted modulating frequency. The modulation index is a measure of the maximum amount of phase change ( $\phi_{MAX}$ ) the modulation signal can cause. For a single-tone modulating signal:

$$\text{Modulation index} = A \times f_d / f_M \text{ (for FM)}$$

$$\text{Modulation index} = (\phi_{MAX}) = k_p \times A \text{ (for PM)}$$

**Figure 11.11 — Graphical representation of frequency modulation. In the unmodulated carrier (A) each RF cycle occupies the same amount of time. When the modulating signal (B) is applied, the radio frequency is increased or decreased according to the amplitude and polarity of the modulating signal (C).**

where the modulation index is calculated in radians and there are  $180/\pi$  radians in the 360° of one complete sine wave cycle (1 radian  $\approx$  57.3°). In addition,

$A$  is the amplitude of the modulation signal in volts

$f_M$  is the frequency of the message signal in hertz

$f_d$  is the *frequency deviation constant* that represents the sensitivity of the modulator in hertz of deviation per volt of the modulating signal

$A \times f_d$  is the *peak deviation*

$\phi_{MAX}$  is the maximum value of phase change caused by the modulation signal

$k_p$  is the *phase deviation constant* and is similar to  $f_d$  in that it specifies the sensitivity of the phase modulator in radians of phase change per volt of the modulating signal.

For PM, the modulation index doesn't depend on message frequency at all. For an FM signal,  $m$  will be larger if the peak deviation gets larger or if  $f_M$  gets smaller. For example, loud low-frequency signals can cause the modulation index to become quite large unless the transmitter limits deviation

and microphone gain or frequency response.

FCC regulations limit the modulation index at the highest modulating frequency to a maximum of 1.0 for frequencies below 29 MHz. If the audio is low-pass filtered to 3 kHz, then the deviation may be no more than 3 kHz. For that reason, FM transmitters for frequencies below 29 MHz are usually set for 3 kHz deviation while FM transmitters for higher frequencies are typically set for about 5 kHz deviation. The term *narrowband FM* generally refers to deviation of no more than 3 kHz and *wideband FM* refers to deviation greater than 3 kHz.

## 11.3.2 Angle Modulation Audio Frequency Response

The only difference between FM and PM is the audio frequency response. An FM transmitter with 6 dB/octave pre-emphasis of the modulating signal is indistinguishable from a PM transmitter. A PM transmitter with 6 dB/octave de-emphasis is indistinguishable from an FM transmitter. The reverse happens at the receiver. A frequency detector followed by a 6 dB/octave de-emphasis network acts like a phase detector. It is interesting to note that most VHF and UHF amateur “FM” transceivers should really be called “PM” transceivers due to the pre-emphasis and de-emphasis networks used in the transmitters and receivers respectively.

Most FM and PM transmitters include some kind of audio compressor before the modulator to limit the maximum deviation. Common usage of the term *deviation* is that it refers to the maximum peak deviation allowed by the audio compressor. If the frequency swings a maximum of 5 kHz above the center frequency and 5 kHz below the center frequency, we say the deviation is 5 kHz.

## 11.3.3 Angle Modulation Bandwidth

The spectrum of an angle-modulated signal is fairly complex. With sine-wave modulation, the RF frequency spectrum from an angle-modulated transmitter consists of the carrier and a series of sideband pairs, each spaced by the frequency of the modulation. For example, with 3 kHz sine-wave modulation, the spectrum includes tones at  $\pm 3$  kHz,  $\pm 6$  kHz,  $\pm 9$  kHz and so on with respect to the carrier. When the modulation index is much less than 1.0, only the first sideband pair is significant, and the spectrum looks similar to that of an AM signal (although the phases of the sidebands are different).

As the modulation index is increased, more

and more sidebands appear. Unlike with AM, the carrier amplitude also changes with deviation and actually disappears altogether for certain modulation indexes. Because the amplitude of an angle-modulated signal does not vary with modulation, the total power of the carrier and all sidebands is constant. **Figure 11.12** shows several graphs of an FM signal with a 1 kHz modulation signal at different modulation indexes. Note how the sidebands increase and decrease as modulation index changes. All of these spectra have the same total power.

The amplitudes of the carrier and the various sidebands are described by a series

of mathematical equations called Bessel functions, which are illustrated graphically in **Figure 11.13**. Note that the carrier disappears when the modulation index equals 2.405 and 5.52. That fact can be used to set the deviation of an FM transmitter. For example, to set 5 kHz deviation, connect the microphone input to a sine-wave generator set for a frequency of  $5/2.405 = 2.079$  kHz, listen to the carrier on a narrowband receiver, and adjust the deviation until the carrier disappears.

### 11.3.4 Carson's Rule

Unlike amplitude modulation, angle

modulation is nonlinear. Recall that with amplitude modulation, the shape of the RF spectrum is the same as that of the modulation spectrum, single-sided with SSB and double-sided with DSB. That is not true with angle modulation. A double-sideband AM signal with audio band-limited to 3 kHz has 6 kHz RF bandwidth. It is easy to see that an FM transmitter with the same audio characteristics but with, say, 5 kHz deviation must have a bandwidth of at least 10 kHz. While you might think that the bandwidth equals twice the deviation, in reality the transmitted spectrum theoretically extends to infinity, although it does become vanishingly small beyond a certain point. As a rule of thumb, approximately 98% of the spectral energy is contained within the bandwidth defined by *Carson's rule*:

$$BW = 2(f_d + f_m)$$

where

$f_d$  = the peak deviation, and

$f_m$  = the highest modulating frequency.

For example, if the deviation is 5 kHz and the audio is limited to 3 kHz, the bandwidth is approximately  $2(5 + 3) = 16$  kHz.

Be careful not to "over apply" Carson's Rule. It is just a method of estimating the bandwidth in which a certain amount (98%) of the signal power is contained. This is not as strict a definition as the FCC definition cited earlier in this chapter. Limiting the modulation index and stating the bandwidth in the rules defines a single FM or PM "channel" and how much energy is allowed to be outside that channel. **Figure 11.14** shows a typical 2 meter FM repeater output and compares Carson's Rule and the FCC bandwidth limits. The bandwidths derived from the two rules are "close" but not equivalent. The FCC would judge the signal to be wider than what Carson's Rule predicts. Relying on Carson's Rule is not sufficient to guarantee that there will be no interference to adjacent channels at minimum spacing.

### 11.3.5 AM Noise and FM Signals

Since the amplitude carries no information, FM receivers are designed to be as insensitive to amplitude variations as possible. Because noise tends to be mostly AM in nature, that results in a quieter demodulated signal. Typically the receiver includes a *limiter*, which is a very high-gain amplifier that causes the signal to clip, removing any amplitude variations, before being applied to the detector. Unlike with AM, as an FM signal gets stronger the volume of the demodulated audio stays the same, but the noise is reduced.

**Figure 11.12** — Charts showing one-half of an FM signal's sidebands for a modulating signal frequency of 1 kHz at different modulation indexes.

HBK05\_09-08

**Figure 11.13 — Amplitude of the FM carrier and the first nine sidebands versus modulation index. This is a graphical representation of mathematical functions developed by F. W. Bessel. Note that the carrier completely disappears at modulation indices of 2.405 and 5.52.**

**Figure 11.14 — Spectrum analyzer display for a typical 2 meter FM repeater. The bandwidths and amplitudes for Carson's Rule and the FCC's bandwidth definition are overlaid on the spectrum.**

HBK0353

**Figure 11.15 — A plot of post-detection signal-to-noise ratio (S/N) versus input carrier-to-noise ratio (C/N) for an FM detector at various modulation indices,  $m$ . For each modulation index the deviation is also noted assuming a maximum modulating frequency of 3 kHz. For comparison, the performance of an SSB product detector is also shown.**

Receiver sensitivity is often specified by how much the noise is suppressed for a certain input signal level. For example, if a  $0.25 \mu\text{V}$  signal causes the noise to be reduced by 20 dB, then we say the receiver sensitivity is “ $0.25 \mu\text{V}$  for 20 dB of quieting.”

The limiter also causes a phenomenon known as *capture effect*. If more than one signal is present at the same time, the limiter tends to reduce the weaker signal relative to the stronger one. We say that the stronger signal “captures” the receiver. The effect is very useful in reducing on-channel interference.

The suppression of both noise and interference is greater the wider the deviation. FM signals with wider deviation do take up more bandwidth and actually have a poorer signal-to-noise (S/N) ratio at the detector output for weak signals but have better S/N ratio and interference rejection for signal levels above a certain threshold. See **Figure 11.15**.

In addition to the noise and interference-reduction advantage, angle-modulated signals share with full-carrier AM the advantages of non-critical frequency accuracy and the continuous presence of a signal, which eases the task of the automatic gain control system in the receiver. In addition, since the signal is constant-amplitude, the transmitter does not need a linear amplifier. Class C amplifiers may be used, which have greater power efficiency.

## 11.4 FSK and PSK

While technically types of angle modulation, frequency-shift keying (FSK) and phase-shift keying are more easily discussed on their own terms. The technique of shifting a signal's frequency or phase to signify the 0 and 1 bit values of digital data is the dominant form of communications outside of Amateur Radio. Amateurs are making wider use of these techniques as they adopt more digital techniques, especially at and above UHF allocations where symbol rate and bandwidth limits are much more favorable than at VHF and below.

*Frequency-shift keying (FSK)* was the first digital angle-modulated format to come into common use. FSK can be thought of as being the same as analog FM that is modulated with a binary (two-level) signal that causes the RF signal to switch between two frequencies. It can also be thought of as equivalent to two on-off-keyed (OOK) signals on two nearby frequencies that are keyed in such a way that whenever one is on the other is off. Just as with OOK, if the transitions between states are instantaneous, then excessive bandwidth occurs — causing interference on nearby channels similar to key clicks. For that reason, the modulating signal must be low-pass filtered to slow down the speed at which the RF signal moves from one frequency to the other.

Although FSK is normally transmitted as a true constant-amplitude signal with only the frequency changing between symbols, it does not have to be received that way. The receiver can treat the signal as two OOK signals and demodulate each one separately. This is an advantage when HF propagation conditions exhibit selective fading — even if one frequency fades out completely the receiver can continue to copy the other, a form of *frequency diversity*. To take advantage of it, wide shift (850 Hz) must normally be used. With narrow-shift FSK (170 Hz), the two tones are generally too close to exhibit selective fading.

As previously discussed, selective fading is caused by the signal arriving at the receiver antenna by two or more paths simultaneously. The same phenomenon can

**Figure 11.16** — Multipath propagation can cause inter-symbol interference (ISI). At the symbol decision points, which is where the receiver decoder samples the signal, the path 2 data is often opposing the data on path 1.

cause another signal impairment known as *inter-symbol interference*. See **Figure 11.16**. If the difference in the two path lengths is great enough, then the signal from one path may arrive delayed by one entire symbol time with respect to the other. The receiver sees two copies of the signal that are time-shifted by one symbol. In effect, the signal interferes with itself. One solution is to slow down the baud rate so that the symbols do not overlap. It is for this reason that symbol rates employed on HF are usually no more than 50 to 100 bauds.

*Multi-level FSK (MFSK)* is one method to reduce the symbol rate. Unlike with conventional binary FSK, more than two shift frequencies are allowed. For example, with eight frequencies, each symbol can have eight possible states. Since three bits are required to represent eight states, three bits are transmitted per symbol. That means you get three times the data rate without increasing the baud rate. The disadvantage is a reduced signal to noise and signal to interference ratio. If the maximum deviation is the same, then the frequencies are seven times closer with 8FSK than with binary FSK and the receiver is theoretically seven times (16.9 dB) more susceptible to noise and interference. However the IF limiter stage removes most amplitude variations before the signal arrives at the FSK detector, so the actual increase in susceptibility is less for signal levels above a certain threshold.

With any type of FSK, you can theoretically make the shift as narrow as you like. The main disadvantage is that the receiver becomes more susceptible to noise and interference, as explained above. In addition, the bandwidth is not reduced as much as you might expect. Just as with analog FM, you still get sidebands whose extent depends on the symbol rate, no matter how small the deviation.

*Minimum-shift keying (MSK)* is FSK with a deviation that is at the minimum practical level, taking bandwidth and signal-to-noise ratio into account. That turns out to be a frequency shift from the center frequency of 0.25 times the baud rate or, using the common definition of frequency shift, a difference between the two tones of 0.5 times the baud rate. If, on a given symbol, the frequency is shifted to the upper tone, then the phase of the RF signal will change by 0.25 cycles, or 90°, during the symbol period. If the lower tone is selected, the phase shift is -90°. Thus, MSK may be regarded as either FSK with a frequency shift of 0.5 times the symbol rate, or as *differential phase-shift keying (DPSK)* with a phase shift of  $\pm 90^\circ$ . The binary data cause the phase to change by either +90 or -90° from one symbol to the next.

*Gaussian minimum-shift keying (GMSK)* refers to MSK where the modulating signal

has been filtered with a low-pass filter that has a Gaussian frequency response. As mentioned before, with any type of angle modulation the spectrum of the modulation is not duplicated at RF, but spreads out into an increased bandwidth. For that reason, there is no point in using a modulation filter with a sharp cutoff since the RF spectrum will be wider anyway. It turns out that a Gaussian filter, with its gradual transition from passband to stopband, has the optimum shape for an angle-modulated digital system. However, a Gaussian filter also has a gradual transition from symbol-to-symbol in the time domain as well. The transition is not totally completed by the time of the next symbol, which means that there is some inter-symbol interference in the transmitted signal, even in the absence of propagation impairments. With the proper choice of filter bandwidth, however, the ISI is small enough not to seriously affect performance.

*Binary phase-shift keying (BPSK)*, often referred to simply as phase-shift keying (PSK), is included in this section because the name suggests that it is true constant-amplitude angle modulation. It is possible to implement it that way. An example is MSK which, as described above, can be considered to be differential BPSK with a  $\pm 90^\circ$  phase shift. However the term BPSK is normally understood to refer to phase-shift keying with a 180° phase difference between symbols. To transition from one state to the other, the modulation filter smoothly reduces the amplitude to zero where the polarity reverses (phase changes 180°) before smoothly ramping up to full amplitude again. For that reason, BPSK as usually implemented really should not be considered to be PSK, but rather a form of amplitude-shift keying (ASK) with two modulation amplitudes, +1 and -1. Unlike true angle modulation, it is linear so that the spectrum of the modulation filter is duplicated at RF. The transmitter must use a linear amplifier to prevent distortion and excessive bandwidth similar to the splatter that results from an over-driven SSB transmitter.

### 11.4.1 Multi-carrier Modulation

An effective method to fit more data bits into each symbol is to use more than one separately-modulated signal at a time, each on its own carrier frequency spaced an appropriate distance from the frequencies of the other carriers. An example is multi-carrier FSK. This is not to be confused with MFSK which also uses multiple frequencies, but only one at a time. With multi-carrier FSK, each carrier is present continuously and is frequency-shifted in response to a separate data stream. The total data rate equals the

data rate of one carrier times the number of carriers. A disadvantage of multi-carrier FSK is that the resulting signal is no longer constant-amplitude—a linear amplifier must be used. In general, multi-carrier signals using any modulation type on each carrier tend to have high peak-to-average power ratios.

In the presence of selective fading, one or more of the carriers may disappear while the others are still present. An advantage of multi-carrier modulation is that error-correcting coding can use the unaffected carriers to reconstruct the missing data. Also, since each carrier signal is relatively narrowband, propagation conditions are essentially constant within that bandwidth. That makes it easier for the receiver to correct for other frequency-selective propagation impairments such as phase distortion. If a single-carrier signal of the same total bandwidth had been used instead, the receiver would need an adaptive equalizer to correct for the amplitude and phase variations across the transmission channel.

By using multiple carriers each with

multiple-bit-per-symbol modulation it is possible to obtain quite high data rates while maintaining the low symbol rates that are required to combat the effects of multi-path propagation on the HF bands. For example, PACTOR-III achieves a raw data rate of 3600 bits per second with a 100-baud symbol rate using 18 carriers of DQPSK. (100 bauds  $\times$  2 bits/symbol  $\times$  18 carriers = 3600 bits per second.) Similarly, Clover-2000 modulation gets 3000 bits per second with a 62.5-baud symbol rate using eight carriers of 16-DPSK combined with 4-level DASK. (62.5 bauds  $\times$  (4+2) bits/symbol  $\times$  8 carriers = 3000 bits per second.) Decoding is rather fragile using these complex modulation techniques, so PACTOR and Clover include means to automatically switch to simpler, more-robust modulation types as propagation conditions deteriorate.

What is the minimum carrier spacing that can be used without excessive interference between signals on adjacent frequencies? The answer depends on the symbol rate and the filtering. It turns out that it is easy

to design the filtering to be insensitive to interference on frequencies that are spaced at integer multiples of the symbol rate. (See the following section on filtering and bandwidth.) For that reason, it is common to use a carrier spacing equal to the symbol rate. The carriers are said to be *orthogonal* to each other since each theoretically has zero correlation with the others.

*Orthogonal frequency-division multiplexing* (OFDM), sometimes called *coded OFDM* (COFDM), refers to the multiplexing of multiple data streams onto a series of such orthogonal carriers. The term usually implies a system with a large number of carriers. In that case, an efficient decoding method is to use a DSP algorithm called the fast Fourier transform (FFT). (See the **DSP and SDR Fundamentals** chapter) The FFT is the software equivalent of a hardware spectrum analyzer. It gathers a series of samples of a signal taken at regular time intervals and outputs another series of samples representing the frequency spectrum of the signal. See **Figure 11.17**. If the length of the series of

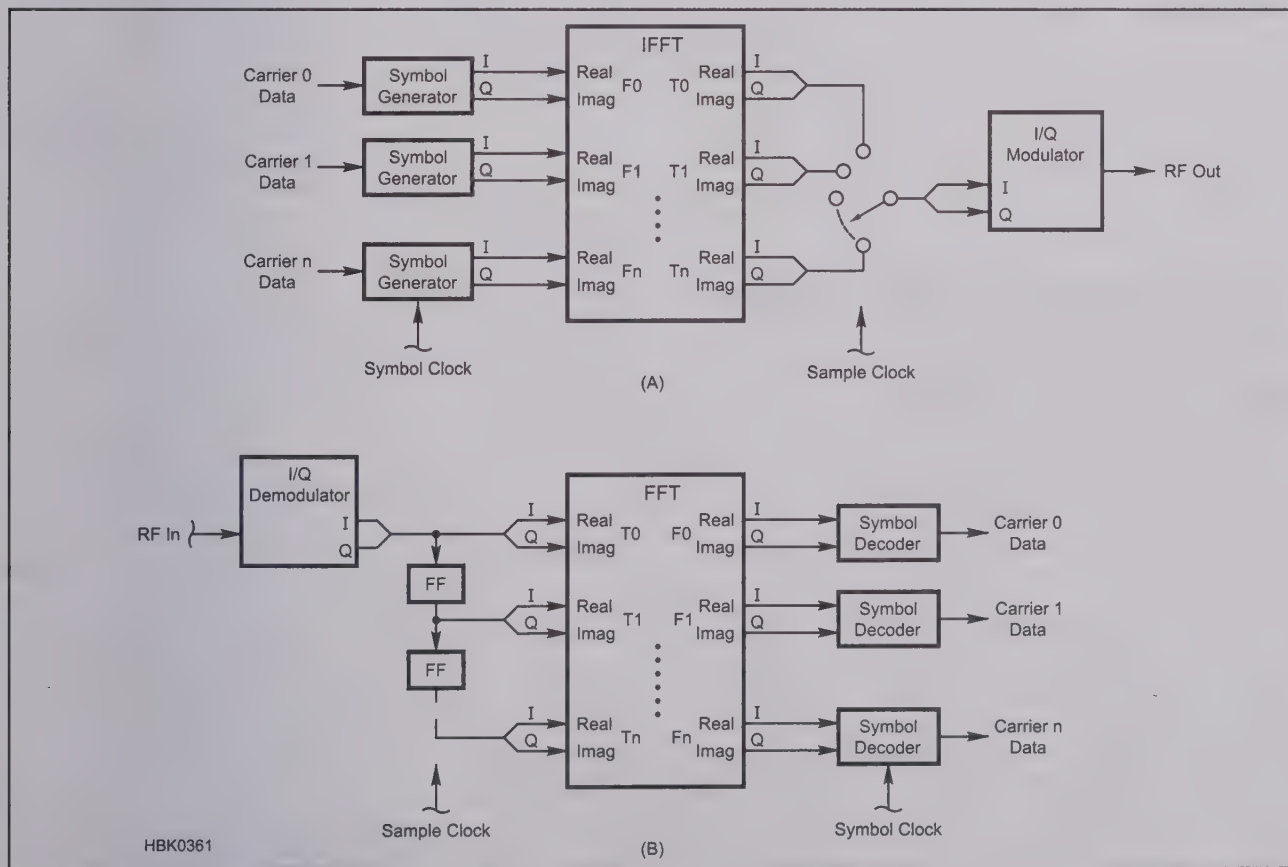

Figure 11.17 — Block diagram of an OFDM modulator (A) and demodulator (B) using the FFT/IFFT technique. The number of carriers is  $n$ , and the sample rate is  $n$  times the symbol rate. Once per symbol, all the symbol generators in the modulator are loaded with new data and the inverse fast-Fourier transform (IFFT) generates  $n$  output samples, which are selected in succession by the switch. In the demodulator,  $n$  samples are stored in a shift register (string of flip-flops) for each symbol, then the FFT generates one “frequency” output for each carrier frequency. From the amplitude and phase of each frequency, the symbol decoders can determine the symbol locations and thus the data.

input samples equals one symbol time and if the sample rate is selected properly, then each frequency sample of the FFT output corresponds to one carrier. Each frequency sample is a complex number (containing a “real” and “imaginary” part) that represents the amplitude and phase of one of the carriers during that symbol period. Knowing the amplitude and phase of a carrier is all the information required to determine the symbol location in the I/Q diagram and thus decode the data. At the transmitter end of the circuit, an inverse FFT (IFFT) can be used to encode the data, that is, to convert the amplitudes and phases of each of the carriers into a series of I and Q time samples to send to the I/Q modulator. See Figure 11.17A.

One advantage of OFDM is high spectral efficiency. The carriers are spaced as closely as theoretically possible and, because of the narrow bandwidth of each carrier, the overall spectrum is very square in shape with a sharp drop-off at the passband edges. One disadvantage is that the receiver must be tuned very accurately to the transmitter’s frequency to avoid loss of orthogonality, which causes cross-talk between the carriers.

### 11.4.2 Audio Frequency-Shift Keying (AFSK)

*Audio frequency-shift keying (AFSK)* is the generation of radio-frequency FSK using an audio-frequency FSK signal fed into the microphone input of an SSB transmitter. Assume the SSB transmitter is tuned to 14,000 MHz, USB. If the audio signal consists of a sine wave that shifts between 2125 Hz and 2295 Hz (170-Hz frequency shift), then the RF signal is a sine wave shifting between 14.002125 and 14.002295 MHz. The frequency shift and spectral characteristics are theoretically unchanged, other than being translated 14 MHz upward in frequency. The RF signal should be indistinguishable from one generated by varying the frequency of an RF oscillator directly.

This technique works not only for FSK but also for nearly any modulation type with a bandwidth narrow enough to fit within the passband of an SSB transmitter and receiver. The most common non-voice analog modulation type to use this technique on the amateur bands is *slow-scan television (SSTV)*, which uses frequency modulation for the video signal. In addition, nearly all narrowband digital signals today are generated

in this manner. The audio is generated and received either from a dedicated hardware modulator/demodulator (modem) or using the sound card that is found in virtually all personal computers.

Whatever the method, it is important to ensure that unwanted interference is not caused by audio distortion or by insufficient suppression of the carrier and unwanted sideband. For example, with the AFSK tone frequencies mentioned above, 2125 and 2295 Hz, the tone harmonics cause no trouble because they fall outside of the transmitter’s passband. However, some AFSK modems use 1275 and 1445 Hz (to accommodate 850-Hz shift without changing the 1275-Hz mark frequency). In that case, the second harmonics at 2550 and 2890 Hz must be suppressed since those frequencies are not well-attenuated by the transmitter. With non-constant-envelope modulation types such as QPSK or the various multi-carrier modes, it is important to set the amplitude of the audio input to the SSB transmitter below the level that activates the transmitter’s automatic level control (ALC). That is because the ALC circuit itself generates distortion of signals within the bandwidth of its feedback loop.

## 11.5 Quadrature Modulation

Quadrature modulation encodes digital signals using a combination of amplitude and phase modulation. With two types of modulation to work with, it is possible to cram more data bits into each modulation symbol, which allows more throughput for a given bandwidth. Modulation formats in use today have up to 8 or more bits per symbol which would be impractical for ASK, FSK or PSK alone.

Since quadrature-modulated symbols are defined by both amplitude and phase, the most common way to represent symbol states is with a polar plot, called a *constellation diagram*. See Figure 11.18, which shows a *four-level quadrature amplitude modulation (4-QAM)* signal, often referred to simply as QAM. The distance of each state from the origin represents the amplitude. The phase angle with respect to the +I axis represents the phase. The four states shown have phase angles of +45°, +135°, -45° and -135°. Normally, the receiver has no absolute phase information and can only detect phase differences between the states. For that reason, we could just as easily have drawn

Figure 11.18 — Constellation diagram of a 4-QAM signal, also known as QPSK. The four symbol locations all have the same amplitude and have phase angles of 45°, 135°, -135° and -45°. 4-QAM is a two-bits-per-symbol format. The four symbols are selected by the four possible states of the two data bits, which can be assigned in any order. With the assignment shown, the Q value depends only on the first bit and the I value depends only on the second, an arrangement that can simplify symbol encoding.

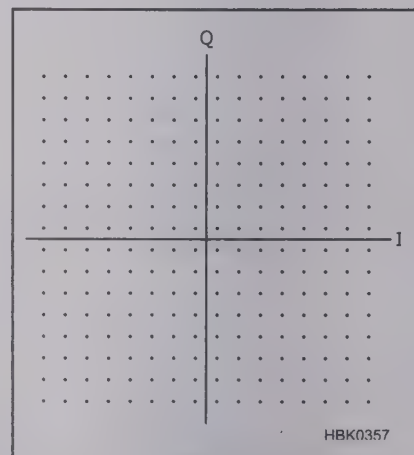

Figure 11.19 — Constellation diagram of a 256-QAM signal. Since an 8-bit number has 256 possible states, each symbol represents 8 bits of data.

the four states directly on the I and Q axes, at  $0^\circ$ ,  $+90^\circ$ ,  $180^\circ$  and  $-90^\circ$ . Note that each of the four states has the same amplitude, differing only in phase. For that reason 4-QAM is often referred to as *quadrature phase-shift keying* (QPSK), in the same manner that two-level ASK is normally referred to as BPSK.

Since 4-QAM has four possible states, there are two data bits per symbol. However QAM is not limited to four states. **Figure 11.19** illustrates a 256-QAM signal. It takes 8 bits to represent 256 states, so 256-QAM packs 8 data bits into each symbol. The disadvantage of using lots of states is that the effect of noise and interference is worse at the receiver. Since, for the same peak power, the states of a 256-QAM signal are 15 times closer together than with 4-QAM, the receiver's decoder has to determine each symbol's location to 15 times greater accuracy. That means the ratio of peak power to noise and interference must be  $20 \log(15) = 23.5$  dB greater for accurate decoding. That is why QAM with a large number of states is normally not used on the HF bands where fading, noise and interference are common. A more common application is digital cable television where the coaxial-cable transmission channel is much cleaner. For example, the European DVB-C standard provides for 16-QAM through 256-QAM, depending on bandwidth and data rate.

There are at least two ways to generate a QAM signal. One is to combine a phase modulator and an amplitude modulator. The phase modulator places the symbol location at the correct phase angle and the amplitude modulator adjusts the amplitude so the symbol is the correct distance from the origin. That method is seldom used, both because of the circuit complexity and because the nonlinear phase modulator makes the signal difficult to filter so as to limit the bandwidth.

A much more common method of generating QAM is with an *I/Q modulator*. See **Figure 11.20**. By using two modulators (mixers) fed with RF sine waves in quadrature ( $90^\circ$  out of phase with each other), any amplitude and phase may be obtained by varying the amplitudes of the two modulation inputs. The input labeled I (for in-phase) moves the symbol location horizontally in the constellation diagram and the one labeled Q (for quadrature) moves it vertically. For example, to obtain an amplitude of I and a phase angle of  $-45^\circ$ , set I to  $+0.707$  and set Q to  $-0.707$ .

It is possible to generate virtually any type of modulation using an I/Q modulator. For example, to generate BPSK or on-off keying, simply disconnect the Q input and apply the modulation to I. For angle modulation, such as FM or PM, a waveform generator applies a varying signal to I and Q in such a manner to cause the symbol to rotate at

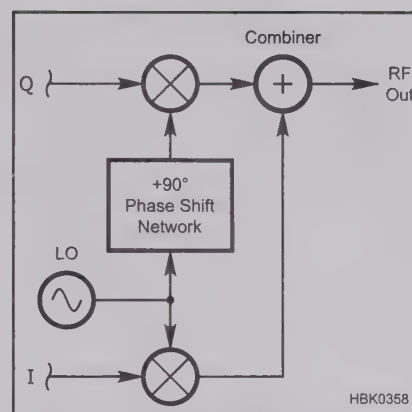

constant amplitude with the correct phase and frequency (rotation rate). Even a multi-carrier signal may be generated with a single I/Q modulator by applying the sum of a number of signals, each representing one carrier, to the I and Q inputs. The phase of each signal rotates at a rate equal to the frequency offset of its carrier from the center.

One problem with QAM is that whenever the signal trajectory between two symbol states passes through the origin, the signal amplitude momentarily goes to zero. That imposes stringent linearity requirements on the RF power amplifier, since many amplifiers exhibit their worst linearity near zero power. One solution is *offset QPSK* (OQPSK) modulation. In this case, the symbol transitions of the I and Q channels are offset by half a symbol. That is, for each symbol, the I channel changes state first then the Q channel changes half a symbol time later. That allows the symbol trajectory to sidestep around the origin, allowing use of a higher-efficiency or lower-cost power amplifier that has worse linearity.

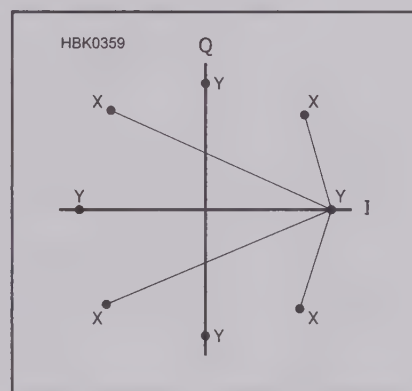

Another solution to the zero-crossing problem is called *PI over 4 differential QPSK* ( $\pi/4$  DQPSK). See **Figure 11.21**. This is actually a form of 8-PSK, where the eight symbol locations are located every  $45^\circ$  around a constant-amplitude circle. On any given symbol, however, only four of the symbol locations are used. The symbol location always changes by an odd multiple of  $45^\circ$  ( $\pi/4$  radians). If the current symbol is located on the I or Q axis, then on the next symbol only the four non-axis locations are available and vice versa. As with OQPSK, that avoids transitions that pass through the origin.

Another advantage of  $\pi/4$  DQPSK which is shared with other types of differential modulation is that absolute phase doesn't matter. The information is encoded only in the *difference* in the phase of successive symbols. That greatly simplifies the job of the receiver's demodulator.

The block diagram of an I/Q demodulator looks like an I/Q modulator drawn backward. See **Figure 11.22**. If the local oscillator is not tuned to exactly the same frequency as the one in the transmitter (after downconversion to the IF, assuming a superhet receiver) then the demodulated signal will rotate in the I/Q plane at a rate equal to the frequency error. Most receivers include a *carrier-recovery* circuit, which phase-locks the local oscillator to the average frequency of the incoming signal to obtain stable demodulation. While that corrects the frequency error, it does not correct the phase, which must be accounted for in some other manner such as by using differential modulation or some kind of symbol-recovery mechanism.

**Figure 11.20** — Block diagram of an I/Q modulator. By connecting an audio  $90^\circ$  phase-shift network to the I and Q inputs, an I/Q modulator can generate an analog SSB signal by the phasing method.

**Figure 11.21** — Constellation diagram of a  $\pi/4$  DQPSK signal. There are eight possible symbol locations. If the current symbol location is at one of the four positions labeled "X" then the next symbol will be at one of the four locations labeled "Y" and vice versa. That guarantees that no possible symbol trajectories (the lines between symbol locations) can ever pass through the origin.

**Figure 11.22** — Block diagram of an I/Q demodulator.

# 11.6 Analytic Signals and Modulation

In the area of modulation, the topic that seems to give people the most trouble is the concept of negative frequency. What in the world is meant by that? Consider a single-frequency signal oscillating at  $\omega$  radians per second. (Recall that  $\omega = 2\pi f$ , where  $f$  is frequency in Hz.) Let's represent the signal by a cosine wave with a peak amplitude of 1.0,  $x(t) = \cos(\omega t)$ , where  $t$  is time. Changing the sign of the frequency is equivalent to running time backwards because  $(-\omega)t = \omega(-t)$ . By examining **Figure 11.23A** you can see that, because a cosine wave is symmetrical about the time  $t = 0$  point, a negative frequency results in exactly the same signal. That is, as you may remember from high-school trigonometry,  $\cos(-\omega t) = \cos(\omega t)$ . If, for example, you add a positive-frequency cosine wave to its negative-frequency twin, you get the same signal with twice the amplitude.

That assumes that the phase of the signal is such that it reaches a peak at  $t = 0$ . What if instead we had a sine wave, which is zero at  $t = 0$ ? From **Figure 11.23B** you can see that running time backwards results in a reversal of polarity,  $\sin(-\omega t) = -\sin(\omega t)$ . If you add positive and negative-frequency sine waves of the same frequency and amplitude, they cancel, resulting in zero net signal.

A sinusoidal wave of any arbitrary amplitude and phase may be represented by the weighted sum of a sine and cosine wave:

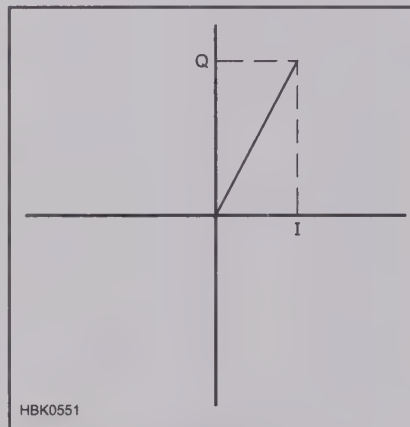

$$x(t) = I \cos(\omega t) + Q \sin(\omega t)$$

For computational purposes, it is convenient to consider the *in-phase* ( $I$ ) and *quadrature* ( $Q$ ) components separately. Since the  $I$  and  $Q$  components are  $90^\circ$  out of phase in

the time domain, they are often plotted on a polar graph at a  $90^\circ$  angle from each other. See **Figure 11.24**. For example if  $Q = 0$ , then as time increases the signal oscillates along the  $I$  (horizontal) axis, tracing out the path back and forth between  $I = +1$  and  $I = -1$  in a sinusoidal fashion. Conversely, if  $I = 0$ , then the signal oscillates along the  $Q$  axis.

What if both  $I$  and  $Q$  are non-zero, for example  $I = Q = 1$ ? Recall that the cosine and sine are  $90^\circ$  out of phase. When  $t = 0$ ,  $\cos(\omega t) = 1$  and  $\sin(\omega t) = 0$ . A quarter cycle later,  $\cos(\omega t) = 0$  and  $\sin(\omega t) = 1$ . Comparing **Figure 11.24** with **Figure 11.23** it should not be hard to convince yourself that the signal is tracing out a circle in the counter-clockwise direction.

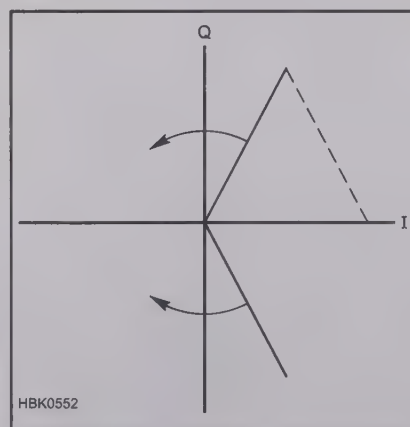

What about negative frequency? Again, it should not be hard to convince yourself that changing  $\omega$  to  $-\omega$  results in a signal that

**Figure 11.24** — In-phase ( $I$ ) and quadrature ( $Q$ ) portions of a signal.

**Figure 11.23** — Cosine wave (A) and sine wave (B).

**Figure 11.25** — A real frequency is the sum of a positive and negative analytic frequency.

circles the origin in the clockwise direction. If you combine equal-amplitude signals of opposite frequency, the sine portions cancel out and you are left with a simple cosine wave of twice the amplitude:

$$x(t) = [\cos(\omega t) + \sin(\omega t)] + [\cos(-\omega t) + \sin(-\omega t)] = 2\cos(\omega t)$$

You can see that graphically in **Figure 11.25**. Imagine the two vectors rotating in opposite directions. If you mentally add them by placing the tail of one vector on the head of the other, as shown by the dotted line, the result always lies on the  $I$  axis and oscillates between  $+2$  and  $-2$ .

That is why we say that a single scalar sinusoidal signal,  $\cos(\omega t)$ , actually contains two frequencies,  $+\omega$  and  $-\omega$ . It also offers a logical explanation of why a mixer or modulator produces the sum and difference of the frequencies of the two inputs. For example, an AM modulator produces sidebands at the carrier frequency plus and minus the modulating frequency precisely because those positive and negative frequencies are actually already present in the modulating signal.

For many purposes, it is useful to separate the portion of the signal that specifies the amplitude and phase ( $I$  and  $Q$ ) from the oscillating part ( $\sin(\omega t)$  and  $\cos(\omega t)$ ). For mathematical convenience, the  $I/Q$  part is represented by a complex number,  $x = I + jQ$ . The oscillating part is also a complex number  $e^{-j\omega t} = \cos(\omega t) - j\sin(\omega t)$ . (Don't worry if you don't know where that equation comes from — concentrate on the part to the right of the equals sign.<sup>4</sup>) In the equations,  $j = \sqrt{-1}$ . Of course,  $-1$  does not have a real square root (any real number multiplied by itself is positive) so  $j$ , or any real number multiplied by  $j$ , is called an *imaginary number*. A number with both real and imaginary parts is called a *complex number*. The total *analytic signal* is a complex number equal to

$$x(t) = xe^{-j\omega t} = (I + jQ) (\cos(\omega t) - j\sin(\omega t))$$

In the above equation, the  $\cos(\omega t) - j\sin(\omega t)$  portion generally represents an RF carrier, with  $\omega$  being the carrier frequency (a positive or negative value). The  $I + jQ$  part is the modulation. The *scalar* value of a modulated signal (what you would measure with an oscilloscope) is just the real ( $\text{Re}$ ) part of the analytic signal. Using the fact that  $j^2 = -1$ ,

$$\text{Re}[x(t)] = \text{Re}[(I + jQ) (\cos(\omega t) - j\sin(\omega t))]$$

$$\text{Re}[x(t)] = \text{Re}[(I \cos(\omega t) + Q \sin(\omega t)) + j(Q \cos(\omega t) - I \sin(\omega t))]$$

$$\text{Re}[x(t)] = I \cos(\omega t) + Q \sin(\omega t)$$

Note that if the modulation ( $I$  and  $Q$ ) var-

ies with time, the above equation assumes that the modulated signal does not overlap zero Hz. That is, I and Q have no frequency components greater than  $\omega$ .

Normally the I/Q diagram shows only I and Q (the modulation) and not the oscillating part. We call such a representation a *phasor diagram*. The I/Q vector represents the *difference* in phase and amplitude of the RF signal compared to the unmodulated carrier. For example, if the I/Q vector is at  $90^\circ$ , that means the carrier has been phase-shifted by  $90^\circ$  from what it otherwise would have been. If the I/Q vector is rotating counter-clockwise 10 times per second, then the carrier frequency has been increased by 10 Hz.

It is worth noting that the modulation can be specified either by the in-phase and quadrature (I and Q) values as shown or alternatively by the amplitude and phase. The amplitude is the length of the I/Q vector in the phasor diagram,

$$A = \sqrt{I^2 + Q^2}$$

The phase is the angle of the vector with respect to the +I axis,

$$\varphi = \arctan\left[\frac{Q}{I}\right]$$

An alternative expression for the modulated analytic signal using amplitude and phase is

$$\begin{aligned} x(t) &= Ae^{-j(\varphi + \omega t)} \\ &= A[\cos(\varphi + \omega t) + j\sin(\varphi + \omega t)] \end{aligned}$$

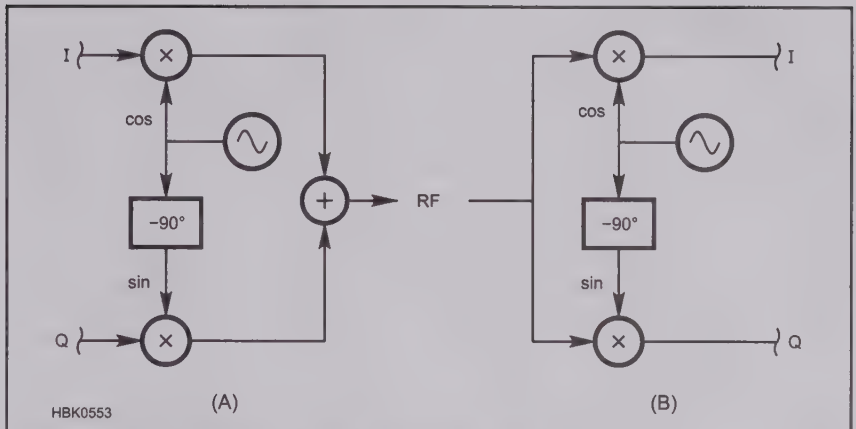

and for the scalar signal

$$\text{Re}[x(t)] = A \cos(\varphi + \omega t)$$

One final comment. So far we have been looking at signals that consist of a single sinusoidal frequency. In any linear system, anything that is true for a single frequency is also true for a combination of many frequencies. Each frequency is affected by the system as though the others were not present. Since any complicated signal can be broken down into a (perhaps large) number of single-frequency sinusoids, all our previous conclusions apply to multi-frequency signals as well.

### 11.6.1 I/Q Modulation and Demodulation

An *I/Q modulator* is just a device that controls the amplitude and phase of an RF signal directly from the in-phase (I) and quadrature (Q) components. See **Figure 11.26A**. An *I/Q demodulator* is basically the same circuit in reverse. It puts out I and Q signals that represent the in-phase and quadrature components of the incoming RF signal. See **Figure 11.26B**. Assuming the demodulator's

**Figure 11.26 — I/Q modulator (A) and demodulator (B).**

**Figure 11.27 — Generating a USB signal with an I/Q modulator.**

local oscillator is on the same frequency and is in phase with the carrier of the signal being received then the I/Q output of the receiver's demodulator is theoretically identical to the I/Q input at the transmitter end.

I/Q modulators and demodulators can be built with analog components. The LO could be a transistor oscillator and the  $90^\circ$  phase-shift network could be implemented with coils and capacitors. The circles with the multiplication symbol would be double-balanced mixers. Not shown in the diagram are trim adjustments to balance the amplitude between the I and Q channels and to adjust the phase shift as close as possible to  $90^\circ$ .

No analog circuit is perfect, however. If the  $90^\circ$  phase-shift network is not exactly  $90^\circ$  or the amplitudes of the I and Q channels are not perfectly balanced, you don't get perfect opposite-sideband rejection. The modulator output includes a little bit of signal on the unwanted sideband and the I/Q signal

from the demodulator includes a small signal rotating in the wrong direction. If there is a small dc offset in the amplifiers feeding the modulator's I/Q inputs, that shows up as carrier feedthrough. On receive, a dc offset makes the demodulator think there is a small signal at a constant amplitude and phase angle that is always there even when no actual signal is being received. Nor is analog circuitry distortion-free, especially the mixers. Intermodulation distortion shows up as out-of-channel "splatter" on transmit and unwanted out-of-channel responses on receive.

All those problems can be avoided by going digital. If the analog I/Q inputs to the modulator are converted to streams of digital numbers with a pair of ADCs, then the mixers, oscillator, phase-shift network and summer can all be digital. In many systems, the I and Q signals are also generated digitally, so that the digital output signal has perfect unwanted sideband rejection, no carrier feedthrough

and no distortion within the dynamic range afforded by the number of bits in the data words. A similar argument holds for a digital demodulator. If the incoming RF signal is first digitized with an ADC, then the demodulation can be done digitally without any of the artifacts caused by imperfections in the analog circuitry.

You can think of an I/Q modulator as a device that converts the analytic signal  $I + jQ$  into a scalar signal at some RF frequency. The spectrum of the I/Q signal, both positive and negative frequencies, is translated upward in frequency so that it is centered on the carrier frequency. Thinking in terms of the phasor diagram, any components of the I/Q signal that are rotating counter-clockwise appear above the carrier frequency and clockwise components appear below.

### 11.6.2 SSB Using I/Q Modulators and Demodulators

As an example of how this works, let's walk through the process of generating an upper-sideband signal using an I/Q modulator. See Figure 11.27. We'll first describe the mathematics in the following paragraph and then give the equivalent explanation using the phasor diagram.

The modulating signal is a sine wave at a frequency of  $\omega_m$  radians per second ( $\omega_m / 2\pi$  cycles per second). Because  $\omega_m$  is a positive frequency the signals applied to the I/Q inputs are  $I(t) = \cos(\omega_m t)$  and  $Q(t) = \sin(\omega_m t)$ . Assume the modulating frequency  $\omega_m$  is much less than the RF frequency  $\omega$ . The analytic signal is

$$x(t) = [\cos(\omega_m t) + j\sin(\omega_m t)] \times [\cos(\omega t) - j\sin(\omega t)]$$

so that the real, scalar signal that appears at the modulator output is

$$\text{Re}[x(t)] = \cos(\omega_m t)\cos(\omega t) + \sin(\omega_m t)\sin(\omega t)$$

At the moment when  $t = 0$ , then  $\cos(\omega_m t) = 1$  and  $\sin(\omega_m t) = 0$ , so the real signal is just  $\cos(\omega t)$ , the RF signal with zero phase. One quarter of a modulation cycle later  $\omega_m t = \pi/2$ , so  $\cos(\omega_m t) = 0$  and  $\sin(\omega_m t) = 1$ , and the real signal is now  $\sin(\omega t)$ , the RF signal with a phase of  $+\pi/2$ , or  $+90^\circ$ . Every quarter cycle of the modulating signal, the RF phase, increases by  $90^\circ$ . That means that the RF phase increases by one full cycle for every cycle of the modulation, which is another way of saying the frequency has shifted by  $\omega_m$ . We have an upper sideband at a fre-

quency of  $\omega + \omega_m$ .

On the phasor diagram, the I/Q signal is rotating counterclockwise at a frequency of  $\omega_m$  radians per second. As it rotates it is increasing the phase of the RF signal at the same rate, which causes the frequency to increase by  $\omega_m$  radians per second. To cause the phasor to rotate in the opposite direction, you could change the polarity of either I or Q or you could swap the I and Q inputs. In that case you would have a lower sideband.

For that to work, the baseband signals applied to the I and Q inputs must be  $90^\circ$  out of phase. That's not hard to do for a single sine wave, but to generate a voice SSB signal, all frequencies in the audio range must be simultaneously phase-shifted by  $90^\circ$  without changing their amplitudes. To do that with analog components requires a broadband phase-shift network consisting of an array of precision resistors and capacitors and a number of operational amplifiers.

### THE HILBERT TRANSFORMER

To do that with DSP requires a *Hilbert transformer*, an FIR filter with a constant  $90^\circ$  phase shift at all frequencies. Recall that a symmetrical FIR filter has a constant *delay* at all frequencies. That means that the phase shift is not constant — it increases linearly with frequency. It turns out that with an *anti-symmetrical* filter, in which the top half of the coefficients are the negative of the mirror image of the lower half, the phase shift is  $90^\circ$  at all frequencies, which is exactly what we need to generate an SSB signal.

The Hilbert transformer is connected in series with either the I or Q input, depending on whether USB or LSB is desired. Just as with any FIR filter, a Hilbert transformer has a delay equal to half its length, so an equal delay must be included in the other I/Q chan-

nel as shown in Figure 11.28. It is possible to combine the Hilbert transformer with the normal FIR filter that may be needed anyway to filter the baseband signal. The other I/Q channel then simply uses a similar filter with the same delay but without the  $90^\circ$  phase shift.

Because the RF output of the modulator is normally at a much higher frequency than the audio signal, it is customary to use a higher sample rate for the output signal than for the input. The FIR filters can still run at the lower rate to save processing time, and their output is then upsampled to a higher rate with an interpolator. It is convenient to use an output sample rate that is exactly four times the carrier frequency because each sample advances the RF phase by exactly  $90^\circ$ . The sequence of values for the sine wave is 0, 1, 0 and  $-1$ . To generate the  $90^\circ$  phase shift for the cosine wave, simply start the sequence at the second sample: 1, 0,  $-1$ , 0. The complete block diagram is shown in Figure 11.29.

Amateurs who have been in the hobby for many years may recognize this as the "phasing method" of SSB generation<sup>7</sup>. It was popular when SSB first became common on the amateur bands back in the 1950s because suitable crystal filters were expensive or difficult to obtain. The phasing method had the reputation of producing signals with excellent-quality audio, no doubt due to the lack of the phase distortion caused by crystal filters.

A Hilbert transformer may also be used in an SSB demodulator at the receiver end of the communications system. It is basically the same block diagram drawn backwards, as illustrated in Figure 11.30.

It is important to note that an ideal Hilbert transformer is impossible to construct because it theoretically has an infinitely-long impulse response. However, with a sufficiently-long impulse response, the accuracy

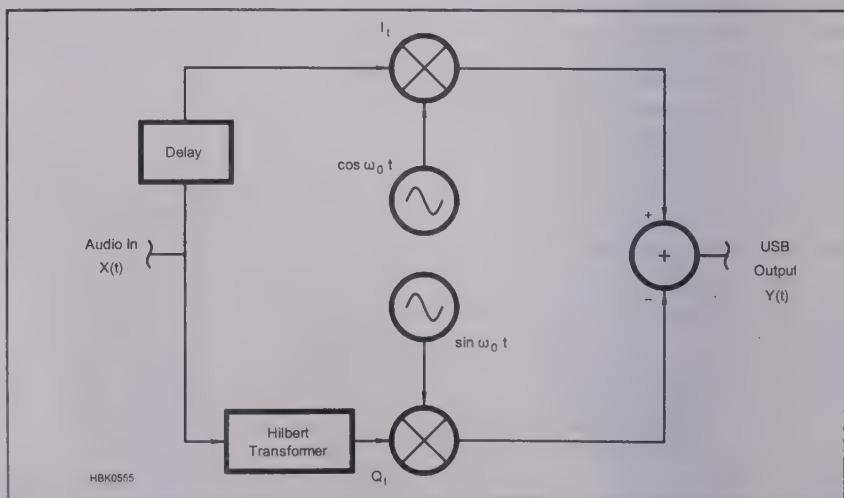

Figure 11.28 — Generating a non-sinusoidal USB signal with an I/Q modulator.

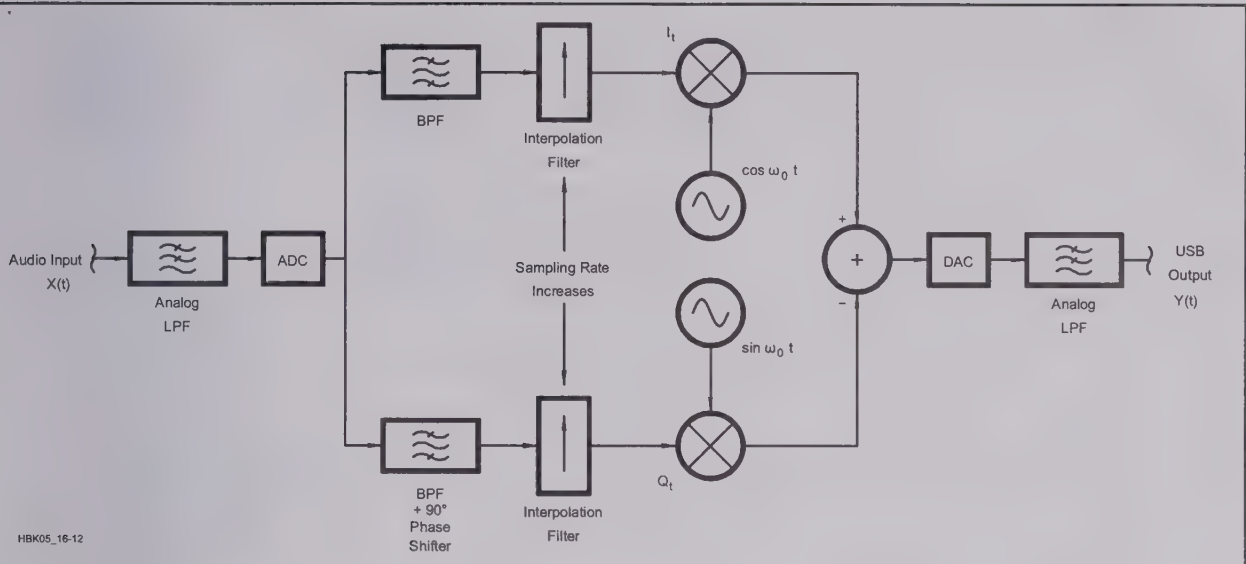

Figure 11.29 — Block diagram of a digital SSB modulator.

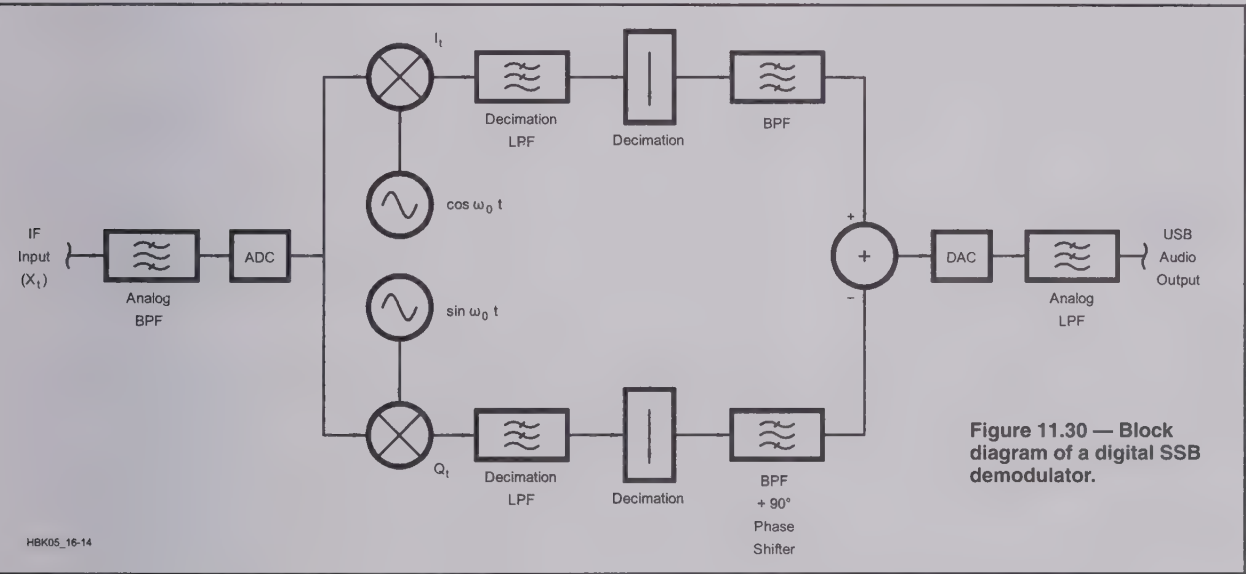

Figure 11.30 — Block diagram of a digital SSB demodulator.

much better than an analog phase-shift network. Just as with an analog network, the frequency passband must be limited both at the low end as well as the high end. That is, the audio must be band-pass filtered before the 90° phase shift. Actually, the filtering and phase shifting can be combined into one operation using the following method.

First design a low-pass FIR filter with a bandwidth one-half the desired audio bandwidth. For example, if the desired passband is 300 to 2700 Hz, the low-pass filter bandwidth should be  $(2700 - 300)/2 = 1200$  Hz. Then multiply the impulse response coefficients with a sine wave of a frequency equal to the center frequency of the desired passband,

$(2700 + 300)/2 = 1500$  Hz in this case. That results in a band-pass filter with the desired 300–2700 Hz response. By using sine waves 90° out of phase for the I and Q channels, you end up with two band-pass filters with the same amplitude response and delay but a 90° phase difference at all frequencies. Multiply by a cosine for zero phase and by a sine for a 90° phase shift.

This bears a striking resemblance to the Weaver method, the so-called “third method” of SSB generation (after “filter” and “phasing”). It was originally used back in the late 1950s to eliminate the need for a wide-band audio phase-shift network.<sup>6,7</sup> It is almost as if there is no such thing as truly new technol-

ogy, just old ideas coming back with new terminology!

### THE FILTER METHOD IN DSP

As DSP hardware has grown more powerful, it has also become possible to implement the filter method of SSB generation in software. In fact, the DSP filters that can be constructed in software are quite a bit better than the best analog filters. The result is a very simple system as shown in Figure 11.31 that is equivalent to the analog method. Ray Mack, WS1FS, discusses the various tradeoffs and filter characteristics required of this method in his Sep/Oct 2012 QEX SDR Simplified column.

Phil Karn, KA9Q, uses a DSP-based filter method for SSB generation because it avoids the need for a Hilbert transformer function. He performs his filtering by converting the signal to the frequency domain with an FFT (see the **DSP and SDR Fundamentals** chapter), multiplies each frequency component by a constant that defines the desired filter shape, and then converts back to the time domain with the inverse FFT. The windowing functions discussed with the FFT material can be applied to this filtering operation as well, with the Kaiser window recommended as supporting smooth trade-offs for sharp response against stop-band attenuation.

Karn has developed a fairly general purpose package in C that downconverts, filters, and detects a range of modulation/demodulates methods. The modulation/demodulation package and code for a WWV emulator is available as a github repository. For more information, see this book's website at [www.arrrl.org/arrrl-handbook-reference](http://www.arrrl.org/arrrl-handbook-reference). It currently demodulates AM, CAM (coherent AM), LSB, USB, FM, ISB (independent sideband) and IQ (straight IQ pass through). The software should work on processors that support C and floating point operations. It's not yet a polished product for the end user, but rather a set of building blocks for the experimenter.

### 11.6.3 Uses for I/Q Modulators and Demodulators

While I/Q modulators and demodulators can be used for analog modes such as SSB, they really shine when used with digital modulation modes. The modulation states of the various digital formats map to positions in the phasor diagram, what is called a *constellation diagram* (see this chapter's section on Quadrature Modulation). The transmitter can generate the correct modulation states simply by placing the correct values on the I and Q inputs to the I/Q modulator. In the receiver, the filtered I and Q values are sampled at the symbol decision times to determine which modulation state they most closely match.

I/Q modulators and demodulators can also be used as so-called *imageless mixers*. A normal mixer with inputs at  $f_1$  and  $f_2$  produces outputs at  $f_1$ ,  $f_2$ ,  $f_1 + f_2$ , and  $f_1 - f_2$ . A balanced mixer eliminates the  $f_1$  and  $f_2$  terms but both the sum and difference terms remain, even though normally only one is desired. By feeding an RF instead of AF signal into the input of an SSB modulator, we can choose the sum or difference frequency in the same way as choosing the upper or lower sideband. If the input signal is a sine wave, the Hilbert transformer can be replaced by a simple 90° phase shifter. Similarly, a mixer with the same architecture as an SSB demodulator can be used to downconvert an RF signal to IF with zero

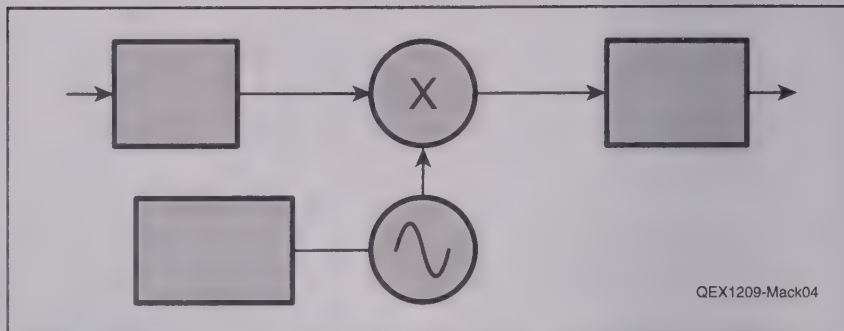

Figure 11.31 — The DSP method of using filters to create a SSB signal is simple and equivalent to the analog filter method.

Table 11.1  
Software AM Detector

```

```

image response. Analog imageless mixers are covered in the **Receiving** chapter. They are sometimes used in microwave receivers and transmitters where it is difficult to build filters narrow enough to reject the image response, but they typically only achieve image rejection in the 20-30 dB range. With a digital imageless mixer, the image rejection is “perfect” within the dynamic range of the bit resolution.

### SOFTWARE AM MODULATORS AND DEMODULATORS

In this chapter we’ve already covered many of the algorithms needed for a software-defined radio. For example, we know how to make I/Q modulators and demodulators and use them to build an SSB modulator and detector. Let’s say we want our software-defined transceiver to operate on AM voice as well. How do you make an AM modulator and demodulator using DSP and software?

The modulator is easy. Simply add a constant value, representing the carrier, to the audio signal and multiply the result by a sine wave at the carrier frequency, as shown in **Figure 11.32**.

Demodulation is almost as easy. We could

Figure 11.32 — A digital AM modulator

Figure 11.33 — A digital quadrature detector.

just simulate a full-wave rectifier by taking the absolute value of the signal, as mentioned previously, and low-pass filter the result to remove the RF energy. If the signal to be demodulated is complex, with I and Q components, then instead of absolute value we take the magnitude

$$A = \sqrt{I^2 + Q^2}$$

The dc bias can be removed by adding a “series blocking capacitor” — a high-pass filter with a suitable cut-off frequency.

A little more elegant way to do it would be to include the AM detector as part of the AGC loop. In the C code snippet shown in **Table 11.1**, the variable “carrier” is the average AM carrier level. It is passed to another subroutine to control the gain.

Note that no “series capacitor” is needed since the audio signal is computed by subtracting the average historical value, carrier, from the magnitude of the current I/Q signal, am. A small fraction of its value is added to the historical value so that the AGC tracks the average AM carrier level. AGC speed is controlled by that fraction. Dividing by 2<sup>10</sup>

= 1024 gives a time constant of about 1024 clock cycles.

Another type of detector we haven't discussed yet is for frequency modulation. For a scalar signal, the *quadrature detector* shown in **Figure 11.33** is one elegant solution. This is the same circuit whose analog equivalent has been used in millions of FM receivers around the world. In the digital implementation, the delay block is a FIFO buffer constructed from a series of shift registers. Multiplying the signal by a delayed version of itself gives an output with a sinusoidal response versus frequency. The response crosses zero whenever the carrier frequency is  $f = N/(4\tau)$ , where  $N$  is an odd integer and the delay in seconds is  $\tau = n/f_s$ , where  $n$  is the number of samples of delay and  $f_s$  is the sample frequency. As the carrier deviates above and below the zero-crossing frequency the output varies above and below zero, just what we want for an

FM detector.

For an I/Q signal, probably the most straightforward FM detector is a phase detector followed by a differentiator to remove the 6 dB per octave rolloff caused by the phase detector. The phase is just

$$\varphi = \arctan\left(\frac{Q}{I}\right)$$

You have to be a little careful since there is a 180° phase ambiguity in the arctangent function. For example,

$$\arctan\left(\frac{1}{1}\right) = \arctan\left(\frac{-1}{-1}\right)$$

Software will have to check which quadrant of the phasor diagram the I/Q signal is in and add 180° when necessary. If there is no arctan function in the library, one can be constructed using a look-up table. Frequency

is the derivative of the phase. A differentiator is nothing more than a subtractor that takes the difference between successive samples.

$$f = \frac{\varphi_n - \varphi_{n-1}}{2\pi f_s}$$

where  $n$  is the sample number and  $f_s$  is the sample rate. It is important to make sure that the difference equation functions properly around 360°. If the phase variable is scaled so that 360° equals the difference between the highest and lowest representable numbers, then standard two's complement subtraction should roll over to the right value at the 360° / 0° transition. Another thing to watch out for is that the derivative of the phase may be a rather small signal, so it might be necessary to carry through all the calculations using long integers or floating point numbers.

## 11.7 Image Modulation

The following section covers the modulation aspects of amateur television and facsimile communications. More detailed information on protocols and operating standards can be found in the **Image Communications** operating chapter in this book's downloadable supplemental information.

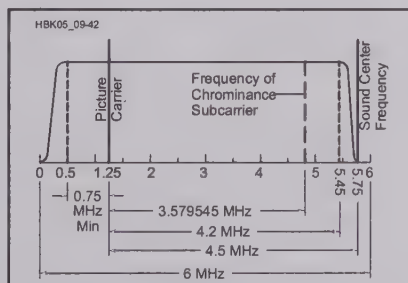

### 11.7.1 Fast-Scan Television

Amateur fast-scan television (ATV) is a wideband mode used in the amateur bands above 420 MHz. It is called "fast scan" to differentiate it from slow-scan TV.

#### NTSC

NTSC is named after the National Television Standards Committee that developed the modulation standard. It was released initially in 1941 (black-and-white only) and again in 1953 (color). It remained the dominant television standard until the late 1990s.

Although obsolete commercially, there is much ATV activity using NTSC, the same technical standard used by commercial analog television stations in the United States before most switched to digital TV in 2009. **Figure 11.34** shows the spectrum of an NTSC analog TV channel. It's basically a full-carrier, double-sideband AM signal, with filtering to partially remove the lower sideband. The partially-filtered *vestigial sideband* (VSB) extends 1.25 MHz below the carrier frequency. The channel is 6 MHz wide to accommodate the composite video and two subcarriers, one at 3.58 MHz for the color burst and the other an FM-modulated signal at 4.5 MHz for the sound. For simplicity, amateur stations

**Figure 11.34** — An analog NTSC 6-MHz video channel with the video carrier 1.25 MHz up from the lower edge. The color subcarrier is at 3.58 MHz and the sound subcarrier at 4.5 MHz above the video subcarrier.

often transmit unfiltered full-DSB AM, but the normally-removed portion of the lower sideband is unused by the TV receiver. Since less than 5% of the video energy appears more than 1 MHz below the carrier, little of the transmitter power is wasted. If needed, to reduce interference to other band users, a VSB filter in the antenna line can attenuate the lower sideband color and sound subcarrier frequencies by 20-30 dB.

The video signal includes pulses to synchronize the vertical and horizontal scan oscillators in the receiver. See **Figure 11.35**. The sync pulses and the "front porch" and "back porch" areas that bracket them are "blacker than black" so that the signal is

**Figure 11.35** — An ATV waveform, showing the relative camera output as well as the transmitter output RF power during one horizontal line scan for black-and-white TV. (A color camera would generate a "burst" of 8 cycles at 3.58 MHz on the back porch of the blanking pedestal.) Note that "black" corresponds to a higher transmitter power than "white."

blanked during retrace. The video-to-sync ratio must remain constant throughout all of the linear amplifiers in the transmit chain as the video level from the camera changes. To maintain the sync tips at 100% of peak power, the modulator usually contains a clamp circuit that also acts as a sync stretcher to compensate for amplifier gain compression.

Given NTSC's 525 horizontal lines and its 30 frames per second scan rate, the resulting horizontal resolution bandwidth is 80 lines per MHz. Therefore, with the typical TV set's 3-dB rolloff at 3 MHz (primarily in the IF filter), up to 240 vertical black lines can be seen, corresponding to 480 pixels per line. Color bandwidth in a TV set is less than that, resulting in up to 100 color lines. (Lines of resolution should not be confused with the number of horizontal scan lines per frame.)

The PAL analog TV system is an AM system based on NTSC. The SECAM system uses FM color subcarriers. As described previously, FM achieves superior noise and interference suppression for signal levels above a certain threshold, although AM seems to work better for receiver signal levels below about 5  $\mu$ V. FM ATV in the United States typically uses 4 MHz deviation with NTSC video and a 5.5-MHz sound subcarrier set to 15 dB below the video level. Using Carson's rule, the occupied bandwidth comes out to just under 20 MHz. Most available FM ATV equipment is made for the 1.2, 2.4 and 10.25-GHz bands.

### DIGITAL TV MODULATION

Digital fast-scan TV has been explored by amateurs in Europe and the US using the commercial DVB-S satellite digital video broadcasting standard. It uses MPEG2 audio and video data compression and QPSK modulation with symbol rates up to 20 Mbaud. Much of work has been on the 23 cm band since inexpensive set-top boxes are available that cover that frequency range.

DTV operates on the same 6 MHz-wide channels used for analog TV. However, instead of each channel slot carrying an analog NTSC television signal (visual carrier, color subcarrier and aural carrier), the channel slot carries an 8-VSB digitally modulated signal. The 6 MHz-wide over-the-air channel slots themselves didn't change, just the signals carried in them! So, channel 2 is still 54-60 MHz, channel 3 is 60-66 MHz, and so forth, up to channel 51. Channels 2-6 have largely been abandoned in the US as stations moved to broadcast digital TV on UHF channels. UHF channels 52-69 will be reallocated to other uses.

The designation "8-VSB" refers to 8-level vestigial sideband modulation. This is similar to 256-QAM, which means 256-state *quadrature amplitude modulation* — the 256 "states" are 256 combinations of signal phase

**Figure 11.36** — The spectrum of three analog NTSC TV channels (left of center) and three QAM signals (right of center). The digital channel power of the QAM "haystacks" is about 6 dB below the analog visual carrier PEP.

and amplitude values that represent the 256 different transmitted symbols — a digital format used in cable TV networks (64-QAM is also used by cable companies). In the case of 8-VSB, the "8" refers to the eight-level baseband DTV signal that amplitude modulates an IF signal. For more info about 8-VSB modulation, see the online article, "What Exactly Is 8-VSB Anyway?" by David Sparano at [www.arrl.org/files/file/Technology/TV\\_Channels/8\\_Bit\\_VSB.pdf](http://www.arrl.org/files/file/Technology/TV_Channels/8_Bit_VSB.pdf) and other references at [www.arrl.org/tv-channels-air-cdv](http://www.arrl.org/tv-channels-air-cdv).

The eight levels result in three bits per symbol, resulting in approximately 32 Mbits/second raw data rate with a 10.76 Mbaud symbol rate. The net data rate with error correction and other overhead is 19.39 Mbits/second. The DTV signal fits into the same 6 MHz channel as analog TV.

Digitally modulated signals used to transport video — whether 8-VSB for over-the-air or 64-QAM or 256-QAM in cable networks — are noise-like signals over their 6 MHz bandwidth. If a digital TV signal interferes with analog radio communications such as FM or SSB, the effect is similar to degraded signal-to-noise ratio. Indeed, a digital TV signal can be thought of as a 6 MHz wide "pile of noise." On a spectrum analyzer, it looks like a "haystack" as shown in **Figure 11.36**. Of course, the IF bandwidth of the amateur receiver is quite narrow relative to the 6 MHz-wide digital TV channel, so the actual noise level seen by the receiver (assuming no overload or IMD problems) will in part be determined by the receiver's IF bandwidth. Still, the effect on the

**Figure 11.37** — The basic 8-second black and white transmission format developed by early SSTV experimenters. The sync pulses are "blacker than black" to blank the signal during retrace. A complete frame has 120 lines (8 seconds at 15 lines per second). Horizontal sync pulses occur at the beginning of every line; a 30-ms vertical sync pulse precedes each frame.

receiver is what amounts to an elevated noise floor, similar to the effects of wide-spectrum broadband noise.

### 11.7.2 Slow-Scan Television

Despite its name, so-called *slow-scan television* (SSTV) is actually a method for sending still images, like facsimile. The original monochrome analog SSTV format illustrated in **Figure 11.37** takes approximately 8 seconds to send one complete frame. The 1500 to 2300-Hz frequency-modulated audio tone resembles that of a

ax signal, but is sent at a faster rate and includes pulses at 1200 Hz for synchronization.

Color may be sent using any of several methods. The first to be used was the *frame-sequential* method, in which each of the three primary colors (red, green and blue) is sent sequentially, as a complete frame. That has the disadvantage that you have to wait for the third frame to begin before colors start to become correct, and any noise or interference is three times more likely to corrupt the image and risks ruining the image registration (the overlay of the frames) and thus spoil the picture.

In the *line-sequential* method, each line is electronically scanned three times: once each for red, green and blue. Pictures scan down the screen in full color as they are received and registration problems are reduced. The Wraase SC-1 modes are examples of early line-sequential color transmission. They have a horizontal sync pulse for each of the color component scans. The major weakness of this method is that if the receiving system gets out of step, it doesn't know which scan represents which color.

Rather than sending color images with the usual RGB (red, green, blue) components, Robot Research decided to use luminance and chrominance signals for their 1200C modes. The first half or two thirds of each scan line contains the luminance information, which is a weighted average of the R, G and B components. The remainder of each line contains the chrominance signal with the color information. Existing black-and-white equipment could display the B&W-compatible image on the first part of each scan line and the rest would go off the edge of the screen. That compatibility was very beneficial when most people still had only B&W equipment.

The luminance-chrominance encoding

makes more efficient use of the transmission time. A 120-line color image can be sent in 12 seconds, rather than the usual 24. Our eyes are more sensitive to details in changes of brightness than color, so the time is used more efficiently by devoting more time to luminance than chrominance. The NTSC and PAL broadcast standards also take advantage of this vision characteristic and use less bandwidth for the color part of the signal. For SSTV, luminance-chrominance encoding offers some benefits, but image quality suffers. It is acceptable for most natural images but looks bad for sharp, high-contrast edges, which are more and more common as images are altered via computer graphics. As a result, all newer modes have returned to RGB encoding.

The 1200C introduced another innovation, called *vertical interval signaling* (VIS). It encodes the transmission mode in the vertical sync interval. By using narrow FSK encoding around the sync frequency, compatibility is maintained. This new signal just looks like an extra-long vertical sync to older equipment.

The Martin and Scottie modes are essentially the same except for the timings. They have a single horizontal sync pulse for each set of RGB scans. Therefore, the receiving end can easily get back in step if synchronization is temporarily lost. Although they have horizontal sync, some implementations ignore them on receive. Instead, they rely on very accurate time bases at the transmitting and receiving stations to keep in step. The advantage of this "synchronous" strategy is that missing or corrupted sync pulses won't disturb the received image. The disadvantage is that even slight timing inaccuracies produce slanted pictures.

In the late 1980s, yet another incompatible mode was introduced. The AVT mode is different from all the rest in that it has *no*

*horizontal sync*. It relies on very accurate oscillators at the sending and receiving stations to maintain synchronization. If the beginning-of-frame sync is missed, it's all over. There is no way to determine where a scan line begins. However, it's much harder to miss the 5-s header than the 300-ms VIS code. Redundant information is encoded 32 times and a more powerful error-detection scheme is used. It's only necessary to receive a small part of the AVT header in order to achieve synchronization. After this, noise can wipe out parts of the image, but image alignment and colors remain correct.

Digital images may be sent over Amateur Radio using any of the standard digital modulation formats that support binary file transfer. *Digital SSTV* (DSSTV) is one method of transmitting computer image files, such as JPEG or GIF, as described in an article by Ralph Taggart, WB8DQT, in the Feb 2004 issue of *QST*. This format phase-modulates a total of eight subcarriers (ranging from 590 to 2200 Hz) at intervals of 230 Hz. Each subcarrier has nine possible modulation states. This signal modulation format is known as *redundant digital file transfer* (RDFT) developed by Barry Sanderson, KB9VAK.

Most digital SSTV transmission has switched to using Digital Radio Mondiale (DRM), derived from a system developed for shortwave digital voice broadcasting. The DRM digital SSTV signal occupies the bandwidth between 350 and 2750 Hz. As many as 57 subcarriers may be sent simultaneously, all at the same level. Three pilot carriers are sent at twice the level of the other subcarriers. The subcarriers are modulated using OFDM and QAM, which were described earlier in this chapter. DRM SSTV includes several methods of error correction.

# 11.8 Spread Spectrum Modulation

A *spread-spectrum* (SS) system is one that intentionally increases the bandwidth of a digital signal beyond that normally required by means of a special spreading code that is independent of the data sequence. There are several reasons for spreading the spectrum in that way.

Spread spectrum was first used in military systems, where the purpose was to encrypt the transmissions to make it harder for the enemy to intercept or jam them. Amateurs are not allowed to encrypt transmissions for the purpose of concealing the information, but reducing interference, intentional or otherwise, is an obvious benefit. The signal is normally spread in such a fashion that it appears like random noise to a receiver not designed to receive it, so other users of the band may not even be aware that an SS signal is present.

Another advantage to spreading the spectrum is that it can make frequency accuracy less critical. In addition, the wide bandwidth means that expensive narrow-bandwidth filters are not required in the receiver. It also provides a measure of frequency diversity. If certain frequencies are unusable because of interference or selective fading, the signal can often be reconstructed using information in the rest of the bandwidth.

There are several ways to spread the spectrum — we will cover the two most common methods below — but they all share certain characteristics. Imagine that the unspread signal occupies a 10 kHz bandwidth and it is spread by a factor of 100. The resulting SS signal is 1000 kHz (1 MHz) wide. Each 10-kHz channel contains 1/100 of the total signal power, or -20 dB. That means that any narrowband stations using one of those 10-kHz channels experience a 20 dB reduction in interference, but also are more likely to be interfered with because of the 100-times greater bandwidth of the SS station's emissions.

How is the spread-spectrum station affected by interference from narrowband stations? In effect, the SS receiver attenuates the signal received on each 10 kHz channel by 20 dB in order to obtain a full-power signal when all 100 channels are added together. That means that the interference from a narrowband station is reduced by 20 dB but, again, the interference is more likely to occur because of the 100-times greater bandwidth of the SS station's receiver.

How is the spread-spectrum station affected by interference from another SS station on the same frequency? It turns out that if the other station is using a different orthogonal spreading code then, once again, the interference reduction is 20 dB

for 100-times spreading. That means that many SS stations can share the same channel without interference as long as they are all received at roughly the same signal level. Commercial mobile-telephone SS networks use an elaborate system of power control with real-time feedback to ensure that the signals from all the mobile stations arrive at the base station at approximately the same level.

That scheme works well in a one-to-many (base station to mobile stations) system architecture but would be much more difficult to implement in a typical amateur many-to-many arrangement because of the different distances and thus path losses between each pair of stations in the network. On the HF bands it is not uncommon to see differences in signal levels of 80 to 90 dB or more. (For example, the difference between S1 and 40 dB over S9 is 88 dB, assuming 6 dB per S-unit.) A spread spectrum signal at S9 + 40 dB with a spreading ratio of 100 times would interfere with any other signals below about S9 + 20 dB. It works the same in the other direction as well. The SS signal would experience interference from any other stations that are more than 20 dB louder than the desired signal.

Normally, increasing the bandwidth of a transmission degrades the signal-to-noise (S/N) ratio at the receiver. A 100-times greater bandwidth contains 100 times as much noise, which causes a 20 dB reduction in S/N ratio. However SS receivers benefit from a phenomenon known as processing gain. Just as the receiver is insensitive to other SS signals with different orthogonal spreading codes, so it is insensitive to random noise. The improvement in S/N ratio due to processing gain is:

Processing gain =

$$10 \times \log \left( \frac{\text{spread bandwidth}}{\text{unspread bandwidth}} \right) \text{ dB}$$

That is exactly equal to the reduction in S/N ratio due to the increased bandwidth. The net result is that an SS signal has neither an advantage nor a disadvantage in signal-to-noise ratio compared to the unspread version of the same signal. When someone states that, because of processing gain, an SS receiver can receive signals that are below the noise level (signals that have a negative S/N ratio), that is a true statement. However, it does not imply better S/N performance than could be obtained if the signal were not spread.

## 11.8.1 Frequency Hopping Spread Spectrum

One simple way to spread the spectrum

**Figure 11.38 — Power versus frequency for a frequency-hopping spread spectrum signal. Emissions jump around to discrete frequencies in pseudo-random fashion. Normally the spacing of the frequencies is approximately equal to the bandwidth of the unspread signal so that the average spectrum is approximately flat.**

of a narrowband signal is to repetitively sweep it across the frequency range of the wider spectrum, either continuously or in a series of steps at discrete frequencies. That technique, called *chirp modulation*, can be considered a special case of *frequency-hopping spread spectrum* (FHSS), in which the narrowband signal covers the expanded spectrum by rapidly hopping back and forth from frequency to frequency in a pseudo-random manner. On average, each frequency is used the same percentage of time so that the average spectrum is flat across the bandwidth of the FHSS signal. See **Figure 11.38**.

If the receiver hops in step with the transmitter, using the same pseudo-random sequence synchronized to the one in the transmitter, then the transmitter and receiver are always tuned to the same frequency and the receiver's detector sees a continuous, non-hopped narrowband signal which can be demodulated in the normal way. We say that the signal has been *de-spread*, that is, returned to its normal narrowband form. Synchronization between the receiver and transmitter is one of the challenges in an FHSS system. If the timing of the two sequences differs by even one hop, then the receiver is always tuned to the wrong frequency, unless the same frequency happens to occur twice in succession in the pseudo-random sequence. Any signal with an unsynchronized sequence, or with a different sequence, is reduced in amplitude by the processing gain.

There are two types of FHSS based on the rate at which the frequency hops take place. *Slow-frequency hopping* refers to a hop rate slower than the baud rate. Several symbols are sent per hop. With *fast-frequency hopping*, the hop rate is faster than the baud rate. Several hops occur during each symbol. The term *chip* refers to the shortest-duration modulation state in the system. For slow-frequency hopping, that is the baud rate. For fast-frequency hopping it is the hop rate. Fast-

**Figure 11.39 — Block diagram of an FHSS transmitter (A) and receiver (B).** The receiver may be thought of as a conventional superheterodyne receiver with a local oscillator (LO) that is continually hopping its frequency in response to a pseudo-random code generator. The transmitter has a similar architecture to up-convert a conventionally-modulated intermediate frequency (IF) to a frequency-hopped radio frequency (RF).

frequency hopping can be useful in reducing the effects of multi-path propagation. If the hop period is less than the typical time delay of secondary propagation paths, then those signals are uncorrelated to the main path and are attenuated by the processing gain.

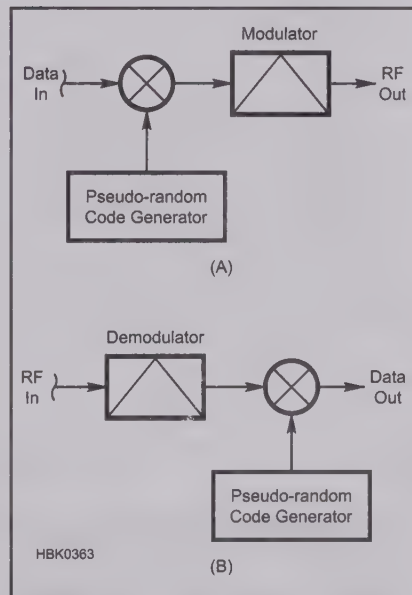

A diagram of a frequency-hopping spread spectrum system is shown in **Figure 11.39**. In both the transmitter and the receiver, a pseudo-random code generator controls a frequency synthesizer to hop between frequencies in the correct order. In this way, the narrowband signal is first spread by the transmitter, then sent over the radio channel, and finally de-spread at the receiver to obtain the original narrowband signal again. One issue with FHSS is that many synthesizers do not maintain phase coherence over successive frequency hops. That means the basic (non-spread) modulation must be a type that does not depend on phase information. That rules out PSK, QPSK and QAM. That is the reason that modulation types that do not depend on phase, such as FSK and MFSK with non-coherent detection, are frequently used as the base modulation type in FHSS systems.

chops the data into smaller time increments called *chips*. The ratio of the chip rate to the data's bit rate equals the ratio of the spread bandwidth to the unspread bandwidth, which is just the processing gain:

$$\text{Processing gain} = 10 \times \log \left( \frac{\text{chip rate}}{\text{bit rate}} \right) \text{ dB}$$

Although it doesn't have to, DSSS normally uses a one-bit-per-symbol modulation type such as BPSK. In that case, the modulator and demodulator in **Figure 11.40** would consist simply of a mixer, which multiplies the RF local oscillator by the bipolar DSSS modulating signal. Since unfiltered BPSK is constant-envelope, a nonlinear class-C power amplifier may be used for high efficiency. The demodulator in the receiver would also be a mixer, which multiplies the RF signal by a local oscillator to regenerate the DSSS modulating signal. Not shown are additional mixers and filters that would be used in a superheterodyne receiver to convert the received signal to an intermediate frequency before demodulation and decoding.

The unfiltered spectrum has the form of a sinc function. That shows up clearly in the spectrum of an actual DSSS signal in **Figure 11.41A**, which is plotted on a logarithmic scale calibrated in decibels. The humps in the response to the left and right (and additional ones not shown off scale) are not needed for communications and should be filtered out to avoid excessive occupied bandwidth. **Figure 11.41B** shows the DSSS signal in the presence of noise at the input to the receiver, and **Figure 11.41C** illustrates the improvement in signal-to-noise ratio of the de-spread narrowband signal.

**Figure 11.40 — Block diagram of a DSSS transmitter (A) and receiver (B).** For BPSK modulation, the modulation has the same format as the bipolar data ( $\pm 1$ ), so the modulator and demodulator could be moved to the other side of the multiplier if desired.

### 11.8.2 Direct Sequence Spread Spectrum

Whereas an FHSS system hops through a pseudo-random sequence of frequencies to spread the signal, a *direct-sequence spread spectrum* (DSSS) system applies the pseudo-random sequence directly to the data in order to spread the signal. See **Figure 11.40**. The binary data is considered to be in *polar* form, that is, the two possible states of each bit are represented by  $-1$  and  $+1$ . The data bits are multiplied by a higher-bit-rate pseudo-random sequence, also in polar form, which

### 11.8.3 Code-Division Multiple-Access (CDMA)

As mentioned before, to receive an SS signal, the de-spreading sequence in the receiver must match the spreading sequence in the transmitter. The term *orthogonal* refers to two sequences that are coded in such a way that they are completely uncorrelated. The receiver's response to an orthogonal

**Figure 11.41** — (A) The frequency spectrum of an actual unfiltered biphas-modulated spread spectrum signal as viewed on a spectrum analyzer. In this practical system, band-pass filtering is used to confine the spread spectrum signal to the amateur band. (B) At the receiver end of the line, the filtered spread spectrum signal is apparent only as a 10-dB hump in the noise floor. (C) The signal at the output of the receiver de-spreader. The original carrier — and any modulation components that accompany it — has been recovered. The peak carrier is about 45 dB above the noise floor — more than 30 dB above the hump shown at B. (These spectrograms were made at a sweep rate of 0.1 s/division and an analyzer bandwidth of 30 kHz; the horizontal scale is 1 MHz/division.)

code is the same as to random noise, that is, it is suppressed by a factor equal to the processing gain. One can take advantage of this property to allow multiple SS stations to access the same frequency simultaneously, a technique known as *code-division multiple access* (CDMA). Each transmitter is assigned a different orthogonal code. A receiver can “tune in” any transmitter’s signal by selecting the correct code for de-spreading.

If multiple stations want to be able to transmit simultaneously without using spread spectrum, they must resort to either

*frequency-division multiple access* (FDMA), where each station transmits on a different frequency channel, or *time-division multiple access* (TDMA), where each transmission is broken up into short time slots which are interleaved with the time slots of the other stations. Compared to TDMA, CDMA has the advantage that it does not require an external synchronization network to make sure that different stations’ time slots do not overlap. Compared to both TDMA and FDMA, CDMA has the further advantage

that it experiences a gradual degradation in performance as the number of stations on the channel increases. It is relatively easy to add new users to the system. Also CDMA has inherent resistance to interference due to multi-path propagation or intentional jamming. The primary disadvantages of CDMA are the relative complexity and the necessity for accurate power-level control to make sure that unwanted signals do not exceed the level that can be rejected through processing gain.

## 11.9 Pulse Modulation

Another type of digital amplitude modulation comes under the general category of *pulse modulation*. The RF signal is broken up into a series of pulses, which are usually equally-spaced in time and separated by periods of no signal. We will discuss three types of pulse modulation, PAM, PWM and PPM.

*Pulse-amplitude modulation* (PAM) consists of a series of pulses of varying amplitude that correspond directly to the amplitude of the modulating signal. See **Figure 11.42B**. The pulses can be positive or negative, depending on the polarity of the signal. The modulating signal can be recovered simply by low-pass filtering the pulse train. The effect of the negative pulses is to reverse the polarity of the RF signal. The result is very similar to a double-

sideband, suppressed-carrier signal that is rapidly turned on and off at the pulse rate of the PAM. In other words, the DSBSC signal is periodically sampled at a certain pulse repetition rate.

For the signal to be properly represented, its highest modulating frequency must be less than the *Nyquist frequency*, which is one-half the sample rate. That condition, known as the *Nyquist criterion*, applies not only to PAM but to any digital modulation technique.

There are two variations of PAM that should be mentioned. *Natural sampling* does not hold the amplitude of each pulse constant throughout the pulse as shown in **Figure 11.42B**, but rather follows the shape of the analog modulation. The *single-polarity method* adds a fixed offset, or pedestal, to the modulating signal before the PAM modulator.

As long as the pedestal is greater than or equal to the peak negative modulation, then the RF phase never changes and the signal is equivalent to sampled full-carrier AM rather than DSB-SC.

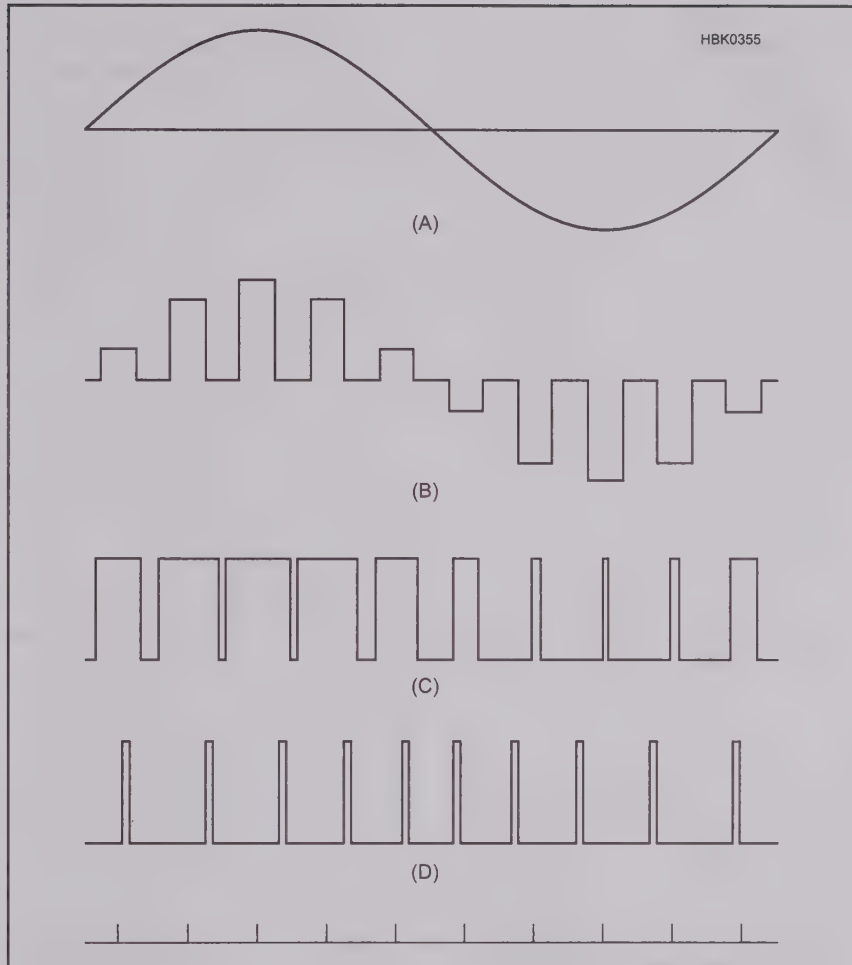

PAM is rarely used on the amateur bands because it increases the transmitted bandwidth and adds circuit complexity with no improvement in signal-to-noise ratio for most types of noise and interference. The concept is useful, however, because PAM is similar to the signal generated by the sample-and-hold circuit that is used at the input to an analog-to-digital converter (ADC). An ADC is used in virtually every digital transmitter to convert the analog voice signal to a digital signal suitable for digital signal processing.

*Pulse-width modulation* (PWM) is a series of pulses whose width varies in proportion

to the amplitude of the modulating signal. Figure 11.42C shows the pulses centered on the sample times, but in some systems the sample times may correspond to the leading or trailing pulse edges. With either method, the modulating signal can be recovered by low-pass filtering the pulse train and passing it through a coupling capacitor to remove the dc component.

*Pulse-position modulation (PPM)*, Figure 11.42D, varies the position, or phase, of the pulses in proportion to the amplitude of the modulating signal. With both PWM and PPM, the peak amplitude of the signal is constant. That allows the receiver to be designed to be insensitive to amplitude variations, which can result in a better post-detection signal-to-noise ratio, in a manner similar to analog angle modulation.

**Figure 11.42 — Three types of pulse-code modulation. A sine-wave modulating signal (A) is shown at the top. Pulse-amplitude modulation (B) varies the amplitude of the pulses, pulse-width modulation (C) varies the pulse width, and pulse-position modulation (D) varies the pulse position, proportional to the modulating signal. The tic marks show the nominal pulse times. The RF signal is created by an AM modulator using (B), (C) or (D) as the modulating signal.**

## 11.10 Modulation Bandwidth and Impairments

Most of the previous discussion of the various modulation types has assumed the modulation is perfect. With analog modulation, that means the audio or video modulating signal is perfectly reproduced in the RF waveform without distortion, spurious frequencies or other unwanted artifacts. With digital modulation, the symbol timing and the locations and trajectories in the I/Q constellation are perfectly accurate. In all cases, the RF power amplifier is perfectly linear, if so required by the modulation type, and it introduces no noise or other spurious signals close to the carrier frequency.

In the real world, of course, such perfection can never be achieved. Some modulation impairments are caused by the transmitting system, some by the transmission medium through which the signal propagates, and some in the receiving system. This section will concentrate on impairments caused by

the circuitry in the transmitter and, to some extent, in the receiver. Signal impairments due to propagation are covered in detail in the **Propagation of Radio Signals** chapter.

### 11.10.1 Filtering and Bandwidth of Digital Signals

We have already touched on this topic in previous sections, but let us now cover it a little more systematically. The bandwidth required by a digital signal depends on the filtering of the modulation, the symbol rate and the type of modulation. For linear modulation types such as OOK, BPSK, QPSK and QAM, the bandwidth depends only on the symbol rate and the modulation filter.

As an example, an unfiltered BPSK modulating signal with alternating ones and zeroes for data (10101010...) is a square wave at one-half the symbol rate. Like any square

wave, its spectrum can be broken down into a series of sine waves at the fundamental frequency (symbol rate / 2) and all the odd harmonics. If the data consists of alternating pairs of ones and pairs of zeroes (11001100...) then we have a square wave at one-fourth the symbol rate and the spectrum is a series of sine waves at one-fourth the symbol rate and all its odd harmonics. Random data contains energy at all frequencies from zero to half the symbol rate and all the odd harmonics of those frequencies. The harmonics are not needed for proper demodulation of the signal, so they can be filtered out with a low-pass filter with a cutoff frequency of one-half the symbol rate.

With random data, the shape of the unfiltered spectrum is a sinc function,

$$\text{sinc}(f / f_s) = \frac{\sin(\pi f / f_s)}{\pi f / f_s}$$

where  $f_s$  is the symbol rate. See **Figure 11.43**. Note that the response is zero (minus infinity dB) whenever  $f$  is an integer multiple of the symbol rate. That is why multi-carrier modulation generally uses a carrier spacing equal to the symbol rate.

The previous discussion applies to the baseband signal, before it modulates the RF carrier. BPSK is a double-sideband-type modulation so the baseband spectrum appears above and below the RF carrier frequency, doubling the bandwidth to  $2 \times (\text{symbol rate} / 2) = \text{symbol rate}$ . In reality, since no practical filter has an infinitely-sharp cutoff, the occupied bandwidth of a BPSK signal must be somewhat greater than the symbol rate. That is also true for all other double-sideband linear modulation types, such as OOK and the various forms of QPSK and QAM.

If the low-pass filtering is not done

**Figure 11.43** — The sinc function, which is the spectrum of an unfiltered BPSK modulating signal with random data, plotted with a linear vertical scale. The center (zero) point corresponds to the RF carrier frequency. To see what the double-sided RF spectrum looks like on a logarithmic (dB) scale, see **Figure 11.41A**.

**Figure 11.44** — Amplitude versus frequency for a 0.5-alpha, raised-cosine filter. The vertical scale is linear, not logarithmic as would be seen on a spectrum analyzer. The amplitude is 0.5 (-6 dB) at the cutoff frequency,  $F_c$ . The amplitude is 1.0 for frequencies less than  $F_c \times (1 - \alpha)$  and is 0.0 for frequencies above  $F_c \times (1 + \alpha)$ .

properly, it may slow down the transition between symbols to the point where one symbol starts to run into another, causing *inter-symbol interference* (ISI). A type of filter that avoids that problem is called a *Nyquist filter*. It ensures that each symbol's contribution to the modulating signal passes through zero at the center of all other symbols, so that no ISI occurs. The most common type of Nyquist filter is the *raised-cosine* filter, so-called because the frequency response (plotted on a linear scale) in the passband-to-stopband transition region follows a raised-cosine curve. See **Figure 11.44**. The sharpness of the frequency cutoff is specified by a parameter called *alpha*. If alpha is 1.0, then the transition from passband to stopband is very gradual — it starts to roll off right at zero hertz and finally reaches zero response at two times the nominal cutoff frequency. An alpha of 0.0 specifies an ideal “brick-wall” filter that transitions instantaneously from full response to zero right at the cutoff frequency. Values in the range of 0.3 to 0.5 are common in communications systems.

Unfortunately, if any additional filter is placed before or after the Nyquist filter it destroys the anti-ISI property. In order to allow filtering in both the transmitter and the receiver many systems effectively place half the Nyquist filter in each place. Because the frequency response of each filter is the square root of the response of a Nyquist filter, they are called *root-Nyquist* filters. The *root-raised-cosine* filter is an example. While a Nyquist or root-Nyquist response theoretically could be approximated with an analog filter, they are almost always implemented as digital filters. More information on digital filters appears in the **DSP and SDR Fundamentals** and the **Analog and Digital Filtering** chapters.

As mentioned before, filtering is more difficult with angle modulation because it is nonlinear. The RF spectrum is not a linear transposition of the baseband spectrum as it is with linear modes and Nyquist filtering doesn't work. Old-fashioned RTTY transmitters traditionally just used an R-C low-pass filter to slow down the transitions between mark and space. While that does not limit the bandwidth to the minimum value possible, the baud rate is low enough that the resulting bandwidth is acceptable anyway. In more modern systems, there is a tradeoff between making the filter bandwidth as narrow as possible for interference reduction and widening the bandwidth to reduce inter-symbol interference. For example, the GSM (Global System for Mobile communications) standard, used for some cellular telephone systems, uses minimum-shift keying and a Gaussian filter with a BT (bandwidth-symbol-time product) of 0.3. A 0.3 Gaussian filter has a 0.3 ratio of 3-dB bandwidth to baud rate, which results in a small but acceptable

amount of ISI and a moderate amount of adjacent-channel interference.

## CHANNEL CAPACITY

It is possible to increase the quantity of error-free data that can be transmitted over a communications channel by using an error-correcting code. That involves adding additional error-correction bits to the transmitted data. The more bits that are added, the greater the errors that can be corrected. However, the extra bits increase the data rate, which requires additional bandwidth, which increases the amount of noise. For that reason, as you add more and more error-correction bits, requiring more and more bandwidth, you eventually reach a point of limited additional return. In the 1940s, Claude Shannon worked out a formula (called the *Shannon-Hartley theorem*) for the maximum capacity possible over a communications channel, assuming a theoretically-perfect error-correction code:

$$C = B \log_2 \left( 1 + \frac{S}{N} \right) \text{ bit / s}$$

where

$C$  = the net channel capacity, not including error-correcting bits,

$B$  = the bandwidth in Hz, and

$S/N$  = the signal-to-noise ratio, expressed as a power ratio.

Note that as  $B$  increases,  $N$  increases in the same proportion. **Figure 11.45** is a plot of channel capacity versus bandwidth based on the formula. As bandwidth is increased, channel capacity increases rapidly until the point where the  $S/N$  ratio drops to unity (labeled Bandwidth = 1 in the graph) after which channel capacity increases much more slowly.

### 11.10.2 Intermodulation Distortion

To minimize distortion of the modulation, each stage in the signal chain must be linear,

**Figure 11.45** — Plot of channel capacity versus bandwidth, calculated by the Shannon-Hartley theorem. The  $S/N$  ratio has been selected to be unity at Bandwidth = 1.

from the microphone or modem, through all the intermediate amplifiers and processors, to the modulator itself. For the linear modulation types, all the amplifiers and other stages between the modulator and the antenna must be linear as well.

If the modulation consists of a single sine wave, then nonlinearity causes only harmonic distortion, which produces new frequencies at integer multiples of the sine-wave frequency. If multiple frequencies are present in the modulation, however, then *intermodulation distortion* (IMD) products are produced. IMD occurs when a nonlinear amplifier or other device acts as a mixer, producing sum and difference frequencies of all the pairs of frequencies and their harmonics. For example if two frequencies,  $F_1$  and  $F_2 > F_1$ , are present, then IMD will cause spurious frequencies to appear at  $F_1 + F_2$ ,  $F_2 - F_1$ ,  $2F_1$ ,  $2F_2$ ,  $2F_1 - F_2$ ,  $2F_2 - F_1$ ,  $2F_2 - 2F_1$ ,  $3F_1$ ,  $3F_2$ , and so on. *Odd-order* products are those that include the original frequencies an odd number of times, such as  $3F_1$ ,  $2F_1 + F_2$ ,  $3F_1 - 2F_2$ , and so on. *Even-order* products contain an even number of the original frequencies, such as  $2F_2$ ,  $F_1 + F_2$ ,  $3F_1 + F_2$ , and so on. If more than two frequencies are present in the undistorted modulation, then the number of unwanted frequencies increases exponentially.

Although intermodulation distortion that occurs before modulation is fundamentally the same as IMD that occurs after the modulator (at the intermediate or radio frequency), the effects are quite different. Consider two frequency components of a modulating signal at, for example, 1000 Hz and 1200 Hz that modulate an SSB transmitter tuned to 14.000 MHz, USB. The desired RF signal has components at 14.001 and 14.002 MHz. If the IMD occurs before modulation, then the  $F_1 + F_2$  distortion product occurs at  $1000 + 1200 = 2200$  Hz. Since that is well within the audio passband of the SSB transmitter, there is no way to filter it out so it shows up at 14.0022 MHz at the RF output. However, if the distortion had occurred after the modulator, the  $F_1 + F_2$  product would be at  $14.001 + 14.002 = 28.0022$  MHz which is easily filtered out by the transmitter's low-pass filter.

That explains why RF speech processors work better than audio processors. A speech processor clips or limits the peak amplitude of the modulating signal to prevent over-modulation in the transmitter. However, the limiting process typically produces considerable intermodulation distortion. If the limiter is located after the modulator rather than before it, then it is an RF signal being clipped, rather than audio. If the RF limiter is followed by a band-pass filter then many of the distortion products are removed, resulting in a less-distorted signal.

If the distortion is perfectly symmetrical

(for example equal clipping of positive and negative peaks) then only odd-order products are produced. Most distortion is not symmetrical so that both even and odd-order products appear. However, the odd-order products are of particular interest when measuring the linearity of an RF power amplifier. The reason is that even-order products that occur after the modulator occur only near harmonics of the RF frequency where they are easy to filter out. Odd-order products can fall within the desired channel, where they cause distortion of the modulation, or at nearby frequencies, where they cause interference to other stations.

The informal term for such IMD that interferes with other stations outside the desired channel is *splatter*. It becomes severe if the linear amplifier is over-driven, which causes clipping of the modulation envelope with the resulting odd-order IMD products.

The method commonly used to test the linearity of an SSB transmitter or RF power amplifier is the *two-tone test*. Two equal amplitude audio-frequency tones are fed into the microphone input, the transmitter and/or amplifier is adjusted for the desired power level, and the output signal is observed on a spectrum analyzer. See Figure 11.46. If the modulating tones are  $F_1$  and  $F_2$ , the third-order IMD products closest to the modulation sidebands have frequencies of  $2F_1 - F_2$  and  $2F_2 - F_1$ . The difference in frequency between the third-order IMD products is  $3(F_1 - F_2)$ . Similarly, the fifth-order IMD products occur at  $3F_1 - 2F_2$  and  $3F_2 - 2F_1$ , so they are spaced at  $5(F_1 - F_2)$ . As in the

figure, if  $F_1$  and  $F_2$  are 1 kHz apart, the two third-order products are 1 kHz above the upper modulation sideband and 1 kHz below the lower sideband. That is a spacing of  $3 \times 1 \text{ kHz} = 3 \text{ kHz}$ . The fifth-order products are twice the tone spacing (2 kHz) from the modulation sidebands for a product-to-product spacing of  $2 + 1 + 2 \text{ kHz} = 5 \text{ kHz}$ .

### 11.10.3 Transmitted Bandwidth

We have already discussed the necessary bandwidth for each of the various modulation types. The previous section explained how intermodulation distortion is one phenomenon that can cause unwanted emissions outside of the desired communications channel. Another is failing to properly low-pass filter the modulating signal to the minimum necessary bandwidth. That is especially a concern for linear modulation modes such as SSB, AM, OOK (CW), BPSK and QAM. For angle-modulated modes like FM and FSK, excessive bandwidth can result from simply setting the deviation too high.

There are other modulation impairments that cause emissions outside the desired bandwidth. For example, in an SSB transmitter, if the unwanted sideband is not sufficiently suppressed, the occupied bandwidth is up to twice as large as it should be. Also, an excessively strong suppressed carrier causes particularly annoying heterodyne interference to stations tuned near that frequency. In some SSB modulators, there is an adjustment provided to optimize carrier suppression.

The carrier suppression may be degraded by a modulating signal that is too low in amplitude. For example, if the signal from the microphone to an SSB transmitter is one-tenth (-20 dB) of the proper amplitude, and if the gain of the RF amplifier stages is increased to compensate, then the carrier suppression is degraded by 20 dB.

The term *adjacent-channel power* (ACP) refers to the amount of transmitted power that falls into an adjacent communications channel above or below the desired channel. Normally the unwanted out-of channel power is worse for the immediately-adjacent channels than for those that are two channels away, the so-called *alternate* channels. ACP is normally specified as a power ratio in dB. It is measured with a spectrum analyzer that can measure the total power within the desired channel and the total power in an adjacent channel, so that the dB difference can be calculated.

The *occupied bandwidth* is the bandwidth within which a specified percentage of the total power occurs. A common percentage used is 99%. For a properly-adjusted, low-distortion transmitting system, the occupied

**Figure 11.46 — Intermodulation (IMD) products from an SSB transmitter modulated by a pair of audio tones (see text). The two signals at the center are the desired modulation sidebands. The frequencies of the third-order IMD products are separated from the frequencies of the desired sidebands by the tone spacing (1 kHz) and from each other by three times the tone spacing (3 kHz). The fifth-order products are separated from the third-order products by twice the tone spacing (2 kHz) and from each other by five times the tone spacing (5 kHz).**

bandwidth is determined mainly by the modulation type and filtering and, in the case of digital modulation, the symbol rate. For example, the IS-54 TDMA format that has been used in some US digital cellular networks has about 30 kHz occupied bandwidth using 24.3-kilosymbols/sec,  $\pi/4$ -DQPSK modulation with a 0.35-alpha root-raised-cosine filter. The GSM cellular standard requires about a 350-kHz occupied bandwidth for its 270.833-kilosymbols/sec, 0.3 Gaussian-filtered MSK signal.

#### 11.10.4 Modulation Accuracy

For analog modes, modulation accuracy is mainly a question of maintaining the proper frequency response across the desired bandwidth with minimal distortion and unwanted signal artifacts. In-band artifacts like noise and spurious signals should not be a problem with any reasonably-well-designed system. Maintaining modulation peaks near 100% for AM signals or the proper deviation for FM signals is facilitated by an audio compressor. It can be either the type that uses a detector and an automatic-gain-control feedback loop to vary the gain in the modulation path or a clipper-type compressor that limits the peak amplitude and then filters the clipped signal to remove the harmonics and intermodulation products that result. SSB transmitters can also use audio speech compression to maintain the proper peak power level although, as explained previously, clipping of the signal before it reaches the modulator can cause unacceptable distortion unless special techniques are used.

For digital signals, there are a number of other possible sources of modulation inaccuracy. For modes that use Nyquist filtering, the cutoff frequency and filter shape must be accurate to ensure no inter-symbol interference (ISI). Fortunately, that is easy to do with digital filters. However any additional filtering in the signal path can degrade the ISI. For example, most HF digital modes use an analog SSB transceiver to up-convert the signal from audio to RF for transmission and to down-convert from RF to audio again at the receiver end. The crystal filters used in the transmitter and receiver can significantly degrade group delay flatness, especially near the edges of the filter passband. That is why most HF digital modes use a bandwidth substantially less than a typical transceiver's passband and attempt to center the signal near the crystal filters' center frequency.

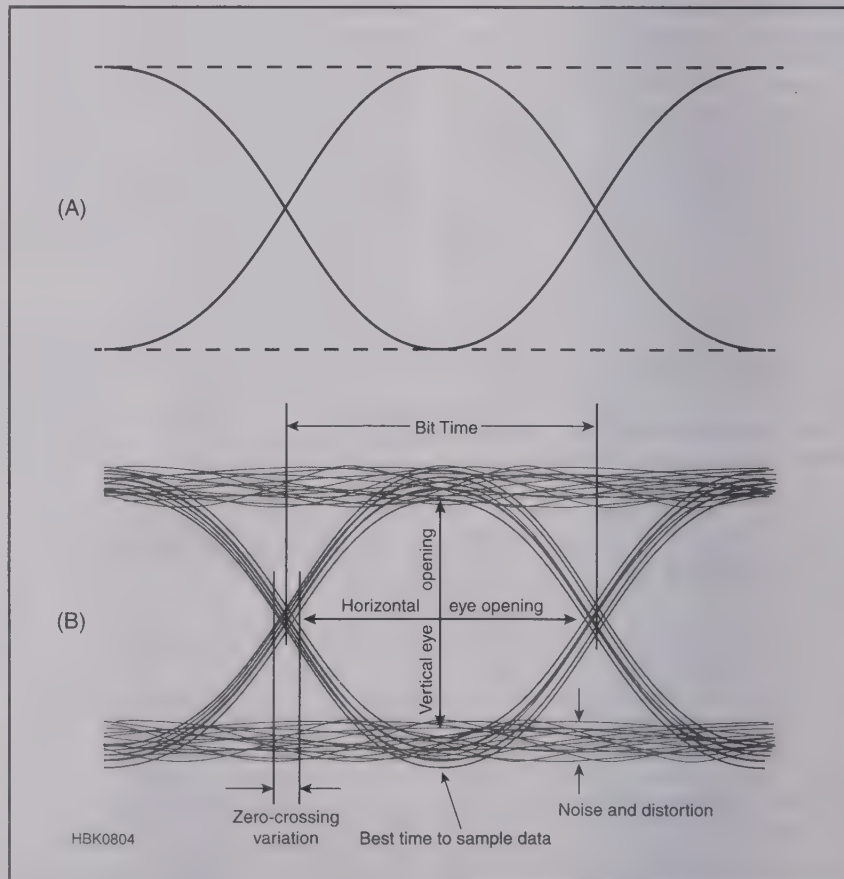

Distortion can also impair the proper decoding of digital signals, especially formats with closely-spaced symbols such as 256-QAM. Any "flat-topping" in the final amplifier causes the symbols at the outermost corners of the constellation to be closer together than they should be. The

**Figure 11.47 — Simulated I/Q constellation display of the trajectory of a QPSK signal over an extended period. A 0.5-alpha raised-cosine filter was used. Because it is a Nyquist filter, the trajectories pass exactly through each symbol location.**

accuracy of the symbol clock is critical in formats like JT65 that integrate the detection process over a large number of symbols. Perhaps surprisingly, the clock rate on some inexpensive computer sound cards can be off on the order of a percent, which results in a similar error in symbol rate.

The modulation accuracy of an FSK signal is normally characterized by the frequency shift at the center of each symbol time, the point at which the receiver usually makes the decision of which symbol is being received. For other digital formats, the modulation accuracy is normally characterized by the amplitude and phase at the symbol decision points. Amplitude error is typically measured as a percentage of the largest symbol amplitude. The phase error is quoted in degrees. In both cases one can specify either the average RMS value or the peak error that was detected over the measurement period. Amplitude error is the most important consideration for modulation types such as BPSK where the information is encoded as an amplitude. For

**Figure 11.48 — The eye diagram is an oscilloscope-style diagram showing repeated samples of the digital signal as it transitions between points in the constellation. The eye diagram at A is for a perfect, undistorted signal. The eye diagram in B shows a signal with noise, distortion, and timing variations.**

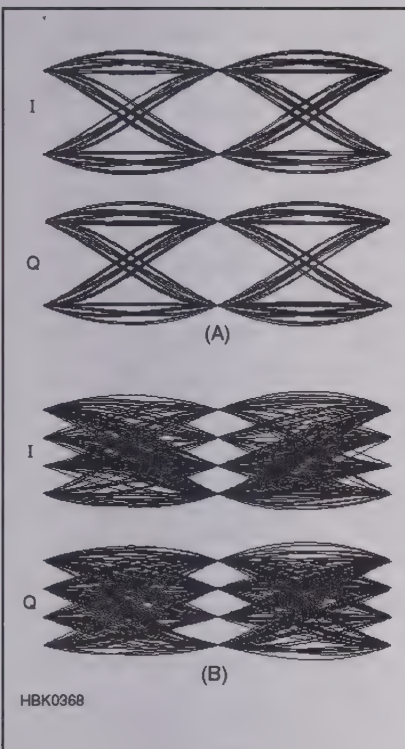

Figure 11.49 — Eye diagrams of the I and Q outputs of a QPSK generator (A) and a 16-QAM generator (B). The “eye” is the empty area between the symbol decision points, visible as the points where all the symbol trajectories come together. The bigger the “eye” the easier the signal is to decode.

a constant-envelope format like MSK, phase error is a more important metric.

For formats like QPSK and QAM, both amplitude and phase are important in determining symbol location. A measurement that includes both is called *error vector magnitude* (EVM). It is the RMS average distance between the ideal symbol location in the constellation diagram and the actual signal value at the symbol decision point, expressed as a percentage of either the RMS signal power or the maximum symbol amplitude. This is a measurement that requires specialized test equipment not generally available to home experimenters. However it is possible to estimate the effect on EVM of various design choices using computer simulations.

Previously, we have plotted constellation diagrams with the transitions between symbol locations indicated by straight lines. In an actual system, both the I and Q signals are low-pass filtered which makes the symbol transitions smoother, with no abrupt changes of direction at the symbol locations. Figure 11.47 shows the actual symbol trajectories for a QPSK signal using a 0.5-alpha raised-cosine filter with random data. Since a raised-cosine is a type of Nyquist filter, the trajectories pass exactly through each symbol location. This is what you would see if you connected the I and Q outputs from a QPSK baseband generator to the X (horizontal) and Y (vertical) inputs of an oscilloscope. It is also what you would see in a receiver at the input to the symbol detector after the carrier and clock-recovery circuits have stabilized the signal. If the symbol trajectories were not accurate, then the dark areas at the symbol points would be less distinct and more spread

out. Such a constellation diagram is also a good troubleshooting tool for other purposes, for example to check for amplitude distortion or to see if a faulty symbol encoder is missing some symbols or placing them at the wrong location.

In a system where a root-Nyquist filter is used in both the transmitter and receiver to obtain a net Nyquist response, the transmitter output will not display sharply defined symbol locations as in the figure. In that case, the measuring instrument must supply the missing root-Nyquist filter that is normally in the receiver, in order to obtain a clean display. Professional modulation analyzers normally include a means of selecting the proper matching filter.

Another way to view modulation accuracy is with an *eye diagram*. See Figures 11.48 and 11.49. In this case the oscilloscope’s horizontal axis is driven by its internal sweep generator, triggered by the symbol clock. The two vertical channels of the oscilloscope are connected to the I and Q outputs of the baseband generator. The “eye” is the empty area at the center of the I and Q traces in between the symbol decision points, where all the traces come together. The eye should be as “open” as possible to make the job of the receiver’s symbol decoder as easy as possible. The oscilloscope would typically be set for infinite persistence, so that the worst-case excursions from the ideal symbol trajectory are recorded. QPSK has four symbol locations, one in each quadrant, such that I and Q each only have two possible values and there is only one “eye” for each. 16-QAM has 16 symbol locations with four possible locations for I and Q, which forms three “eyes.”

# 11.11 Modulation Glossary

## GENERAL

**AM** — Amplitude modulation.

**Angle modulation** — Modulation of an RF carrier by varying the phase or frequency.

**Emission designator** — Official ITU code to specify the bandwidth and modulation type of a radio transmission.

**Frequency diversity** — The use of a wideband signal to compensate for selective fading. While one band of frequencies is faded, the data can be reconstructed from other frequencies that are not faded.

**FM** — Frequency modulation.

**IMD** — Intermodulation distortion. Unwanted frequencies that occur at the sum and difference of the desired frequencies and their harmonics.

**ITU** — International Telecommunications Union. An agency of the United Nations that coordinates and recommends technical standards for electronic communications.

**Modulation** — The periodic alteration of some parameter of a carrier wave in order to transmit information.

**PM** — Phase modulation.

**Protocol** — A formal set of rules and procedures for the exchange of information within a communications network.

**Selective fading** — A propagation phenomenon in which closely-spaced frequencies experience markedly different fading at the same time.

**Telemetry** — The use of telecommunication for automatically indicating or recording measurements at a distance from the measuring instrument.

**Telephony** — A form of telecommunication primarily intended for the exchange of information in the form of speech.

**Telegraphy** — A form of telecommunication in which the transmitted information is intended to be recorded on arrival as a graphic document; the transmitted information may sometimes be presented in an alternative form or may be stored for subsequent use.

**Television** — A form of telecommunication for the transmission of transient images of fixed or moving objects.

## AMPLITUDE AND ANGLE MODULATION (INCLUDING IMAGE)

**ATV** — Amateur fast-scan television.

**BFO** — Beat frequency oscillator.

In an SSB or DSBSC receiver, the intermediate-frequency oscillator in the receiver that re-inserts the suppressed carrier.

**Carson's rule** — A rule of thumb to calculate FM bandwidth that says that 98% of the energy is typically contained within a bandwidth equal to two times the sum of the peak frequency deviation and the highest modulating frequency.

**Capture effect** — The tendency of the strongest signal to suppress other signals in an FM detector, which improves the signal-to-noise and signal-to-interference ratio.

**Deviation ratio** — The ratio of the maximum permitted peak deviation of an angle-modulated signal to the maximum permitted modulating frequency.

**DSB-SC** — Double sideband, suppressed carrier. An AM signal in which the carrier has been removed but both sidebands remain.

**Frame** — In television, one complete scanned image. On systems with interlaced scanning, there are two vertical scans per frame.

**Frequency deviation** — The amount the RF frequency of an angle-modulated signal deviates from the center (carrier) frequency in response to the modulating signal. The term is often understood to mean the maximum deviation available in a given system.

**Limitter** — A high-gain amplifier in an FM receiver that limits the peak amplitude of the signal in order to eliminate any AM component.

**LSB** — Lower sideband. An SSB signal with the upper sideband removed.

**Martin** — A series of analog SSTV formats, especially popular in Europe.

**Modulation index (AM)** — The ratio of the peak value of the modulation of an AM signal to the value that just causes the modulation envelope of the RF signal to reach zero on negative peaks and twice the average value on positive peaks.

**Modulation index (FM)** — The ratio of the peak deviation of an angle-modulated signal to the highest modulating frequency.

**Narrowband FM** — An FM signal with a modulation index less than or equal to 1.0.

**NTSC** — National Television System Committee. The analog television standard used in the US, Japan and several other countries.

**PAL** — Phase alteration line. The analog television standard used in many parts of Europe.

**Phasing method** — A method of generating an SSBSC signal that does not require a filter to remove the unwanted sideband.

**Pixel** — Picture element. The dots that make up images on a computer's monitor.

**Product detector** — A detector that multiplies a BFO signal with the received signal, typically SSB or DSBSC-modulated.

**RGB** — Red, green and blue. The three primary colors required to transmit a full-color image in many television and facsimile systems.

**Scottie** — A series of analog SSTV formats, especially popular in the US.

**SSB** — Single sideband. An AM signal in which one sideband has been removed. The term is usually understood to mean SSBSC.

**SSB-SC** — Single sideband, suppressed carrier. An AM signal in which one sideband and the carrier have been removed.

**SSTV** — Slow scan TV, a system for sending and receiving still images.

**Sync** — Modulation pulses used in ATV and SSTV to synchronize the horizontal and/or vertical scanning.

**Synchronous detector** — A type of AM detector in which the carrier is regenerated in the receiver.

**Two-tone test** — A procedure for testing the IMD of an SSB transmitter. Two equal-amplitude tones are fed to the microphone input and the transmitter RF output is examined with a spectrum analyzer to determine the amplitudes of the IMD products.

**USB** — Upper sideband. An SSB signal with the lower sideband removed.

**Vestigial sideband** — The filtering of all but the bottom MHz or so of the lower sideband of an ATV or NTSC television signal.

**VIS** — Vertical interval signaling. Digital encoding of the transmission mode during the vertical sync interval of an SSTV frame.

**Wideband FM** — An FM signal with a modulation index greater than 1.0.

## DIGITAL MODULATION

**AFSK** — Audio FSK. The use of an SSB transceiver to transmit and receive FSK using an audio-frequency modem.

- ASK** — Amplitude-shift keying. Digital amplitude modulation in which the amplitude depends on the modulating code.
- Baud** — The rate at which a digital signal transitions between symbol states. Symbol rate. Symbols per second. Unit of symbol rate.
- Bit rate** — The total number of physically transferred bits per second over a communication link. Bit rate can be used interchangeably with **baud rate** only when each modulation transition carries exactly one bit of data.
- BPSK** — Binary PSK. PSK with only two possible states. The term is usually understood to mean a non-constant-envelope signal in which the two states differ by 180°.
- Chirp** — Incidental frequency modulation of a carrier as a result of oscillator instability during keying.
- CW** — Continuous wave. The term used for on-off keying using Morse code.
- Constellation diagram** — A diagram showing the constellation of possible symbol locations on a polar plot of modulation amplitude and phase.
- DBPSK** — Differential BPSK.
- Decision point** — The point, typically in the center of a symbol time, at which the receiver decides which symbol is being sent.
- Differential modulation** — A modulation technique that encodes the information in the difference between subsequent symbols, rather than in the symbols themselves.
- Equalization** — Correction for variations in amplitude and/or phase versus frequency across a communications channel.
- DQPSK** — Differential QPSK.
- Eye diagram** — An oscilloscope measurement of a digital modulating signal with the horizontal sweep synchronized to the symbol times. With Nyquist filtering, there should be a clear separation, or “eye”, in the trajectories at the symbol decision points.
- EVM** — Error vector magnitude. A measure of the RMS error in the symbol locations at the symbol decision points in the constellation plot of a digital signal.
- FFT** — Fast Fourier transform. The Fourier transform is a mathematical function that calculates the frequency spectrum of a signal. The FFT is a software algorithm that does the calculations very efficiently.
- FSK** — Frequency-shift keying. A form of digital frequency modulation in which the frequency deviation depends on the modulating data.
- GMSK** — Gaussian MSK. MSK with a Gaussian modulation filter.
- I/Q modulation** — Quadrature modulation implemented with an I/Q modulator, one that uses in-phase (I) and quadrature (Q) modulating signals to generate the zero-degree and 90° components of the RF signal.
- ISI** — Inter-symbol interference. Interference of a signal with itself, caused when energy from one symbol is delayed long enough to interfere with a subsequent symbol.
- MFSK** — Multi-level FSK. FSK with more than two states represented by different frequency deviations.
- Modem** — Modulator/demodulator. A device that generates and demodulates digital modulation signals, usually at audio frequencies. It connects between the data terminal (usually a computer) and the radio.
- MSK** — Minimum-shift keying. A form of FSK with a frequency shift equal to one-half the symbol rate.
- Nyquist criterion** — A principle that states that the sampling frequency must be greater than twice the highest frequency in the sampled signal.
- Nyquist frequency** — One-half the sampling frequency.
- OFDM** — Orthogonal frequency-division multiplexing. A transmission mode that uses multiple carriers, spaced such that modulation on each carrier is orthogonal with the others.
- OOK** — On-off keying. A type of ASK with only two states, on and off.
- OQPSK** — Offset QPSK. By offsetting in time the symbol transitions of the I and Q channels, symbol trajectories through the origin are eliminated.
- Orthogonal** — Refers to streams of data that are uncorrelated with each other such that there is no mutual interference.
- PAM** — Pulse amplitude modulation. A type of pulse modulation where the modulating signal is encoded in the pulse amplitude.
- $\pi/4$  DQPSK** — PI-over-four differential QPSK. A form of differential 8PSK in which the only allowed transitions are  $\pm 45$  and  $\pm 135^\circ$ , resulting in four allowed states per symbol.
- PPM** — Pulse position modulation. A type of pulse modulation where the modulating signal is encoded in the pulse position.
- PSK** — Phase-shift keying. A form of digital phase modulation in which the phase of the RF signal depends on the modulating code. The term often is understood to refer to BPSK.
- Pulse modulation** — The modulating signal is sampled at regular intervals to generate a series of modulation symbols in the form of pulses.
- PWM** — Pulse width modulation. A type of pulse modulation where the modulating signal is encoded in the pulse width.
- QAM** — Quadrature amplitude modulation. A digital modulation type in which both amplitude and phase are varied. The number that precedes it, for example 64QAM, is the number of different possible states of the amplitude and phase.
- QPSK** — PSK with four possible states. The term is usually understood to be equivalent to four-level QAM, in which the four states have the same amplitude and differ in phase by 90°.
- Quadrature modulation** — Refers to modulation using two RF carriers in phase quadrature, that is, 90° out of phase.
- Symbol rate** — The rate at which a digital signal transitions between different states. Baud rate.
- Varicode** — A coding method in which the length of each character code depends on its frequency of occurrence. It is used to optimize the ratio of characters per second to baud rate.

## SPREAD SPECTRUM

- CDMA** — Code-division multiple access. A method of allowing several stations to use the same frequency band simultaneously by assigning each station a different orthogonal spreading code.
- Chip** — The shortest-duration modulation state in a SS system.
- De-spreading** — Conversion of an SS signal back to its narrowband equivalent by convolving it with the spreading code.
- DSSS** — Direct-sequence SS. Spreading of a signal by multiplying the data stream by a higher-rate pseudo-random digital sequence.
- FHSS** — Frequency-hopping SS. Spreading of a signal by means of pseudo-random frequency-hopping of the unspread signal.
- Processing gain** — The increase in signal-to-noise ratio that occurs when an SS signal is de-spread.
- SS** — Spread spectrum. A system that intentionally increases the bandwidth of a digital signal by means of a special spreading code.

## FILTERING AND BANDWIDTH

- ACP** — Adjacent channel power. The amount of transmitted power that falls into a communications channel immediately adjacent to the desired one.

- Alpha** — A design parameter for a Nyquist or root Nyquist filter. The smaller the alpha, the sharper the passband-to-stopband transition at the cutoff frequency.
- Cutoff frequency** — The frequency at which a filter response changes from the passband to the stopband.
- Gaussian filter** — A modulation filter with a Gaussian frequency response. The transition between passband and stopband is more gradual than with most Nyquist filters.
- Key clicks** — Out-of-channel interference from an OOK signal caused by too-sharp transitions between the on and off states.
- Nyquist filter** — A filter that causes no inter-symbol interference (ISI). It is so-called because the cutoff frequency is at one-half the symbol rate, the Nyquist frequency.
- Nyquist criterion** — The rule that states that the sample rate must be greater than twice the highest frequency to be sampled.
- Occupied bandwidth** — The bandwidth within which a specified percentage of the total power occurs, typically 99%.
- Raised-cosine filter** — A type of Nyquist filter whose passband-to-stopband transition region has the shape of the first half-cycle of a cosine raised so that the negative peak is at zero.
- Root Nyquist filter** — A filter that, when cascaded with another identical filter, forms a Nyquist filter. The frequency response is the square root of that of the Nyquist filter.
- Root raised-cosine filter** — A root Nyquist filter with a frequency response that is the square root of a raised-cosine filter.
- Shannon-Hartley theorem** — A formula that predicts the maximum channel capacity that is theoretically possible over a channel of given bandwidth and signal-to-noise ratio.
- Sinc function** — The spectrum of a pulse or random series of pulses, equal to  $\sin(x)/x$ .
- Splatter** — Out-of-channel interference from an amplitude-modulated signal such as SSB or QPSK caused by distortion, typically in the power amplifier stages.

# Receiving

Receivers have traditionally been at the forefront of Amateur Radio technology and certainly are today, even as the long-reigning analog superheterodyne architecture is being overtaken by the digital software defined radio. While commercial designs and devices abound, receiving in the crowded amateur bands is still a demanding application with strong signals immediately adjacent to signals at the noise floor, a variety of natural and man-made interferences to reject, and modes ranging from manually sent Morse to the latest experimental modulations. Like the equipment in use today, expect this chapter to change from edition to edition as technology marches on.

In order to address these challenges, this chapter focuses on the functions of receiving and how they are implemented, whether by analog or digital technologies. Metrics of receiver performance are discussed, recognizing that digital receivers behave differently than their established analog counterparts, requiring new measurement definitions and techniques. Receiver home-brew projects from past editions have been collected into a set of projects in the downloadable supplemental information accompanying this book.

This chapter's material has been adapted and updated from or provided by a number of authors. A great deal of the receiver material was originally written by Joel Hallas, W1ZR, and the sections on mixers by Dave Newkirk, W9VES, and Rick Karlquist, N6RK. Some sections on SDR functions were adapted from "SDR: Simplified" columns in *QEX* magazine by Ray Mack, W5IFS. Material on SDR receivers, architecture, and noise reduction was contributed by Steve Hicks, N5AC, and Doug Grant, K1DG. Jim Brown, K9YC provided material on active noise canceling and diversity reception. Bob Allison, WB1GCM, ARRL Lab Staff Engineer, also contributed material on receiver testing. Additional material was taken from Chapters 10 and 11 in *Experimental Methods in RF Design* by Hayward, Campbell, and Larkin. The reader interested in the professional perspective and depth of detail is referred to the comprehensive *Communications Receivers — Principles and Design, 4th Edition* by Rohde, Whitaker, and Zahnd.

Coverage of VHF/UHF/microwave receivers from previous editions is included in the downloadable supplemental material. Coverage of this topic will be revised and updated in future editions of the *ARRL Handbook*.

The major subsystems of a radio receiving system are the antenna, the receiver and the information processor. The antenna's task is to provide a transition from an electromagnetic wave in space to an electrical signal that can be conducted on wires. The receiver has the job of retrieving the information content from a particular signal coming from the antenna and presenting it in a useful format to the processor for use.

The processor typically is an operator, but can also be an automated system. When you consider that most "processors" require signals in the range of volts (to drive an operator's speaker or headphones, or even the input of an A/D converter), and the particular signal of interest arrives from the antenna at a level of mere microvolts, the basic function of the receiver is to amplify the desired signal by a factor of a million. It must do this, while in the presence of signals many orders of magnitude greater and of completely different characteristics, without distortion of the desired signal or loss of the information it carries.

## 12.1 Characterizing Receivers

As we discuss receivers we will need to characterize their performance, and often their performance limitations, using certain key parameters. The most commonly encountered are as described in the following sections. These are often the key performance parameters, but in many cases there are others that are important to specify, as well. Examples are audio output power, power consumption, size, weight, control capabilities and so forth.

The ARRL Lab has developed an extensive set of standardized tests that it performs on transceivers in support of *QST* Product Reviews. These tests are described in the test procedure document referenced in the **Test Equipment and Measurements** chapter and in the book *Amateur Radio Transceiver Performance Testing* by ARRL Lab Staff Engineer, Bob Allison WB1GCM.

### 12.1.1 Receiver Sensitivity and Noise

*Sensitivity* is a measure of how weak a signal the receiver can extract information from. This generally is expressed at a particular signal-to-noise ratio (SNR) since noise is generally the limiting factor. A typical specification might be: "Sensitivity: 1  $\mu$ V for 10 dB SNR with 3 kHz bandwidth." The bandwidth is stated because the amount (or power) of the noise, the denominator of the SNR fraction, increases directly with bandwidth. Generally the noise

parameter refers to the noise generated within the receiver, often less than the noise that arrives with the signal from the antenna. (See the **RF Techniques** chapter for a more complete discussion of noise and noise sources.)

The sensitivity of a receiver is a measure of the lowest power input signal that can be received with a specified signal-to-noise ratio. In the early days of radio, this was a very important parameter and designers tried to achieve the maximum practical sensitivity. In recent years, device and design technology have improved to the point that other parameters may be of higher importance, particularly in the HF region and below. Sensitivity remains an issue for receiving systems at VHF and above, particular with respect to noise.

Noise level is as important as signal level in determining sensitivity. This section builds on the discussion of noise in the **RF Techniques** chapter. The most important noise parameters affecting receiver sensitivity are *noise bandwidth*, *noise figure*, *noise factor*, and *noise temperature*.

Since received noise power is directly proportional to receiver bandwidth, any specification of sensitivity must be made for a particular noise bandwidth. For DSP receivers with extremely steep filter skirts, receiver bandwidth is approximately the same as the filter or operating bandwidth. For other filter types, noise bandwidth is somewhat larger than the filter's 6 dB response bandwidth.

The relationship of noise bandwidth to noise power is one of the reasons that narrow bandwidth modes, such as CW, have a significant signal-to-noise advantage over modes with wider bandwidth, such as voice, assuming the receiver bandwidth is the minimum necessary to receive the signal. For example, compared to a 2400-Hz SSB filter bandwidth, a CW signal received in a 200 Hz bandwidth will have a  $2400/200 = 12 = 10.8$  dB advantage in received noise power. That is the same difference as an increase in transmitter from 100 to 1200 W.

## SOURCES OF NOISE

Any electrical component will generate a certain amount of noise due to random electron motion. Any gain stages after the internal noise source will amplify the noise along with the signal. Thus a receiver with no signal input source will have a certain amount of noise generated and amplified within the receiver itself.

Upon connecting an antenna to a receiver, there will be introduction of any noise external to the receiver that is on the received frequency. The usual sources and their properties are described below. **Table 12.1** presents typical levels of external noise in a 10 kHz bandwidth present in the environ-

**Table 12.1**

### Typical Noise Levels (Into the Receiver) and Their Source, by Frequency

Frequency Range	Dominant Noise Sources	Typical Level ( $\mu\text{V/m}$ )*
LF 30 to 300 kHz	atmospheric	150
MF 300 to 3000 kHz	atmospheric/man-made	70
Low HF 3 to 10 MHz	man-made/atmospheric	20
High HF 10 to 30 MHz	man-made/thermal	10
VHF 30 to 300 MHz	thermal/galactic	0.3
UHF 300 to 3000 MHz	galactic/thermal	0.2

\*The level assumes a 10 kHz bandwidth. Data from *Reference Data for Engineers*, 4th Ed, p 273, Figure 1.

ment from different sources.

**Atmospheric noise.** This is noise generated within our atmosphere due to natural phenomena. The principal cause is lightning which sends wideband signals great distances. All points on the Earth receive this noise, but it is much stronger in some regions than others depending on the amount of local lightning activity. This source is usually the strongest noise source in the LF range and may dominate well into the HF region, depending on the other noises in the region. The level of atmospheric noise tends to drop off by around 50 dB every time the frequency is increased by a factor of 10. This source usually drops in importance by the top of the HF range (30 MHz).

**Man-made noise.** This source acts in a similar manner to atmospheric noise, although it is more dependent on local activity rather than geography and weather. The sources tend to be sparks from rotating and other kinds of electrical machinery as well as gasoline engine ignition systems and some types of lighting. In recent years, noise from computing and network equipment, switch-mode power supplies, and appliances has increased significantly in urban and suburban environments. All things being equal, this source, on average, drops off by about 20 dB every time the frequency is increased by a factor of ten. The slower decrease at higher frequencies is due to the sparks having faster rise times than lightning. The effect tends to be comparable to atmospheric noise in the broadcast band, less at lower frequencies and a bit more at HF.

**Galactic Noise.** This is noise generated by the radiation from heavenly bodies outside our atmosphere. Of course, while this is noise to communicators, it is the desired signal for radio-astronomers. This noise source is a major factor at VHF and UHF and is quite dependent on exactly where you point an antenna (antennas for those ranges tend to be small and are often pointable). It also happens that the Earth turns and sometimes moves an antenna into a position where it inadvertently is aimed at a noisy area of the galaxy. If the Sun, not surprisingly the strongest signal in our solar system, appears behind a commu-

nications satellite, communications is generally disrupted until the Sun is out of the antenna's receiving pattern. Galactic noise occurs on HF, as well: Noise from the planet Jupiter can be heard on the 15 meter band under quiet conditions, for example.

**Thermal Noise.** Unlike the previous noise sources, this one comes from our equipment. All atomic structures have electrons that move within their structures. This motion results in very small currents that generate small amounts of wideband signals. While each particle's radiation is small, the cumulative effect of all particles becomes significant as the previous sources roll off with increasing frequency. The reason that this effect is called *thermal* noise is because the electron motion increases with the particle's temperature. In fact the noise strength is directly proportional to the temperature, if measured in terms of absolute zero (0 K). For example, if we increase the temperature from 270 to 280 K, that represents an increase in noise power of  $10/270 = 0.037$ , or about 0.16 dB. Some extremely sensitive microwave receivers use cryogenically-cooled front-end amplifiers to provide large reductions in thermal noise.

**Oscillator Phase Noise.** As noted in the **Oscillator and Synthesizers** chapter, real oscillators will have phase-noise sidebands that extend out on either side of the nominal carrier frequency at low amplitudes. Any such noise will be transferred to the received signal and through *reciprocal mixing* create noise products from signals on adjacent channels through the mixer. A good receiver will be designed to have phase noise that is well below the level of other internally generated noise.

## NOISE POWER AND SENSITIVITY

There are a number of related measures that can be used to specify the amount of noise that is generated within a receiver. If that noise approaches, or is within perhaps 10 dB of the amount of external noise received, then it must be carefully considered and becomes a major design parameter. If the internally generated noise is less than perhaps 10 dB below that expected from the environ-

ment, efforts to minimize internal noise are generally not beneficial and can, in some cases, be counterproductive.

While the total noise in a receiving system is, as discussed, proportional to bandwidth, the noise generating elements are generally not. Thus it is useful to be able to specify the internal noise of a system in a way that is independent of bandwidth. It is important to note that even though such a specification is useful, the actual noise is still directly proportional to bandwidth and any bandwidth beyond that needed to receive signal information will result in reduced SNR.

To evaluate the effect of noise power on sensitivity, refer to the discussion of noise in the **RF Techniques** chapter. The discussion hinges on the value of  $N_i$ , the equivalent noise power in watts at the input of a perfect receiver that would result in the same noise output.  $N_i$  is generally expressed in  $\text{dBm}_i$ :

$$\text{dBm}_i = -198.6 + (10 \times \log_{10} B) + (10 \times \log_{10} T_E)$$

where  $B$  is the system bandwidth in Hz and  $T_E$  is the equivalent noise temperature expressed in K.

If input noise ( $N_i$ ) is greater than the noise generated internally by the receiver, the receiver's sensitivity is limited by the external noise. This is usually the case for HF receivers where atmospheric and man-made noise are much stronger than the receiver's internal noise floor. If  $N_i$  is within, perhaps, 10 dB greater than the receiver's internal noise, then the effect of the receiver's internal circuits on overall system sensitivity must be taken into account. At VHF and above, noise generated by the system components begins to exceed input noise.

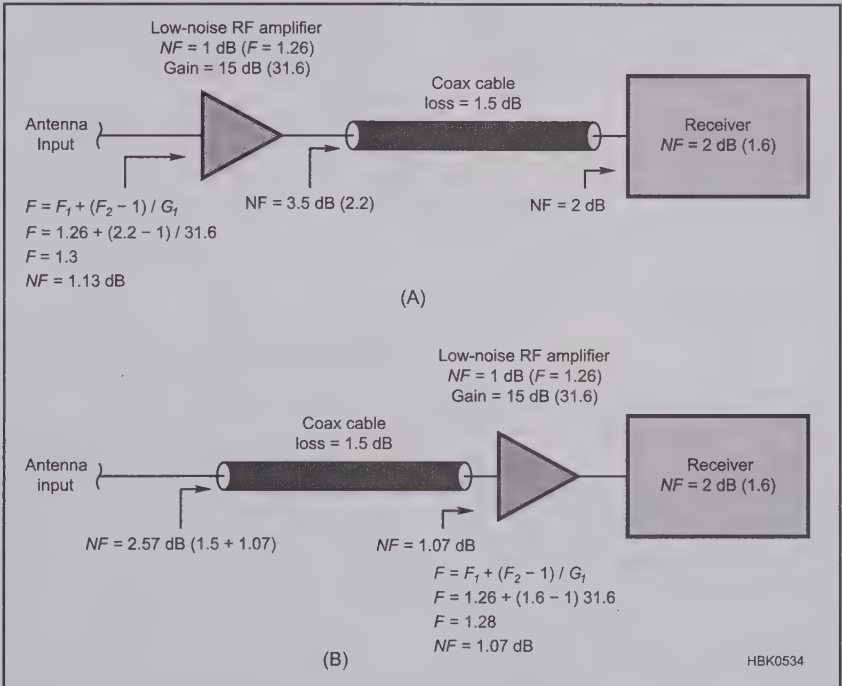

**EFFECT OF INPUT NOISE**

A receiver designer needs to know how strong the signals are to establish the range of signals the receiver will be required to handle. One may compare the equivalent noise power ( $N_i$ ) with the expected external noise to determine whether the overall receiver SNR will be determined by external or internal noise. A reasonable design objective is to have the internal noise be less than perhaps 10 to 20 dB below the expected noise. As noted above, this is related closely to the frequency of signals we want to receive. Any additional sensitivity will not provide a noticeable benefit to SNR, and may result in reduced dynamic range, as will be discussed in the next section.

For frequencies at which external noise sources are strongest, the noise power (and signal power) will also be a function of the antenna design. In such cases, the signal-to-noise ratio can be improved by using an antenna that picks up more signal and less noise, such as with a directional antenna that can reject noise from directions other than

**Figure 12.1 — The effect of adding a low-noise preamplifier ahead of a noisy receiver system.**

**Figure 12.2 — Examples comparing the effect on input NF of placing the preamplifier at different places in the antenna system. At (A), the preamplifier is ahead of the coax cable loss, resulting in an input NF of 1.13 dB. At (B), the coax loss before the preamp results in an input NF of 2.57 dB, a reduction in sensitivity.**

that of the signal. Some antennas improve SNR simply by rejecting noise, such as the Beverage antenna. Signals from a Beverage antenna are usually much weaker than from a conventional antenna but their ability to reject noise from undesired directions creates a net improvement in the SNR at the receiver output.

**MINIMUM DETECTABLE (DISCERNABLE) SIGNAL (MDS)**

Also referred to as the *noise floor* of a receiver, the MDS is the strength of the smallest input signal that produces a specified increase in the output noise power of a receiver. MDS depends on the required SNR ( $\text{SNR}_{\text{MIN}}$  in dB), the system bandwidth ( $B$  in

Hz), the temperature of the receiver ( $T_E$ ), and the receiver noise figure (NF). (Measurement of MDS is discussed in the **Test Equipment and Measurements** chapter.)

An ideal receiver at room temperature with a bandwidth of 1 Hz has a theoretical MDS of  $-174 \text{ dBm}$ . This is often referred to as the "1 Hz noise floor."

As bandwidth, noise figure, and temperature increase, so does MDS as follows:

$$\text{MDS (in dBm)} = -174 + 10 \log(B) + \text{NF} + \text{SNR}_{\text{MIN}} + 10 \log(T_E/290)$$

For example, if a receiver at room temperature has a bandwidth of 1 kHz and a noise figure of 2.5 dB, for an  $\text{SNR}_{\text{MIN}}$  of 3 dB:

## Noise Measurement Terminology

There are many ways to measure and specify noise, each with its unique name and abbreviation. Most amateurs are familiar with SNR (signal-to-noise ratio) at least in a general sense, but fewer are aware of the need to specify bandwidth and possibly temperature. Communications professionals and receiver designers use a variety of names and methods to specify noise performance. Many of these are explained in Walt Kester's excellent tutorial "Understand SINAD, ENOB, SNR, THD, THD+N, and SFDR so You Don't Get Lost in the Noise Floor" published by Analog Devices as MT-003. See the References section for the complete URL for this document.

$$\text{MDS} = -174 + 30 + 2.5 + 3 + 0 = -138.5 \text{ dBm}$$

If the receiver's equivalent temperature then increases to 300 K, the MDS also increases to:

$$\text{MDS} = -174 + 30 + 2.5 + 3 + 0.15 = -138.35 \text{ dBm}$$

Many commercial radios achieve an MDS of  $-135$  to  $-140$  dBm in a 500 Hz bandwidth — which is quite good — but at HF the external noise is much higher, making the lower MDS specification somewhat irrelevant. As frequency increases through the higher HF bands and into VHF, MDS becomes more important.

### 12.1.2 Preamplifiers and Noise

Often we are faced with the requirement of determining the noise figure of a system of multiple stages. In general adding an amplification stage between the antenna and the rest of the system will reduce the equivalent noise figure of the system by the amount of gain of the stage but adds in the noise of the added stage directly. In general, to improve system sensitivity, the preamp's internal noise must be much lower than the noise generated by the receiver. (See the discussion of Cascaded Amplifiers in the **RF Techniques chapter**.) A number of preamplifier projects are included in the downloadable supplemental information for this chapter.

In many cases elements of a receiving system exhibit loss rather than gain. Since they reduce the desired signal, while not changing the noise of following stages, they increase the noise figure at their input by an amount equal to the loss. This is the reason that a VHF *low noise amplifier* is mounted at the antenna, ahead of a noisy receiver as shown in **Figure 12.1**. As shown in the figure for fairly typical values, while the addition of a low noise amplifier does reduce the system's noise figure, as can be observed, the amplifier gain and noise figure of the rest of the receiver can make a big difference.

As an example of the difference, if the coax between the antenna and radio has a loss of 1 dB, and the preamp has a noise figure

of 1 dB, the resulting noise figure with the preamp at the radio will be 2 dB, while if at the antenna, the noise added by the coax will be reduced by the gain of the preamp, resulting in a significant improvement in received SNR at VHF and above. **Figure 12.2** shows a typical example.

Along with noise figure, the preamplifier's effect on distortion and dynamic range must be considered. As discussed in later sections of this chapter, distortion products can be generated by intermodulation from in-band and out-of-band signals. These distortion products can be considered noise and can reduce receiving system sensitivity.

System *spurious-free dynamic range* (SFDR) is the difference between MDS (see previous section) and the highest level of input signal that does not create spurious signals. Although the preamp may increase the amplitude of the desired signal, it also increases the amplitude of the unwanted distortion products even more. For this reason, spurious-free dynamic range of the receiving system can be degraded by adding a preamplifier with a limited dynamic range.

Both dynamic range and noise figure must be considered when choosing a preamp. A thorough discussion of how to evaluate and balance gain and noise figure when choosing a preamp is available in Paul Shuch, N6TX's online article "Quiet! Preamplifier at Work" ([www.setileague.org/articles/ham/preamp.pdf](http://www.setileague.org/articles/ham/preamp.pdf)) listed in the References section.

### 12.1.3 Receiver Selectivity

*Selectivity* — Selectivity is just the bandwidth discussed above. This is important because to a first estimate it identifies the receiver's ability to separate stations. With a perfect "brick wall" filter in an ideal receiver, stations within the bandwidth will be heard, while those outside it won't be detected. The selectivity thus describes how closely spaced adjacent channels can be. With a perfect 3 kHz bandwidth selectivity, and signals restricted to a 3 kHz bandwidth at the transmitter, a different station can be assigned every 3 kHz across the spectrum. In a less than ideal situation, it is usually necessary to include a *guard band* between channels.

## How Phase Noise Affects a Receiver

By Steve Hicks, N5AC

Today's receivers are generally built from one of two primary technologies: mixing or sampling. Some receivers will have components of both. In either case, an oscillator sets the frequency of the mixing or the sampling rate. Let's take a look at how phase noise from an oscillator can affect performance of our receiver, looking first at mixing.

**Figure 12.A1** has a block diagram of a typical mixer circuit. The oscillator used with a mixer is called a local oscillator (LO) and the mixing process is also known as heterodyning. Let's assume for the moment that our radio designer selected an off-the-shelf synthesizer IC to use as a local oscillator. The phase noise chart in **Figure 12.A2** represents the phase noise provided by the manufacturer of the synthesizer integrated circuit. Assuming that the phase noise in our design matches the manufacturer's data, we can use the phase noise plot to determine how phase noise will affect our receiver. Phase noise will generally change as the oscillator frequency is moved and, in the case of a synthesizer can also change with the parameters used to lock to a reference signal (An overview of PLL operation can be found in the **Oscillators and Synthesizers** chapter and in a number of good references — for example: [www.ti.com/lit/an/swra029/swra029.pdf](http://www.ti.com/lit/an/swra029/swra029.pdf) and in [www.analog.com/media/en/training-seminars/tutorials/MT-086.pdf](http://www.analog.com/media/en/training-seminars/tutorials/MT-086.pdf)). For now, let's assume this plot was taken at 14 MHz and this is where our receiver will operate.

The two numbers we will use in our example are at an offset of 2 kHz and 10 kHz. Reading the plot, we see that the 2 kHz phase noise is  $-93$  dBc/Hz and the 10 kHz phase noise is  $-96$  dBc/Hz. The measurement units of dBc/Hz indicates the noise that would be present in a 1 Hz bandwidth receiver, the number of dB below the

**Figure 12.A1** — Typical mixer block diagram.

Figure 12.A2 — Plot of phase noise versus frequency separation from the carrier.

carrier. For example,  $-93 \text{ dBc/Hz}$  indicates that the noise floor would be  $93 \text{ dB}$  below a carrier signal measured using a  $1 \text{ Hz}$  bandwidth receiver. To convert this to a  $100 \text{ Hz}$  bandwidth we might use in a CW filter we must add  $10 \log(100 \text{ Hz}/1 \text{ Hz})$  or  $20 \text{ dB}$  to our phase noise numbers. So at a  $2 \text{ kHz}$  offset from our carrier, we have  $-93 \text{ dBc} + 20 \text{ dB} = -73 \text{ dBc}$  and at  $10 \text{ kHz}$ ,  $-96 \text{ dBc} + 20 \text{ dB} = -76 \text{ dBc}$ . In a mixer, this noise will be added to all signals present in the receiver.

Looking at Figure 12.A3, we show a strong S8 CW signal at  $14.000 \text{ MHz}$ . S8 corresponds to  $-79 \text{ dBm}$  as shown in the graph. Two kilohertz away is the signal we are trying to receive, an S3 ( $-109 \text{ dBm}$ ) CW signal using a  $100 \text{ Hz}$  CW filter. Using our phase noise calculation, the S8 signal at  $-79 \text{ dBm}$  would have phase noise at a  $2 \text{ kHz}$  offset of  $-79 \text{ dBm} - 73 \text{ dB} = -152 \text{ dBm}$ . This is well below our atmospheric noise floor and will not interfere with our ability to listen to the signal at  $14.002 \text{ MHz}$ .

Figure 12.A4 shows a signal in the same location that is S9+40 dB or  $-33 \text{ dBm}$ . Using the same math, at  $14.002 \text{ MHz}$  we will experience phase noise of  $-33 \text{ dBm} - 73 \text{ dB} = -106 \text{ dBm}$ . Since the signal we are trying to receive is S3 ( $-109 \text{ dBm}$ ), our noise floor in  $100 \text{ Hz}$  is  $3 \text{ dB}$  above this level, causing us interference while trying to

copy the signal. The amount of actual interference received also depends on the required signal-to-noise ratio required to successfully copy a signal.

Although it varies by type of oscillator, phase noise generally decreases the further we are from the carrier, meaning that weak signals that are closer to strong signals are more likely to be interfered with than weak signals farther away from a strong carrier. Stations operating in a rural area with modest antennas and no strong neighbors are much less likely to suffer from the effects of phase noise than are multi-multi contest stations with large antennas and local transmitters in the same band. Field Day is another situation where many are familiar with the effects of phase noise. If you've ever operated the sideband station at your local Field Day and heard the noise floor modulated to the sound of the CW station next to you (or vice versa), you've experienced the effects of interference from phase noise.

The effects of phase noise will also vary by mode. A CW signal may be copied with a SNR in the  $-10$  to  $-20 \text{ dB}$  range while a sideband signal may require an SNR of  $>+10 \text{ dB}$ . Since sideband signals require a larger filter, we must also run our calculations with this larger filter, recognizing that more noise will be present. Both the addi-

Figure 12.A3 — Spectrum showing adjacent CW signals and the phase noise from each.

Figure 12.A4 — Same spectrum as Figure 12.A3 but with the left-hand signal replaced with one that is much stronger.

tional noise and the larger SNR required to copy a sideband signal make it more susceptible to phase noise interference than a CW transmission.

### Division is Good

In most local oscillators for superheterodyne receivers, the phase noise of the oscillator will benefit from division. This means that the more the oscillator is reduced in frequency through division, the better the resulting phase noise of the oscillator. Typically, we will see a  $6 \text{ dB}$  improvement in phase noise with each division by two of the original oscillator frequency. So a radio that might have good oscillator performance on  $20 \text{ meters}$  could lose  $11 \text{ dB}$  or more performance when operating on  $6 \text{ meters}$ . The superheterodyne receiver designer can take advantage of this by using a good oscillator design and dividing down the oscillator as much as possible, thereby achieving better phase noise.

**Table 12.2**  
**Typical Communications Bandwidths**  
**for Various Operating Modes**

Mode	Bandwidth (kHz)
FM Voice	15
AM Broadcast	10
AM Voice	4-6.6
SSB Voice	1.8-3
Digital Voice	1.0-1.2
RTTY (170-850 Hz shift)	0.3-1.5
CW	0.1-0.5

Note that the word *channel* is used here in its generic form, meaning the amount of spectrum occupied by a signal, and not defining a fixed frequency such as an AM broadcast channel. A CW channel is about 300 Hz wide, a SSB channel about 2.5-3 kHz wide, and so forth. “Adjacent channel” refers to spectrum immediately higher or lower in frequency. **Table 12.2** shows the bandwidth required for such a “channel” in various services and modes.

Selectivity under linear operating conditions is determined by the receiver’s filters. In analog heterodyne designs, the filters are typically crystal filters with a fixed bandwidth. Clever frequency shifting schemes (Passband Tuning or IF Shift, for example) create a continuously adjustable filter by shifting two fixed passbands relative to each other. DSP is also used in both hybrid and direct-sampling SDR designs to provide performance unavailable to filters using discrete components. Both types of filters are discussed in the **Analog and Digital Filtering** chapter.

### 12.1.4 Receiver Dynamic Range

In the case of all real receivers, there is a range of signals that a receiver can respond to linearly without distortion. This is referred to as *dynamic range* and, as will be discussed in more detail, can be established based on a number of different criteria. In the most general sense, dynamic range can be defined as the ratio of the strongest to the weakest signal that a system, in this case our receiver, can respond to linearly. This range typically extends from the receiver’s noise floor to a level at which some intermediate stage or stages overload in some way.

Table 12.1 gives us an idea of how small a signal we might want to receive. The designer must create a receiver that will handle signals from below the noise floor to as strong as the closest nearby transmitter can generate. Most receivers have a specified (or sometimes not) highest input power that can be tolerated, representing the other end of the spectrum. Usually the maximum power

specified is the power at which the receiver will not be damaged, while a somewhat lower power level is generally the highest that the receiver can operate at without overload and the accompanying degradation of quality of reception of the desired signal.

The type and severity of the overload is often part of the specification. A straightforward example might be a 130 dB dynamic range. The nature of the distortion will determine the observed phenomenon. If the weakest and strongest signals are both on the same channel, for example, we would not expect to be able to process the weaker of the two. However, the more interesting case would be with the strong signal in an adjacent channel. In an ideal receiver, we would never notice that the adjacent signal was there. In a real receiver with a finite dynamic range or non-ideal selectivity, there will be some level of adjacent channel signal or signals that will interfere with reception of the weaker on-channel signal.

Dynamic range is also affected by preamplifiers in the receiver front-end circuitry. (Passive resistive attenuators have less effect on dynamic range as they typically remain linear over a very wide range of signals.) Turning on a preamplifier may worsen various types of dynamic range performance if the preamplifier’s dynamic range is less than that of the rest of the receiver. Conversely, in some SDR receivers having the preamp on may improve performance. Dynamic range specifications and measurements must include whether a preamp is on or off.

It is important to note that the behavior of a heterodyne receiver and an SDR receiver are quite different with respect to dynamic range. The notion of an “intercept point” discussed below is based on the assumption of intermodulation products increasing in a certain way that is characteristic of analog circuitry. This assumption is not valid for direct-sampling SDR equipment. An SDR’s input ADC is basically linear up to the point where the instantaneous sum of all signals present at the receiver input exceeds the full-scale range of the input ADC. (See the **DSP and SDR Fundamentals** chapter.) Beyond that point, the receiver will generate spurious products based on its software and how that specific ADC responds. Hybrid analog/digital receivers that apply DSP at IF or audio frequencies behave more like traditional analog receivers.

### ON-CHANNEL DYNAMIC RANGE

The signal you wish to listen to can range from the strongest to the weakest, sometimes changing rapidly with conditions, or in a situation with multiple stations such as a net. While a slow change in signal level can be handled with manual gain controls, rapid changes require automatic systems to avoid

overload and operator discomfort.

This is a problem that has been long solved with automatic gain control (AGC) systems. These systems are described in a later section of the chapter, but it is worth pointing out that the measurement and gain control points need to be applied carefully to the most appropriate portions of the receiver to maintain optimum performance. If all control is applied to early stages, the SNR for strong stations may suffer, while if applied in later stages, overload of early stages may occur in the presence of strong stations. Thus, gain control has to be designed into the receiver distributed from the input to the detector.

The next two sections illustrate a frequent limitation of receiver performance — dynamic range between the reception of a weak signal in the presence of one or more strong signals outside of the channel.

### BLOCKING GAIN COMPRESSION

A very strong signal outside the channel bandwidth can cause a number of problems that limit receiver performance. *Blocking gain compression* (or “blocking”) occurs when strong signals overload the receiver’s high gain amplifiers and reduce its ability to amplify weak signals. (Note that the term “blocking” is often used outside Amateur Radio when referring to reciprocal mixing of oscillator noise with strong local signals.)

While listening to a weak signal, all stages operate at maximum gain. If the weak signal were at a level of S0, a strong signal could be at S9 + 60 dB. Using the standard of S9 representing a 50  $\mu$ V input signal, and each S unit reflecting a change of 6 dB, the receiver’s front-end stages would be receiving a 0.1  $\mu$ V signal and a 50,000  $\mu$ V into the front end at the same time. A perfectly linear receiver would amplify each signal equally until the undesired signal is eliminated at the operating bandwidth setting stage. However, in practical receivers, after a few stages of full gain amplification, the stronger signal causes amplifier clipping, which reduces the gain available to the strong signal. This is seen as a gradual reduction in gain as the input signal amplitude increases. Gain reduction also reduces the amplitude of the weaker signal which is perceived to fade as the strong signal increases in amplitude. Eventually, the weaker signal is no longer receivable and is said to have been “blocked”, thus the name for the effect.

The ratio in dB between the strongest signal that a receiver can amplify linearly, with no more than 1 dB of gain reduction, and the receiver’s noise floor in a specified bandwidth is called the receiver’s *blocking dynamic range* or *BDR* or the *compression-free dynamic range* or *CFDR*. In an analog superhet, BDR is established by the linear regions of the IF amplifiers and mixers. If the receiver

## Nonlinear Signal Combinations

Although a mixer is often thought of as nonlinear, it is neither necessary nor desirable for a mixer to be nonlinear. An ideal mixer is one that linearly multiplies the LO voltage by the signal voltage, creating two products at the sum and difference frequencies and only those two products. From the signal's perspective, it is a perfectly linear but time-varying device. Ideally a mixer should be as linear as possible.

If a signal is applied to a nonlinear device, however, the output will not be just a copy of the input, but can be described as the following infinite series of output signal products:

$$V_{OUT} = K_0 + K_1 \times V_{IN} + K_2 \times V_{IN}^2 + K_3 \times V_{IN}^3 + \dots + K_N \times V_{IN}^N$$

What happens if the input  $V_{IN}$  consists of two sinusoids at  $F_1$  and  $F_2$ , or  $A \times [\sin(2\pi F_1) \times t]$  and  $B \times [\sin(2\pi F_2) \times t]$ ? Begin by simplifying the notation to use angular frequency in radians/second ( $2\pi F = \omega$ ). Thus  $V_{IN}$  becomes  $A \sin \omega_1 t$  and  $B \sin \omega_2 t$  and equation A becomes:

$$V_{OUT} = K_0 + K_1 \times (A \sin \omega_1 t + B \sin \omega_2 t) + K_2 \times (A \sin \omega_1 t + B \sin \omega_2 t)^2 + K_3 \times (A \sin \omega_1 t + B \sin \omega_2 t)^3 + \dots + K_N \times (A \sin \omega_1 t + B \sin \omega_2 t)^N$$

The zero-order term,  $K_0$ , represents a dc component and the first-order term,  $K_1 \times (A \sin \omega_1 t + B \sin \omega_2 t)$ , is just a constant times the input signals. The second-order term is the most interesting for our purposes. Performing the squaring operation, we end up with:

$$\text{Second order term} = [K_2 A^2 \sin^2 \omega_1 t + 2K_2 AB (\sin \omega_1 t \times \sin \omega_2 t) + K_2 B^2 \sin^2 \omega_2 t]$$

Using the trigonometric identity (see the **Radio Mathematics** supplement):

$$\sin \hat{a} \sin \hat{b} = 1/2 \{ \cos(\hat{a} - \hat{b}) - \cos(\hat{a} + \hat{b}) \}$$

the product term becomes:

$$K_2 AB \times [\cos(\omega_1 - \omega_2)t - \cos(\omega_1 + \omega_2)t]$$

These products are at the sum and difference frequency of the input signals! The signals, originally sinusoids are now cosinusoids, signifying a phase shift. These signals, however, are just two of the many products created by the nonlinear action of the circuit, represented by the higher-order terms in the original series.

In the output of a mixer or amplifier, those unwanted signals create noise and interference and must be minimized or filtered out. This nonlinear process is responsible for the distortion and intermodulation products generated by amplifiers operated nonlinearly in receivers and transmitters.

employs DSP, the range of the analog-to-digital converter usually establishes the receiver's BDR. The spacing of the signals must also be specified so that any internal filtering is accounted for. Typical signal spacing is 2, 5, 20, and 100 kHz.

A related term is "near-far interference" which is used primarily in the commercial environment to refer to a strong signal causing a receiver to reduce its gain and along with it the strength of weak received signals.

### INTERMODULATION DYNAMIC RANGE

Blocking dynamic range is the straightforward response of a receiver to a single strong

interfering signal outside the operating passband. In amateur operation, we often have more than one interferer. While such signals contribute to the blocking gain compression in the same manner as a single signal described above, multiple signals also result in a potentially more serious problem resulting from *intermodulation (IM) products*. As noted previously, analog heterodyne and SDR receivers behave quite differently with respect to intermodulation.

If we look again at the equation for two sinusoids in the sidebar on Nonlinear Signal Combinations, we note that there are an infinite number of higher order terms. In general, the coefficients of these terms are progres-

sively lower in amplitude, but they are still greater than zero. Of primary interest is third-order term,  $K_3 \times V_{IN}^3$ , when considering  $V_{IN}$  as the sum of two interfering signals ( $f_1$  and  $f_2$ ) near our desired signal ( $f_0$ ) and within the first IF passband, but outside the operating bandwidth.

$$V_{OUT} = K_3 \times [A \sin(f_1)t + B \sin(f_2)t]^3 \\ = K_3 \times \{ A^3 \sin^3(f_1)t + 3A^2B [\sin^2(f_1)t \times \sin(f_2)t] + 3AB^2 [\sin(f_1)t \times \sin^2(f_2)t] + B^3 \sin^3(f_2)t \}$$

The cubic terms (the first and last terms) result in products at three times the frequency and can be ignored in this discussion. Using trigonometric identities to reduce the remaining  $\sin^2$  terms and the subsequent  $\cos(\sin)$  products reveal individual intermodulation (IM) products, recognizing that the signals have cross-modulated each other due to the nonlinear action of the circuit. (Math handbooks such as the *CRC Standard Mathematical Tables and Formulae* have all the necessary trigonometry information.)

IM products have frequencies that are linear combinations of the input signal frequencies, written as  $n(f_1) \pm m(f_2)$ , where  $n$  and  $m$  are integer values. The entire group of products that result from intermodulation are broadly referred to as *intermodulation distortion* or *IMD*. The ratio in dB between the amplitude of the interfering signals,  $f_1$  and  $f_2$ , and the resulting IM products is called the *intermodulation ratio*.

If all of the higher-order terms in the original equation are considered,  $n$  and  $m$  can take on any integer value. If the sum of  $n$  and  $m$  is odd, (2 and 1, or 3 and 2, or 3 and 4, etc.) the result is products that have frequencies near our desired signal, for example,  $2(f_1) - 1(f_2)$ . Those are called *odd-order* products. Odd-order products have frequencies close enough to those of the original signals that they can cause interference to the desired signal. If the sum of  $n$  and  $m$  is three, those are *third-order IM products* or *third-order IMD*. For fifth-order IMD, the sum of  $n$  and  $m$  is five, and so forth. The higher the order of the IM products, the smaller their amplitude, so our main concern is with third-order IMD.

If the two interfering signals have frequencies of  $f_0 + \Delta$ , and  $f_0 + 2\Delta$ , where  $\Delta$  is some offset frequency, we have for the third-order term:

$$V_{OUT} = K_3 \times [A \sin(f_0 + \Delta)t + B \sin(f_0 + 2\Delta)t]^3$$

A good example would be interfering signals with offsets of 2 kHz and  $2 \times 2$  kHz or 4 kHz from the desired frequency, a common situation on the amateur bands.

Discarding the cubic terms and applying

the necessary trigonometric identities shows that a product can be produced from this combination of interfering frequencies that has a frequency of exactly  $f_0$ —the same frequency as the desired signal! (The higher-order terms of the sidebar's equation for sinusoid signals can also produce products at  $f_0$ , but their amplitude is usually well below those of the third-order products.)

Thus we have two interfering signals that are not within our operating bandwidth so we don't hear either by themselves. Yet they combine in a nonlinear circuit and produce a signal exactly on top of our desired signal. If the interfering signals are within the pass-band of our first IF and are strong enough the IM product will be heard.

As the strength of the interfering signals increases, so does that of the resulting intermodulation products. For every dB of increase in the interfering signals, the third-order IM products increase by approximately 3 dB. Fifth-order IM increases by 5 dB for every dB increase in the interfering signals, and so forth. Our primary concern, however, is with the third-order products because they are the strongest and cause the most interference.

**Third-order IMD dynamic range (3IMD<sub>DR</sub>)** is the difference between a receiver's MDS and the input level of two interfering signals that create an IMD product on the same frequency and as strong as a desired signal. (The complete test is described in the **Test Measurements and Instruments** chapter and in the book by Allison.) The test is performed with the interfering signals at different spacings (usually 2, 5, and 20 kHz) and with the desired signal at several different levels. The ARRL uses a signal at the MDS, at S5 (-97 dBm) and 0 dBm. For *QST* Product Reports, the test is performed on the 3.5, 14, and 50 MHz bands. All of these conditions must be specified and no single number characterizes 3IMD<sub>DR</sub> performance entirely.

This dynamic range is particularly important to the contest and DX community since they often need to copy very weak signals with very strong signals on an adjacent channel or just a few kHz away. Combined with reciprocal mixing, band noise, and spurious emissions from transmitters, third-order IMD products can make for very difficult reception. Note that SDR receivers do not specify this dynamic range because their circuitry does not behave the same as analog superheterodyne receivers as discussed the sections below.

### INTERCEPT POINT

**Intercept point** describes the IMD performance of an individual stage or a complete receiver. For example, in an analog heterodyne receiver, third-order IM products increase at

the rate of 3 dB for every 1-dB increase in the level of each of the interfering input signals (ideally, but not always exactly true). As the input levels increase, the distortion products seen at the output on a spectrum analyzer could catch up to, and equal, the level of the two desired signals if the receiver did not begin to exhibit blocking as discussed earlier. Remember that SDR equipment will behave differently.

The input level at which this occurs is the **input intercept point**. **Figure 12.3** shows the concept graphically, and also derives from the geometry an equation that relates signal level, distortion and intercept point. The intercept point of the most interest in receiver evaluation is that for third-order IM products and is called the **third-order intercept point** or **IP<sub>3</sub>**. A similar process is used to get a second-order intercept point for second-order IMD. A higher **IP<sub>3</sub>** means that third-order IM products will be weaker for specific input signal strengths and the operator will experience less interference from IM products from strong adjacent signals.

**Figure 12.3 — Graphical representation of the third-order intercept concept.**

## Testing and Calculating Intermodulation Distortion in Receivers

Second and third-order IMD can be measured using the setup of **Figure 12.B1**. The outputs of two signal generators are combined in a 3-dB hybrid coupler. Such couplers are available from various companies, and can be homemade. The 3-dB coupler should have low loss and should itself produce negligible IMD. The signal generators are adjusted to provide a known signal level at the output of the 3-dB coupler, say, -20 dBm for each of the two signals. This combined signal is then fed through a calibrated variable attenuator to the device under test. The shielding of the cables used in this system is important: At least 90 dB of isolation should exist between the high-level signal at the input of the attenuator and the low-level signal delivered to the receiver.

The measurement procedure is simple: adjust the variable attenuator to produce a signal of known level at the frequency of the expected IMD product ( $f_1 \pm f_2$  for second-order,  $2f_1 - f_2$  or  $2f_2 - f_1$  for third-order IMD).

To do this, of course, you have to figure out what equivalent input signal level at the receiver's operating frequency corresponds to the level of the IMD product you are seeing. There are several ways of doing this. One way — the way used by the ARRL Lab in their receiver tests — uses the minimum discernible signal. This is defined as the signal level that produces a 3-dB increase in the receiver audio output power. That is, you measure the receiver output level with no input signal, then insert a signal at the operating frequency and adjust the level of this input signal until the output power is 3 dB greater than the no-signal power. Then, when doing the IMD measurement, you adjust the attenuator of **Figure 12.B1** to cause a 3-dB increase in receiver output. The level of the IMD product is then the same as the MDS level you measured.

There are several things I dislike about doing the measurement this way. The problem is that you have to measure noise power. This can be difficult. First, you need an RMS voltmeter or audio power meter to do it at all. Second, the measurement varies with time (it's noise!), making it difficult to nail down a number. And third, there is the question of the audio response of the receiver; its noise output may not be flat across the output spectrum. So I prefer to measure, instead of MDS, a higher reference level. I use the receiver's S meter as a reference. I first determine the input signal level it takes to get an S1 reading. Then, in the IMD measurement, I adjust the attenuator to again give an S1 reading. The level of the IMD product signal is

now equal to the level I measured at S1. Note that this technique gives a different IMD level value than the MDS technique. That's OK, though. What we are trying to determine is the *difference* between the level of the signals applied to the receiver input and the level of the IMD product. Our calculations will give the same result whether we measure the IMD product at the MDS level, the S1 level or some other level.

An easy way to make the reference measurement is with the setup of Figure 12.B1. You'll have to switch in a lot of attenuation (make sure you have an attenuator with enough range), but doing it this way keeps all of the possible variations in the measurement fairly constant. And this way, the difference between the reference level and the input level needed to produce the desired IMD product signal level is simply the difference in attenuator settings between the reference and IMD measurements.

### Calculating Intercept Points

Once we know the levels of the signals applied to the receiver input and the level of the IMD product, we can easily calculate the intercept point using the following equation:

$$IP_n = \frac{n \times P_A - P_{IM_n}}{n - 1} \quad (A)$$

Here,  $n$  is the order,  $P_A$  is the receiver input power (of one of the input signals),  $P_{IM_n}$  is the power of the IMD product signal, and  $IP_n$  is the  $n$ th-order intercept point. All powers should be in dBm. For second and third-order IMD, equation A results in the equations:

$$IP_2 = \frac{2 \times P_A - P_{IM_2}}{2 - 1} \quad (B)$$

$$IP_3 = \frac{3 \times P_A - P_{IM_3}}{3 - 1} \quad (C)$$

You can measure higher-order intercept points, too.

### Example Measurements

To get a feel for this process, it's useful to consider some actual measured values.

The first example is a Rohde & Schwarz model EK085 receiver with digital preselection. For measuring second-order IMD, signals at 6.00 and 8.01 MHz, at -20 dBm each, were applied at the input of the attenuator. The difference in attenuator settings between the reference measurement and the level needed to produce the

desired IMD product signal level was found to be 125 dB. The calculation of the second-order IP is then:

$$IP_2 = \frac{2(-20 \text{ dBm}) - (-20 \text{ dBm} - 125 \text{ dB})}{2 - 1} \\ = -40 \text{ dBm} + 20 \text{ dBm} + 125 \text{ dB} = +105 \text{ dB}$$

For  $IP_3$ , we set the signal generators for 0 dBm at the attenuator input, using frequencies of 14.00 and 14.01 MHz. The difference in attenuator settings between the reference and IMD measurements was 80 dB, so:

$$IP_3 = \frac{3(0 \text{ dBm}) - (0 \text{ dBm} - 80 \text{ dB})}{3 - 1} \\ = \frac{0 \text{ dBm} + 80 \text{ dB}}{2} = +40 \text{ dBm}$$

We also measured the  $IP_3$  of a Yaesu FT-1000D at the same frequencies, using attenuator-input levels of -10 dBm. A difference in attenuator readings of 80 dB resulted in the calculation:

$$IP_3 = \frac{3(-10 \text{ dBm}) - (-10 \text{ dBm} - 80 \text{ dB})}{3 - 1} \\ = \frac{-30 \text{ dBm} + 10 \text{ dBm} + 80 \text{ dB}}{2} \\ = \frac{-20 \text{ dBm} + 80 \text{ dB}}{2} \\ = +30 \text{ dBm}$$

### Synthesizer Requirements

To be able to make use of high third-order intercept points at these close-in

spacings requires a low-noise LO synthesizer. You can estimate the required noise performance of the synthesizer for a given  $IP_3$  value. First, calculate the value of receiver input power that would cause the IMD product to just come out of the noise floor, by solving equation A for  $P_A$ , then take the difference between the calculated value of  $P_A$  and the noise floor to find the dynamic range. Doing so gives the equation:

$$ID_3 = \frac{2}{3}(IP_3 + P_{min}) \quad (D)$$

where  $ID_3$  is the third-order IMD dynamic range in dB and  $P_{min}$  is the noise floor in dBm. Knowing the receiver bandwidth, BW (2400 Hz in this case) and noise figure, NF (8 dB) allows us to calculate the noise floor,  $P_{min}$ :

$$P_{min} = -174 \text{ dBm} + 10 \log(\text{BW}) + \text{NF} \\ = -174 \text{ dBm} + 10 \log(2400) + 8 \\ = -132 \text{ dBm}$$

The synthesizer noise should not exceed the noise floor when an input signal is present that just causes an IMD product signal at the noise floor level. This will be accomplished if the synthesizer noise is less than:

$$ID + 10 \log(\text{BW}) = 114.7 \text{ dB} + 10 \log(2400) = 148.5 \text{ dBc/Hz}$$

in the passband of the receiver. Such synthesizers hardly exist.  
— Dr Ulrich L. Rohde, N1UL

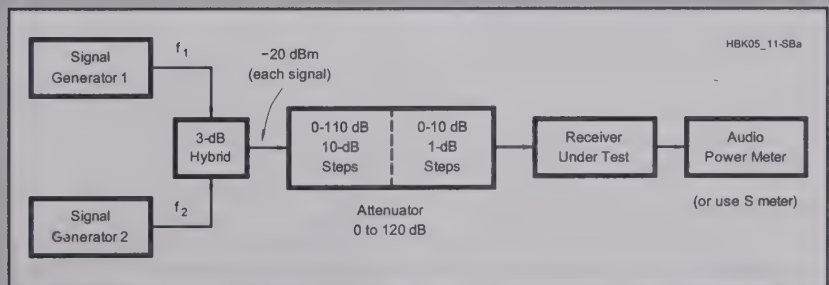

Figure 12.B1 — Test setup for measurement of IMD performance. Both signal generators should be types such as HP 608, HP 8640, or Rohde & Schwarz SMDU, with phase noise performance of -140 dBc/Hz or better at 20 kHz from the signal frequency.

These formulas are very useful in designing radio systems and circuits. If the input intercept point (dBm) and the gain of the stage (dB) are added the result is an output intercept point (dBm). Receivers are specified by input intercept point, referring distortion back to the receive antenna input. Intercept point is a major performance limitation of receivers used in high density contest or DX operations. Keep in mind that we have been discussing this as an effect of two signals, one that is  $\Delta$  away from our operating frequency and another at twice  $\Delta$ . In real life, we may be trying to copy a weak signal at  $f_0$ , and have other signals at  $f_0 \pm 500, 750, 1000, 1250 \dots 5000$  Hz. There will be many combinations that produce products at or near our weak signal's frequency.

Note that the products don't need to end up exactly on top of the desired signal to cause a problem; they just need to be within the operating bandwidth. So far we have been talking about steady carriers, such as would be encountered during CW operation with interference from nearby CW stations. SSB or other wider bandwidth modes with spectrum distributed across a few kHz will have signal components that go in and out of a relationship that results in on-channel interference from IMD. This manifests itself as a time-varying synthetic noise floor, composed of all the resulting products across the channel. The difference in this low level "noise" can be dramatic between different receivers, especially when added to phase noise received from other stations and reciprocal mixing inside the receiver!

### SPURIOUS-FREE DYNAMIC RANGE (SFDR)

IM products increase with the amplitude of the interfering signals that cause them and at some point become detectable above the receiver's noise floor. The ratio of the strength of the interfering signals to the noise floor, in dB, is the receiver's *spurious-free dynamic range* or *SFDR*. This is the range of signal strengths over which the receiver does not produce any detectable spurious products. SFDR can be specified for a specific order of IM products; for example, SFDR3 is the SFDR measured for third-order IM products only. The bandwidth for which the receiver's noise floor is measured must also be specified, since smaller bandwidths will result in a lower noise floor.

### INTERFERENCE FREE SIGNAL STRENGTH (IFSS)

To address the behavior of SDR receivers for which the  $IP_3$  specification is irrelevant new performance metrics have been proposed. One such measurement is the *interference-free signal strength* or *IFSS*. This measures the largest input signal for which no interference

products are produced above the receiver noise floor. The noise floor is specified using the Rec. ITU P.372.7 band-noise levels. IFSS is similar to SFDR but does not specify a type of intermodulation products.

As a consequence of using the ITU band-noise levels noise levels (see the **RF Techniques** chapter), the IFSS for a given receiver can be much higher on the lower HF bands, where external band noise is high and will mask any interfering products. On the upper HF and VHF bands where band noise is lower, the IFSS can also be lower. Similarly, there can be a difference between the rural, suburban, and urban environments. As such, IFSS measurements ignore distortion products below the noise floor.

IFSS measurements on current receivers show a great deal of variation in the performance over a wide range of signal levels. The best performers show a smooth increase in the distortion product level beginning at the input signal level where the interference products are equal to the noise floor. These radios exhibit predictable performance over a wide range of inputs. Other models show large swings in distortion product levels, even decreasing with increased input over some ranges of signal levels. This indicates a need for better understanding of SDR behavior and design. Nevertheless, IFSS is a useful tool in assessing SDR performance.

### RECIPROCAL MIXING DYNAMIC RANGE (RMDR)

All oscillators produce some phase noise. When the oscillator is used to control a receiver or transmitter, the noise is transferred to signals, causing extra noise in the receiver passband and in the transmitter output signal. In an analog heterodyne receiver, the noise is transferred to the signals in the mixing process from the local oscillator(s). While all of the LOs contribute some noise, in practice the first mixer is the dominant source. In an SDR receiver, phase noise is transferred primarily from the sampling clock for the input ADC and the DDS signal sources in the receiver. Some noise is contributed by jitter in the digitizing ADC, as well.

RMDR is measured by increasing a test input signal until the noise in the receive channel increases by a specified amount, usually 3 dB. The difference between the input signal level and the receiver's noise floor (MDS) is the RMDR.

The raised background noise will mask weak signals, in effect raising the receiver's noise floor when a nearby strong signal is present to transfer the oscillator noise. For example, if a receiver's noise floor or MDS is  $-127$  dBm and an input signal of  $-37$  dBm causes the 3 dB increase in noise, the receiver's RMDR =  $-37 - (-127) = 90$  dB.

Since oscillator noise is lower farther from

the oscillator frequency, the transferred noise will have a similar profile. (The discussion of phase noise in the **Oscillators and Synthesizers** chapter shows the noise profile of typical oscillators.) This requires RMDR to be measured with the strong signal a specified distance from the receiver channel in which noise is being measured. Typical separations are 2, 5, and 20 kHz.

RMDR tends to be the most limiting dynamic range at the close signal spacing of 2 and 5 kHz. Since close-spaced signals are typical of the most demanding receiver environments for contesting and DXing, this is an important measurement to compare when purchasing a transceiver.

### NOISE POWER RATIO (NPR)

Another test method applicable to both SDR and heterodyne receivers, *noise power ratio* tests were originally developed for multiplexed telephone systems. These early system combined many individual channels on one transmission system, cable or radio. Nonlinearities in the system would generate distortion products and interfere with the channels. To simulate the effect of many active channels, wideband noise was transmitted with one channel removed by a narrow notch filter. (See **Figure 12.4**)

The noise simulated the presence of complex speech waveforms in the other channels. Any distortion products from the noise would appear as a raised noise floor in the notched channel. As the noise amplitude was raised, the in-channel noise would rise, as well.

This is a close analogue to a busy band with multiple channels of communication. Nonlinearities in the receiver generate distortion products in the monitored channel. The ratio of the out-of-channel to in-channel noise is the noise power ratio. The more linear the receiver, the more noise power can be injected for a given amount of increase in the in-channel noise. (NPR is explained in the March/April 2015 *QEX* article, "Noise Power Ratio (NPR) Testing on HF Receivers" by Adam Farson, VA7OJ, and in the Analog Devices tutorial MT-005, "Noise Power Ratio (NPR)" — see the References section.

### TYPICAL PERFORMANCE

As we would expect, the blocking and IMD dynamic range (IMD DR) performance of a heterodyne receiver will depend on a combination of the early stage filtering, the linearity of the mixers and amplifiers, and the dynamic range of any ADC used for DSP at the IF or audio stages.

Product reviews of receivers and the receiver sections of transceivers published in *QST* now provide the measured dynamic range in the presence of interfering signals with spacings of 2, 5 and 20 kHz. (Details of the test procedures used are given in the **Test**

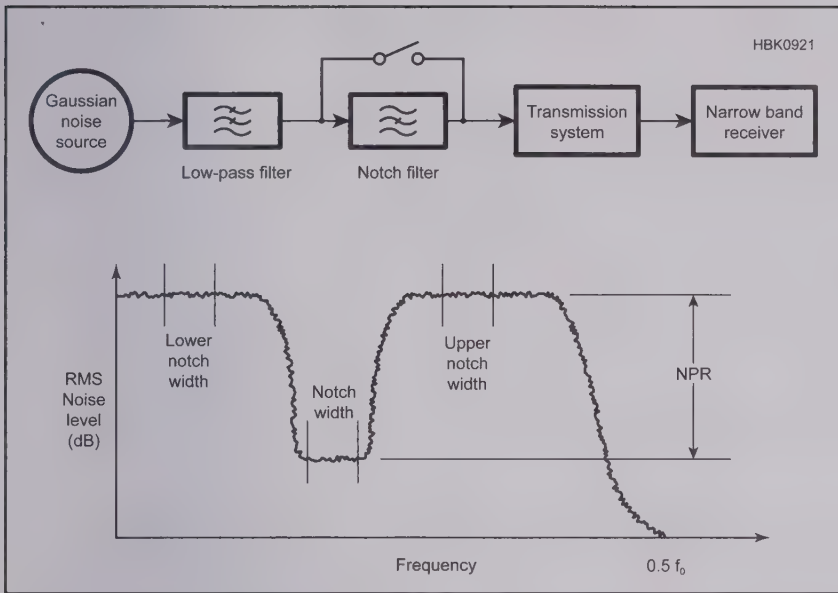

Figure 12.4 — Noise power measurement test set and typical spectrum (after Analog Devices MT-005, see References).

**Equipment and Measurements** chapter and in the book by Allison.) At 20 kHz spacing, the interfering signal is usually outside of the roofing filter bandwidth of any of the above architectures. Spacing of 2 and 5 kHz represents likely conditions on a crowded band.

A look at recent top-performing receiver measurements indicates that receivers have IMD (or distortion-product) dynamic range with 2 kHz spacing results in the following ranges:

- Direct-sampling SDR: 80 to 108 dB
- Upconverting with VHF IF: 80 to 105 dB
- Downconverting with HF IF: 75 to 110 dB

- Hybrid superhet/DSP architecture: Omni VII, 82 dB (2007); Icom IC-PRO3, 75 dB (2009)

(Note that SDR distortion products are not necessarily IMD. Receiver block diagrams are provided in the following sections. Data is taken from ARRL Lab tests and the long-term test program conducted by Rob Sherwood, NCØB, at [www.sherweng.com/table.html](http://www.sherweng.com/table.html).)

Let's take an example of what this would mean. If we are listening to a signal at  $S_3$ , for signals to generate a third-order IMD product at the same level in a receiver with a dynamic range of 60 dB, the  $f_0 + \Delta$  and  $f_0 + 2\Delta$  signals

would have to have a combined power equal to  $S_9 + 27$  dB, or each at  $S_9 + 24$  dB. This is not unusual on today's amateur bands. On the other hand, if we had an IMD dynamic range of 102 dB, the interfering signals would have to be  $S_9 + 66$  dB, much less likely. How much dynamic range you need depends in large measure on the kind of operating you do, how much gain your receiving antennas have and the closeness of the nearest station that operates on the same bands as you. Given that transmitters generate both phase noise and IMD products of their own, the dynamic range of most receivers on the market today is quite adequate for even the most demanding situations. Receivers may have other performance issues to consider such as filter design, AGC reaction, audio distortion, and so forth.

Keep in mind also that it is often difficult to tell whether or not you are hearing internal receiver-generated IMD — it just sounds like there are many more signals than are really present. A good test to assess the source of interference is first switch off any preamplifiers and noise-blankers or noise-reduction systems that affect the receiver's linearity. Observe the level of the interference (if it's still there) and then switch in some attenuation at the front-end of the receiver. If the level of the interference goes down by *more* than the level of attenuation (estimate 6 dB per S unit), then the interference is being generated (or at least aggravated) by non-linearity inside the receiver. Continue to increase attenuation until the interference either goes away or goes down at the same rate as the attenuation is increased. You might be surprised at how much better the band "sounds" when your receiver is operating in its linear region!

## 12.2 Heterodyne Receivers

The *heterodyne* receiver combines the input signal with a signal from a *local oscillator* (LO) in a mixer as discussed previously to generate the sum and difference frequencies as shown in **Figure 12.5**. The receiver may be designed so the output signal is anything from dc (a so-called *direct conversion* receiver) to any frequency above or below either of the two frequencies. The major benefit is that most of the gain, bandwidth setting and processing are performed at a single frequency, simplifying the design dramatically.

By changing the frequency of the LO, the operator shifts a signal at the input frequency the output, along with all its modulated infor-

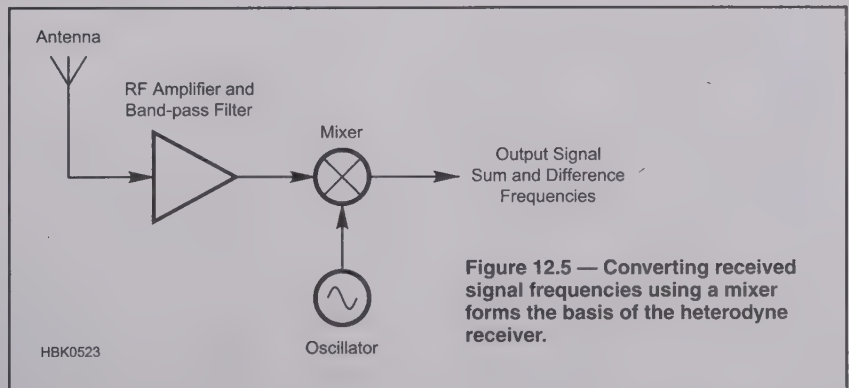

Figure 12.5 — Converting received signal frequencies using a mixer forms the basis of the heterodyne receiver.

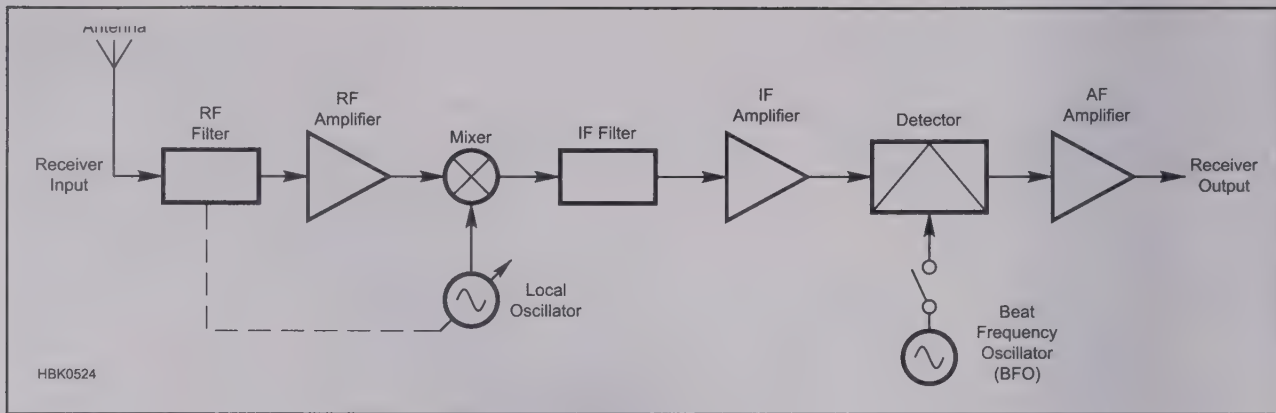

Figure 12.6 — Elements of an analog superheterodyne radio receiver.

mation. In most receivers the mixer output frequency is designed to be an RF signal, either the sum or difference — the other being filtered out at this point. This output frequency is called an *intermediate frequency* or *IF*. The IF amplifier system can be designed to provide the selectivity and other desired characteristics centered at a single fixed frequency.

When more than one frequency conversion process is used, the receiver becomes a *superheterodyne* or *superhet*. A block diagram of a typical superhet receiver is shown in **Figure 12.6**. In traditional form, the RF filter is used to limit the input frequency range to those frequencies that include only the desired sum or difference but not the other — the so-called *image* frequency. The dotted line represents the fact that in receivers with a wide tuning range, such as a simple AM broadcast receiver that tunes from 500 to 1700 kHz, a more than 3:1 range, the input RF amplifier and filter is often tracked along with the local oscillator. The IF filter is used to establish selectivity — the operating bandwidth required by the information. Circuits from the antenna input through and including the mixer (the first mixer if more than one mixing stage is used) are generally referred to as the receiver's *front-end*.

For reception of suppressed carrier single-sideband voice (SSB) or on-off or frequency-shift keyed (FSK) signals, a second *beat frequency oscillator* or *BFO* is employed to provide an audible voice, an audio tone or tones at the output for operator or FSK processing. This is the same as a heterodyne mixer with an output centered at dc, although the IF filter is usually designed to remove one of the output products.

Recent superhet receivers convert the incoming signal to digital form at one of the intermediate frequencies. DSP techniques are then used to control operating bandwidth and demodulate the input signal. See the **DSP**

and **SDR Fundamentals** chapter for more information on these techniques.

### 12.2.1 The Direct Conversion Receiver

The heterodyne process can occur at a number of different points in the receiver. The simplest form of heterodyne receiver is called a *direct conversion* or *DC* receiver because it performs the translation directly from the signal frequency to the audio output. It is, in effect, just the BFO and detector of the general superhet shown in **Figure 12.6**. In this case, the detector is often preceded by an RF amplifier with a typical complete receiver shown in **Figure 12.7**. Such a receiver can be very simple to construct, yet can be quite effective — especially for the ultra-compact low-power consumer-oriented portable station known as the mobile telephone! In fact, given the direct conversion receiver's use in the mobile telephone, it is the most widely used of all receivers.

The basic function of a mixer is to multiply two sinusoidal signals and generate two new signals with frequencies that are the sum

and difference of the two original signals. This function can be performed by a linear multiplier, a switch that turns one input signal on and off at the frequency of the other input signal, or a nonlinear circuit such as a diode. (The output of a nonlinear circuit is made up of an infinite series of products, all different combinations of the two input signals, as described in the sidebar on Nonlinear Signal Combinations.) Much more information about the theory, operation and application of mixers may be found in this chapter's section on them.

**Figure 12.8** shows the progression of the spectrum of an on-off keyed CW signal through such a receiver based on the relationships described above. (This example is based on the "Rock-Bending Receiver for 7 MHz" which is included in the online projects.) In 12.8C, we include an undesired image signal on the other side of the local oscillator that also shows up in the output of the receiver. Note each of the desired and undesired responses that occur as outputs of the mixer.

Some mixers are designed to be *balanced* in order to cancel one of the input signals at the output while a *double-balanced* mixer

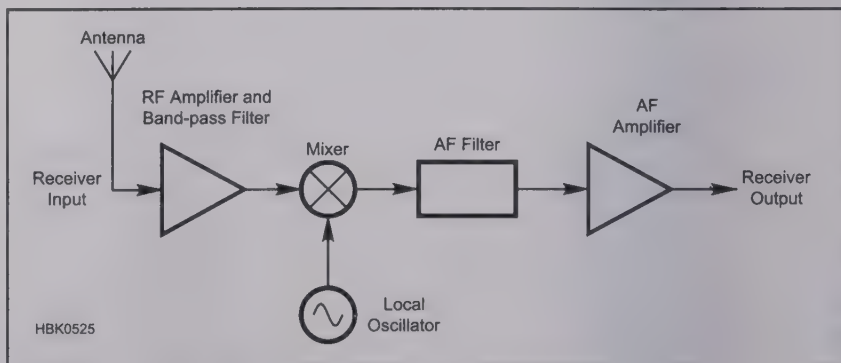

Figure 12.7 — Block diagram of a direct conversion receiver.

**Figure 12.8 — Frequency relationships in a direct conversion receiver.** At (A), the desired receive signal from antenna, a 7050 kHz on-off keyed carrier. At (B), the internal local oscillator (LO) and receive frequency relationships. At (C), the frequency relationships of mixer/detector products (not to scale). At (D), the sum and difference outputs from a double balanced mixer (not to scale). Note the mixer inputs that are balanced out so that they cancel in the output (dashed lines).

cancel both. A double-balanced mixer simplifies the output filtering job as shown in Figure 12.8D.

Products generated by nonlinearities in the mixing process (see the previous sidebar on Nonlinear Signal Combinations) are heard as intermodulation distortion signals that we will discuss later. Note that the nonlinearities also allow mixing with unwanted signals near multiples of local oscillator frequency. These signals, such as those from TV or FM broadcast stations, must be eliminated in the filtering before the mixer since their audio output will be right in the desired passband on the output of the mixer.

### 12.2.2 Superheterodyne Receivers

In many instances, it is not possible to achieve all the receiver design goals with a single-conversion receiver and multiple conversion steps are used, creating the superheterodyne architecture. Traditionally, the first conversion is tasked with removing the RF image signals, while the second generates the IF signal where the signal is amplified and filtered.

The superheterodyne concept was introduced by Major Edwin Armstrong, a US Army artillery officer, just as WW I was coming to a close. He is the same Armstrong who invented frequency modulation (FM) some years later and who held many radio patents between WW I and WW II.

In a superhet, a local oscillator and mixer are used to translate the received signal to an intermediate frequency rather than directly to audio. This provides an opportunity for additional amplification and processing. Then a second mixer is used as in the DC receiver to detect the IF signal, translating it to audio. The configuration was shown previously in Figure 12.6.

An example will illustrate how this works. Let's pick a common IF frequency used in a simple AM broadcast radio, 455 kHz. If we want to listen to a 600 kHz broadcast station,

the RF stage would be set to amplify the 600 kHz signal and the LO should be set to 600 + 455 kHz or 1055 kHz. The 600 kHz signal, along with any audio information it contains, is translated to the IF frequency and is amplified and then detected.

Note that we could have also set the local oscillator to 600 – 455 kHz or 145 kHz. By setting it to the sum, we reduce the relative range that the oscillator must tune. To cover the 500 to 1700 kHz with the difference, our LO would have to cover from 45 to 1245, a 28:1 range. Using the sum requires LO coverage from 955 to 2155 kHz, a range of about 2.5:1 — much easier to implement.

Note that to detect standard AM signals, the receiver's second oscillator, the beat frequency oscillator (BFO), is turned off since the AM station provides its own carrier signal over the air. Receivers designed only for standard AM reception generally don't have a BFO at all.

It's not clear yet that we've gained anything by doing this; so let's look at another example. If we decide to change from listening to the station at 600 kHz and want to listen to another station at, say, 1560 kHz, we can tune the single dial of our superhet to 1560 kHz. The RF stage is tuned to 1560 kHz, the LO is set to 1560 + 455 or 2010 kHz, and now the desired station is translated to our 455 kHz IF where the bulk of our amplification can take place. Note also that with the superheterodyne configuration, selectivity (the ability to separate stations) occurs primarily in the intermediate-frequency (IF) stages and is thus the same no matter what frequencies we choose to listen to. This simplifies the design of each stage considerably.

### 12.2.3 Superheterodyne Bandwidth

Now we will discuss the bandwidth requirements of different operating modes and how that affects superhet design. One advantage of a superhet is that the operating bandwidth can be established by the IF stages, and further limited by the audio system. It is thus independent of the RF frequency to

**Table 12.3**  
**Typical Communications Bandwidths for Various Operating Modes**

Mode	Bandwidth (kHz)
FM Voice	15
AM Broadcast	10
AM Voice	4-6.6
SSB Voice	1.8-3
Digital Voice	1.0-1.2
RTTY (170-850 Hz shift)	0.3-1.5
CW	0.1-0.5

**Figure 12.9** — Spectrum of sidebands of an AM voice signal with a carrier frequency of 600 kHz.

which the receiver is tuned. It should not be surprising that the detailed design of a superhet receiver is dependent on the nature of the signal being received. We will briefly discuss the most commonly received modulation types and the bandwidth implications of each below. The typical operating modes expected to be encountered by an HF communications receiver are tabulated in **Table 12.3**. (Each modulation type is discussed in more detail in the **Modulation or Digital Protocols and Modes** chapters.) The same concerns for receiver bandwidth apply to SDR receivers although the filters are implemented using DSP techniques.

#### AMPLITUDE MODULATION AM)

As shown in Figure 12.8, multiplying (in other words, modulating) a carrier with a single tone results in the tone being translated to frequencies of the sum and difference of the two. Thus, if a transmitter were to multiply a 600 Hz tone and a 600 kHz carrier signal, we would generate additional new frequencies at 599.4 and 600.6 kHz. If instead we were to modulate the 600 kHz carrier signal with a band of frequencies corresponding to human speech of 300 to 3300 Hz (the usual range of communication quality voice signals), we would have a pair of information-carrying sidebands extending from 596.7 to 603.3 kHz, as shown in **Figure 12.9**.

Note that the total bandwidth of this AM voice signal is twice the highest modulation signal frequency, or 6600 Hz. If we choose to transmit speech and limited-range music, we might allow modulating frequencies up to 5000 Hz, resulting in a bandwidth of 10,000 Hz or 10 kHz. This is the standard channel spacing that commercial AM broadcasters use in the US. (9 kHz is used in Europe) In actual use, transmitters on adjacent channels are generally geographically separated, so broadcasters can extend some energy into the next channels for improved fidelity. We would refer to this as a *narrow-bandwidth* mode.

What does this say about the bandwidth

**Figure 12.10** — Spectrum of single sideband AM voice signal with the suppressed carrier frequency of 600 kHz.

needed for our receiver? If we want to receive the full information content transmitted by a US AM broadcast station, then we need to set the bandwidth to at least 10 kHz. What if our receiver has a narrower bandwidth? Well, we will lose the higher frequency components of the transmitted signal — perhaps ending up with a radio suitable for voice but not very good at reproducing music.

On the other hand, what is the impact of having too wide a bandwidth in our receiver? In that case, we will be able to receive the full transmitted spectrum but we will also receive some of the adjacent channel information. This will sound like interference and reduce the quality of what we are receiving. If there are no adjacent channel stations, we will get any additional noise from the additional bandwidth and minimal additional information. The general rule is that the received bandwidth should be matched to the bandwidth of the signal we are trying to receive to maximize SNR and minimize interference.

As the receiver bandwidth is reduced, intelligibility suffers, although the SNR is improved. With the carrier centered in the receiver bandwidth, most voices are difficult to understand at bandwidths less than around 4 kHz. In cases of heavy interference, full carrier AM can be received as if it were SSB, as described below, with the carrier inserted at the receiver, and the receiver tuned to whichever sideband has the least interference.

#### SINGLE-SIDEBAND (SSB)

A single-sideband signal is contains just one of the AM signal's sideband and no carrier, as shown in **Figure 12.10**. To receive the SSB signal, the receiver uses a BFO (beat frequency oscillator) in the receiver to provide a substitute carrier. The BFO oscillator signal is multiplied with the sideband in order to provide demodulated audio output. The implications in the receiver are that the bandwidth can be slightly less than half that required for double sideband AM (DSB). The tradeoff is that the BFO signal must be at

exactly the right frequency. If the frequency is improperly set, the frequency of the demodulated audio will be offset from the original signal. The effect is quite audible even for small frequency errors of a few tens of Hz. (The *QST* article “About SSB” by the editor illustrates this effect, including a video on tuning in an SSB signal — see the References section.)

This results in a requirement for a much more stable receiver design with a much finer tuning system — a more expensive proposition than the DC receiver. An alternate is to transmit a reduced level carrier and have the receiver lock on to the weak carrier, usually called a *pilot* carrier. Note that the pilot carrier need not be of sufficient amplitude to demodulate the signal, just enough to allow a BFO to lock to it. These alternatives are effective, but tend to make SSB receivers expensive, complex and most appropriate for the case in where a small number of receivers are listening to a single transmitter, as is the case of two-way amateur communication.

Note that the bandwidth required to effectively demodulate an SSB signal is actually less than half that required for the AM signal because the range centered on the AM carrier need not be received. Thus the communications-quality range of 300 to 3300 Hz can be received in a bandwidth of 3000 not 3300 Hz. Early SSB receivers typically used a bandwidth of around 3 kHz, but with the heavy interference frequently found in the amateur bands, it is more common for amateurs to use bandwidths of 1.8 to 2.4 kHz with the corresponding loss of some of the higher- and lower-frequency speech sounds.

## RADIOTELEGRAPHY (CW)

We have described radiotelegraphy as being transmitted by “on-off keying of a carrier.” You might think that since a carrier takes up just a single frequency, the receive bandwidth needed should be almost zero. This is only true if the carrier is never turned on and off. In the case of CW, it will be turned on and off quite rapidly. The rise and fall of the carrier results in sidebands extending on either side of the carrier, and they must be received in order to reconstruct the signal in the receiver.

A rule of thumb is to consider the rise and fall time as about 10% of the pulse width and the bandwidth as the reciprocal of the quickest of rise or fall time. This results in a bandwidth requirement of about 50 to 200 Hz for the usual CW transmission rates. Another way to visualize this is with the bandwidth being set by a high-Q tuned circuit. Such a circuit will continue to “ring” after the input pulse is gone. Thus, too narrow a bandwidth will actually “fill in” between the code elements and act like a “no bandwidth” full

period carrier and this is exactly what is heard if a very narrow crystal filter is used when receiving CW.

## DIGITAL MODULATION

(This is a short overview to establish receiver requirements for the digital modes. See the **Modulation** and **Digital Protocols and Modes** chapters and the **Digital Communications** chapter in the *Handbook* downloadable supplemental information for more in-depth treatment.)

The Baudot code (used for teletype communications) and ASCII code — two popular digital communications codes used by amateurs — are constructed with sequences of elements or bits. The state of each bit — ON or OFF — is represented by a signal at one of two distinct frequencies: one designated *mark* and one designated *space*. This is referred to as *frequency shift keying* (FSK). The transmitter frequency shifts back and forth with each character’s individual elements.

Amateur operators typically use a 170 Hz separation between the mark and space frequencies for the most popular FSK mode, radioteletype or RTTY, depending on the data rate and local convention, although 850 Hz is sometimes used. The minimum bandwidth required to recover the data is approximately twice the spacing between the tones. Note that the tones can be generated by directly shifting the carrier frequency (*direct FSK*), or by using a pair of 170 Hz spaced audio tones applied to the audio input of an SSB transmitter (*audio FSK* or *AFSK*). Direct FSK and AFSK are indistinguishable to a receiver.

Note that if the standard audio tones of 2125 Hz (mark) and 2295 Hz (space) are used, they fall within the bandwidth of a voice channel and thus a voice transmitter and receiver can be employed without any additional processing needed outside the radio equipment.

If the receiver can shift its BFO frequency appropriately, the two tones can be received through a filter designed for CW reception with a bandwidth of about 300 Hz or wider. Some receivers provide such a narrow filter with the center frequency shifted midway between the tones (2210 Hz) to avoid the need for retuning. The most advanced receivers provide a separate filter for mark and space frequencies, thus maximizing interference rejection and signal-to-noise ratio (SNR). Using a pair of tones for FSK or AFSK results in a maximum data rate of about 1200 bit/s over a high-quality voice channel.

*Phase shift keying* (PSK) can also be used to transmit bit sequences, requiring good frequency stability to maintain the required

time synchronization to detect shifts in phase. If the channel has a high SNR, as is often the case at VHF and higher, telephone network data-modem techniques such as Bell 102 and Bell 202 can be used. (FCC §97.307(f) specifies a maximum transmitted symbol rate for each band.)

At HF, the signal is subjected to phase and amplitude distortion as it travels. Noise is also substantially higher on the HF bands. Under these conditions, modulation and demodulation techniques designed for “wireline” connections become unusable at bit rates of more than a few hundred baud. As a result, amateurs have begun adopting and developing state of the art digital modulation techniques. These include the use of multiple carriers (MFSK, Clover, PACTOR III, etc.), multiple amplitudes and phase shifts (QAM and QPSK techniques), and advanced error detection and correction methods to achieve a net data throughput as high as 3600 bits per second (bps) over a voice-bandwidth channel. Newly developed coding methods for digital voice using QPSK modulation result in a signal bandwidth of less than 1200 Hz. (See [freedv.org](http://freedv.org) for more information.) Spread-spectrum techniques are also being adopted on the amateur UHF bands, but are beyond the scope of this discussion.

The bandwidth required for data communications can be as low as 100 Hz for PSK31 to 1 kHz or more for the faster speeds of PACTOR III and Clover. Beyond having sufficient bandwidth for the data signal, the primary requirements for receivers used for data communications are linear amplitude and phase response over the bandwidth of the data signal to avoid distorting these critical signal characteristics. The receiver must also have excellent frequency stability to avoid drift and frequency resolution to enable the receiver filters to be set on frequency.

## FREQUENCY MODULATION (FM)

Another popular voice mode is *frequency modulation* or *FM*. FM can be found in a number of variations depending on purpose. In Amateur Radio and commercial mobile communication use on the shortwave bands, it is universally *narrow band FM* or *NBFM*. In NBFM, the frequency deviation is limited to around the maximum modulating frequency, typically 3 kHz. The bandwidth requirements at the receiver can be approximated by Carson’s Rule of  $BW = 2 \times (D + M)$ , where D is the deviation and M is the maximum modulating frequency. Thus 3 kHz deviation and a maximum voice frequency of 3 kHz results in a bandwidth of 12 kHz, not far beyond the requirements for broadcast AM. (Additional signal components extend beyond this bandwidth, but are not required for voice communications.)

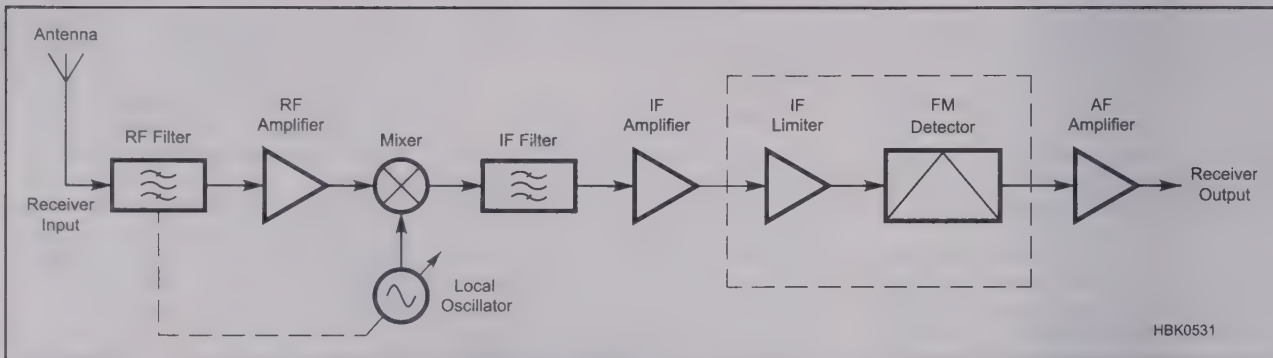

Figure 12.11 — Block diagram of an FM superheterodyne receiver. Changes from an AM/SSB receiver are enclosed by the dashed line.

In contrast, broadcast or *wideband FM* or *WBFM* occupies a channel width of 150 kHz. Originally, this provided for a higher modulation index, even with 15 kHz audio that resulted in an improved SNR. However, with multiple channel stereo and sub-channels all in the same allocated bandwidth the deviation is around the maximum transmitted signal bandwidth.

In the US, FCC amateur rules limit wideband FM use to frequencies above 29 MHz. Some, but not all, HF communication receivers provide for FM reception. For proper FM reception, two changes are required in the receiver architecture as shown within the dashed line in Figure 12.11. The fundamental change is that the detector must recover information from the frequency variations of the input signal. The most common such detector is called a *discriminator*. The discriminator does not require a BFO, so that is turned off, or eliminated in a dedicated FM receiver. Since amplitude variations convey no information in FM, they are generally

eliminated by a *limiter*. The limiter is a high-gain IF amplifier stage that clips the positive and negative peaks of signals above a certain threshold. Since most noise of natural origins is amplitude modulated, the limiting process also strips away noise from the signal.

### 12.2.4 Superheterodyne FM Receivers

Narrow-band frequency modulation (NBFM) is the most common mode used on VHF and UHF. Figure 12.12 is a block diagram of an FM receiver for the VHF/UHF amateur bands. Many FM transmitters are actually phase-modulated (PM) but aside from frequency response of the transmitted audio, the two types of signals can be received with the same equipment. This section's references to FM include PM signals unless noted otherwise.

#### FRONT END

A low-noise front end is desirable because

of the decreasing atmospheric noise level at these frequencies and also because portable gear often uses short rod antennas at ground level. Nonetheless, the possibilities for gain compression and harmonic IMD, multi-tone IMD and cross modulation are also substantial. Therefore dynamic range is an important design consideration, especially if large, high-gain antennas are used. FM limiting should not occur until after the crystal filter. Because of the high occupancy of the VHF/UHF spectrum by powerful broadcast transmitters and nearby two-way radio services, front-end preselection is desirable, so that a low noise figure can be achieved economically within the amateur band. (See the section on Preselectors elsewhere in this chapter.)

#### DOWN-CONVERSION

Down-conversion to the final IF can occur in one or two stages. Favorite IFs are in the 5 to 10 MHz region (10.7 MHz is common), but at the higher frequencies rejection of the image 10 to 20 MHz away can be difficult,

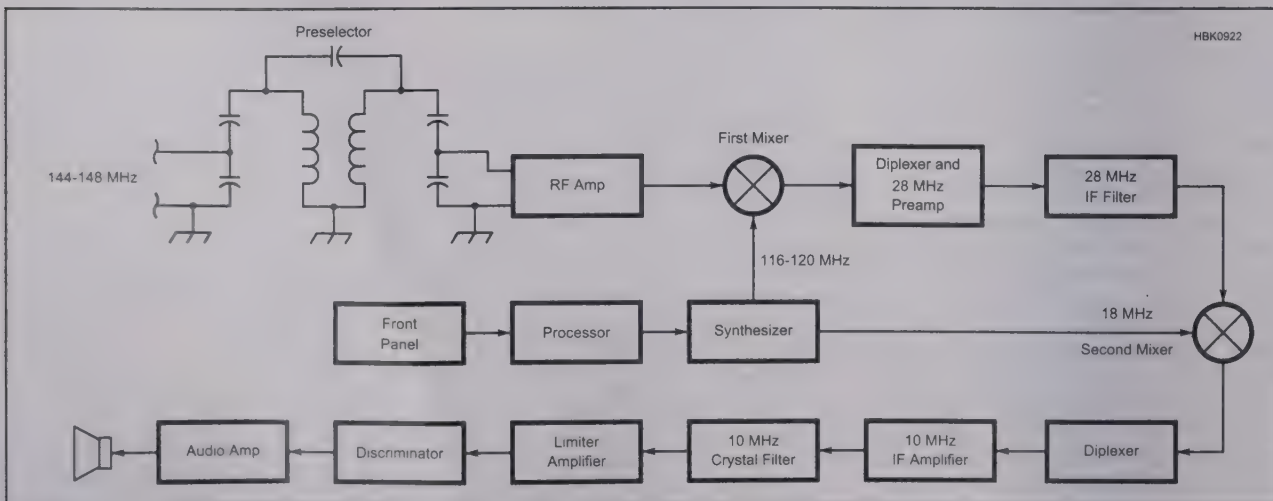

Figure 12.12 — Block diagram of a typical VHF FM receiver using dual down-conversion.

requiring considerable preselection as discussed in the sections below on IF selection and image rejection. At the higher frequencies an intermediate IF in the 30 to 50 MHz region is a better choice. Figure 12.12 shows dual down-conversion.

## IF FILTERS

The customary peak frequency deviation in amateur FM on frequencies above 29 MHz is about 5 kHz and the audio speech band extends to 3 kHz. This defines a maximum modulation index (defined as the deviation ratio) of  $5/3 = 1.67$ . An inspection of the Bessel functions that describe the resulting FM signal shows that this condition confines most of the 300 to 3000 Hz speech information sidebands within a 15 kHz or so bandwidth. Using filters of this bandwidth, channel separations of 20 or 25 kHz are achievable.

Many amateur FM transceivers are channeled in steps that can vary from 1 to 25 kHz. For low distortion of the audio output (after FM detection), this filter should have good phase linearity across the bandwidth. This would seem to preclude filters with very steep descent outside the passband, which tend to have very nonlinear phase near the band edges. But since the amount of energy in the higher speech frequencies is naturally less, the actual distortion due to this effect may be acceptable for speech purposes. The normal practice is to apply pre-emphasis to the higher speech frequencies at the transmitter and de-emphasis compensates at the receiver.

## LIMITING AND DEMODULATION

After the filter, hard limiting of the IF is needed to remove any amplitude modulation components. In a high-quality receiver, special attention is given to any nonlinear phase shift that might result from the limiter circuit design. This is especially important in data receivers in which phase response must be controlled. In amateur receivers for speech it may be less important. Also, the *ratio detector* largely eliminates the need for a limiter stage, although the limiter approach is probably still preferred. FM demodulation is described in the section on Demodulation and Detection.

## FM PERFORMANCE FOR WEAK SIGNALS

The noise bandwidth of the IF filter is not much greater than twice the audio bandwidth of the speech modulation, less than it would be in wideband FM. Therefore such things as capture effect, the threshold effect and the noise quieting effect so familiar to wideband FM are still operational, but somewhat less so, in FM. For FM receivers, sensitivity is

specified in terms of a SINAD (see the **Test Equipment and Measurements** chapter) ratio of 12 dB. Typical values are  $-110$  to  $-125$  dBm, depending on the low-noise RF pre-amplification that often can be selected or deselected (in strong signal environments).

## EFFECT OF LO PHASE NOISE

In an FM receiver, LO phase noise is superimposed on phase modulation, and therefore creates frequency modulation of the desired signal. This reduces the ultimate signal-to-noise ratio within the passband. This effect is called *incidental FM (IFM)*. The power density of IFM (W/Hz) is proportional to the phase noise power density (W/Hz) multiplied by the square of the modulating frequency (the familiar parabolic effect in FM). If the receiver uses high-frequency de-emphasis at the audio output ( $-6$  dB per octave from 300 to 3000 Hz, a common practice), the IFM level at higher audio frequencies can be reduced. Ordinarily, as the signal increases the noise would be “quieted” (that is, “captured”) in an FM receiver, but in this case the signal and the phase noise riding “piggy back” on the signal increase in the same proportion as described in this and the **Oscillators and Synthesizers** chapter’s discussion of reciprocal mixing. IFM is not a significant problem in modern FM radios, but phase noise can become a concern for adjacent-channel interference.

As the signal becomes large the signal-to-noise ratio therefore approaches some final value. A similar ultimate SNR effect occurs in SSB receivers. On the other hand, a perfect AM receiver tends to suppress LO phase noise. (See the reference entry for Sabin.)

## FM RECEIVER ICs

A wide variety of special ICs for communications-bandwidth FM receivers are available. Many of these were designed for “cordless” or mobile telephone applications and are widely used. One is an RF amplifier chip (NE/SA5204A) for  $50\ \Omega$  input to  $50\ \Omega$  output with 20 dB of gain. The second chip (NE/SA602A) is a front-end device with an RF amplifier, mixer and LO. The third is an IF amplifier, limiter and quadrature FM detector (NE/SA604A) that also has a very useful RSSI (logarithmic Received Signal Strength Indicator) output and also a “mute” function. The fourth is the LM386, a widely used audio-amplifier chip. Another FM receiver chip, complete in one package, is the MC3371P.

The MC13135 features double conversion and two IF amplifier frequencies. This allows more gain on a single chip with less of the cross coupling that can degrade stability. This desirable feature of multiple down-conversion was mentioned previously in this chapter.

Design details and specific parts values can be learned from a careful study of the data sheets and application notes provided by the IC vendors. Amateur designers should learn how to use these data sheets and other information such as application notes available online from the manufacturers.

## 12.2.5 Superhetrodyne Image Rejection

Now that we have established the range of bandwidths that our receiver will need to pass, we are in a position to discuss the selection of the IF frequency at which those bandwidths will be established.

In addition, selection of the first and any following IF frequencies is important in receiving weak signals on bands where strong signals are present. If the desired signal is near the noise, a signal at an image frequency could easily be 100 dB stronger, and thus to avoid interference, an image rejection of 110 dB would be needed. While some receivers meet that target, the receiver sections of most current amateur transceivers are in the 70 to 100 dB range.

## IF IMAGE RESPONSE

As noted earlier, a superhet with a single local oscillator or LO and specified IF can receive two frequencies, selected by the tuning of the RF stage. For example, using a receiver with an IF of 455 kHz to listen to a desired signal at 7000 kHz can use an LO of 7455 kHz. However, the receiver will also receive a signal at 455 kHz above the LO frequency, or 7910 kHz. This undesired signal frequency, located at twice the IF frequency from the desired signal, is called an *image*.

Images will be separated from the desired frequency by twice the IF and the filter ahead of the associated mixer must reduce the image signal by the amount of the required *image rejection*. For a given IF, this gets more difficult as the received frequency is increased. For example, with a 455 kHz single conversion system tuned to 1 MHz, the image will be at 1.91 MHz, almost a 2:1 frequency ratio and relatively easy to reject with a filter. The same receiver tuned to 30 MHz, would have an image at 30.91 MHz, a much more difficult filtering problem.

While an image that falls on an occupied channel is obviously a problem — it’s rarely desirable to receive two signals at the same time — problems occur even if the image frequency is clear of signals. This is because the atmospheric noise in the image bandwidth is added to the noise of the desired channel, as well as any internally-generated noise in the RF amplifier stage. If the image response is at the same level as the desired

signal response, there will be a 3 dB reduction in SNR.

### REDUCING IMAGES BY INCREASING IF

An obvious solution to the RF image response is to raise the IF frequency high enough so that signals at twice the IF frequency from the desired signal are sufficiently attenuated by filters ahead of the mixer. This can easily be done with IF stages operating at 5 to 10% of the highest receiving frequency (1.5 to 3 MHz for a receiver that covers the 3-30 MHz HF band). The concept is used at higher frequencies as well. The FM broadcast band (150 kHz wide channels over 87.9 to 108 MHz in the US) is generally received on superhet receivers with an IF of 10.7 MHz, which places all image frequencies outside the FM band, eliminating interference from other FM stations.

The use of higher-frequency tuned circuits for IF selectivity works well for the 150 kHz wide FM broadcast channels, but not so well for the relatively narrow channels encountered on HF or lower, or even for many V/UHF narrowband services. Fortunately, there are three solutions that were commonly used to resolve this problem.

The first, *double conversion*, converted the desired signal to a relatively high IF followed by a second conversion to a lower IF to set the selectivity. This was a popular technique in the 1950s. Improvements on the double conversion technique led to *triple conversion* with a very low, highly selective third IF. The *Collins system* of moving a single-range VFO to the second mixer and using switchable crystal oscillators for the first mixer also became popular. The *pre-mixed* arrangement,

a third approach to double conversion was a combination of the two, used a single variable oscillator range, as with the Collins, but mixes the VFO and LO before applying them to the first mixer – outside of the signal path.

These methods are obsolete for current receivers but are commonly encountered in vintage equipment. They are discussed in previous editions of the *Handbook*.

### HIGH-FREQUENCY CRYSTAL LATTICE FILTERS

Commercial quartz-crystal filters with bandwidths appropriate for CW and SSB became available in the 1970s with center frequencies into the 10 MHz range. This allowed a single-conversion receiver (see Figure 12.2) with an IF in the HF range to provide both high image rejection and needed channel selectivity. This single-conversion architecture remains popular among designers of portable and low-power equipment. Crystal filter design is discussed in the *Analog and Digital Filtering* chapter along with downloadable supplemental information.

As an example Figure 12.13 shows the IF section of a single-conversion superhet using simple filters centered 1500 kHz. While the filters shown are actually buildable by amateurs at low cost, multiple-section filters with much better performance can be purchased or constructed. Other IF frequencies can be used, depending on crystal or filter availability.

The circuit shown demonstrates the concepts involved and can be reproduced at low cost. Remaining receiver functional blocks such as the AGC circuitry, detectors and BFO, and audio amplifiers and filters can be found elsewhere in the book.

### DSP IF FILTERS

Digital signal processing provides a level of filter performance not practical with other technologies. (See the *Analog and Digital Filtering* chapter) While much better than most low frequency IF LC bandwidth filters, the very good crystal or mechanical bandwidth filters in amateur gear are not very close to the rectangular shaped frequency response of an ideal filter, but rather have skirts with a 6 to 60 dB response of perhaps 1.4 to 1. That means if we select an SSB filter with a nominal (6 dB) bandwidth of 2400 Hz, the width at 60 dB down will typically be  $2400 \times 1.4$  or 3360 Hz. Thus a signal in the next channel that is 60 dB stronger than the signal we are trying to copy (as often happens) will have energy just as strong as our desired signal.

DSP filtering approaches the ideal response. Figure 12.14 shows the ARRL Lab measured response of a DSP bandwidth filter with a 6 dB bandwidth of 2400 Hz. Note how rapidly the skirts drop to the noise level. In addition, while analog filtering generally requires a separate filter assembly for each desired bandwidth, DSP filtering is adjustable — often in steps as narrow as 50 Hz — in both bandwidth and center frequency. In addition to bandwidth filtering, the same DSP can often provide digital noise reduction and digital notch filtering to remove interference from fixed frequency carriers.

### UP-CONVERSION AND DOWN-CONVERSION

Current crystal filter technology allows *down-conversion* HF receivers to use an IF in the 4-10 MHz range. With a 10 MHz IF and an LO above the signal frequency, a

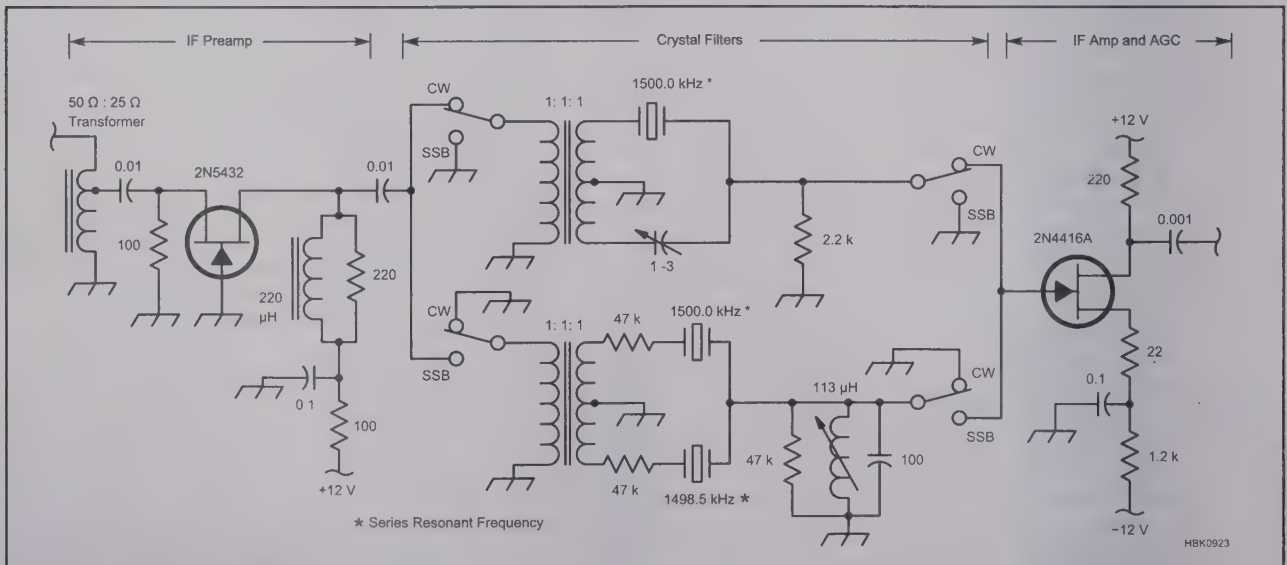

Figure 12.13 — The IF section of a superhet using crystal filters to establish receiver bandwidth.

Figure 12.14 — ARRL Lab measured response of an aftermarket 2400 Hz DSP bandpass filter.

30 MHz signal would have an image at 50 MHz. This makes image-rejection filtering relatively straightforward, although many receiver IF frequencies tend to be at the lower end of the above range. Still, as will be discussed in the next section, they have other advantages.

Many current HF receivers (or receiver

sections of transceivers) have elected to employ an *up-conversion* architecture. They typically have an IF in the VHF range, perhaps 60 to 70 MHz, making HF image rejection easy. A 30 MHz signal with a 60 MHz IF will have an image at 150 MHz. Not only is it five times the signal frequency, but signals in this range (other than perhaps the occasional taxicab) tend to be weaker than some undesired HF signals. Receivers with this architecture have image responses at the upper end of the above range, often with the image rejected by a relatively simple low-pass filter with a cut off at the top of the receiver range.

Another advantage of this architecture is that the local oscillator can cover a wide continuous range, making it convenient for a general coverage receiver. For example, with a 60 MHz IF, a receiver designed for LF through HF would need an LO covering 60.03 to 90 MHz, a 1.5 to 1 range, easily provided by a number of synthesizer technologies, as described in the **Oscillators and Synthesizers** chapter. The article “A High Performance 45 MHz IF Amplifier” by Colin Horrabin, G3SBI, has been includ-

ed in the downloadable supplemental information as an example of circuits suitable for up-conversion receivers.

The typical up-converting receiver uses multiple conversions to move signals to frequencies at which operating bandwidth can be established. While crystal filters in the VHF range used by receivers with upconverting IFs have become available with bandwidths as narrow as around 3 kHz, they do not yet achieve the shape factor of similar bandwidth filters at MF and HF. Thus, these are commonly used as *roofing filters*, discussed in the next section, prior to a conversion to one or more lower IF frequencies at which the operating bandwidth is established. Figure 12.15 is a block diagram of a typical upconverting receiver using DSP for setting the operating bandwidth.

### THE IMAGE-REJECTING MIXER

Another technique for reduction of image response in receivers is not as commonly encountered in HF receivers as the preceding designs, but it deserves mention because it has some very significant applications. The *image-rejecting mixer* requires phase-shift networks, as shown in Figure 12.16. Frequency  $F_1$  represents the input frequency while  $F_2$  is that of the local oscillator. Note that the two  $90^\circ$  phase shifts are applied at different frequencies. The phase shift network following Mixer 1 is at a fixed center frequency corresponding to the IF, while the phase shift network at  $F_2$  must provide the required phase shift as the local oscillator tunes across the band.

If the local oscillator is required to tune over a limited fractional frequency range, this is a very feasible approach. On the other hand, maintaining a  $90^\circ$  phase shift over a wide range can be tricky. The good news is that this approach provides image reduction that is independent of, and in addition to, any other mechanisms such as filters that are employed toward that end.

Additionally, with the ability of DSP components to operate at higher and higher frequencies, the necessary operations seen in Figure 12.16 can be performed in software which does not depend on precision hardware design to maintain nearly exact phase relationships.

The image-rejecting mixing process has several attractive features:

- It is the only way to provide “single signal” reception with a direct conversion receiver, effectively reducing the audio image. This can make the DC receiver a very good performer, although the added complexity is not always warranted in typical amateur DC applications.
- This option is frequently found in microwave receivers in which sufficiently selective RF filtering can be difficult to obtain. Since

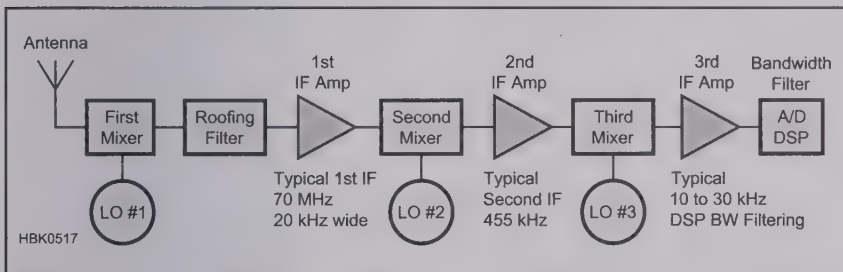

Figure 12.15 — Block diagram of a typical upconverting receiver using DSP for the 3rd IF filter which sets operating bandwidth. Hybrid heterodyne/SDR receivers applying DSP filters at IF frequencies are common.

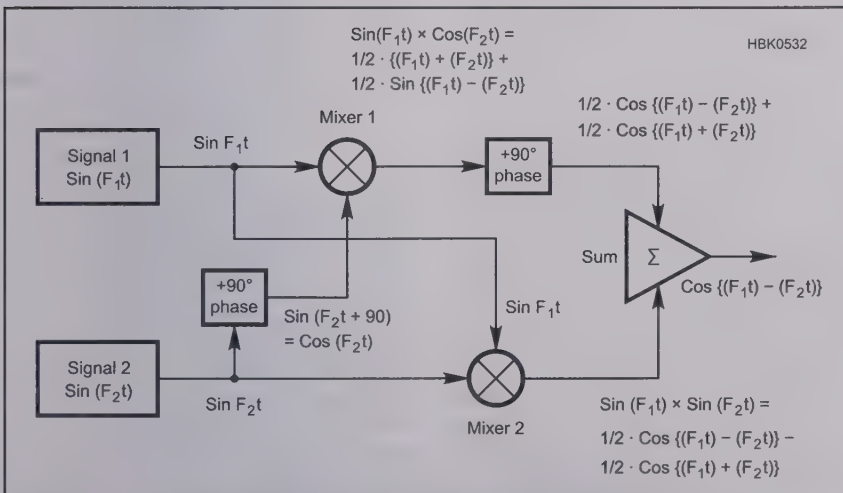

Figure 12.16 — Image rejecting mixer, block diagram, and signal relationships.

they often operate on fixed frequencies, maintaining the required phase shift can be straightforward.

- It is found in advanced receivers that are trying to achieve optimum performance. Even with a high first IF frequency, additional image rejection can be provided.

- In transmitters, the same system is called the *phasing method* of SSB generation. The same blocks run “backwards” — one of the phase shift networks can be applied to the speech band and used to cancel one sideband. This is discussed in the **Transmitting** chapter.

### 12.2.6 Preselectors

Placing a filter at the receiver’s antenna input, called a *preselector*, is a technique that improves both image rejection and overload from out-of-band signals. You can see such a filter at the front-end of several of the receiver block diagrams in this chapter. Preselection to avoid overload is often required with the inexpensive USB “dongle” style SDR receivers that are designed for DTV reception and not for strong-signal performance.

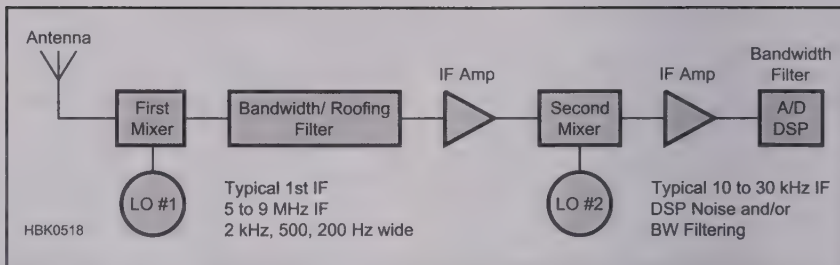

There are three types of preselectors:

- Manually-tuned — a tuned circuit or tuned input transformer that is adjusted by the operator for maximum signal level. The tuned circuit usually has several ranges that are selected by the receiver band switch. These were once common, especially on general-coverage receivers. Preselectors were also very popular in European equipment where extremely strong signals from high-power shortwave broadcast (SWBC) stations often caused receiver overload unless attenuated with a filter.

- Switched band-pass — a bank of band-pass filters selected by the band switch or under control of the receiver’s controlling microprocessor. Most of the top-performing receivers feature switched band-pass preselectors that do not require manual adjustment.

- Tracking — a continuously-variable tuned circuit or band-pass filter that is controlled by software to have peak response at the frequency of operation. This feature is relatively expensive to implement so it is only available on high-end receivers.

The downloadable supplemental content includes a pair of preselector designs. The manual general-coverage preselector from *Ham Radio* magazine is by George Hirshfield, W5OZF, covers from 0.5 to 30 MHz with a tuning capacitor augmented by fixed capacitors and tapped inductors. A software-controlled switched band-pass preselector covering 1.8 to 30 MHz from *QEX* is included as a project. Designed by Juan Onate, MØWWA and Xavier de Fortuny, the preselector

**Figure 12.17 — Block diagram of a down-converting amateur band receiver with “roofing” and operating bandwidth filters to improve performance in the presence of strong in-band signals.**

lector includes a number of auxiliary features (input protection, attenuators, LNA, and so on) and is controlled by a PIC microcontroller. All software is available from the ARRL as described in the article.

### 12.2.7 Superhet Design for Dynamic Range

In the past, the receivers with the best close-in third order intermodulation distortion and maximum blocking dynamic range were amateur-band-only receivers, such as the primary receiver in the TEN-TEC Orion and Omni series, and the receivers in the Elecraft K2 and K3. A look at a typical block diagram, as shown in **Figure 12.17**, makes it easy to see why. The problems resulting from strong unwanted signals near a desired one are minimized if the unwanted signals are kept out of the places in the receiver where they can be amplified even more and cause the nonlinear effects that we try to avoid.

Note that in **Figure 12.17**, the only place where the desired and undesired signals all coexist is before the first mixer. If the first mixer and any RF preamp stages have sufficient strong-signal handling capability, the undesired signals will be eliminated in the filter immediately behind the first mixer. This HF crystal filter is generally switchable to support desired bandwidths as narrow as 200 Hz. The later amplifier, mixer and DSP circuits only have to deal with the signal we want. For additional discussion of these issues, see “International Radio Roofing Filters for the Yaesu FT-1000 MP Series Transceivers,” by Joel Hallas, W1ZR, in *QST* Product Review for February 2005.

Now look at a typical modern general-coverage receiver as shown previously in **Figure 12.15**. In this arrangement, a single digital synthesizer, perhaps covering from 70 to 100 MHz, shifts the incoming signal(s) to a VHF IF, often near 70 MHz. A roofing filter at 70 MHz follows the first mixer. This arrangement offers simplified local oscillator

(LO) design and the possibility of excellent image rejection. Unfortunately, crystal filter technology has only recently been able to produce narrow filters for 70 MHz, and so far they have much wider skirts than the crystal filters used in **Figure 12.17**. As technology is rapidly shifting to SDR designs, the current models are likely exhibiting the peak performance level for upconverting receivers.

Many receivers and transceivers set the roofing filter bandwidth wider than any operating bandwidth and use DSP filtering much later in the signal chain to set the final operating bandwidth. For a receiver that will receive FM and AM, as well as SSB and CW, that usually means a roofing filter with a bandwidth of around 20 kHz. With this arrangement, all signals in that 20 kHz bandwidth pass all the way through IF amplifiers and mixers and into the A/D converter before we attempt to eliminate them using DSP filters. By that time they have had an opportunity to generate intermodulation products and cause the blocking and IMD problems that we are trying to eliminate. However, top of the line heterodyne radios feature both general coverage at HF and VHF roofing filters, such as the Icom IC-7851 and Yaesu FTdx9000 transceivers. (See the Transceiver Survey by W1ZR in the *Handbook*’s downloadable supplemental material for more information on the latest models.)

A hybrid architecture was implemented in the TEN-TEC Omni VII transceiver that effectively combines the two technologies. The first IF has a 20 kHz wide roofing filter at 70 MHz, followed by selectable steep skirted 455 kHz Collins mechanical filters at the second IF and then DSP filters at the third IF. This transceiver is no longer in production but offered excellent performance at the time of its introduction.

Careful attention to gain distribution among the stages between the filters maintains desired sensitivity, but not so high that the undesired products have a chance to become a serious problem. With bandwidths

of 20, 6 and 2.5 kHz supplied, and 500 and 300 Hz as accessories, the undesired close-in signals are eliminated before they have an opportunity to cause serious trouble in the

DSP stages that follow.

Another variation is found in the Kenwood TS-590S and SG models which switch between down-conversion on the more

crowded “contest bands” (160, 80, 40, 20 and 15 meters) and up-conversion on the remaining bands. In effect, this trades sensitivity for dynamic range.

## 12.3 SDR Receivers

The SDR was introduced in the **DSP and SDR Fundamentals** chapter. Repeated here are the sections of that chapter describing SDR architecture and performance issues. This section presents and compares several block-diagram-level concepts for software-defined radio. For the basic elements of SDR and DSP, see the chapter referenced above.

### 12.3.1 Digitizing at IF

The first generation of radios to make use of DSP techniques at RF performed the analog-digital conversion on an IF signal. **Figure 12.18** shows such a design. In such a receiver, placing the A/D converter after a crystal IF filter improves the blocking dynamic range (BDR) for interfering signals that fall outside the crystal filter bandwidth. As shown, the down-conversion to I/Q format still uses lower-speed A/D converters, but often the signal is actually at a low IF, say, 15 kHz or so. This allows an SSB-bandwidth signal to be contained within the 20 kHz bandwidth of a typical audio codec and avoids errors due to dc offsets in the signal path. With careful design, a receiver with such an architecture can achieve 140 dB or more of BDR (if there are no other limiting factors such as LO phase noise). The third-order dynamic range is similar to that achieved with a conventional analog architecture since the circuitry up to the crystal filter, including amplifiers and mixer(s) is the same.

Another advantage of the IF-based

approach compared to directly sampling the RF frequency is that the ADC does not have to run at such a high sample rate. In fact, because the crystal filter acts as a high-performance, narrow-bandwidth anti-aliasing filter, *undersampling* is possible if the A/D converter has sufficient sampling bandwidth (ADCs intended for audio applications generally do not). With bandwidths of a few kHz or less, sample rates in the tens of kHz can be used even though the center frequency of the IF signal is much higher, so long as the ADC’s sample-and-hold circuit has sufficient bandwidth.

### 12.3.2 Direct RF Digitizing

The ultimate SDR architecture is to convert between the analog and digital domains right at the frequency to be transmitted or received, or convert a wide range of frequencies and

do all filtering in the digital domain. The receive path of such a design is shown in **Figure 12.19**. In this receiver, the only remaining analog components in the signal chain are a wide-band anti-aliasing filter and an amplifier to improve the noise figure of the ADC if necessary. A preselector stage may be used to prevent overload from strong signals far from the selected frequency or frequency band. The local oscillator, mixer, IF filters, AGC, demodulators and other circuitry are all replaced by digital hardware and software. The digital/software implementations of these functions are perfectly stable with time, temperature, and need no adjustments.

It has only been recently that low-cost high-speed ADCs have become available with specifications good enough to allow reasonable performance in an RF-sampling communications receiver. Today it is possible

### Sampling Rates

Digital audio equipment, that is audio equipment that uses digital sampling at some point in the device, has been around since the 1970s. There are two primary fundamental sampling rates that are used in all digital audio equipment: 44.1 ksp/s and 48 ksp/s. From these two rates, all other rates are derived by using factors of these two numbers. In amateur radio, the latter number, 48 kHz, is most often used and is why all our signal chains typically operate at a multiple or sub-multiple of these numbers. The most common processing speeds are 24 ksp/s, 36 ksp/s, 48 ksp/s, 96 ksp/s and 192 ksp/s. 48 ksp/s is by far the most common, but it varies by the manufacturer and radio design.

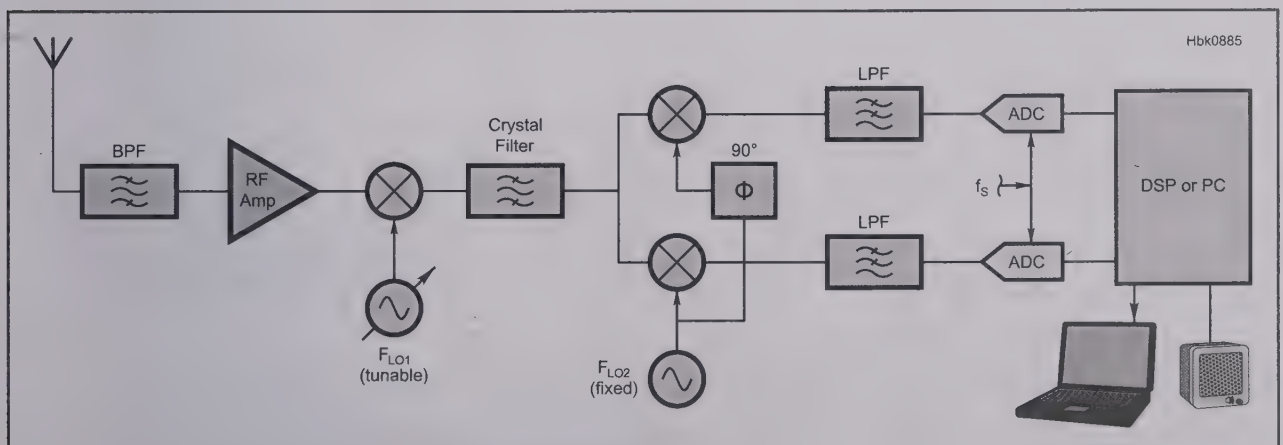

Figure 12.18 — Hybrid superhetro/DSP SDR receiver architecture.

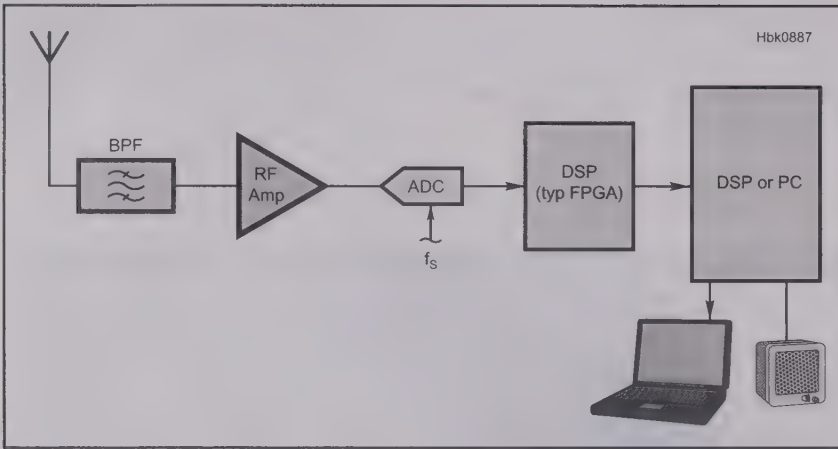

Figure 12.19 — Direct RF-sampling DSP SDR receiver architecture.

to achieve blocking dynamic range of 130 dB. That is not quite as good as the best analog or hybrid radios, but with every new generation of A/D converter that becomes available for use in SDR, the performance gap becomes narrower.

It is worth noting here that while huge BDR numbers can be measured in the laboratory, the performance achieved in a real-world environment with a receiver connected to an antenna is quite different. Often local noise sources raise the noise floor such that the receiver's full BDR cannot be utilized and other specifications become more important. In many of these specifications (dynamic range for close-spaced signals, etc.), RF-sampling SDRs can provide performance comparable or superior to conventional all-analog and IF-sampling receivers.

Third-order dynamic range (3IMD\_DR) is not a meaningful specification for this type of radio because it is based on the behavior of analog circuits. In addition, calculation of  $IP_3$  assumes that distortion products increase 3 dB for each 1 dB increase in signal level, which is not always true for an ADC. The level of the distortion products in an ADC tends to be more-or-less independent of signal level until the signal peak exceeds the ADC's full scale input, at which point the distortion increases dramatically. It is important to read the data sheet carefully and note the test conditions for the distortion measurements.

There are definite advantages to sampling at RF. For one thing, it saves a lot of analog circuitry. Even though a high-speed ADC is more expensive than an audio converter, the radio may be end up being cheaper to build because of the reduced component count and fewer adjustments. Performance is improved in some areas. For example, image rejection is no longer a worry, as long as the anti-aliasing filter is doing its job. (As well as any

preselector filters that may be present.) The dynamic range of an SDR theoretically does not depend on signal spacing — close-in dynamic range is often better than with a conventional architecture that uses a wide IF filter. With no crystal filters in the signal chain, the entire system has a completely linear phase response, which can improve the quality of both analog and digital signals after demodulation.

The biggest challenge with RF sampling is what to do with the torrent of high-speed data coming out of the receiver's ADC. To cover 0-54 MHz without aliasing requires a sample rate of at least 120 or 130 MHz, and com-

mercial products typically operate the ADC at sample rates well over 200 MHz. That is much faster than a typical microprocessor or programmable DSP can handle. The local oscillator, mixer, and decimator or interpolator must be implemented in digital hardware so that the DSP can send and receive data at a more-reasonable sample rate. *Digital down-converters* (DDC) perform those functions and output a lower-sample-rate digital I/Q signal to the DSP. Stand-alone DDC ICs were available in the past, but the function is now usually integrated with the A/D converter. It is also possible to implement a DDC in a *field-programmable gate array* or FPGA. (See the "Hands-On SDR" QEX columns provided in the downloadable supplemental information.) *Digital upconverters* (DUC) do the same conversion in reverse for the transmitter and are available integrated with the D/A converter or can be implemented in an FPGA. Some commercial integrated DDC/DAC products even include the capability to encode several digital modulation formats such as GMSK, QPSK and  $\pi/4$  DQPSK. In an attempt to simplify the interface to the digital domain, many high-speed converters now use a standardized serial interface specification called JESD204B, capable of handling up to 12 Gb/s. Code to implement this interface on the digital FPGA is readily available.

Some designers have been successful in repurposing a graphics processor (GPU) for this purpose, and some GPU manufacturers now offer FFT libraries to assist in the design process.

Figure 12.20 — The baseband spectrum of an analog signal before sampling is given at A, showing both positive and negative frequencies. Part B shows the spectrum of the baseband signal after it is sampled by an ideal sampling waveform. Note that there is an upper and lower sideband version of the baseband for each harmonic of the sampling frequency, just as if it were a double sideband suppressed carrier signal.)

### 12.3.3 Sample-Rate Down-Conversion

SDR receivers generally do not use analog mixers to convert RF frequencies to an IF or to baseband. Down-conversion is achieved by the process of *decimation* as described in the **DSP and SDR Fundamentals** chapter. It describes how the frequency of a sampled signal can be divided by  $N$  by removing every  $N$ th sample from the digital signal data. This actually creates an alias of the original signal as if it had been sampled at a rate lower than the Nyquist rate. As shown in **Figure 12.20**, this process creates a replica of the original signal or original spectrum at harmonics of the sampling rate. One of the replica spectra can then be selected with a filter and operated on just as if it had been processed by an analog mixer.

This is one example *multirate signal processing* which is not nearly as complicated as it sounds. The topic we are interested in now is sample-rate down conversion (decimation). (*Sample-rate up conversion* is another multirate signal processing technique that performs frequency multiplication in much the same way as down-conversion performs frequency division.)

If we want to receive directly at the 40 meter band for instance, we would need to sample above 14.6 MHz in order to satisfy the Nyquist criterion. We do not need a sample rate that fast to actually manipulate the information on receive, though, since the bandwidth of the widest signal will be on the order of 7 kHz or less. Even if we want to look at the entire band and generate a spectrum display, we only need about 650 kHz for the sample rate since the band is only 300 kHz wide. Any higher sample rate on receive is a waste of processor resources.

There are two main reasons why we would want to match the sample rate closely to our intended bandwidth. The first reason to lower the sample rate is that the transition band and ripple of our filters are dependent on the ratio of the filter length (the number of taps) to the sample rate. The second reason is to allow more CPU cycles for processing each sample.

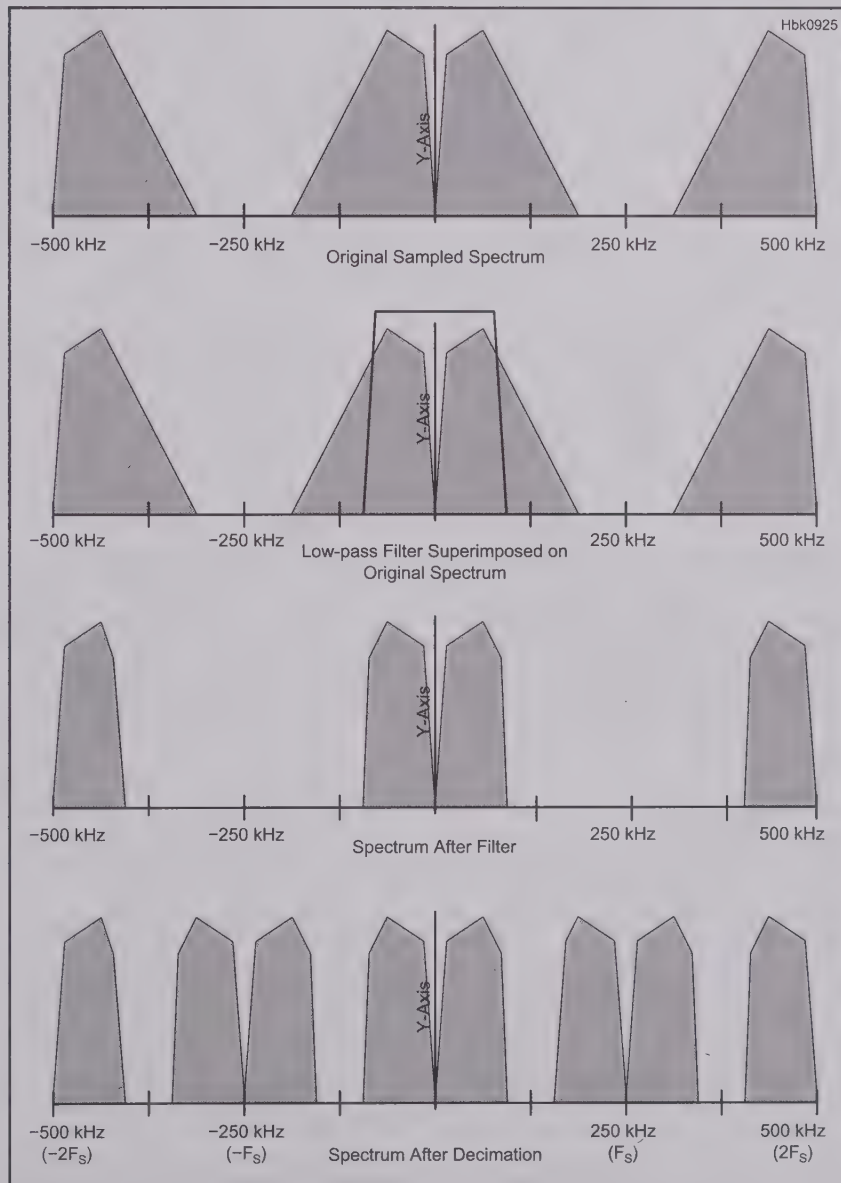

An AM radio is a good example for sample rate conversion. Let's say we want to receive a band of signals through a tuned-circuit input filter with a bandwidth of 80 kHz centered at 590 kHz. If we undersample the input at a rate of 100 kHz, we create a range of signals centered at 90 kHz so that the energy is all within the range of dc to 125 kHz. This is *low-pass filter decimating*. (See the *QEX SDR*: Simplified column for July/August 2009 for a more complete discussion of this process.)

The first step in the decimation process is to filter the input signal so that there is no energy above one fourth the sample fre-

quency. A DSP low-pass filter with cutoff at one fourth of the sample frequency has a very easy set of coefficients and can be implemented with a small number of taps. We sampled our AM radio at 500 kHz, so we need 125 kHz cutoff for the low pass filter. We now have a signal that has no energy above 125 kHz and is sampled at 500 kHz. We can throw away every other sample at this point to create a signal that is sampled at 250 kHz, with energy up to 125 kHz. The

Nyquist criterion is satisfied with this new signal. **Figure 12.21** shows the spectrum of the process.

The signal at 90 kHz is only about 40 kHz wide (70 kHz to 110 kHz), so it would be nice if we could drop the sample frequency even further. It turns out that our signal will fit into the band from dc to 62.5 kHz if it were translated down in frequency. That would only require a 125 kHz sample rate. This is *integer band-pass decimating*. If we throw

**Figure 12.21** — Part A shows the spectrum of the sampled signal. Note that the frequency only extends from  $-500$  kHz to  $+500$  kHz since that is the extent that the math will manage. Part B shows the digital low-pass filter response superimposed on the sampled spectrum. The spectrum of the filtered signal, which is still sampled at 500 kHz, is shown at C. Part D shows the spectrum of the resulting sampled waveform after decimation by 2 (every other sample discarded). This is the spectrum of the signal when it is sampled at 250 kHz.)

**Figure 12.22 — Part A** shows the spectrum of a 90 kHz signal that was band-pass filtered and then sampled at 500 kHz (only one-half of the spectrum is shown for clarity). The resulting spectrum when the signal is decimated by 4 (3 of every 4 samples discarded) is shown in Part B. Notice that this causes the signal to be aliased and the signal in the first Nyquist zone ( $k=0$ ) has its frequencies inverted just as a lower sideband signal is inverted. The signal is now sampled at 125 kHz. The initial sampled signal, showing the Nyquist zones that would occur if a decimation by 5 were attempted, is shown at C. Note that input energy exists in both the second and third Nyquist zones.

away every 3 samples of the original data, we can accomplish both frequency translation and sample rate reduction. The energy now spans from 15 kHz to 55 kHz. The signal spectrum is also inverted. In a superhet AM radio, you would need to band-pass filtered the signal before sampling. It is possible to do the band pass filtering digitally with a small number of taps, and then do the decimation.

We succeeded in reducing the sample rate by a factor of 4. We cannot further reduce the sample rate using straight decimation. Each integer sample rate reduction requires that the band limited data fit completely within one of the Nyquist regions for the new sample rates. The next integer sample rate would reduce the sample rate by 5. The new sample rate would be 100 kHz. The data is contained in both the  $k=1$  (50 kHz to 100 kHz) and  $k=2$  (100 kHz to 150 kHz) Nyquist bands. **Figure 12.22** shows the overlap. The overlap

into the third Nyquist zone prevents further rate reduction. The requirement that all of the energy fits into one Nyquist zone limits the usefulness of this technique.

Integer sample rate reduction is a very useful tool because the filters are easily realized in hardware such as a field programmable gate array (FPGA) or other dedicated hardware.

### 12.3.4 Decimation and Dynamic Range

When we talk about dynamic range, we are discussing the range of largest to smallest signals that can be represented simultaneously. What does dynamic range buy us? Having a high dynamic range allows us to represent or hear weak signals in the presence of large signals. With a lower dynamic range, our receiver may overload in the presence of a

large signal or we may be forced to shift what dynamic range we have to accommodate the large signals. For example, if we only had 80 dB of dynamic range in our receiver with the weakest signal possible of  $-120$  dBm and the largest of  $-40$  dBm, this means the strongest signal we can hear is  $S9+33$  dB ( $-50$  dBm). If an  $S9+50$  dB ( $-23$  dBm) signal is present in our receiver, we would overload.

To allow the reception of large and small signal, receivers can implement automatic gain control (AGC) in the RF section. The AGC will add attenuation to the receiver, shifting the available dynamic range up. For example, if the AGC adds 20 dB of attenuation, we can now hear signals from  $-100$  dBm to  $-20$  dBm. Note that we have just reduced the sensitivity of our receiver by 20 dB and if we were trying to listen to a weak CW signal with a power of  $-110$  dBm, we will now be unable to hear it. RF AGC is necessary in some receivers where the instantaneous dynamic range is not sufficient to handle both very strong and very weak signals simultaneously. This should not be confused with audio-derived AGC which is discussed in the section on AGC below.

A common question about direct sampling receivers centers around available dynamic range. We are taught that for each bit in an ADC, we can have 6 dB of dynamic range. Often, someone will attempt to look at wideband sampled converter (ADC), multiply the bits by 6 dB and state that this is the available dynamic range for narrowband operation. As it turns out, this is an incorrect if not uncommon error. In a wideband sampled system where the receiver outputs are narrowband, we use a process called decimation to reduce the bandwidth for our narrowband receiver and increase dynamic range. How does this work?

Decimation is a two-step process: we first apply a digital filter to the samples and then we discard a portion of the samples. In decimation by two, we apply a filter to cut the RF bandwidth in half and then we discard one half of the samples. In doing so, the digital filter combines multiple samples to produce the output sample stream and in this combination, we pick up additional bits of resolution in the output samples. This increase in dynamic range is called *processing gain*. Specifically, in decimation by two we typically pickup about  $\frac{1}{2}$ -bit of resolution for each decimation by two. Imagining for a moment a sampled system with 16-bits of resolution at 196.608 Msps, if we decimate down to 48 kbps, this represents twelve decimate-by-two operations. This means that we pick up about six bits per sample, increasing our dynamic range by about 36 dB. As a practical matter, the dynamic range of an ADC depends not only on the number of samples in the output, but also the level of

the spurs. ADC manufacturers consider any level below the spurs to be tarnished by the spurs and therefore not included in the specified dynamic range. As a first order approximation for the dynamic range that can be achieved, we can take the dynamic range specified by the ADC manufacturer and add the processing gain that we've computed.

Finally, in Amateur Radio we generally talk about dynamic range in terms of a 500 Hz bandwidth. So for the purposes of dynamic range in the amateur world, we don't use the entire 48 ksp/s bandwidth, we look just at the 500 Hz bandwidth as if we had a 500 Hz filter. To determine the total processing gain we would achieve through decimation and filtering, we use can use the formula  $3\log_2(\text{sampling rate}/\text{final bandwidth})$  to get an approximation of the processing gain from our original sampling rate to a 500 Hz bandwidth receiver. Using a logarithmic identity, it may be easier to compute on a calculator as  $3\log_{10}(\text{sampling rate}/\text{final bandwidth})/\log_{10}(2)$ .

### 12.3.5 Phase Noise in Sampled Systems

Just like with mixers, analog to digital converters that sample signals and produce a digital output are also susceptible to phase noise. Many of today's older transceivers use

superheterodyne receivers which use mixers and terminate in an ADC operating at baseband. For receiver systems where the ADC is operating in the tens to hundreds of ksp/s, phase noise introduced by the ADC is rarely an issue. Since good phase noise is easily achievable in this frequency range, most designers ensure that phase noise will not impact the design in the ADC. It's much more likely in such a radio that the LO feeding the mixers nearer the antenna would be at fault. With today's technology, the high we go in oscillator frequency, the more difficult it is to design a low phase noise oscillator.

In an RF sampled system where the ADC is placed either right on the antenna or just behind an amplifier and/or preselectors, we will be sampling at a significantly higher frequency. Because of the Nyquist sampling theorem, if we want to design an HF through 6 meter receiver, we must sample at least 2x the highest frequency, 54 MHz. This means we will be sampling above 108 MHz, with 122.88 MHz being a common frequency because it divides evenly down to standard audio sampling rates (see the sidebar on sampling rates). In these systems, the local oscillator may be called a clock oscillator and phase noise may be referred to as jitter. While phase noise and jitter are roughly interchangeable, jitter benefits the digital designer's view of the world and discusses a

time-domain effect while phase noise benefits the RF designer and discusses a frequency domain effect. Most ADCs that will be used for RF will specify both. In case you're wondering, there is no absolute conversion from jitter directly to phase noise, but there are estimates that make assumptions about the characteristics of the oscillator.

Unlike the superheterodyne system, phase noise in a direct sampling receiver is imparted on the signal during the sampling process at the sampling frequency. What does this mean? While a superheterodyne system may rely on the division of the clock to produce an excellent phase noise signal on the band of interest, signals in a direct sampling system inherit the phase noise of the ADC clock at the sampling frequency. So if our phase noise is  $-110$  dBc/Hz at 10 kHz for a 122.88 MHz clock, this is the phase noise we will have on all sampled frequencies. This makes clock (or LO) selection for the direct sampling receiver all the more important. We must ensure that the oscillator's phase noise characteristics will not be an issue at any frequency of interest.

More detailed discussions about the effects of phase noise in direct-sampled receivers can be found in Analog Devices application notes AN-741 and AN-756. (See the reference section.)

## 12.4 Mixing and Mixers

This section examines mixers which are used for frequency shifting or conversion in heterodyne receivers and transmitters. Mixers are often used as modulators and demodulators because they translate information to an RF signal and back again. These translation processes can be thought of as forms of frequency translation or frequency shifting — the function traditionally ascribed to mixers. We'll therefore begin our investigation by examining what a mixer is (and isn't), and what a mixer does.

### MULTIPLYING VERSUS ADDING

*Mixer* is the term for a circuit that shifts one signal's frequency up or down by combining it with another signal. The word *mixer* is also the name of a device used to blend multiple audio inputs together for recording, broadcast or sound reinforcement. A radio mixer makes new frequencies from its input signals and an audio mixer does not. In their most basic, ideal forms, both devices have two inputs and one output.

The audio mixer is a *combiner* that simply adds the instantaneous voltages of the two signals together to produce the output at each

point in time (**Figure 12.23**). The radio mixer, on the other hand, *multiplies* the instantaneous voltages of the two signals together to produce its output signal from instant to instant (**Figure 12.24**). Comparing the output spectra of the combiner and mixer, we see that the combiner's output contains only the frequencies of the two inputs, and nothing else, while the mixer's output contains *new* frequencies. The process is called *heterodyning* as used in the heterodyne receivers described in the preceding sections. The sidebar, "Mixer Math: Mixing as Multiplication," describes this process mathematically. Use of the word "mixer" in this book should be assumed to mean the radio mixer.

The key principle of a radio mixer is that in mixing multiple signal voltages together, *it adds and subtracts their frequencies to produce new frequencies*. (In the field of signal processing, this process, *multiplication in the time domain*, is recognized as equivalent to the process of *convolution in the frequency domain*. Those interested in this alternative approach to describing the generation of new frequencies through mixing

can find more information about it in the many textbooks available on this subject.)

The difference between the mixer we've been describing and any mixer, modulator or demodulator that you'll ever use is that it's ideal. We put in two signals and got just two signals out. *Real* mixers, modulators and demodulators, on the other hand, also produce *distortion* products that make their output spectra "dirtier" or "less clean," as well as putting out some energy at input-signal frequencies and their harmonics. Much of the art and science of making good use of multiplication in mixing, modulation and demodulation goes into minimizing these unwanted multiplication products (or their effects) and making multipliers perform frequency translation as efficiently as possible.

### 12.4.1 Mixers and Distortion

This radio-amateur-oriented discussion of mixers, modulators and demodulators will begin with a look at their common underlying mechanism before discussing practical mixer, modulator and demodulator circuits. This will make it easier to understand the

Figure 12.23 — Adding or summing two sine waves of different frequencies ( $f_1$  and  $f_2$ ) combines their amplitudes without affecting their frequencies. Viewed with an *oscilloscope* (a real-time graph of amplitude versus time), adding two signals appears as a simple superimposition of one signal on the other. Viewed with a *spectrum analyzer* (a real-time graph of signal amplitude versus frequency), adding two signals just sums their spectra. The signals merely coexist on a single cable or wire. All frequencies that go into the adder come out of the adder, and no new signals are generated. Drawing B, a block diagram of a summing circuit, emphasizes the stage's mathematical operation rather than showing circuit components. Drawing C shows a simple summing circuit, such as might be used to combine signals from two microphones. In audio work, a circuit like this is often called a *mixer* — but it does not perform the same function as an RF mixer.

Figure 12.24 — Multiplying two sine waves of different frequencies produces a new output spectrum. Viewed with an *oscilloscope*, the result of multiplying two signals is a composite wave that seems to have little in common with its components. A *spectrum-analyzer* view of the same wave reveals why: The original signals disappear entirely and are replaced by two new signals — at the *sum* and *difference* of the original signals' frequencies. Drawing B diagrams a multiplier, known in radio work as a *mixer*. The circled X emphasizes the stage's mathematical operation. (The circled X is only one of several symbols you may see used to represent mixers in block diagrams, as Figure 12.25 explains.) Drawing C shows a very simple multiplier circuit. The diode, D, does the mixing. Because this circuit does other mathematical functions and adds them to the sum and difference products, its output is more complex than  $f_1 + f_2$  and  $f_1 - f_2$ , but these can be extracted from the output by filtering.

## Mixer Math: Mixing as Multiplication

Since a mixer works by means of multiplication, a bit of math can show us how they work. To begin with, we need to represent the two signals we'll mix, A and B, mathematically. Signal A's instantaneous amplitude equals

$$A_a \sin 2\pi f_a t$$

in which A is peak amplitude, f is frequency, and t is time. Likewise, B's instantaneous amplitude equals

$$A_b = A \sin (2\pi f_b t)$$

Since our goal is to show that multiplying two signals generates sum and difference frequencies, we can simplify these signal definitions by assuming that the peak amplitude of each is 1. The equation for Signal A then becomes

$$a(t) = A \sin (2\pi f_a t)$$

and the equation for Signal B becomes

$$b(t) = B \sin (2\pi f_b t)$$

Each of these equations represents a sine wave and includes a subscript letter to help us keep track of where the signals go.

Merely combining Signal A and Signal B by letting them travel on the same wire develops nothing new:

$$a(t) + b(t) = A \sin (2\pi f_a t) + B \sin (2\pi f_b t)$$

As simple as that equation may seem, we include it to highlight the fact that multiplying two signals is a quite different story. From trigonometry, we know that multiplying the sines of two variables can be expanded according to the relationship

$$\sin x \sin y = \frac{1}{2} [\cos (x - y) - \cos (x + y)]$$

Conveniently, Signals A and B are both sinusoidal, so we can use equation 6 to determine what happens when we multiply Signal A by Signal B. In our case,  $x = 2\pi f_a t$  and  $y = 2\pi f_b t$ , so plugging them into equation 6 gives us

$$a(t) \times b(t) = \frac{AB}{2} \cos (2\pi [f_a - f_b] t) - \frac{AB}{2} \cos (2\pi [f_a + f_b] t)$$

Now we see two momentous results: a sine wave at the frequency *difference* between Signal A and Signal B  $2\pi(f_a - f_b)t$ , and a sine wave at the frequency *sum* of Signal A and Signal B  $2\pi(f_a + f_b)t$ . (The products are cosine waves, but since equivalent sine and cosine waves differ only by a phase shift of  $90^\circ$ , both are called *sine waves* by convention.)

This is the basic process by which we translate information into radio form and translate it back again. If we want to transmit a 1-kHz audio tone by radio, we can feed it into one of our mixer's inputs and feed an RF signal — say, 5995 kHz — into the mixer's other input. The result is two radio signals: one at 5994 kHz ( $5995 - 1$ ) and another at 5996 kHz ( $5995 + 1$ ). We have performed modulation.

Converting these two radio signals back to audio is just as straightforward. All we do is feed them into one input of another mixer, and feed a 5995-kHz signal into the mixer's other input. Result: a 1-kHz tone. We have performed demodulation.

functions of those circuits. **Figure 12.25** shows the block symbol for a traditional mixer along with several IEC symbols for other functions mixers may perform.

### NONLINEAR DISTORTION

The mechanism underlying multiplication, mixing, modulation and demodulation is a pretty straightforward thing: Any circuit structure that *nonlinearly distorts* ac waveforms acts as a multiplier to some degree.

The phrase *nonlinear distortion* sounds redundant, but isn't. Distortion, an externally imposed change in a waveform, can be linear;

that is, it can occur independently of signal amplitude. Consider a radio receiver front-end filter that passes only signals between 6 and 8 MHz. It does this by *linearly distorting* the single complex waveform corresponding to the wide RF spectrum present at the radio's antenna terminals, reducing the amplitudes of frequency components below 6 MHz and above 8 MHz relative to those between 6 and 8 MHz. (Considering multiple signals on a wire as one complex waveform is just as valid, and sometimes handier, than considering them as separate signals. In this case, it's a bit easier to think of distortion as something

**Figure 12.25** — The traditional symbol for a mixer is a circled X (A) although current standards allocate this symbol to a lamp. Current practice is to use one of the three IEC symbols shown at B, C, or D. For the frequency converter or changer symbol at D, a third connection can be included for the local oscillator. (IEC stands for *International Electrotechnical Commission* and the symbols are published in the IEEE 315A standard.)

that happens to a waveform rather than something that happens to separate signals relative to each other. It would be just as valid — and certainly more in keeping with the consensus view — to say merely that the filter attenuates signals at frequencies below 6 MHz and above 8 MHz.) The filter's output waveform certainly differs from its input waveform; the waveform has been distorted. But because this distortion occurs independently of signal level or polarity, the distortion is linear. No new frequency components are created; only the amplitude relationships among the wave's existing frequency components are altered. This is *amplitude* or *frequency* distortion, and all filters do it or they wouldn't be filters.

*Phase* or *delay distortion*, also linear, causes a complex signal's various component frequencies to be delayed by different amounts of time, depending on their frequency but independently of their amplitude. No new frequency components occur, and amplitude relationships among existing frequency components are not altered. Phase distortion occurs to some degree in all real filters.

The waveform of a non-sinusoidal signal can be changed by passing it through a circuit that has only linear distortion, but only *non-*

linear distortion can change the waveform of a simple sine wave. It can also produce an output signal whose output waveform changes as a function of the input amplitude, something not possible with linear distortion. Nonlinear circuits often distort excessively with overly strong signals, but the distortion can be a complex function of the input level.

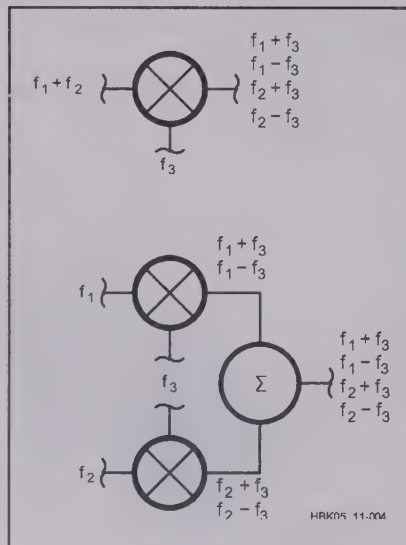

Nonlinear distortion may take the form of *harmonic distortion*, in which integer multiples of input frequencies occur, or *intermodulation distortion (IMD)*, in which different components multiply to make new ones, as described in previous sections.

Any departure from absolute linearity results in some form of nonlinear distortion, and this distortion can work for us or against us. Any amplifier, including a so-called linear amplifier, distorts nonlinearly to some degree; any device or circuit that distorts nonlinearly can work as a mixer, modulator, demodulator or frequency multiplier. An amplifier optimized for linear operation will nonetheless mix, but inefficiently; an amplifier biased for nonlinear amplification may be practically linear over a given tiny portion of its input-signal range. The trick is to use careful design and component selection to maximize nonlinear distortion when we want it (as in a mixer), and minimize it when we don't. Once we've decided to maximize nonlinear distortion, the trick is to minimize the distortion products we don't want, and maximize the products we want.

### MINIMIZING UNWANTED DISTORTION PRODUCTS

Ideally, a mixer multiplies the signal at one of its inputs by the signal at its other input, but does not multiply a signal at the same input by itself, or multiple signals at the same input by themselves or by each other. (Multiplying a signal by itself — squaring it — generates harmonic distortion [specifically, *second-harmonic* distortion] by adding the signal's frequency to itself. Simultaneously squaring two or more signals generates simultaneous harmonic and intermodulation distortion.)

Consider what happens when a mixer must handle signals at two different frequencies ( $f_1$  and  $f_2$ ) applied to its first input, and a signal at a third frequency ( $f_3$ ) applied to its other input. Ideally, a mixer multiplies  $f_1$  by  $f_3$  and  $f_2$  by  $f_3$ , but does not multiply  $f_1$  and  $f_2$  by each other. This produces output at the sum and difference of  $f_1$  and  $f_3$ , and the sum and difference of  $f_2$  and  $f_3$ , but *not* the sum and difference of  $f_1$  and  $f_2$ . **Figure 12.26** shows that feeding two signals into one input of a mixer results in the same output as if  $f_1$  and  $f_2$  are each first mixed with  $f_3$  in two separate mixers, and the outputs of these mixers are combined. This shows that a mixer, even though constructed with nonlinearly

**Figure 12.26** — Feeding two signals into one input of a mixer results in the same output as if  $f_1$  and  $f_2$  are each first mixed with  $f_3$  in two separate mixers, and the outputs of these mixers are combined.

distorting components, actually behaves as a *linear frequency shifter*. Traditionally, we refer to this process as mixing and to its outputs as *mixing products*, but we may also call it *frequency conversion*, referring to a device or circuit that does it as a *converter*, and to its outputs as *conversion products*. If a mixer produces an output frequency that is higher than the input frequency, it is called an up-converter; if the output frequency is lower than the input, a down-converter.

Real mixers, however, at best act only as reasonably linear frequency shifters, generating some unwanted IMD products — spurious signals, or *spurs* — as they go. Receivers are especially sensitive to unwanted mixer IMD because the signal-level range over which they must operate without generating unwanted IMD is often 90 dB or more, and includes infinitesimally weak signals. In a receiver, IMD products so weak that you'd never notice them in a transmitted signal can easily obliterate weak signals. This is why receiver designers apply so much effort to achieving “high dynamic range.”

The degree to which a given mixer, modulator or demodulator circuit produces unwanted IMD is often the reason why we use it, or don't use it, instead of another circuit that does its wanted-IMD job as well or even better.

### MISCELLANEOUS MIXING PRODUCTS

In addition to desired sum-and-difference products and unwanted IMD products, real mixers also put out some energy at their input

frequencies. Some mixer implementations may *suppress* these outputs — that is, reduce one or both of their input signals by a factor of 100 to 1,000,000, or 20 to 60 dB. This is good because it helps keep input signals at the desired mixer-output sum or difference frequency from showing up at the IF terminal — an effect reflected in a receiver's *IF rejection* specification. Some mixer types, especially those used in the vacuum-tube era, suppress their input-signal outputs very little or not at all.

Input-signal suppression is part of an overall picture called *port-to-port isolation*. Mixer input and output connections are traditionally called *ports*. By tradition, the port to which we apply the shifting signal is the *local-oscillator (LO)* port. By convention, the signal or signals to be frequency-shifted are applied to the *RF (radio frequency)* port, and the frequency-shifted (product) signal or signals emerge at the *IF (intermediate frequency)* port. This illustrates the function of a mixer in a heterodyne receiver: Since it is often impractical to achieve the desired gain and filtering at the incoming signal's frequency (at RF), a mixer is used to translate the incoming RF signal to an intermediate frequency (the IF), where gain and filtering can be applied. The IF may be either lower or higher than the incoming RF signal. In a transmitter, the modulated signal may be created at an IF, and then translated in frequency by a mixer to the operating frequency.

A mixer may be used in an SDR to convert a range of signals into the range the SDR can process. This is very common when using SDR equipment designed for VHF and higher frequencies to receive HF signals. In that case an up-converting mixer is required.

Some mixers are *bilateral*; that is, their RF and IF ports can be interchanged, depending on the application. Diode-based mixers are usually bilateral. Many mixers are not bilateral (*unilateral*); the popular SA602/612 Gilbert cell IC mixer is an example of this.

It's generally a good idea to keep a mixer's input signals from appearing at its output port because they represent energy that we'd rather not pass to subsequent circuitry. It therefore follows that it's usually a good idea to keep a mixer's LO-port energy from appearing at its RF port, or its RF-port energy from making it through to the IF port. But there are some notable exceptions.

### 12.4.2 Switching Mixers

Depending on the application, mixers may vary from the extremely simple to the complex. For example, a simple half-wave rectifier (a signal diode, such as a 1N34 [germanium] or a 1N914 [silicon]) can do the job. This is an example of a *switching mixer*, in which mixing occurs as one signal

— in this case, the carrier, which in effect turns the diode on and off as its polarity reverses — interrupts the transmission of another (in demodulation of full-carrier AM, the sidebands).

A switch can be thought of as an amplifier toggled between two gain states, off and on, by a control signal. It turns out that a binary amplifier is not necessary; any device that can be gain-varied in accordance with the amplitude of a control signal can serve as a mixer.

Most modern radio mixers act more like fast analog switches than analog multipliers. In using a mixer as a fast switching device, we apply a square wave to its LO input with a square wave rather than a sine wave, and feed sine waves, audio, or other complex signals to the mixer's RF input. The RF port serves as the mixer's "linear" input, and therefore must preferably exhibit low intermodulation and harmonic distortion. Feeding a  $\pm 1$ -V square wave into the LO input alternately multiplies the linear input by +1 or -1. Multiplying the RF-port signal by +1 just transfers it to the output with no change. Multiplying the RF-port signal by -1 does the same thing, except that the signal inverts (flips 180° in phase). The LO port need not exhibit low intermodulation and harmonic distortion; all it has to do is preserve the fast rise and fall times of the switching signal.

### REVERSING-SWITCH MIXERS

We can multiply a signal by a square wave without using an analog multiplier at all. All we need is a pair of balun transformers and four diodes (Figure 12.27A).

With no LO energy applied to the circuit, none of its diodes conduct. RF-port energy (1) can't make it to the LO port because there's no direct connection between the secondaries of T1 and T2, and (2) doesn't produce IF output because T2's secondary balance results in energy cancellation at its center tap, and because no complete IF-energy circuit exists through T2's secondary with both of its ends disconnected from ground.

Applying a square wave to the LO port biases the diodes so that, 50% of the time, D1 and D2 are on and D3 and D4 are reverse-biased off. This unbalances T2's secondary by leaving its upper wire floating and connecting its lower wire to ground through T1's secondary and center tap. With T2's secondary unbalanced, RF-port energy emerges from the IF port.

The other 50% of the time, D3 and D4 are on and D1 and D2 are reverse-biased off. This unbalances T2's secondary by leaving its lower wire floating, and connects its upper wire to ground through T1's secondary and center tap. With T2's secondary unbalanced, RF-port energy again emerges from the IF port — shifted 180° relative to the first case

Figure 12.27 — Part A shows a general-purpose diode reversing-switch mixer. This mixer uses a square-wave LO and a sine-wave input signal. The text describes its action. Part B is an ideal multiplier mixer. The square-wave LO and a sine-wave input signal produce the output waveform shown in part C. The solid lines of part D show the output spectrum with the square-wave LO. The dashed lines show the output spectrum with a sine-wave LO.

because T2's active secondary wires are now, in effect, transposed relative to its primary.

A reversing switch mixer's output spectrum is the same as the output spectrum of a multiplier fed with a square wave. This can be analyzed by thinking of the square wave in terms of its Fourier series equivalent, which consists of the sum of sine waves at the square wave frequency and all of its odd harmonics. The amplitude of the equivalent series' fundamental sine wave is  $4/\pi$  times (2.1 dB greater than) the amplitude of the square wave. The amplitude of each harmonic is inversely proportional to its harmonic number, so the third harmonic is only  $1/3$  as strong as the fundamental (9.5 dB below the fundamental), the 5th harmonic is only  $1/5$  as strong (14 dB below the fundamental) and so on. The input signal mixes with each harmonic separately from the others, as if each harmonic were driving its own separate mixer, just as we illustrated with two sine waves in Figure 12.26. Normally, the harmonic outputs are so widely removed from the desired output frequency that they are easily filtered out, so a reversing-switch mixer is just as good as a sine-wave-driven analog multiplier for most practical purposes, and usually better — for radio purposes — in terms of dynamic range and noise.

An additional difference between multiplier and switching mixers is that the signal flow in a switching mixer is reversible (that is, bilateral). It really only has one dedicated input (the LO input). The other terminals can be thought of as I/O (input/output) ports, since either one can be the input as long as the other is the output.

### CONVERSION LOSS IN SWITCHING MIXERS

Figure 12.27B shows a perfect *multiplier* mixer. That is, the output is the product of the input signal and the LO. The LO is a perfect square wave. Its peak amplitude is  $\pm 1.0$  V and its frequency is 8 MHz. Figure 12.27C shows the output waveform (the product of two inputs) for an input signal whose value is 0 dBm and whose frequency is 2 MHz. Notice that for each transition of the square-wave LO, the sine-wave output waveform polarity reverses. There are 16 transitions during the interval shown, at each zero-crossing point of the output waveform. Figure 12.27D shows the mixer output spectrum. The principle components are at 6 MHz and 10 MHz, which are the sum and difference of the signal and LO frequencies. The amplitude of each of these is  $-3.9$  dBm. Numerous other pairs of output frequencies occur that are also spaced 4 MHz apart and centered at 24 MHz, 40 MHz and 56 MHz and higher odd harmonics of 8 MHz. The ones shown are at  $-13.5$  dBm,  $-17.9$  dBm and  $-20.9$  dBm. Because the mixer is lossless,

the sum of all of the outputs must be exactly equal to the value of the input signal. As explained previously, this output spectrum can also be understood in terms of each of the odd-harmonic components of the square-wave LO operating independently.

If the mixer switched without losses, such as in Figure 12.27A, with diodes that are perfect switches, the results would be mathematically identical to the above example. The diodes would commutate the input signal exactly as shown in Figure 12.27C.

Now consider the perfect multiplier mixer of Figure 12.27B with an LO that is a perfect sine wave with a peak amplitude of  $\pm 1.0$  V. In this case the dashed lines of Figure 12.27D show that only two output frequencies are present, at 6 MHz and 10 MHz (see also Figure 12.24). Each component now has a  $-6$  dBm level. The product of the 0 dBm sine-wave input at one frequency and the  $\pm 1.0$  V sine-wave LO at another frequency (see equation 6 in this chapter) is the  $-3$  dBm total output.

These examples illustrate the difference between the square-wave LO and the sine-wave LO, for a perfect multiplier. For the same peak value of both LO waves, the square-wave LO delivers 2.1 dB more output at 6 MHz and 10 MHz than the sine-wave LO. An actual diode mixer such as Figure 12.27A behaves more like a switching mixer. Its sine-wave LO waveform is considerably flattened by interaction between the diodes and the LO generator, so that it looks somewhat like a square wave. The diodes have nonlinearities, junction voltages, capa-

citances, resistances and imperfect parameter matching. (See the **RF Techniques** chapter.) Also, "re-mixing" of a diode mixer's output with the LO and the input is a complicated possibility. The practical end result is that diode double-balanced mixers have a conversion loss, from input to each of the two major output frequencies, in the neighborhood of 5 to 6 dB. (Conversion loss is discussed in a later section.)

### 12.4.3 The Diode Double-Balanced Mixer (DBM)

The diode *double-balanced mixer* (DBM) is standard in many commercial, military and amateur applications because of its excellent balance and high dynamic range. DBMs can serve as mixers (including image-reject types), modulators (including single- and double-sideband, phase, biphasic, and quadrature-phase types) and demodulators, limiters, attenuators, switches, phase detectors and frequency doublers. In some of these applications, they work in conjunction with power dividers, combiners and hybrids.

#### THE BASIC DBM

We have already seen the basic diode DBM circuit (Figure 12.27A). In its simplest form, a DBM contains two or more unbalanced-to-balanced transformers and a Schottky-diode ring consisting of  $4 \times n$  diodes, where  $n$  is the number of diodes in each leg of the ring. Each leg commonly consists of up to four diodes.

Figure 12.28 — The triple-balanced mixer uses a pair of diode rings and adds an additional balancing transformer to the IF port.

As we've seen, the degree to which a mixer is *balanced* depends on whether either, neither or both of its input signals (RF and LO) emerge from the IF port along with mixing products. An unbalanced mixer suppresses neither its RF nor its LO; both are present at its IF port. A single-balanced mixer suppresses its RF or LO, but not both. A double-balanced mixer suppresses its RF and LO inputs. Diode and transformer uniformity in the Figure 12.27 circuit results in equal LO potentials at the center taps of T1 and T2. The LO potential at T1's secondary center tap is zero (ground); therefore, the LO potential at the IF port is zero.

Balance in T2's secondary likewise results in an RF null at the IF port. The RF potential between the IF port and ground is therefore zero — except when the DBM's switching diodes operate!

The Figure 12.27 circuit normally also affords high RF-IF isolation because its balanced diode switching precludes direct connections between T1 and T2. A diode DBM can be used as a current-controlled switch or attenuator by applying dc to its IF port, albeit with some distortion. This causes opposing diodes (D2 and D4, for instance) to conduct to a degree that depends on the current magnitude, connecting T1 to T2.

### TRIPLE-BALANCED MIXERS

The triple-balanced mixer shown in Figure 12.28 (sometimes called a "double double-balanced mixer") is an extension of the single-diode-ring mixer. The diode rings are fed by power-splitting baluns at the RF and LO ports. An additional balun is added at the IF output. The circuit's primary advantage is that the IF output signal is balanced and isolated from the RF and LO ports over a large bandwidth — commercial mixer IF ranges of 0.5 to 10 GHz are typical.

It has higher signal-handling capability and dynamic range (a 1-dB compression point within 3 to 4 dB below LO signal levels) and lower intermodulation levels (by 10 dB or more) than a single-ring mixer. The triple-balanced mixer is used when a very wide IF range is required.

Adding the balancing transformer in the IF output path increases IF-to-LO and IF-to-RF isolation. This makes the conversion process much less sensitive to IF impedance mismatches. Since the IF port is isolated from the RF and LO ports, the three frequency ranges (RF, LO and IF) can overlap. A disadvantage of IF transformer coupling is that a dc (or low-frequency) IF output is not available, so the triple-balanced mixer cannot be used for direct-conversion receivers.

### DIODE DBM COMPONENTS

Commercially manufactured diode DBMs generally consist of a supporting base, a diode

**Figure 12.29 — The port-to-port isolation of a diode DBM depends on how well its diodes match and how well its transformers are balanced. (A) shows LO-IF and LO-RF isolation versus frequency and (B) shows conversion loss for a typical diode DBM, the Synergy Microwave CLP-403 mixer. In (B), LO driver level is +7 dBm.**

ring, two or more ferrite-core transformers commonly wound with two or three twisted-pair wires, encapsulating material, an enclosure.

### Diodes

Hot-carrier (Schottky) diodes are the devices of choice for diode-DBM rings because of their low ON resistance, although ham-built DBMs for non-critical MF/HF use commonly use switching diodes like the 1N914 or 1N4148. The forward voltage drop,  $V_f$ , across each diode in the ring determines the mixer's optimum local-oscillator drive level. Depending on the forward voltage drop of each of its diodes and the number of diodes in each ring leg, a diode DBM will often be specified by the optimum LO drive level in dBm (typical values are 0, 3, 7, 10, 13, 17, 23 or 27). As a rule of thumb, the LO signal must be 20 dB stronger than the RF and IF signals for proper operation. This ensures that the LO signal, rather than the RF or IF signals, switches the mixer's diodes on and off — a critical factor in minimizing IMD and maximizing dynamic range.

### Transformers

From the DBM schematic shown in Figure 12.27, it's clear that the LO and RF transformers are unbalanced on the input side and balanced on the diode side. The diode ends of

the balanced ports are 180° out of phase throughout the frequency range of interest. This property causes signal cancellations that result in higher port-to-port isolation. Figure 12.29A plots LO-RF and LO-IF isolation versus frequency for Synergy Microwave's CLP-403 DBM, which is specified for +7 dBm LO drive level. Isolations on the order of 70 dB occur at the lower end of the band as a direct result of the balance among the four diode-ring legs and the RF phasing of the balanced ports.

As we learned in our discussion of generic switching mixers, transformer efficiency plays an important role in determining a mixer's conversion loss and drive-level requirement. Core loss, copper loss and impedance mismatch all contribute to transformer losses. Ferrite in toroidal, bead, balun (multi-hole) or rod form can serve as DBM transformer cores. Radio amateurs commonly use Fair-Rite Mix 43 ferrite ( $\mu = 950$ ) in HF and VHF applications.

RF transformers combine lumped and distributed capacitance and inductance. The interwinding capacitance and characteristic impedance of a transformer's twisted wires sets the transformer's high-frequency response. The core's  $\mu$  and size, and the number of winding turns, determine the transformer's lower frequency limit. Covering a specific frequency range requires a compromise in the number of turns used with a given core. Increasing a transformer's core size and number of turns improves its low-frequency response. Cores may be stacked to meet low-frequency performance specs.

Inexpensive mixers operating up to 2 GHz most commonly use twisted trifilar (three-wire) windings made of a wire size between #36 and #32. The number of twists per unit length of wire determines a winding's characteristic impedance. Twisted wires are analogous to transmission lines. The transmission-line effect predominates at the higher end of a transformer's frequency range.

### PRACTICAL DIODE DBMS

Important DBM specifications include conversion loss and amplitude flatness across the required IF bandwidth; variation of conversion loss with input frequency; variation of conversion loss with LO drive, 1-dB compression point; LO-RF, LO-IF and RF-IF isolation; intermodulation products; noise figure (usually within 1 dB of conversion loss); port SWR; and dc offset, which is directly related to isolation among the RF, LO and IF ports. Most of these parameters also apply to other mixer types.

### Conversion Loss of Diode DBMs

Figure 12.29B shows conversion loss versus intermediate frequency in a typical DBM. The curves show conversion loss for two fixed

**Figure 12.30** — Simulated diode-DBM output spectrum with four LO harmonics evaluated. Note that the desired output products (the highest two products, RF – LO and RF + LO) emerge at a level 5 to 6 dB below the mixer’s RF input (–40 dBm). This indicates a mixer conversion loss of 5 to 6 dB. (*Serenade SV8.5* simulation.)

RF-port signals, one at 100 kHz and the other at 500 MHz, while varying the LO frequency from 100 kHz to 500 MHz.

**Figure 12.30** graphs a diode DBM’s simulated output spectrum. Note that the RF input (900 MHz) is –40 dBm and the desired IF output (51 MHz, the frequency difference between the RF and LO signals) is –46 dBm, implying a conversion loss of 6 dB. Very nearly the same value (5 dB) applies to the sum of both signals (RF + LO). We minimize a diode DBM’s conversion loss, noise figure and intermodulation by keeping its LO drive high enough to switch its diodes on fully and rapidly. Increasing a mixer’s LO level beyond that sufficient to turn its switching devices all the way on merely makes them dissipate more LO power without further improving performance.

Insufficient LO drive results in increased noise figure and conversion loss. IMD also increases because RF-port signals have a greater chance to control the mixer diodes when the LO level is too low.

### APPLYING DIODE DBMS

At first glance, applying a diode DBM is easy: We feed the signal(s) we want to frequency-shift (at or below the maximum level called for in the mixer’s specifications, such as –10 dBm for the Mini-Circuits SBL-1 and TUF-3, and Synergy Microwave S-1, popular 7 dBm LO power parts) to the DBM’s RF port, feed the frequency-shifting signal (at

the proper level) to the LO port, and extract the sum and difference products from the mixer’s IF port.

There’s more to it than that, however, because diode DBMs (along with most other modern mixer types) are *termination-sensitive*. That is, their ports — particularly their IF (output) ports — must be resistively terminated with the proper impedance (commonly 50 Ω, resistive). A wideband, resistive output termination is particularly critical if a mixer is to achieve its maximum dynamic range in receiving applications. Such a load can be achieved by:

- Terminating the mixer in a 50-Ω resistor or attenuator pad (a technique usually avoided in receiving applications because it directly degrades system noise figure);
- Terminating the mixer with a low-noise, high-dynamic-range *post-mixer amplifier* designed to exhibit a wideband resistive input impedance; or
- Terminating the mixer in a *diplexer*, a frequency-sensitive signal splitter that appears as a two-terminal resistive load at its input while resistively dissipating unwanted outputs and passing desired outputs through to subsequent circuitry.

*Termination-insensitive* mixers are available, but this label can be misleading. Some termination-insensitive mixers are nothing more than a termination-sensitive mixer packaged with an integral post-mixer amplifier. True termination-insensitive mixers are

less common and considerably more elaborate. Amateur builders will more likely use one of the many excellent termination-sensitive mixers available in connection with a diplexer, post-mixer amplifier or both.

**Figure 12.31** shows one diplexer implementation. In this approach, L1 and C1 form a series-tuned circuit, resonant at the desired IF, that presents low impedance between the diplexer’s input and output terminals at the IF. The high-impedance parallel-tuned circuit formed by L2 and C2 also resonates at the desired IF, keeping desired energy out of the diplexer’s 50-Ω load resistor, R1.

The preceding example is called a *band-pass diplexer*. **Figure 12.32** shows another type: a *high-pass/low-pass diplexer* in which each inductor and capacitor has a reactance of 70.7 Ω at the 3-dB cutoff frequency. It can be used after a “difference” mixer (a mixer in which the IF is the difference between the signal frequency and LO) if the desired IF and its image frequency are far enough apart so that the image power is “dumped” into the network’s 51-Ω resistor. (For a “summing” mixer — a mixer in which the IF is the sum of the desired signal and LO — interchange the 50-Ω idler load resistor and the diplexer’s “50-Ω Amplifier” connection.)

**Figure 12.33** shows a BJT post-mixer amplifier design made popular by Wes Hayward, W7ZOI, and John Lawson, K5IRK. RF feedback (via the 1-kΩ resistor) and emitter degeneration (the ac-coupled 5.6-Ω emitter resistor) work together to keep the stage’s input impedance near 50 Ω and uniformly resistive across a wide bandwidth. Performance comparable to the Figure 10.28 circuit can be obtained at MF and HF by using paralleled 2N3904s as shown in **Figure 12.34**.

### Phase Detection with a DBM

As we saw in our exploration of quadrature detection, applying two signals of equal frequency to a DBM’s LO and RF ports produces an IF-port dc output proportional to the cosine of the signals’ phase difference (**Figure 12.35**). This assumes that the DBM has a dc-coupled IF port, of course. If it doesn’t — and some DBMs don’t — phase-detector operation is out. Any dc output offset introduces error into this process, so critical phase-detection applications use low-offset DBMs optimized for this service.

### 12.4.4 Active Mixers

We’ve covered diode DBMs in depth because their ease of use in homebrew projects, high performance, and suitability for direct connection into 50-Ω systems makes them attractive to amateur builders. The abundant availability of high-quality manufac-

HBK05\_11-031

(C)

(D)

Figure 12.31 — A diplexer resistively terminates energy at unwanted frequencies while passing energy at desired frequencies. This band-pass diplexer (A) uses a series-tuned circuit as a selective pass element, while a high-C parallel-tuned circuit keeps the network's terminating resistor R1 from dissipating desired-frequency energy. Computer simulation of the diplexer's response with *ARRL Radio Designer 1.0* characterizes the diplexer's insertion loss and good input match from 8.8 to 9.2 MHz (B) and from 1 to 100 MHz (C); and the real and imaginary components of the diplexer's input impedance from 8.8 to 9.2 MHz with a 50-Ω load at the diplexer's output terminal (D). The high-C, low-L nature of the L2-C2 circuit requires that C2 be minimally inductive; a 10,000-pF chip capacitor is recommended. This diplexer was described by Rohde and Bucher in *Communications Receivers: Principles and Design, 3rd Edition*.

Figure 12.32 — All of the inductors and capacitors in this high-pass/low-pass diplexer (A) exhibit a reactance of 70.7 Ω at its tuned circuits' 3-dB cutoff frequency (the geometric mean of the IF and IF image). B and C show *ARRL Radio Designer* simulations of this circuit configured for use in a receiver that converts 7 MHz to 3.984 MHz using a 10.984-MHz LO. The IF image is at 17.984 MHz, giving a 3-dB cutoff frequency of 8.465 MHz. The inductor values used in the simulation were therefore 1.33 μH (Q = 200 at 25.2 MHz); the capacitors, 265 pF (Q = 1000). This drawing shows idler load and "50-Ω Amplifier" connections suitable for a receiver in which the IF image falls at a frequency *above* the desired IF. For applications in which the IF image falls *below* the desired IF, interchange the 50-Ω idler load resistor and the diplexer's "50-Ω Amplifier" connection so the idler load terminates the diplexer low-pass filter and the 50-Ω amplifier terminates the high-pass filter.

tured diode mixers at reasonable prices makes them excellent candidates for home construction projects. Although diode DBMs are common in telecommunications as a whole, their conversion loss and relatively high LO power requirement have usually driven the manufacturers of high-performance MF/HF Amateur Radio receivers and transceivers to other solutions. Those solutions have generally involved single- or double-balanced FET

mixers — MOSFETs in the late 1970s and early 1980s, JFETs from the early 1980s to date. A comprehensive paper that explores the differences between various forms of active mixers, "Performance Capabilities of Active Mixers," by Ulrich Rohde, NIUL, is included in the downloadable supplemental information accompanying this *Handbook*.

Many of the JFET designs are variations of a single-balanced mixer circuit introduced

to *QST* readers in 1970. **Figure 12.36** shows the circuit as it was presented by William Sabin in "The Solid-State Receiver," *QST*, July 1970. Two 2N4416 JFETs operate in a common-source configuration, with push-pull RF input and parallel LO drive. **Figure 12.37** shows a similar circuit as implemented in the ICOM IC-765 transceiver. In this version, the JFETs (2SK125s) operate in common-gate, with the LO applied across a 220-Ω

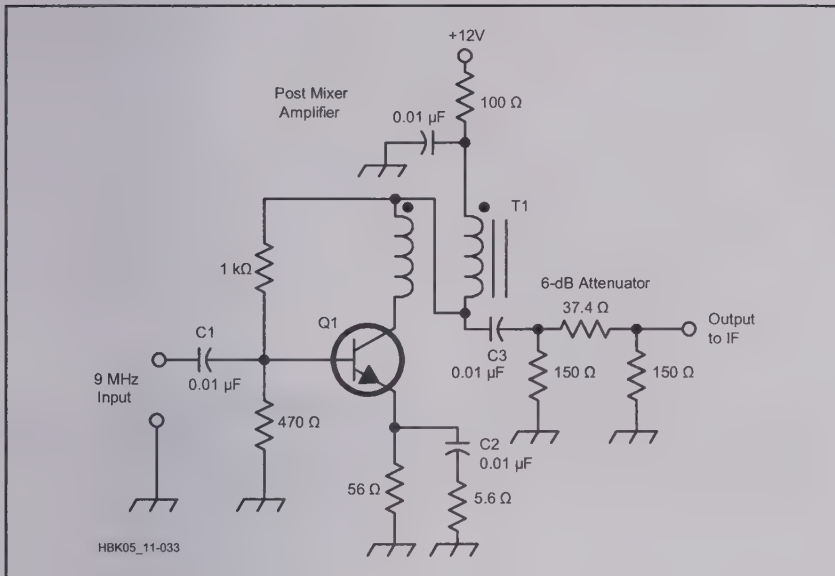

Figure 12.33 — The post-mixer amplifier from Hayward and Lawson's "Progressive Communications Receiver" (November 1981 *QST*). This amplifier's gain, including the 6-dB loss of the attenuator pad, is about 16 dB; its noise figure, 4 to 5 dB; its output intercept, 30 dBm. The 6-dB attenuator is essential if a crystal filter follows the amplifier; the pad isolates the amplifier from the filter's highly reactive input impedance. This circuit's input match to 50 Ω below 4 MHz can be improved by replacing 0.01-μF capacitors C1, C2 and C3 with low-inductance 0.1-μF units (chip capacitors are preferable). Q1 is a TO-39 CATV-type bipolar transistor,  $f_T = 1$  GHz or greater (2N3866, 2N5109, 2SC1252, 2SC1365 or MRF586 suitable.) Use a small heat sink on this transistor. T1 is a broadband ferrite transformer,  $\approx 42$  μH per winding; 10 bifilar turns of #28 enameled wire on an FT 37-43 core.

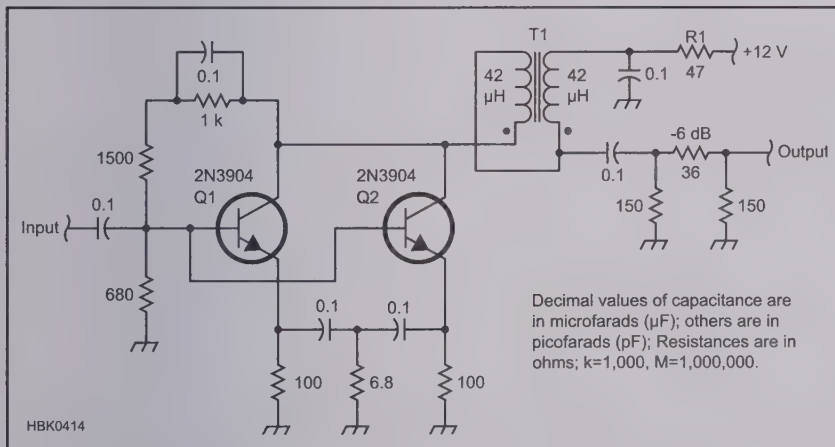

Figure 12.34 — At MF and HF, paralleled 2N3904 BJTs can provide performance comparable to that of the Figure 12.33 circuit with sufficient attention paid to device standing current, here set at  $\gg 30$  mA for the pair. The value of decoupling resistor R1 is critical in that small changes in its value cause a relatively large change in the 2N3904s' bias point. This circuit is part of the "EZ-90 Receiver," described by Hayward, Campbell and Larkin in *Experimental Methods in RF Design*.

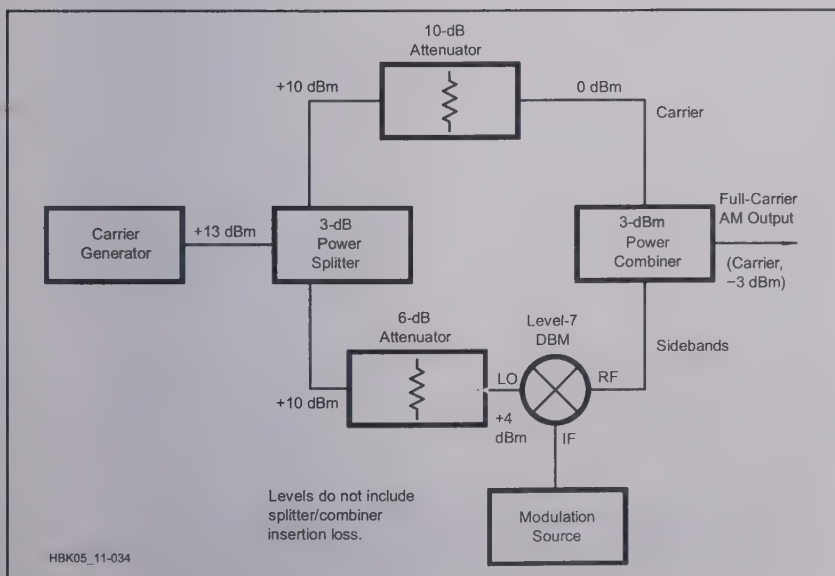

Figure 12.35 — Generating full-carrier AM with a diode DBM. A practical modulator using this technique is described in *Experimental Methods in RF Design*.

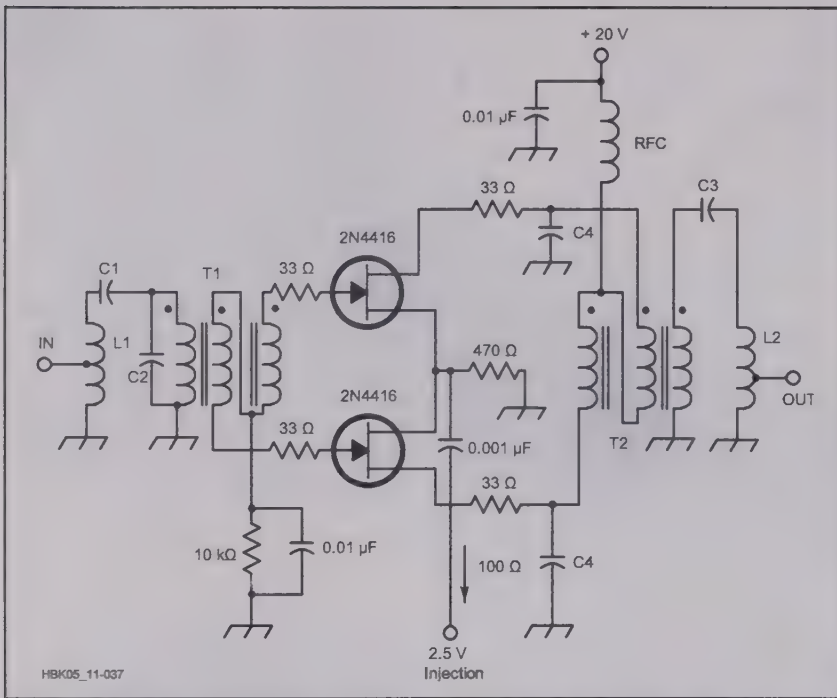

Figure 12.36 — Two 2N4416 JFETs provide highdynamic range in this mixer circuit from Sabin, *QST*, July 1970. L1, C1 and C2 form the input tuned circuit; L2, C3 and C4 tune the mixer output to the IF. The trifilar input and output transformers are broadband transmission-line types.

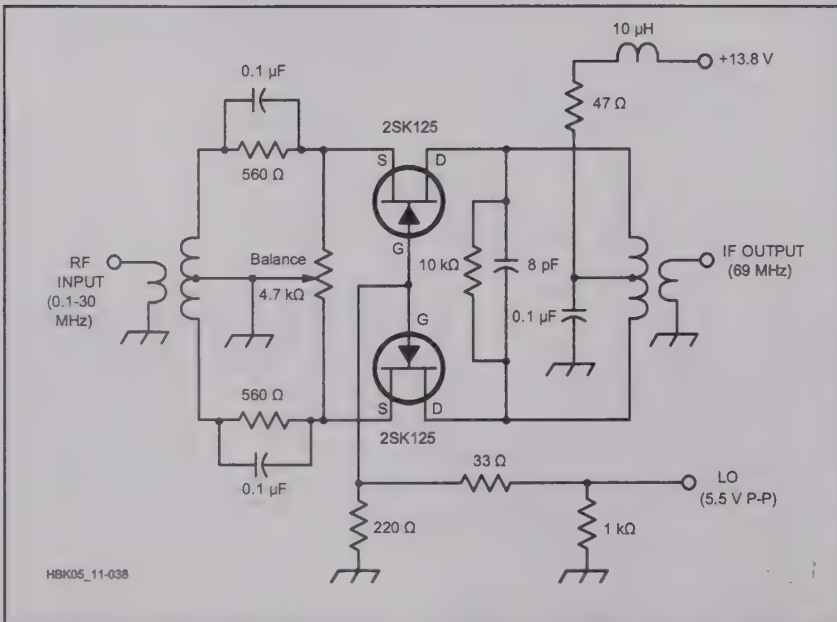

Figure 12.37 — The ICOM IC-765's single-balanced 2SK125 mixer achieves a high dynamic range (per *QST* Product Review, an  $IP_3$  of 10.5 dBm at 14 MHz with preamp off). The first receive mixer in many commercial Amateur Radio transceiver designs of the 1980s and 1990s used a pair of 2SK125s or similar JFETs in much this way.

resistor between the gates and ground.

Current state of the art for active mixers in the HF through GHz range replaces discrete device designs with integrated designs such as the Analog Devices AD8342 ([www.analog.com](http://www.analog.com)). Using an IC greatly improves matching of the active devices, improving circuit balance. The AD8342 has a conversion gain of 3.7 dB, a noise figure of 12.2 dB, and an input  $IP_3$  of 22.7 dBm. The device operates with a single-voltage power supply and is well-suited to interface with digital hardware,

## Testing Mixer Performance

In order to make proper tests on mixers using signal generators, a hybrid coupler with at least 40 dB of isolation between the two input ports and an attenuator are required. The test set-up provided by DeMaw and Collins in *QST*, January 1981, shown in Figure 12.C1 is ideal for this.\* Two signal generators operating near 14 MHz are combined in the hybrid coupler, then isolated from the mixer under test (MUT) by a variable attenuator. The LO is supplied by a VFO covering 5.0-5.5 MHz and applied to the MUT through another variable attenuator. The output is isolated with another attenuator, amplified and applied to a spectrum analyzer for analysis.

Attenuation should be sufficient to provide isolation (minimum of 6 to 10 dB required) and to result in signal levels to the mixer under test (MUT) appropriate for the required testing and as suitable for the particular mixer device.

The 2N5109 amplifier shown may not be sufficient for extremely high intercept point tests as this stage may no longer be transparent (operate linearly) at high signal levels. For stability tests, it is recommended to have a reactive network at the output of the mixer for the sole purpose of checking whether the mixer can become unstable.

The two 14 MHz oscillators must have extremely low harmonic content and very low noise sidebands. A convenient oscillator circuit is provided in Figure 12.C2, based on a 1975 *Electronic Design* article.\*\* — Dr Ulrich L. Rohde, N1UL

such as for SDR applications. Reference circuits for applications at HF and VHF/UHF are provided in the device's datasheet.

### 12.4.5 The Tayloe Mixer

[The following description of the Tayloe Product Detector (a.k.a. — the Tayloe Mixer) is adapted from the July 2002 QEX article, "Software-Defined Radio For the Masses, Part 1" by Gerald Youngblood AC5OG, now K5SDR. — Ed.]

The beauty of the Tayloe detector (see reference listings for Tayloe) is found in both its design elegance and its exceptional performance. In its simplest form, you can build a complete quadrature downconverter with only three or four ICs (less the local oscillator) at a cost of less than \$10.

Figure 12.38 illustrates a single-balanced version of the Tayloe detector. It can be visualized as a four-position rotary switch revolving at a rate equal to the carrier frequency. The 50-Ω antenna impedance is connected

to the rotor and each of the four switch positions is connected to a sampling capacitor. Since the switch rotor is turning at exactly the RF carrier frequency, each capacitor will track the carrier's amplitude for exactly one-quarter of the cycle and will then hold its value for the remainder of the cycle. The rotating switch will therefore sample the signal at 0°, 90°, 180° and 270°, respectively.

As shown in Figure 12.39, the 50-Ω impedance of the antenna and the sampling capacitors form an R-C low-pass filter during the period when each respective switch is turned on. Therefore, each sample represents the integral or average voltage of the signal during its respective one-quarter cycle. When the switch is off, each sampling capacitor will hold its value until the next revolution. If the RF carrier and the rotating frequency were exactly in phase, the output of each capacitor will be a dc level equal to the average value of the sample.

If we differentially sum outputs of the 0° and 180° sampling capacitors with an op amp (see Figure 12.38), the output would be a dc voltage equal to two times the value of the individually sampled values when the switch rotation frequency equals the carrier frequency. Imagine, 6 dB of noise-free gain! The same would be true for the 90° and 270° capacitors as well. The 0°/180° summation forms the *I* channel and the 90°/270° summation forms the *Q* channel of a quadrature downconversion. (See the **Modulation** chapter for more information on I/Q modulation.)

As we shift the frequency of the carrier away from the sampling frequency, the values of the inverting phases will no longer be dc levels. The output frequency will vary according to the "beat" or difference frequency between the carrier and the switch-rotation frequency to provide an accurate representation of all the signal components converted to baseband.

Figure 12.40 is the schematic for a simple, single-balanced Tayloe detector. It consists of a P15V331, 1:4 FET demultiplexer (an analog switch) that switches the signal to each of the four sampling capacitors. The 74AC74 dual flip-flop is connected as a divide-by-four Johnson counter to provide the two-phase clock to the demultiplexer chip. The outputs of the sampling capacitors are differentially summed through the two LT1115 ultra-low-noise op amps to form the *I* and *Q* outputs, respectively.

Note that the impedance of the antenna forms the input resistance for the op-amp gain as shown in the equation for gain below. This impedance may vary significantly with the actual antenna. In a practical receiver, a buffer amplifier should be used to stabilize and control the impedance presented to the mixer.

Since the duty cycle of each switch is 25%, the effective resistance in the RC network is

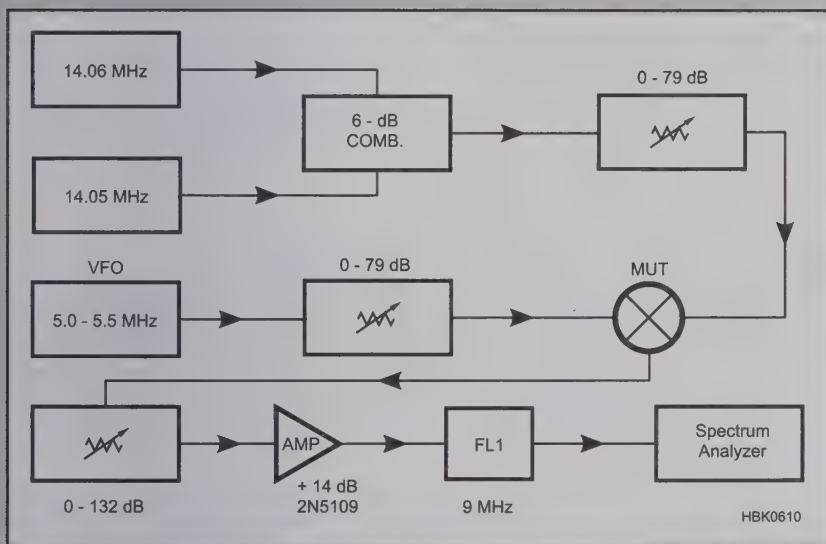

Figure 12.C1 — The equipment setup for measuring mixer performance at HF.

Figure 12.C2 — A low-noise VXO circuit for driving the LO port of the mixer under test in Figure 12.C1.

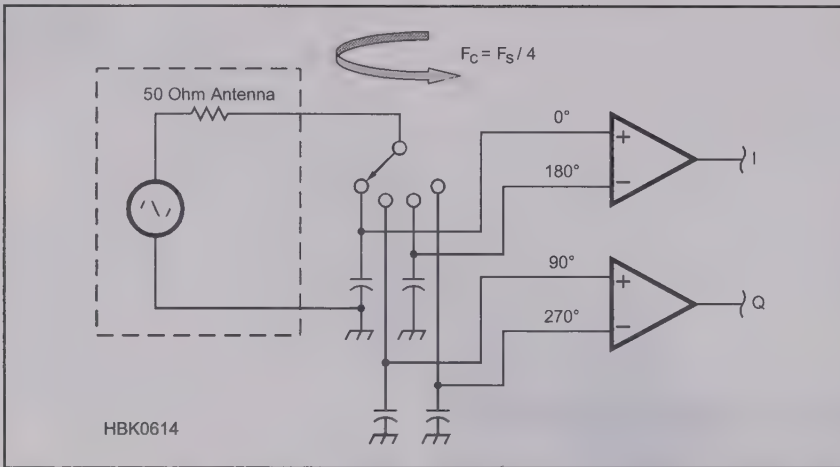

Figure 12.38 — Taylor detector: The switch rotates at the carrier frequency so that each capacitor samples the signal once each revolution. The 0° and 180° capacitors differentially sum to provide the in-phase (I) signal and the 90° and 270° capacitors sum to provide the quadrature (Q) signal.

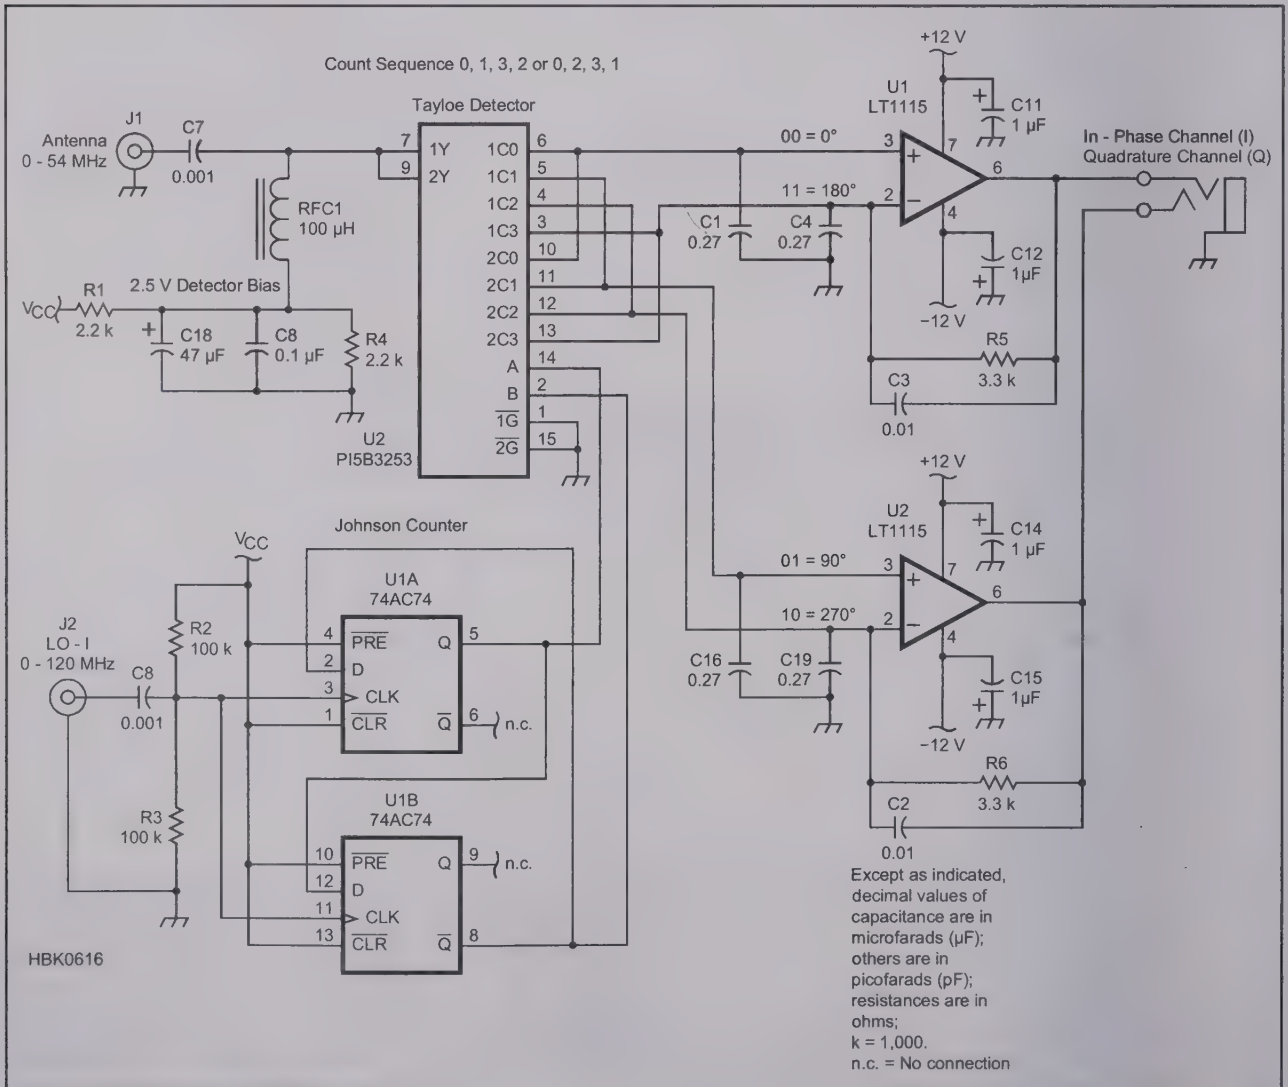

Figure 12.39 — Track-and-hold sampling circuit: Each of the four sampling capacitors in the Taylor detector form an RC track-and-hold circuit. When the switch is on, the capacitor will charge to the average value of the carrier during its respective one-quarter cycle. During the remaining three-quarters cycle, it will hold its charge. The local-oscillator frequency is equal to the carrier frequency so that the output will be at baseband.

Figure 12.40 — Single-balanced Taylor detector.

the antenna impedance multiplied by four in the op-amp gain formula:

$$G = \frac{R_f}{4R_{ant}}$$

For example, with a feedback resistance,  $R_f$ , of 3.3 k $\Omega$  and antenna impedance,  $R_{ant}$ , of 50  $\Omega$ , the resulting gain of the input stage is:

$$G = \frac{3300}{4 \times 50} = 16.5$$

The Tayloe detector may also be analyzed as a *digital commutating filter* (see reference by Kossor). This means that it operates as a very-high-Q tracking filter, where the following equation determines the bandwidth:

$$BW_{det} = \frac{1}{\pi n R_{ant} C_s}$$

where  $n$  is the number of sampling capacitors,  $R_{ant}$  is the antenna impedance and  $C_s$  is the value of the individual sampling capacitors.  $Q_{det}$  of the filter is:

$$Q_{det} = \frac{f_c}{BW_{det}}$$

where  $f_c$  is the center frequency and  $BW_{det}$  is the bandwidth of the filter.

By example, if we assume the sampling capacitor to be 0.27  $\mu$ F and the antenna impedance to be 50  $\Omega$ , then  $BW$  and  $Q$  at an operating frequency of 14.001 MHz are computed as follows:

$$BW_{det} = \frac{1}{\pi \times 4 \times 50 \times (2.7 \times 10^{-7})} = 5895 \text{ Hz}$$

$$Q_{det} = \frac{14.001 \times 10^6}{5895} = 2375$$

The real payoff in the Tayloe detector is its performance. It has been stated that the *ideal* commutating mixer has a minimum conversion loss (which determines noise figure — see the **RF Techniques** chapter) of 3.9 dB. Typical high-level diode mixers have a conversion loss of 6-7 dB and noise figures 1 dB higher than the loss. The Tayloe detector has less than 1 dB of conversion loss, remarkably. How can this be? The reason is that it is not really a mixer but a sampling detector in the form of a quadrature track-and-hold circuit. This means that the design adheres to discrete-time sampling theory, which, while similar to mixing, has its own unique characteristics. Because a track and hold actually holds the signal value between samples, the signal output never goes to zero. (See the **DSP and SDR Fundamentals** chapter for more on sampling theory.)

This is where aliasing can actually be used to our benefit. Since each switch and capacitor in the Tayloe detector actually samples

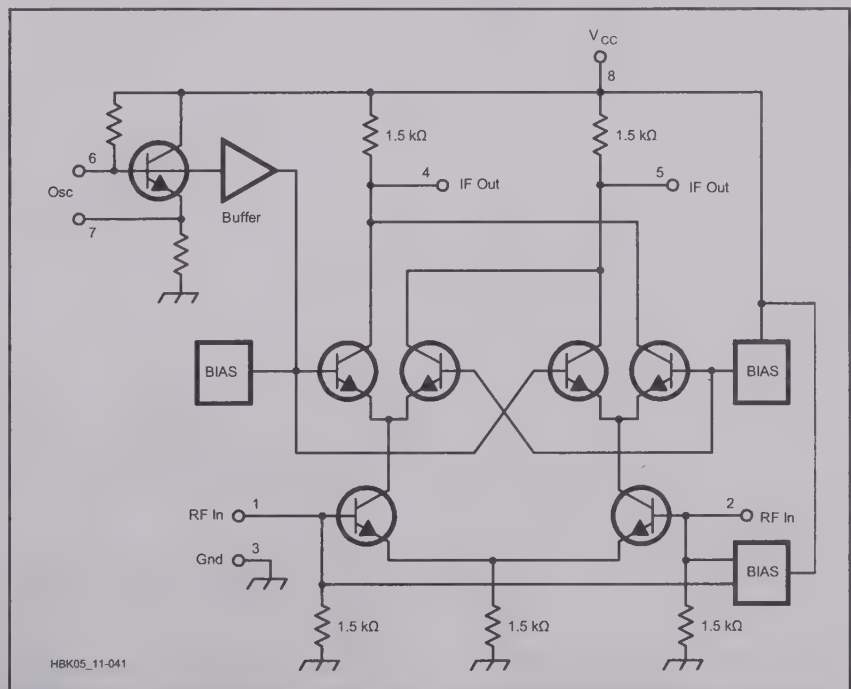

**Figure 12.41 — Alias summing on Tayloe detector output:** Since the Tayloe detector samples the signal, the sum frequency ( $f_c + f_s$ ) and its image ( $-f_c - f_s$ ) are located at the first alias frequency. The alias signals sum with the baseband signals to eliminate the mixing product loss associated with traditional mixers. In a typical mixer, the sum frequency energy is lost through filtering thereby increasing the noise figure of the device.

the RF signal once each cycle, it will respond to alias frequencies as well as those within the Nyquist frequency range. In a traditional direct-conversion receiver, the local-oscillator frequency is set to the carrier frequency so that the difference frequency, or IF, is at 0 Hz and the sum frequency is at two times the carrier frequency. We normally remove the sum frequency through low-pass filtering, resulting in conversion loss and a corresponding increase in noise figure. In the Tayloe detector, the sum frequency resides at the first alias frequency as shown in **Figure 12.41**. Remember that an alias is a real signal and will appear in the output as if it were a baseband signal. Therefore, the alias adds to the

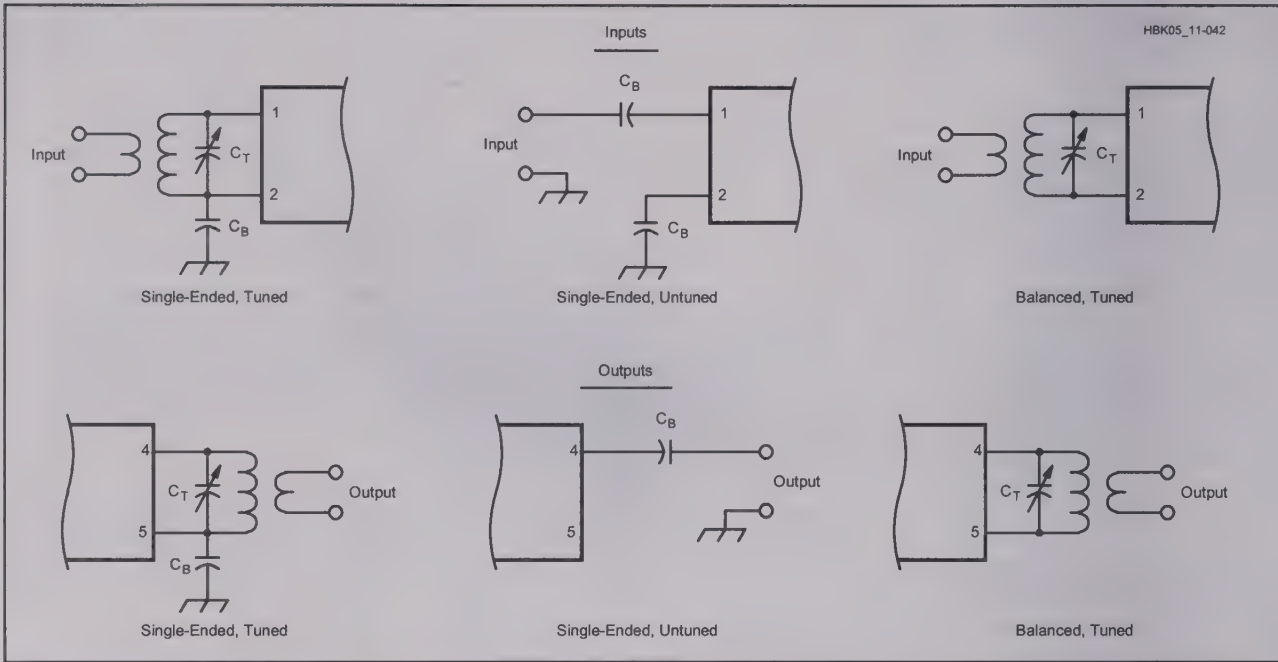

baseband signal for a theoretically lossless detector. In real life, there is a slight loss, usually less than 1 dB, due to the resistance of the switch and aperture loss due to imperfect switching times.

### 12.4.6 The NE602/SA602/SA612 Gilbert Cell Mixer

Introduced as the Philips NE602 in the mid-1980s, the NXP SA602/SA612 mixer-oscillator IC has become greatly popular with amateur experimenters for receive mixers, transmit mixers and balanced modulators. The SA602/612's mixer is a *Gilbert cell* multiplier. **Figure 12.42** shows its equivalent

**Figure 12.42 — The SA602/612's equivalent circuit reveals its Gilbert-cell origins.**

**Figure 12.43** — The SA602/612’s inputs and outputs can be single- or double-ended (balanced). The balanced configurations minimize second-order IMD and harmonic distortion, and unwanted envelope detection in direct-conversion service.  $C_T$  tunes its inductor to resonance;  $C_B$  is a bypass or dc-blocking capacitor. The arrangements pictured don’t show all the possible input/output configurations; for instance, a center-tapped broadband transformer can be used to achieve a balanced, untuned input or output.

circuit. A Gilbert cell consists of two differential transistor pairs whose bias current is controlled by one of the input signals. The other signal drives the differential pairs’ bases, but only after being “predistorted” in a diode circuit. (This circuit distorts the signal equally and oppositely to the inherent distortion of the differential pair.) The resulting output signal is an accurate multiplication of the input voltages.

**SA602/612A VARIANTS**

The SA602/612 began life as the NE602/SA602. SA-prefixed 602/612 parts are specified for use over a wider temperature range than their NE-prefixed equivalents. Parts without the A suffix have a slightly lower  $IP_3$  specification than their A counterparts. The pinout-identical NE612A and SA612A cost less than their 602 equivalents as a result of wider tolerances. All variants of this popular part should work satisfactorily in most “NE602” experimenter projects. The same mixer/oscillator topology, modified for slightly higher dynamic range at the expense of somewhat less mixer gain, is also available in the mixer/oscillator/FM IF chips NE/SA605 (input  $IP_3$  typically -10 dBm) and NE/SA615 (input  $IP_3$  typically -13 dBm).

**SA602/612 USAGE NOTES**

The SA602/612’s typical current drain is 2.4 mA; its supply voltage range is 4.5 to

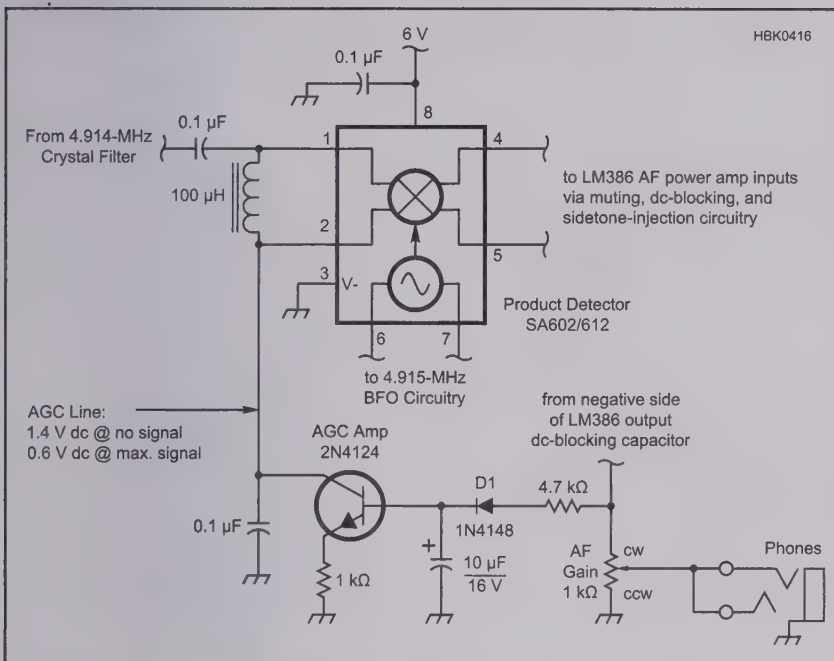

**Figure 12.44** — An NPN transistor at the output of an SA602/612 mixer provides power gain and low-impedance drive for a 4.914-MHz crystal filter. A low-reactance coupling capacitor can be added between the emitter and the circuitry it drives if dc blocking is necessary. [Circuit from the Elecraft KX1 transceiver courtesy of Wayne Burdick, N6KR]

8.0 V. Its inputs (RF) and outputs (IF) can be single- or double-ended (balanced) according to design requirements (Figure 12.43). The equivalent ac impedance of each input is approximately 1.5 kΩ in parallel with 3 pF; each output’s resistance is 1.5 kΩ. Figure 12.44 shows the use of an NPN transistor at

the SA602/612 output to obtain low-impedance drive for a crystal filter; Figure 12.45 shows how AGC can be applied to an SA602/612.

The SA602/612 mixer can typically handle signals up to 500 MHz. At 45 MHz, its noise figure is typically 5.0 dB; its typical con-

**Figure 12.45** — SA602/612 product detector AGC from the Elecraft KX1 transceiver. Designed by Wayne Burdick, N6KR, this circuit first appeared in the Wilderness Radio SST transceiver with an LED used at D1 for simultaneous signal indication and rectification. The selectivity provided by the crystal filter preceding the detector works to mitigate the effects of increasing detector distortion with gain reduction. [Circuit courtesy of Wayne Burdick, N6KR, and Bob Dyer, K6KK]

version gain, 18 dB. Note that in contrast to the diode-based mixers described earlier, which have conversion *loss*, most Gilbert-cell mixers have conversion *gain*. Considering the SA602/612's low current drain, its input  $IP_3$  (measured at 45 MHz with 60-kHz spacing) is usefully good at  $-15$  dBm. Factoring in the mixer's conversion gain results in an equivalent output  $IP_3$  of about 3 dBm.

The SA602/612's on-board oscillator can operate up to 200 MHz in LC and crystal-controlled configurations (Figure 12.46 shows three possibilities). Alternatively, energy from an external LO can be applied to the chip's pin 6 via a dc blocking capacitor. At least 200 mV P-P of external LO drive is required for proper mixer operation.

The SA602/612 was intended to be used as the second mixer in double-conversion

FM cellular radios, in which the first IF is typically 45 MHz, and the second IF is typically 455 kHz. Such a receiver's second mixer can be relatively weak in terms of dynamic range because of the adjacent-signal protection afforded by the high selectivity of the first-IF filter preceding it. When used as a first mixer, the SA602/612 can provide a two-tone third-order dynamic range between 80 and 90 dB, but this figure is greatly diminished if a preamplifier is used ahead of the SA602/612 to improve the system's noise figure.

When the SA602/612 is used as a second mixer, the sum of the gains preceding it should not exceed about 10 dB. An SA602/612 can serve as low-distortion (THD < 1%) product detector if overload is avoided through the use of AGC and appropriate attenuation between the '602/612 and the IF strip that drives it.

The SA602/612 is generally not a good choice for VHF and higher-frequency mixers because of its input noise and diminishing IMD performance at high frequencies. There are applications, however, where 6-dB noise figure and 60- to 70-dB dynamic range performance is adequate. If your target specifications exceed these numbers, you should consider other mixers at VHF and up.

Figure 12.47 shows the schematic of a complete 7-MHz direct-conversion receiver based on the SA602/612 and the widely used LM386 AF power amplifier IC. Such simple product-detector-based receivers sometimes suffer from incidental envelope detection, which causes audio from strong, full-carrier-AM shortwave or medium-wave broadcast stations to be audible regardless of where the receiver LO is tuned. RF attenuation and/or band-limiting the receiver input with a double- or triple-tuned-circuit filter can usually reduce this effect to inaudibility.

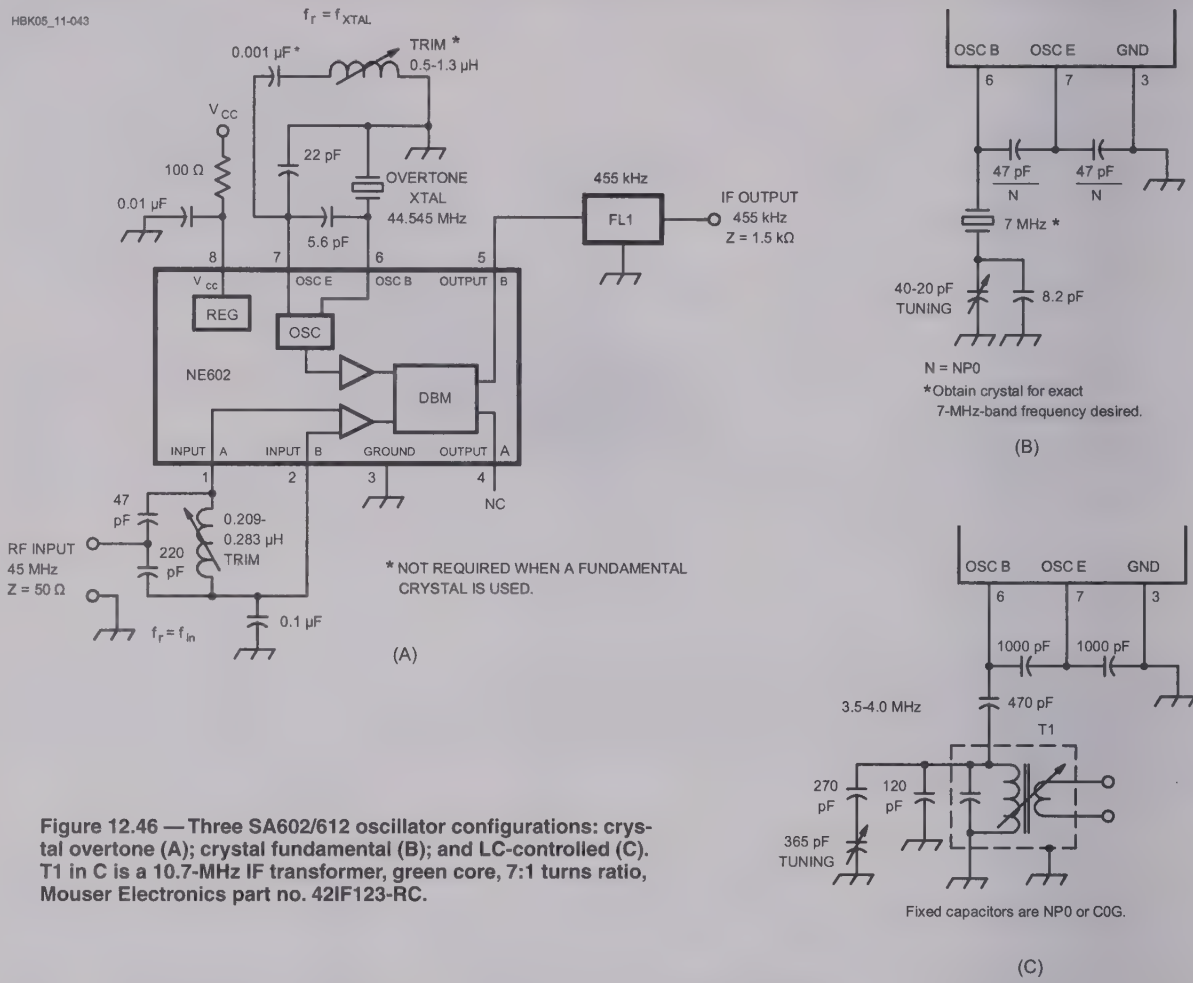

Figure 12.46 — Three SA602/612 oscillator configurations: crystal overtone (A); crystal fundamental (B); and LC-controlled (C). T1 in C is a 10.7-MHz IF transformer, green core, 7:1 turns ratio, Mouser Electronics part no. 42IF123-RC.

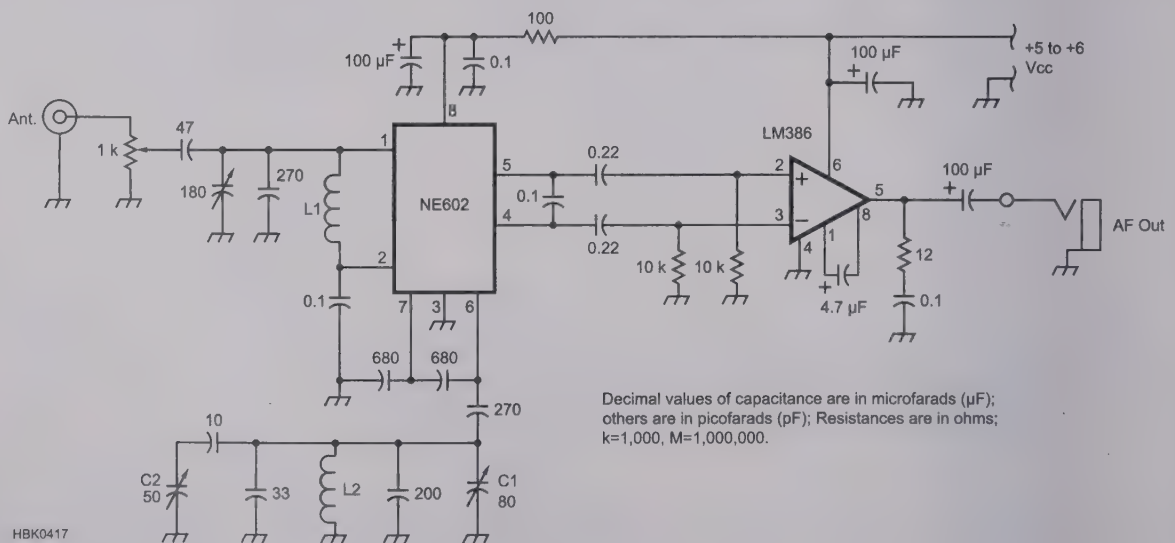

Figure 12.47 — A 7-MHz direct-conversion receiver based on the NE602/SA602/612. Equipped with a stage or two of audio filtering and a means of muting during transmit periods, such a receiver is entirely sufficient for basic Amateur Radio communication at MF and HF. L1 and L2 are 1.2  $\mu\text{H}$ . This receiver is described in greater detail in *Experimental Methods in RF Design*.

# 12.5 Demodulation and Detection

Translating information from radio form back into its original form — demodulation — is also traditionally called *detection*. If the information signal we want to detect consists merely of a baseband signal frequency-shifted into the radio realm, almost any low-distortion frequency-shifter that works according to the sidebar “Mixer Math: Mixing as Multiplication” can do the job acceptably well.

Sometimes we recover a radio signal’s information by shifting the signal back to its original form with no intermediate frequency shifts. This is direct conversion. More commonly, we first convert a received signal to an intermediate frequency so we can amplify, filter and level-control it prior to detection. This is superheterodyne reception.

Whatever the receiver type, however, the received signal ultimately makes its way to one last mixer or demodulator (analog or digital) that completes the final translation of information back into audio, video, or into a signal form suitable for device control or computer processing.

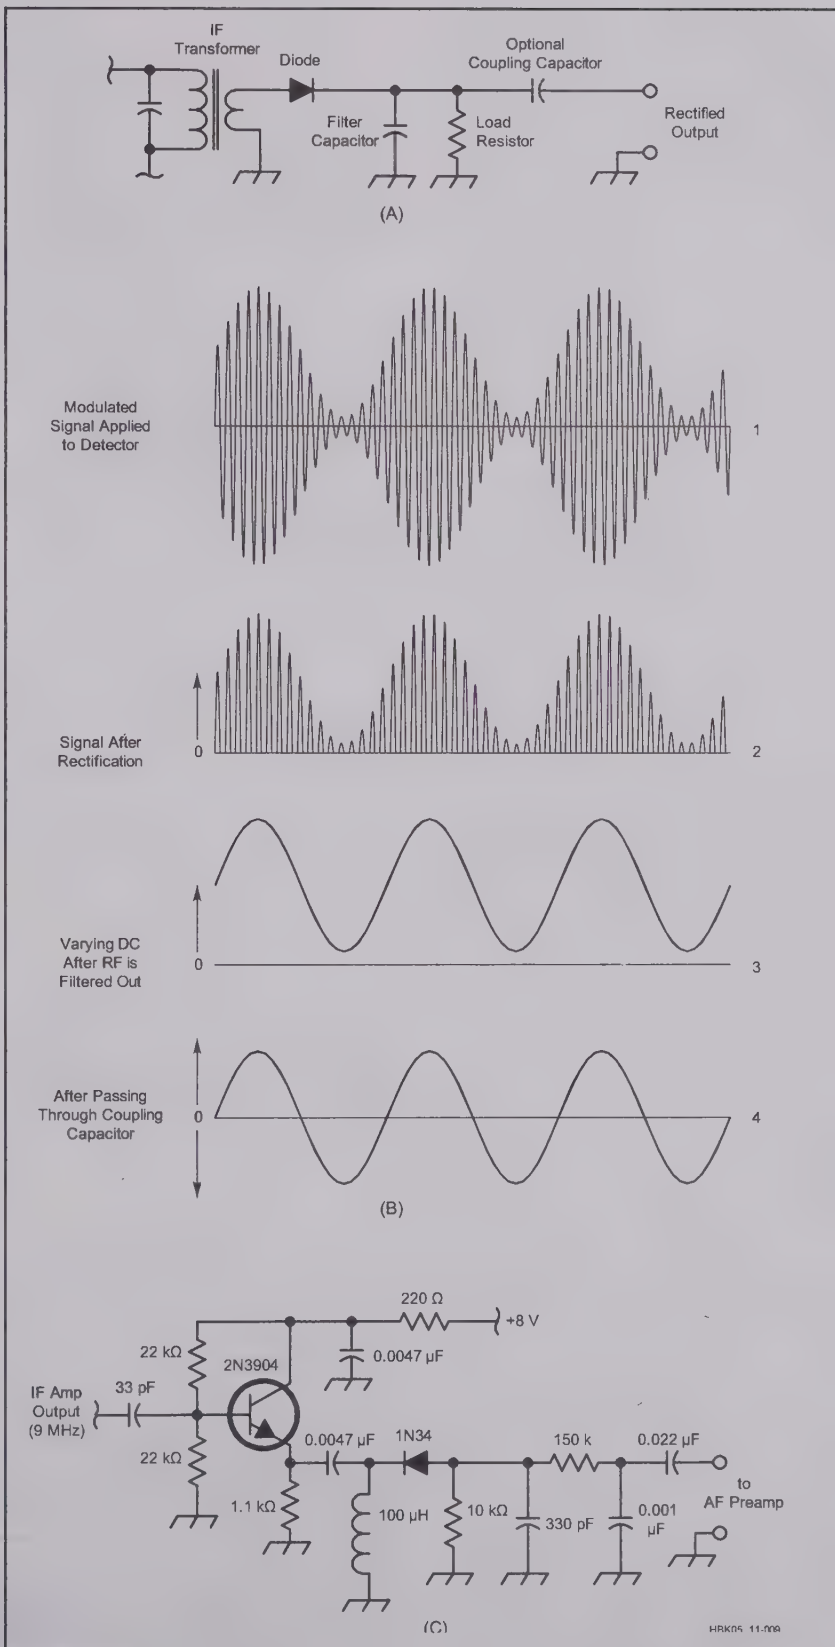

In a heterodyne receiver’s last translation, the incoming signal is converted back to recovered-information form by mixing it with one last RF signal. In heterodyne or *product detection*, that final frequency-shifting signal comes from a BFO. The incoming-signal energy goes into one mixer input port, BFO energy goes into the other, and audio (or whatever form the desired information takes) results.

In SDR receivers, the process may involve the digital equivalent of the analog process or some other mathematical process may be used.

## 12.5.1 Envelope Detection and Full-Carrier AM

If the incoming signal is full-carrier AM and we don’t need to hear the carrier as a tone, we can modify this process somewhat, if we want. We can use the carrier itself to provide the heterodyning energy in a process called *envelope detection*.

A full-carrier AM signal’s *modulation envelope* corresponds to the shape of the modulating wave. If we can derive from the

**Figure 12.48 —** Radio’s simplest demodulator, the diode rectifier (A), demodulates an AM signal by acting as a switch that multiplies the carrier and sidebands to produce frequency sums and differences, two of which sum into a replica of the original modulation (B). Modern receivers often use an emitter follower to provide low-impedance drive for their diode detectors (C).

modulated signal a voltage that varies according to the modulation envelope, we will have successfully recovered the information present in the sidebands. This process is called *envelope detection*, and we can achieve it by doing nothing more complicated than half-wave-rectifying the modulated signal with a diode (**Figure 12.48**).

That a diode demodulates an AM signal by allowing its carrier to multiply with its sidebands may jar those long accustomed to seeing diode detection ascribed merely to “rectification.” But a diode is certainly nonlinear. It passes current in only one direction, and its output voltage is (within limits) proportional to the square of its input voltage. These nonlinearities allow it to multiply.

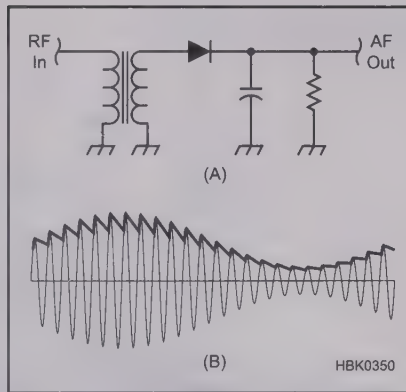

Exploring this mathematically is tedious with full-carrier AM because the process squares three summed components (carrier, lower sideband and upper sideband). Rather than fill the better part of a page with algebra, we’ll instead characterize the outcome verbally: In “just rectifying” a DSB, full-carrier AM signal, a diode detector produces

- Direct current (the result of rectifying the carrier);
- A second harmonic of the carrier;
- A second harmonic of the lower sideband;
- A second harmonic of the upper sideband;
- Two difference-frequency outputs (upper sideband minus carrier, carrier minus lower sideband), each of which is equivalent to the modulating wave-form’s frequency, and both of which sum to produce the recovered information signal; and
- A second harmonic of the modulating waveform (the frequency difference between the two sidebands).

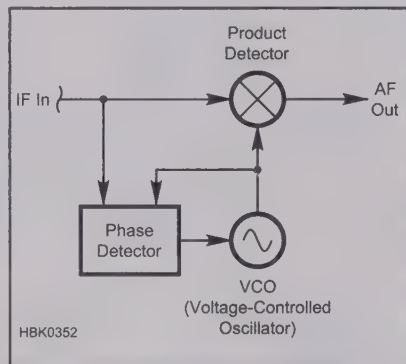

Three of these products are RF signals. Low-pass filtering, sometimes little more than a simple RC network, can remove the RF products from the detector output. A capacitor in series with the detector output line can block the carrier-derived dc component. That done, only two signals remain: the recovered modulation and, at a lower level, its second harmonic — in other words, second-harmonic distortion of the desired information signal.

### 12.5.2 Detecting AM Signals

Note that the shape of the envelope of the modulated RF signal matches the shape of the modulating signal. (This is only true for full AM including the carrier and both sidebands. The envelope of a single-sideband SSB signal is not an accurate reproduction of the modulating signal which is why it cannot be recovered by an envelope detector.) That suggests a possible demodulation method. A diode detector puts out a signal

**Figure 12.49** — A simple diode-type AM detector, also known as an *envelope detector* (A). The demodulated output waveform has the same shape as the envelope of the RF signal (B). In (B) the thin line is the RF signal modulated with a sine wave and the darker line is the demodulated audio frequency with some residual RF ripple.

**Figure 12.50** — Block diagram of a synchronous detector. The voltage-controlled oscillator (VCO) is part of a phase-locked loop that locks the oscillator to the carrier frequency of the incoming AM or DSB-RC signal.

proportional to the envelope of the RF signal, recovering the original modulation. See **Figure 12.49**. The capacitor should be large enough that it filters out most of the RF ripple but not so large that it attenuates the higher audio frequencies.

One problem with AM is that if the amplitude of the carrier becomes attenuated for any reason, then the modulation is distorted, especially the negative-going portion near the 100%-modulation (zero power) point. This can happen due to a propagation phenomenon called *selective fading*. It occurs when the signal arrives simultaneously at the receive antenna via two or more paths, such as ground wave and sky wave. If the difference in the

distance of the two paths is an odd number of half-wavelengths, then the two signals are out of phase. If the amplitudes are nearly the same, they cancel and a deep fade results. Since wavelength depends on frequency, the fading is frequency-selective. On the lower-frequency amateur bands it is possible for an AM carrier to be faded while the two sidebands are still audible.

A solution is to regenerate the carrier in the receiver. Since the carrier itself carries no information about the modulation, it is not necessary for demodulation. The transmitted signal may be a standard full-carrier AM signal or the carrier may be suppressed, resulting in double sideband, suppressed carrier (DSB-SC). An AM detector that regenerates the carrier from the signal is known as a *synchronous detector*. Often the regenerated carrier oscillator is part of a phase-locked loop (PLL) that locks onto the incoming carrier. See **Figure 12.50**. Synchronous detectors not only reduce the effects of selective fading but also are usually more linear than diode detectors so they have less distortion. Some commercial short-wave broadcasts include a reduced, but not suppressed, carrier (DSB-RC) to allow operation with PLL-type synchronous detectors.

Since the advent of single sideband in the 1960s, full-carrier double-sideband AM has become less popular in Amateur Radio. It does retain several advantages however. We have already mentioned the simplicity of the circuitry. Another advantage is that, because of the presence of the carrier, the automatic gain control system in the receiver remains engaged at all times, ensuring a constant audio level. Unlike with SSB, there is no rush of noise during every pause in speech. Also tuning is less critical than with SSB. There is no “Donald Duck” sound if the receiver is slightly mistuned. Finally, the audio quality of an AM signal is usually better than that of SSB because of the lack of a crystal filter in the transmit path and the wider filter in the receiver.

### SDR AM SQUARE-LAW DETECTOR

(This section is taken from the Jul/Aug 2009 *QEX* column SDR: Simplified by W5IFS.) We need to convert the full-carrier double sideband signal into the baseband information. One of the classic AM demodulation methods is a *square-law detector*. Very few devices have a true square law response over a large range of signals. The JFET comes close, but has limited range. With DSP we can implement a square law detector with range that is limited only by the size of the data that the DSP can handle. If we use 16-bit data for the input, our multiplier must have a 32-bit result. This is a very simple and fast operation for the DSP.

The square-law response to a DSB-AM signal with a carrier,  $\sin(y)$ , and two sidebands,  $\cos(x-y)$  and  $\cos(x+y)$  is as follows:

$$V_{\text{out}} = (1\sin(y) + \frac{1}{2}\cos(x-y) - \frac{1}{2}\cos(x+y))^2$$

Applying trig identities and working through the math:

$$V_{\text{out}} = \sin(y)^2 + \sin(y)\cos(x-y) - \sin(y)\cos(x+y) + \frac{1}{4}\cos(x+y)^2 + \frac{1}{4}\cos(x-y)^2$$

$$V_{\text{out}} = \frac{3}{4} - \frac{1}{2}\sin(2y) + \frac{1}{2}\sin(x) + \frac{1}{2}\sin(2y-x) - \frac{1}{2}\sin(-x) - \frac{1}{2}\sin(2y+x) + \frac{1}{8}\cos(2y+2x) + \frac{1}{8}\cos(2y-2x)$$

Finally:

$$V_{\text{out}} = \frac{3}{4} + \sin(x) - \frac{1}{2}\sin(2y) + \frac{1}{2}\sin(2y-x) - \frac{1}{2}\sin(2y+x) + \frac{1}{8}\cos(2y+2x) + \frac{1}{8}\cos(2y-2x)$$

(This result will have 32 bits, but our filter math should only be 16 bits. We can divide the result by 65536 to get the signal back into range for further operations. In software, this just means we throw away the bottom 16 bits of data before we store the result.)

The signal we want is  $\sin(x)$ , but we have a significant dc component ( $\frac{3}{4}$ ) and a whole bunch of unwanted signals at or close to twice the carrier frequency,  $2y$ . The only real problem is the dc component, since it is really close to the desired audio signal. We need to use a band-pass filter to remove the dc and the RF components. Since all but the dc are far removed from the desired audio, we

can use a relatively simple band-pass filter.

### 12.5.3 Demodulating SSB Signals

A complete discussion of the three main techniques used to receive and demodulate SSB signals — filter, phasing, and Weaver — can be found in the **Modulation** chapter. Examples of practical circuits that implement these methods are included in the receiver projects provided in the downloadable supplemental information.

### HETERODYNE RECEIVERS

As with an AM synchronous detector, the carrier is regenerated in a superheterodyne receiver but since only one sideband is present, the synchronous detector's phase-locked loop (described above) is not possible. Instead, the detector uses a free-running *beat-frequency oscillator* (BFO). The detector itself is called a *product detector* because its output is the mathematical product of the BFO and the SSB signal. The BFO must be tuned to the same frequency as the suppressed carrier to prevent distortion of the recovered audio. That is done by carefully tuning the local oscillator (the main tuning dial) such that after conversion to the intermediate frequency, the suppressed carrier aligns with the BFO frequency. Demodulation of SSB signals in an analog heterodyne receiver must be done using a product detector or equivalent technique. Envelope detection will not work because the waveform does not have the shape of the modulating waveform.

### SDR RECEIVERS

SDR receivers use I/Q quadrature demodulator architecture for SSB and many other modes. This technique is discussed in the **Modulation** chapter. A block diagram of an SDR demodulator for SSB is shown in **Figure 12.51**. This particular system shows the phasing method of SSB generation in reverse. The excellent tutorial, "Understanding the 'Phasing Method' of Single Sideband Demodulation" by Rick Lyons ([www.dsp-related.com/showarticle/176.php](http://www.dsp-related.com/showarticle/176.php)) explains the technique in detail. The filter method and the Weaver method can also be implemented with an I/Q architecture although this is not the usual method used by designers.

A quadrature I/Q demodulator generates the  $I_1$  and  $Q_1$  signals which are low-pass filtered to remove high-frequency components, then down-converted using decimation. The I and Q channels are band-pass filtered, with a Hilbert transformer applied to the Q channel as described in the **DSP and SDR Fundamentals** chapter. The resulting streams are then combined so that the Q channel is subtracted from the I channel. This leaves the USB signal, which is converted to analog audio, and low-pass filtered.

If a LSB signal is being received, change the summing symbol immediately preceding the DAC so as to add the I and Q channels together. This produces the LSB signal which is then converted to audio and filtered as before. In practice, both the LSB and USB signals are available at any time and the digital audio stream can be routed to the DAC and low-pass filter under software control.

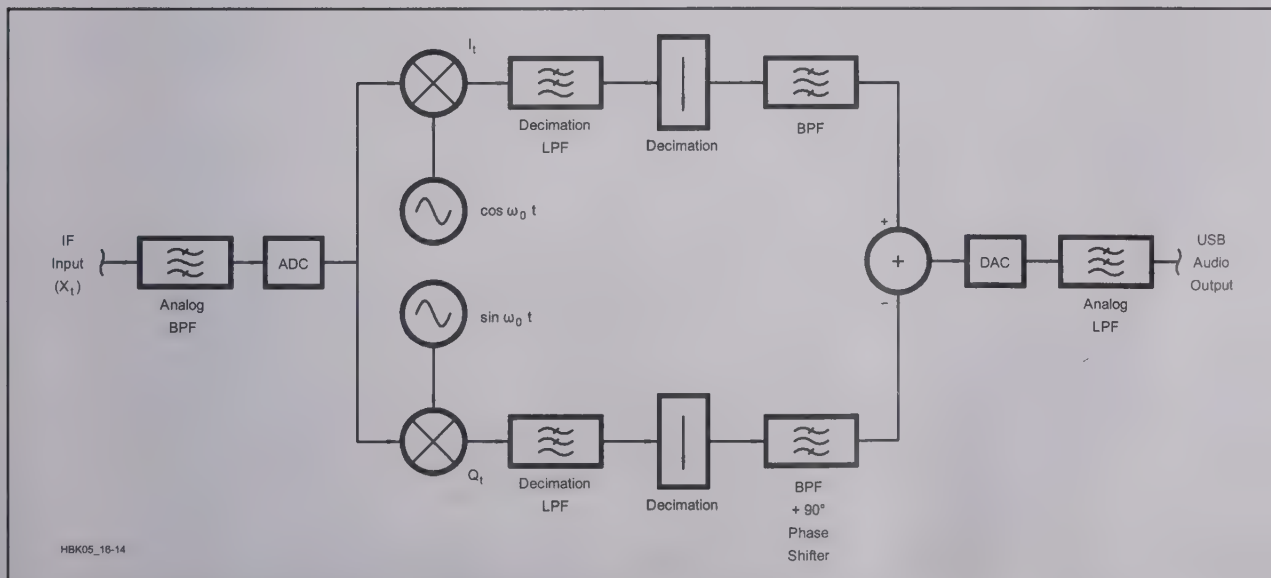

Figure 12.51 — Block diagram of a digital SSB demodulator.

**Figure 12.52** — Frequency-sweeping a constant-amplitude signal and passing it through a low-pass filter results in an output signal that varies in amplitude with frequency. This is the principle behind the angle-demodulation process called *frequency discrimination*.

### 12.5.4 Demodulating FM and PM

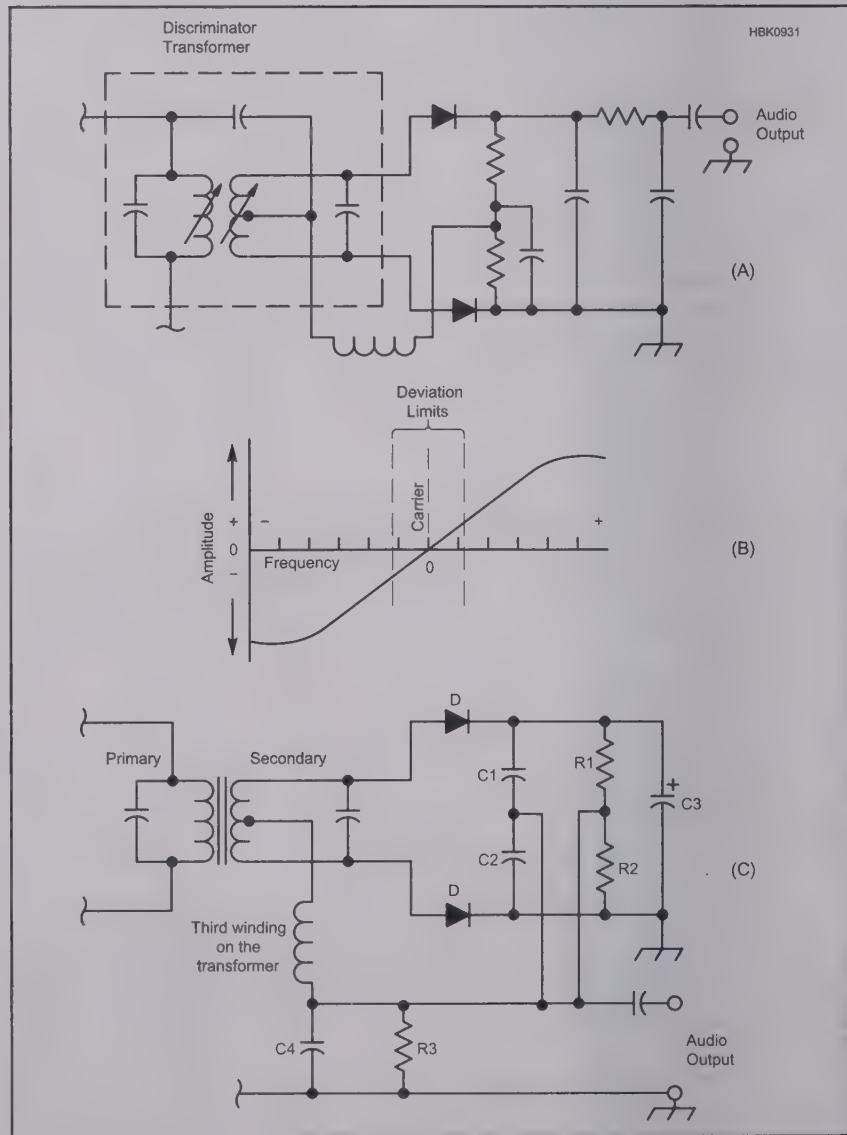

#### ANALOG DEMODULATORS

Although angle modulation does generate an infinite number of sidebands, demodulating angle modulation requires little more than turning it into AM and then envelope- or product-detecting it! But this is what happens in many of our FM receivers and transceivers, and we can get a handle on this process by realizing that a form of angle-modulation-to-AM conversion is created from linear distortion of the modulation by amplitude-linear circuitry. This happens to angle-modulated signals in any linear circuit that doesn't have an amplitude-versus-frequency response that's utterly flat out to infinity.

Think of what happens, for example, when we sweep a constant-amplitude signal up in frequency — say, from 1 kHz to 8 kHz — and pass it through a 6-dB-per-octave filter (Figure 12.52). The filter's rolloff causes the output signal's amplitude to decrease as frequency increases. Now imagine that we linearly sweep our constant-amplitude signal *back and forth* between 1 kHz and 8 kHz at a constant rate of 3 kHz per second. The filter's output *amplitude* now varies cyclically over time as the input signal's *frequency* varies cyclically over time. Right before our eyes, a frequency change turns into an amplitude change. The process of converting angle modulation to amplitude modulation has begun.

This is what happens whenever an angle-modulated signal passes through circuitry with an amplitude-versus-frequency response that isn't flat out to infinity. As the signal deviates across the frequency-response curves of whatever circuitry passes it, its

**Figure 12.53** — A discriminator (A) converts an angle-modulated signal's deviation into an amplitude variation (B) and envelope-detects the resulting AM signal. For undistorted demodulation, the discriminator's amplitude-versus-frequency characteristic must be linear across the input signal's deviation. A *crystal discriminator* uses a crystal as part of its frequency-selective circuitry. The *ratio detector* at (C) operates similarly but has an improved rejection of amplitude modulated noise.

angle modulation is, to some degree, converted to AM — a form of crosstalk between the two modulation types, if we wish to look at it that way. (Variations in system phase linearity also cause distortion and FM-to-AM conversion, because the sidebands do not

have the proper phase relationship with respect to each other and with respect to the carrier.)

All we need to do to put this effect to practical use is develop a circuit that does this frequency-to-amplitude conversion linearly

across the frequency span of the modulated signal's deviation. Then we envelope-demodulate the resulting AM, and we have achieved angle demodulation.

Figure 12.53 shows such a circuit — a Foster-Seeley discriminator — and the sort of amplitude-versus-frequency response we expect from it. ([www.radio-electronics.com/info/rf-technology-design/fm-reception/foster-seeley-fm-detector-discriminator.php](http://www.radio-electronics.com/info/rf-technology-design/fm-reception/foster-seeley-fm-detector-discriminator.php)) It's actually possible to use an AM receiver to recover understandable audio from a narrow angle-modulated signal by "off-tuning" the signal so its deviation rides up and down on one side of the receiver's IF selectivity curve. This *slope detection* process served as an early, suboptimal form of frequency discrimination in receivers not designed for FM. It is always worth trying as a last-resort-class means of receiving narrowband FM with an AM receiver.

The ratio detector in Figure 12.53C is a variation on the discriminator which is better at rejecting AM noise mixed with the FM signal. ([www.radio-electronics.com/info/rf-technology-design/fm-reception/ratio-fm-detector-discriminator.php](http://www.radio-electronics.com/info/rf-technology-design/fm-reception/ratio-fm-detector-discriminator.php)) Note that the diodes are in series in this circuit. A similar phase shift occurs in the third transformer winding as the signal moves away from the frequency of the tuned transformer winding. This causes an imbalance in the transformer secondary and current flows in the third winding. That signal is then filtered by  $C_4$  and  $R_3$  before being passed to the audio stages of the receiver.

## QUADRATURE DETECTORS

It's also possible to demodulate an angle-modulated signal merely by multiplying it with a time-delayed copy of itself in a double-balanced mixer as shown in Figure 12.54; the sidebar, "Mixer Math: Quadrature Demodulation," explains the process numerically.

An ideal quadrature detector puts out 0 V dc when no modulation is present (with the carrier at  $f_c$ ). The output of a real quadrature detector may include a small *dc offset* that requires compensation. If we need the detector's response all the way down to dc, we've got it; if not, we can put a suitable blocking capacitor in the output line for ac-only coupling.

Quadrature detection is more common than frequency discrimination in current receivers because it doesn't require a special discriminator transformer or resonator, and because the necessary balanced-detector circuitry can easily be implemented in IC structures along with limiters and other receiver circuitry. The NXP Semiconductor SA604A FM IF IC is one example of this; Figure 12.55 shows another, the Freescale Semiconductor (formerly Motorola) MC3359

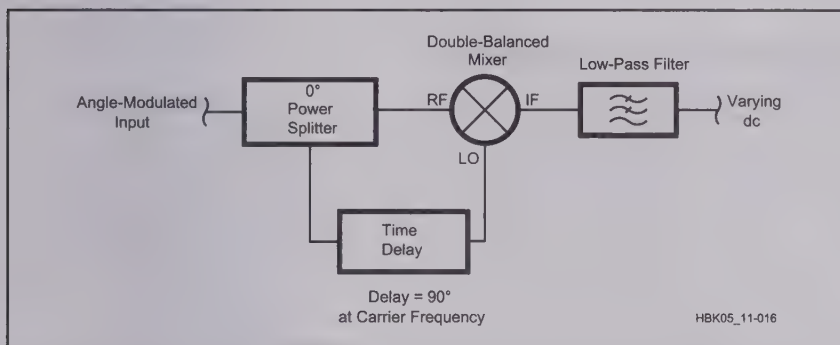

Figure 12.54 — In *quadrature detection*, an angle-modulated signal multiplies with a time-delayed copy of itself to produce a dc voltage that varies with the amplitude and polarity of its phase or frequency excursions away from the carrier frequency. A practical quadrature detector can be as simple as a 0° power splitter (that is, a power splitter with in-phase outputs), a diode double-balanced mixer, a length of coaxial cable  $\frac{1}{4}\lambda$  (electrical) long at the carrier frequency, and a bit of low-pass filtering to remove the detector output's RF components. IC quadrature detectors achieve their time delay with one or more resistor-loaded tuned circuits (Figure 12.55).

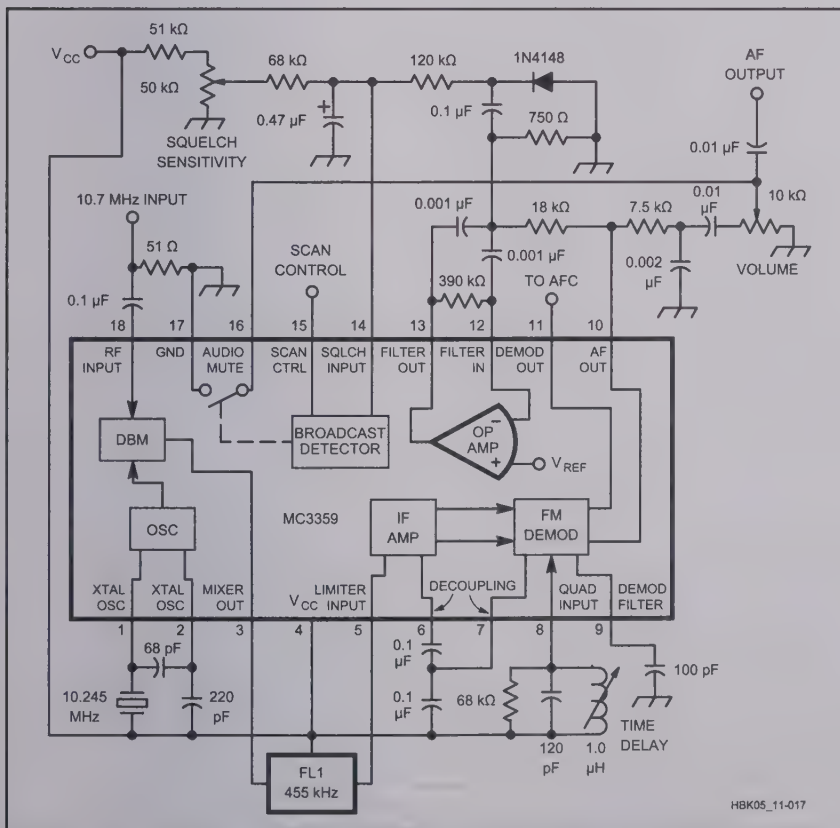

Figure 12.55 — The Freescale MC3359/NTE680 is one of many FM subsystem ICs that include limiter and quadrature-detection circuitry. The TIME DELAY coil is adjusted for minimum recovered-audio distortion.

(equivalent, NTE860). Quadrature detection is also simple to perform in SDR designs.

### AMPLITUDE LIMITING

FM radio communication systems are superior to AM in their ability to suppress and ignore static, manmade electrical noise

and (through a characteristic called *capture effect*) co-channel signals sufficiently weaker than the desired signal. AM-noise immunity and capture effect are not intrinsic to angle modulation, however; they must be designed into the angle-modulation receiver in the form of signal amplitude *limiting*.

The amplitude of a quadrature detector's input signal affects the amplitude of a quadrature detector's three output signals. A quadrature detector therefore responds to AM, and so does a frequency discriminator. To achieve FM's excellent amplitude noise immunity, then, these angle demodulators must be preceded by *limiter* circuitry that removes all amplitude variations from the incoming signal.

## Mixer Math: Quadrature Demodulation

Demodulating an angle-modulated signal merely by multiplying it with a time-delayed copy of itself in a double-balanced mixer results in quadrature demodulation (Figure 12.54). To illustrate this mathematically, for simplicity's sake, we'll represent the mixer's RF input signal as just a sine wave with an amplitude,  $A$ :

$$A \sin(2\pi ft)$$

and its time-delayed twin, fed to the mixer's LO input, as a sine wave with an amplitude,  $A$ , and a time delay of  $d$ :

$$A \sin[2\pi f(t + d)]$$

Setting this special mixing arrangement into motion, we see

$$A \sin(2\pi ft) \times A \sin(2\pi ft + d)$$

$$= \frac{A^2}{2} \cos(2\pi fd) - \frac{A^2}{2} \cos(2\pi fd) \cos(2 \times 2\pi ft) + \frac{A^2}{2} \sin(2\pi fd) \sin(2 \times 2\pi ft)$$

Two of the three outputs — the second and third terms — emerge at twice the input frequency; in practice, we're not interested in these, and filter them out. The remaining term — the one we're after — varies in amplitude and sign according to how far and in what direction the carrier shifts away from its resting or center frequency (at which the time delay,  $d$ , causes the mixer's RF and LO inputs to be exactly 90° out of phase — in *quadrature* — with each other). We can examine this effect by replacing  $f$  in the RF input and LO input sinusoids with the sum term  $f_c + f_s$ , where  $f_c$  is the center frequency and  $f_s$  is the frequency shift. A 90° time delay is the same as a quarter cycle of  $f_c$ , so we can restate  $d$  as

$$d = \frac{1}{4f_c}$$

The first term of the detector's output then becomes

$$\frac{A^2}{2} \cos(2\pi(f_c + f_s)d)$$

$$= \frac{A^2}{2} \cos\left(2\pi(f_c + f_s) \frac{1}{4f_c}\right)$$

$$= \frac{A^2}{2} \cos\left(\frac{\pi}{2} + \frac{\pi f_s}{2f_c}\right)$$

When  $f_s$  is zero (that is, when the carrier is at its center frequency), this reduces to

$$\frac{A^2}{2} \cos\left(\frac{\pi}{2}\right) = 0$$

As the input signal shifts higher in frequency than  $f_c$ , the detector puts out a positive dc voltage that increases with the shift. When the input signal shifts lower in frequency than  $f_c$ , the detector puts out a negative dc voltage that increases with the shift. The detector therefore recovers the input signal's frequency or phase modulation as an amplitude-varying dc voltage that shifts in sign as  $f_s$  varies around  $f_c$  — in other words, as ac. We have demodulated FM by means of quadrature detection.

### SDR ANGLE DEMODULATION

A popular technique for angle demodulation starts with a phase detector as shown in **Figure 12.56**. The angle-modulated signal is down-converted to a convenient frequency and input to a pair of multipliers where it is mixed with a pair of constant frequency LO signals in quadrature. Low-pass filters then remove signals at the sum frequency, leaving only the I and Q baseband signals.

In PM demodulation, the phase comparison is an absolute comparison against the carrier phase. The phase angle of the input signal, relative to the LO center frequency, can be determined from the I and Q signals as:

$$\varphi = \tan^{-1}\left(\frac{V_Q}{V_I}\right)$$

The arctan function can be computed either by polynomial approximations or a lookup table, depending on system resources. If the signal is a PM signal, the phase signal contains the original modulation and can be filtered and output as audio.

FM demodulation requires additional steps as a special case of PM. The change in angle from the unmodulated carrier is constantly increasing or decreasing and exceeds  $\pm 90^\circ$  as a normal part of operation. For that reason, a simple phase comparator using the recovered carrier will not demodulate FM. FM requires that we measure the rate-of-change of phase and sum those incremental phase changes.

Since frequency is defined as the rate-of-change of phase, it is necessary to differentiate the phase signal to recover the FM modulation signal. Implementing differentiation in DSP involves subtracting each sample from the previous sample. It is necessary to account for the point at which phase passes through 360° and resets to 0°. This can be done through special routines or by scaling of fixed-point data in the computations so that the phase rollover and integer rollover (65535 to 0, for example, in 16-bit math) coincide.

The FM signal will also need a de-emphasis filter (see the **Modulation and Transmitting** chapters) to cancel the high-frequency gain that was added during the FM process by the modulator.

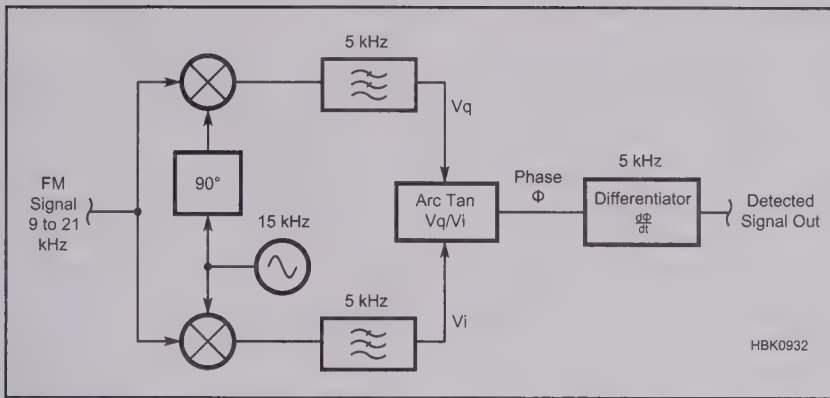

Figure 12.56 — An FM detector using an arctangent phase detector and a differentiator.

## 12.6 Automatic Gain Control (AGC)

The amplitude of the desired signal at each point in the receiver is generally controlled by the AGC system, although manual control is usually provided as well. Each stage has a distortion versus signal level characteristic that must be known, and the stage input level must not become excessive. The signal being received has a certain signal-to-distortion ratio that must not be degraded too much by the receiver. For example, if an SSB signal has  $-30$  dB distortion products the receiver should create additional distortion no greater than  $-40$  dB with respect to the desired signal. The correct AGC design ensures that each stage gets the right input level. It is often necessary to redesign some stages in order to accomplish this task.

While this chapter deals mostly with AGC in the guise of analog circuits, the same function is also implemented digitally in DSP and SDR receivers. The goal of both is the same — to maintain a signal level at all stages of the receiver that is neither too large nor too small so that the various processing systems operate properly. Whether or not the AGC offset and time constant are implemented by an analog component or by a microprocessor output is immaterial. The point is to manage the RF amplifier gain so that the overall receiver behavior is satisfactory.

AGC in the receive signal chain of an SDR should not be confused with AGC in an analog receiver. AGC in the analog receiver will adjust the fixed dynamic range of the receiver up or down, altering the weak and strong signal performance of the radio dynamically.

The effects of an improperly operating AGC system can be quite subtle or nearly disabling to a receiver and vary with how the AGC system is constructed. This chapter attempts to describe the requirements for

proper operation and provides some examples of implementation and common AGC failures in terms of analog circuitry which is somewhat easier to describe than software algorithms, noting that similar behaviors exist even in purely software receivers. The interested student should consider studying the AGC systems of commercial receivers to understand how professional design teams deal with the problem of managing so much gain with such stringent requirements for linearity and distortion.

### THE AGC LOOP

Figure 12.57A shows a typical AGC loop that is often used in amateur superhet receivers. The AGC is applied to the stages through RF decoupling circuits that prevent the stages from interacting with each other. The AGC amplifier helps to provide enough AGC loop gain so that the gain-control characteristic of Figure 12.57B is achieved. If effect, the AGC system causes the receiver to act as a compression amplifier with lower overall gain for stronger signals.

The AGC action does not begin until a certain level, called the *AGC threshold*, is reached. The THRESHOLD VOLTS input in Figure 12.57A serves this purpose. After that level is exceeded, the audio level increases more slowly than for weaker signals. The audio rise beyond the threshold value is usually in the 5 to 10 dB range. Too much or too little audio rise are both undesirable for most operators.

As an option, the AGC signal to the RF amplifier is offset by the 0.6 V forward drop of the diode so that the RF gain does not start to decrease until larger signals appear. This prevents a premature increase of the receiver noise figure. Also, a time constant of one or

two seconds after this diode helps keep the RF gain steady for the short term.

Figure 12.58 is a typical plot of the signal levels at the various stages of a certain ham band receiver using analog circuitry. Each stage has the proper level and a 115 dB change in input level produces a 10 dB change in audio level. A manual gain control could produce the same effect.

### AGC PUMPING

AGC *pumping* can occur in receivers in which the AGC measurement point is located ahead of the stages that determine operating bandwidth, such as when an audio filter is added to a receiver externally and outside the reach of the AGC system. If the weak signal is the only signal within the first IF passband, the AGC will cause the receiver to be at maximum gain and optimum SNR. If an interfering signal is within the first IF passband, but outside the audio DSP filter's passband, we won't hear the interfering signal, but it will enter the AGC system and reduce the gain so we might not hear our desired weak signal. AGC pumping is audible as sudden reductions in signal strength without a strong signal in the passband of the receiver.

AGC pumping is generally not as much of a problem in SDR receivers as it is in heterodyne receivers but the phenomena still exists. The severity depends on the algorithm employed by the SDR and the operating configuration controlled by the user.

### AGC TIME CONSTANTS

There are two primary AGC time constants. AGC *attack time* describes the time it takes the AGC system to respond to the presence of a signal. AGC *decay time* describes the response of the AGC system to changes in a

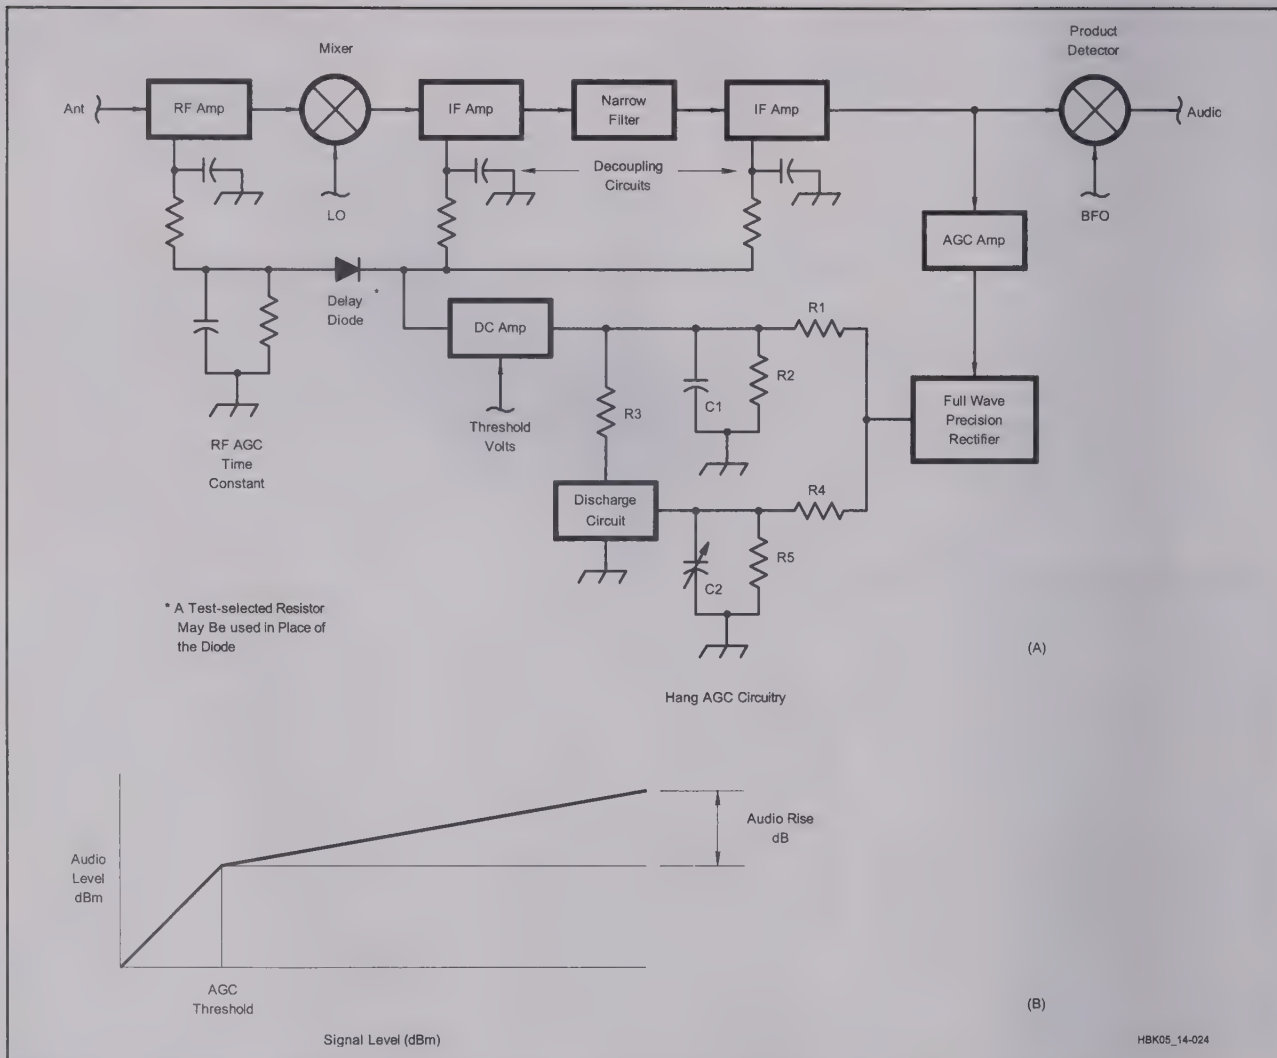

Figure 12.57 — AGC principles. At A: typical superhet receiver with AGC applied to multiple RF and IF stages. At B: audio output level as a function of antenna signal level.

signal that is present. The optimum time constants for the AGC system depends on the type of signal being received, the type of operation being conducted, and the operator's preference.

The operator usually has a control that allows for setting the time that it takes the AGC to recover or decay. If we are listening to two relatively loud stations converse, we may set the AGC to slow. Then as each station stops transmitting, the noise floor is slow to rise and we often hear the next station before the noise floor is again heard. In contrast, we may set the AGC decay time to fast which allows us to hear a weak station immediately after the strong station.

In Figure 12.57, following the precision rectifier, R1 and C1 set an attack time, to prevent excessively fast application of AGC. One or two milliseconds is a good value for

the  $R1 \times C1$  product. If the antenna signal suddenly disappears, the AGC loop is opened because the precision rectifier stops conducting. C1 then discharges through R2 and the  $C1 \times R2$  product can be in the range of 100 to 200 ms. At some point the rectifier again becomes active, and the loop is closed again.

An optional modification of this behavior is the *hang AGC* circuit. If we make  $R2 \times C1$  much longer, say 3 seconds or more, the AGC voltage remains almost constant until the R5, C2 circuit decays with a switch selectable time constant of 100 to 1000 ms. At that time R3 quickly discharges C1 and full receiver gain is quickly restored. This type of control is appreciated by many operators because of the lack of AGC pumping due to modulation, rapid fading and other sudden signal level changes.

In an SDR receiver, the typical AGC algo-

rithm has a fast-attack and slow-decay that is adjustable. The AGC algorithm has a gain value that it applies to the receiver buffers which persists from one buffer to the next. If a loud signal appears while the gain is set high, it immediately lowers the gain to prevent a loud sound in our headphones. Once the sound has subsided, the gain is allowed to slowly increase back to its previous value.

### AGC LOOP RESPONSE PROBLEMS

If the various stages have the property that each 1 V change in AGC voltage changes the gain by a constant amount (in dB), the AGC loop is said to be *log-linear* and regular feedback principles can be used to analyze and design the loop. But there are some difficulties that complicate this textbook model. One has already been mentioned, that when the

**Figure 12.58** — Gain control of a ham-band receiver using AGC. A manual gain control could produce the same result.

signal is rapidly decreasing the loop becomes open and the various capacitors discharge in an open loop manner. As the signal is increasing beyond the threshold, or if it is decreasing slowly enough, the feedback theory applies more accurately.

In SSB and CW receivers rapid changes are the rule and not the exception. It is important that the AGC loop not overshoot or ring when the signal level rises past the threshold. The idea is to design the ALC loop to be stable when the loop is closed. It obviously won't oscillate when open (during decay time). But the loop must have smooth and consistent transient response when the loop goes from open to closed state.

Another problem involves the narrow band-pass analog IF filters. The group delay of analog filters constitutes a time lag in the loop that can make loop stabilization difficult. Moreover, these filters nearly always have much greater group delay at the edges of the passband, so that loop problems are aggravated at these frequencies. Overshoots and undershoots, called *gulping*, are very common. Compensation networks that advance the phase of the feedback help to offset these group delays. The design problem arises because some of the AGC is applied before the filter and some after the filter. It is a good idea to put as much fast AGC as possible after the filter and use a slower decaying AGC ahead of the filter. The delay diode and RC in Figure 12.57A are helpful in that respect. Complex AGC designs using two or more compensated loops are also in the literature. If a second cascaded narrow filter is used in the IF it is usually a lot easier to leave the second or *downstream* filter out of the AGC loop at the risk of allowing AGC pumping as

described in the preceding section.

Another problem is that the control characteristic is often not log-linear. For example, dual-gate MOSFETs tend to have much larger dB/V at large values of gain reduction. Many IC amplifiers have the same problem. The result is that large signals cause instability because of excessive loop gain. Variable gain op amps and other similar ICs are available that are intended for gain control loops.

Audio frequency components on the AGC bus can cause problems because the amplifier gains are modulated by the audio and distort the desired signal. A hang AGC circuit (essentially a low-pass filter) can reduce or eliminate this problem.

Finally, if we try to reduce the change in audio levels to a very low value, the required loop gain becomes very large, and stability problems become very difficult. It is much better to accept a 5 to 10 dB variation of audio output.

Because many parameters are involved and many of them are not strictly log-linear, it is best to achieve good AGC performance through an initial design effort and finalize the design experimentally. Use a signal generator, attenuator and a signal pulser (2 ms rise and fall times, adjustable pulse rate and duration) at the antenna and a synchronized oscilloscope to look at the IF envelope. Tweak the time constants and AGC distribution by means of resistor and capacitor decade substitution boxes. Be sure to test throughout the passband of each filter. The final result should be a smooth and pleasant sounding SSB/CW response, even with maximum RF gain and strong signals. Patience and experience are helpful.

## 12.6.1 Audio-Derived AGC

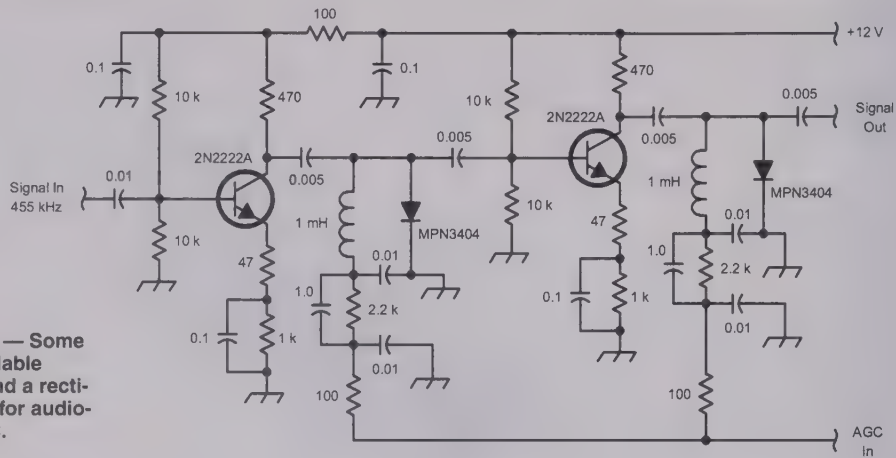

Some receivers, especially direct-conversion types, use audio-derived AGC. There are problems with this approach as well. At low audio frequencies the AGC control action can be slow to develop. That is, low-frequency audio sine waves take longer to reach their peaks than the AGC time constants. During this time the RF/IF/AF stages can be over-driven. If the RF and IF gains are kept at a low level this problem can be reduced. Also, attenuating low audio frequencies prior to the first audio amplifier should help. With audio AGC, it is important to avoid so-called “charge pump” rectifiers or other slow-responding circuits that require multiple cycles of audio to pump up the AGC voltage. Instead, use a peak-detecting circuit that responds accurately on the first positive or negative half-cycle.

## 12.6.2 AGC Circuits

**Figure 12.59** shows some gain-controllable circuits. Figure 12.59A shows a two-stage 455-kHz IF amplifier with PIN diode gain control. This circuit is a simplified adaptation from a production receiver, the Collins 651S. The IF amplifier section shown is preceded and followed by selectivity circuits and additional gain stages with AGC. The 1.0  $\mu$ F capacitors aid in loop compensation. The favorable thing about this approach is that the transistors remain biased at their optimum operating point. Right at the point at which the diodes start to conduct, a small increase in IMD may be noticed, but that goes away as diode current increases slightly. Two or more diodes can be used in series, if this is a problem (it very seldom is). Another solution is to use a PIN diode that is more suitable for such a low-frequency IF. Look for a device with  $\tau > 10 / (2\pi f)$  where  $\tau$  is the minority carrier lifetime in ms and  $f$  is the frequency in MHz.

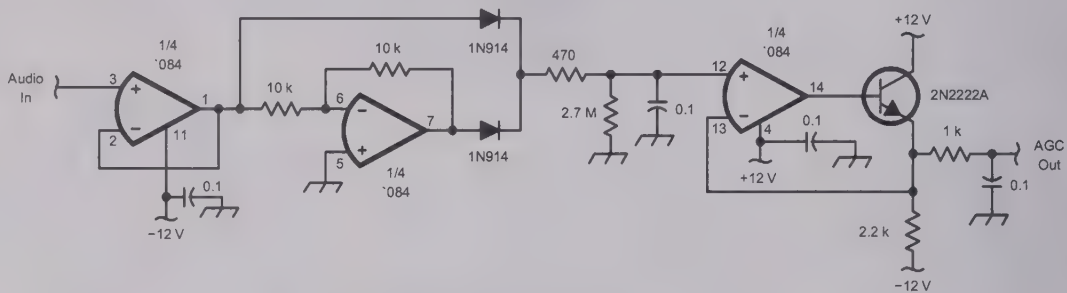

Figure 12.59B is an audio derived AGC circuit using a full-wave rectifier that responds to positive or negative excursions of the audio signal. The RC circuit follows the audio closely.

Figure 12.59C shows a typical circuit for the MC1350P RF/IF amplifier. The graph of gain control versus AGC voltage shows the change in dB/V. If the control is limited to the first 20 dB of gain reduction this chip should be favorable for good AGC transient response and good IMD performance. Use multiple low-gain stages rather than a single high-gain stage for these reasons. The gain control within the MC1350P is accomplished by diverting signal current from the first amplifier stage into a *current sink*. This is also known as the *Gilbert cell multiplier* architecture. Another chip of this type is the

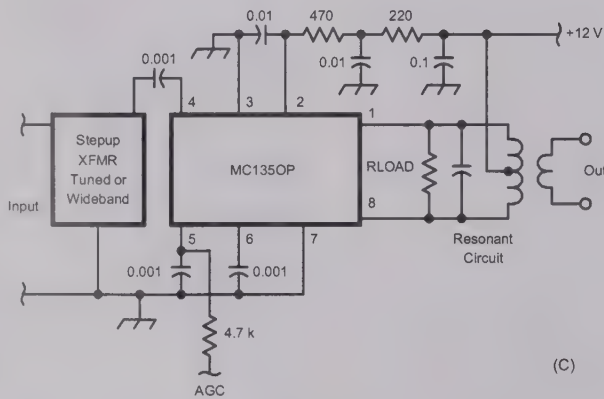

(A)

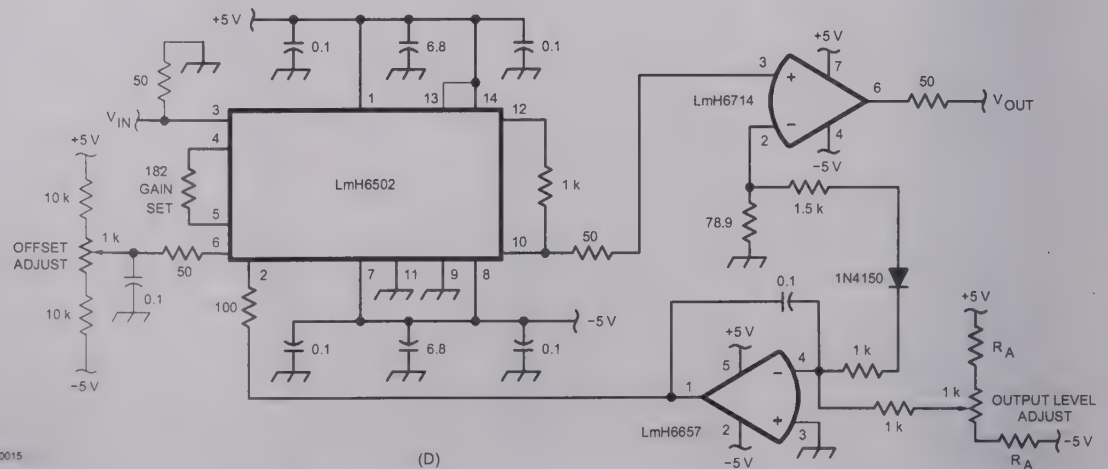

**Figure 12.59** — Some gain-controllable amplifiers and a rectifier suitable for audio-derived AGC.

(B)

(C)

(D)

HBK0015

NE/SA5209. This type of approach is simpler to implement than discrete circuit approaches, such as dual-gate MOSFETs that are now being replaced by IC designs.

Figure 12.59D shows the high performance National Semiconductor LMH6502MA (14-pin DIP plastic package)

voltage controlled amplifier. It is specially designed for accurate log-linear AGC from 0 to 40 dB with respect to a preset maximum voltage gain from 6 to 40 dB. Its  $\pm 3$  dB bandwidth is 130 MHz. It is an excellent IF amplifier for high performance receiver or transmitter projects.

Additional info on voltage-controlled amplifier ICs can be found on the Analog Devices web site ([www.analog.com](http://www.analog.com)). Search the site for Tutorial MT-073, which describes the operation of various types of gain-controlled amplifiers with numerous product examples.

## 12.7 Noise Management

A major problem for those listening to receivers has historically been local impulse noise. For HF and VHF receivers it is often from the sparks of internal combustion engine spark plugs, electric fence chargers, light dimmers, faulty power-line insulators and many other similar devices that put out short duration wide band signals. In the UHF and microwave region, radar systems can cause similar problems.

Additional sources of noise are atmospheric and man-made noise with a variety of different profiles — static crashes, power-line buzz, and the ever-increasing white noise and spurious signals from consumer and industrial electronics, particularly switch-mode devices. The capabilities of DSP can be used to combat these diverse types of noise.

Finally, noise canceling by subtracting it from the incoming signals is available as a station accessory using external antennas for sensing and beam-steering. True diversity reception is also available, pioneered for the amateur station, using the spatial characteristics of the arriving noise signals to discriminate between them and the desired signals. All of these techniques provide formidable tools for noise management that were simply unavailable to amateurs of earlier eras.

### 12.7.1 The Noise Limiter

The first device used in an early (1930s) attempt to limit impulse noise was called a *noise limiter* or *clipper* circuit as originally described by H. Robinson, W3LW. This circuit would *clip* or limit noise (or signal) peaks that exceeded a preset limit. The idea was to have the limit set to about as loud as you wanted to hear anything and nothing louder would get through. This was helpful in eliminating the loudest part of impulse noise or even nearby lightning crashes, but it had two problems. First it didn't eliminate the noise, it just reduced the peak loudness; second, it also reduced the loudness of loud non-noise signals and in the process distorted them considerably.

The second problem was fixed shortly thereafter, with the advent of the *automatic noise limiter* or ANL as described by J.

Dickert. The ANL automatically set the clipping threshold to that of a loud signal. It thus would adjust itself as the loudness of signals you listened to changed with time. An ANL was fairly easy to implement and became standard equipment on amateur receivers from the late 1930s on. While ANL circuits are no longer common, simple receivers used today do sometimes incorporate passive clipping circuits to account for their limited AGC ability.

### 12.7.2 The Noise Blanker

It turned out that improvements in receiver selectivity over the 1950s and beyond, while improving the ability to reduce random noise, actually made receiver response to impulse noise worse. The reason for this is that a very short duration pulse will actually be lengthened while going through a narrow filter. This is due to the filter's different delay times for the pulse's wide spectrum of components, resulting in the components arriving at the filter output at different times. You can demonstrate this in your superhet receiver if it has a narrow crystal filter. Find a frequency with heavy impulse noise and switch between wide and narrow filters. If your narrow filter is 500 Hz or less, the noise pulses will likely be more prominent with the narrow filter. DSP filters with their superior group delay performance exhibit less smearing than their analog counterparts.

The noise limiters described previously were all connected at the output of the IF amplifiers and thus the noise had passed most of the selectivity before the limiter and had been widened by the receiver filters. In SSB receivers, since signals vary in strength as someone talks, the usual AGC responds quickly to reduce the gain of a strong signal and then slowly increases it if the signal is no longer there. This means that a strong noise pulse may reduce the receiver gain for much longer than it lasts.

The solution — a *noise blanker*. An analog noise blanker is almost a separate wideband receiver. It takes its input from an early stage in the heterodyne receiver before much selectivity or AGC has been applied. It amplifies

the wideband signal and detects the narrow noise pulses without lengthening them. The still-narrow noise pulses are used to shut off or “blank” the receiver at a point ahead of the selectivity and AGC, thus keeping the noise from getting to the parts of the receiver at which the pulses would be extended. In other words, the receiver is shut off or *gated* during the noise pulse.

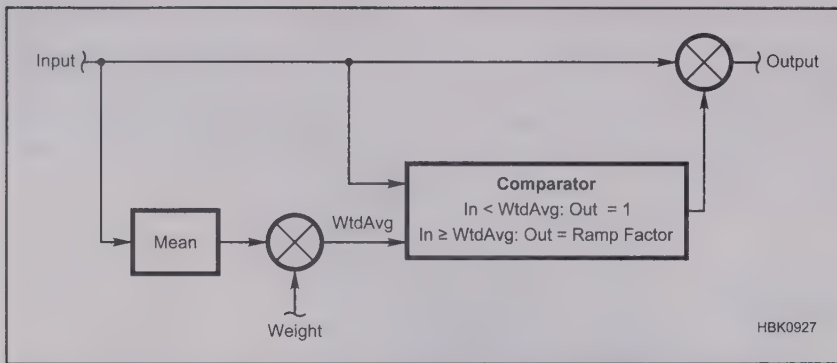

In addition to an ON/OFF switch, noise blankers include a control labeled THRESHOLD. The THRESHOLD control adjusts the level of noise that will blank the receiver. If it is set for too low a level, it will blank on signal peaks as well as noise, resulting in distortion of the signal.

An SDR noise blanker can implement the same detect-and-gate technique as an analog receiver. Once the noise impulse is detected, the samples making up the impulse are replaced by an interpolation between the “normal” samples just before and just after the impulse. It is as if the noise impulse was never received.

An alternative technique that also handles longer noise crashes and other large-amplitude, long-duration noise waveforms is described in Figure 12.60. The basic idea is to create a filtered average amplitude and watch for incoming signals that exceed the average multiplied by a weighting factor which is how the SDR noise blanker threshold is controlled. When the incoming signal is below this value, it is simply passed along to the rest of the receiver. Above this level, the blanker generates a ramp factor that limits the rate at which the signal can increase. This turns short, sharp impulses into relatively slowly increasing and decreasing ramps, leaving normal signals unaffected.

A well-designed noise blanker can be very effective. Instead of just keeping the noise at the level of the signal as a noise limiter does, the noise blanker can actually *eliminate* the noise. If the pulses are narrow enough, the loss of desired signal during the time the receiver is disabled is not noticeable and the noise may seem to disappear entirely.

Noise blankers can also create problems, particularly in heterodyne receivers. The wide-band circuit that detects noise pulses

**Figure 12.60** — Block diagram of a noise blanker. The input signal is compared to a weighted average. If exceeded, the input signal rise and fall times are limited by a ramp factor. [After *Communications Receivers, 4th ed*]

also detects any signals in that bandwidth. If such a signal is strong and has sharp peaks (as voice and CW signals do), the noise blanker will treat them as noise pulses and shut down the receiver accordingly. This causes tremendous distortion and can make it sound as if the strong signal to which the noise blanker is responding is generating spurious signals that cause the distortion. (This is less of a problem in SDR receivers.) Before you assume that the strong signal is causing problems, turn the noise blanker on and off to check. When the band is full of strong signals, a noise blanker may cause more problems than it solves.

### 12.7.3 Operating Noise Limiters and Blankers

Many current receivers include both a noise limiter (often labeled NL) and a noise blanker (labeled NB). If your receiver has both, they will have separate controls and it is worthwhile to try them both. There are

times at which one will work better than the other, and other times when it goes the other way, depending on the characteristics of the noise. There are other times when both work better than either. In any case, they can make listening a lot more pleasant — just remember to turn them off when you don't need them since either type can cause some distortion, especially on strong signals that should otherwise be easy to listen to.

Recognizing that it is difficult for a single noise blanker to work properly with the wide variations of noise pulses, it is common for current receivers to have two noise blankers with different characteristics that are optimized for the different pulse types. One noise blanker is typically optimized for very short pulses and the other for longer pulses. The operator can switch between the blankers to see which works best on the noise at hand.

The usual approach to operating the noise blanker is to activate it, then adjust the THRESHOLD control until the noise is just blanked. You will probably need to make

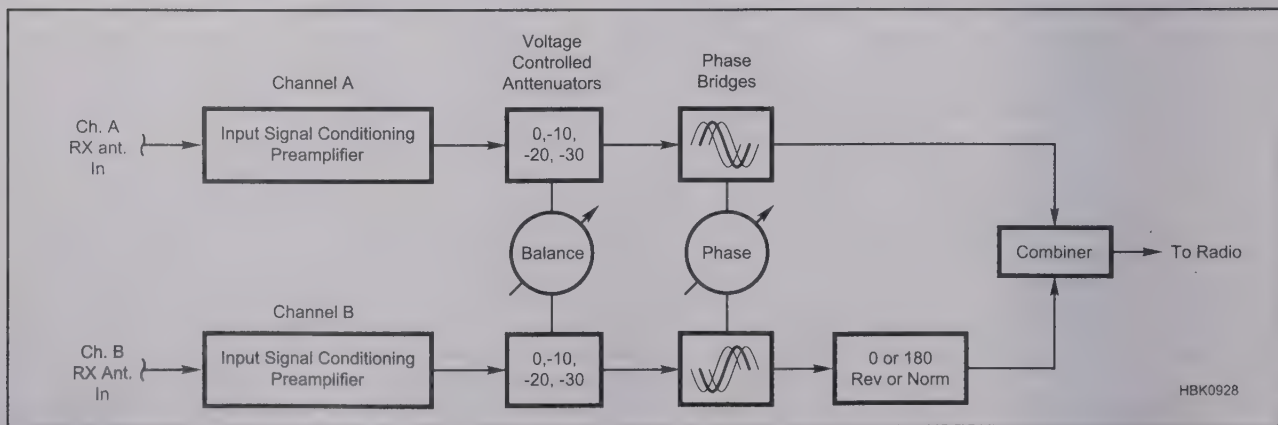

occasional adjustments as the noise impulse characteristics change. Don't forget to turn the noise blanker off when the noise goes away.

The previous techniques represent the most commonly available techniques to reduce impulse noise. There are a few other solutions as well. Note that we haven't been talking about reducing interference here. By interference, we mean another intended signal encroaching on the channel to which we want to listen. There are a number of techniques to reduce interference, and some also can help with impulse noise.

Many times impulse noise is coming from a particular direction. If so, by using a directional antenna, we can adjust the direction for minimum noise. When we think about directional antennas, the giant HF Yagi springs to mind. For receiving purposes, especially on the lower bands such as 160, 80 and 40 meters (where the impulse noise often seems the worst), a small indoor or outdoor receiving loop antenna as described in the *ARRL Antenna Book* can be very effective at eliminating either interfering stations or noise (both if they happen to be in the same direction).

### 12.7.4 Noise Canceling

Noise cancellers work by combining signals from our main antenna with the signal from a "sense" antenna and feeding that combination to the receiver. Adjustable gain stages and phasing networks within the unit must then be carefully adjusted so that the two noise signals are equal in level and 180 degrees out of phase. This adjustment is frequency sensitive, so it must be readjusted each time we change frequency. It must also be readjusted for every noise source. Signals coming from the same direction as the noise source will also be canceled, but this effect

**Figure 12.61** — Block diagram of a noise canceling system following the DX Engineering NCC-2. [Courtesy DX Engineering, used by permission]

is minimized by placing the sense antenna as close as practical to the noise source. An active noise canceller can greatly reduce a single noise source, but it won't help with more than one source at a time. **Figure 12.61** shows the block diagram of a typical noise canceller and antennas, in this case the DX Engineering NCC-2.

Be careful when using any unit in line with the transceiver output; the carrier detect-driven relay that switches from receive to transmit (that is, bypassing the unit in transmit mode) is known to generate key clicks (transients) in some products. The MFJ 1026 and the DX Engineering NCC-1 and NCC-2 are generally good performers in this regard.

Some transceivers provide connectors where an external preamp or receive antenna can be connected. The click problem can be avoided by connecting the noise canceller at this point. Some SDRs have multiple antenna inputs and the ability to feed them to separate software-defined "receivers", and some software has been written to allow those separate receivers to provide the phasing networks needed to provide noise canceling. In some software, this function is improperly labeled "Diversity Receive." (See the Diversity Reception description below.)

### BEAM STEERING

Noise cancellers can also be used to vary the phase of the signals from two receive antennas to vary their directivity. Two vertical antennas, connected to a receiver single receiver by individual feed lines, form a directional antenna. The directional pattern depends on the phase shift provided by the two feed lines (as well as the physical spacing and spatial orientation of the antennas), and it can be adjusted by varying the length of one or both of the feed lines. Used with two omnidirectional verticals, for example, a noise canceller can be used to vary the phase relationship between the two antennas, accomplishing the same result.

### SIGNAL FADING

Most periodic (repetitive) fading is the result of the cancellation of signals from the same source taking slightly different paths, so that one is delayed with respect to the other. The direct and reflected signals cancel when they are nearly equal and nearly 180 degrees out of phase with each other. The frequency(ies) at which this 180-degree phase relationship exists is a function of the time difference; the

fading interval is longer for lower frequencies. This fading mechanism is heard as very slow fading on the AM broadcast band and 160 meters, and as "picket fencing" at VHF and UHF.

### 12.7.5 Diversity Reception

*Diversity reception* has been used since the earliest days of radio to reduce the effects of signal fading. A receiving diversity system consists of two receivers, each connected to its own antenna and to its own loudspeaker (or opposite ears of stereo headphones). When the two antennas are widely separated as a fraction of a wavelength, the probability of cancellation occurring at both antennas at the same time is low, and the operator copies from the receiver providing the best signal.

Diversity reception is also widely used to listen using different receive antennas having different directivity in the horizontal or vertical plane, or aimed in different directions. This use is quite common on the lower HF bands and 160 meters. An operator may listen to the transmit antenna in one ear and a Beverage in the other, or to a loop and a Beverage.

Diversity reception is widely used in consumer FM receivers in vehicles, and in the wireless microphone systems used in live sound and broadcasting. In both of these applications, a circuit called a "voter" chooses the signal from the receiver having the best quality and switches it to the output. Many VHF and UHF repeater systems have receivers at multiple sites that are relayed back to the main transmit site, where a voter chooses between the best signal. Diversity is also used with receive antennas having different wave polarization; cross-polarization between a receive antenna and the wavefront typically results in a 20 dB loss of gain.

### 12.7.6 DSP Noise Reduction

DSP noise reduction (often labeled NR on the receiver controls) can actually look at the statistics of the signal and noise and figure out which is which and then reduce the noise significantly. These *adaptive filters* can't quite eliminate the noise, and need enough of the desired signal to figure out what's happening, so they won't work if the signal is far below the noise. (See the **DSP and SDR Fundamentals** and **Analog and Digital Filtering** chapters for information on adap-

tive filters.) Many DSP systems "color" the resulting audio to a degree. Nonetheless, they do improve the SNR of a signal in random or impulse noise.

Noise reduction is designed to reduce non-correlated noise such as atmospheric noise and thermal noise. Most noise reduction blocks rely on the knowledge that noise is much more random in nature than the signals we are attempting to demodulate. A typical NR will use a Least Mean Squares (LMS) or similar algorithm to detect correlated signals and reduce the amplitude of anything else in the passband.

How does this work? The algorithm looks for signals that are highly correlated, meaning that a copy of the signal shifted in time resembles the same signal at a different time. These are the signals that are preserved while the other signals in the passband are judged to be noise and are deemphasized or reduced in volume. Because there are a number of methods for achieving noise reduction in different classes of noise, some vendors often more than one type of noise reduction. Each manufacturer's algorithms for noise reduction are generally proprietary although the *GNU Radio* community's (see the **Transceiver Design Topics** chapter) open-source design approach offers some guidance in how noise reduction is achieved.

As with noise blankers, receivers frequently offer two or more noise reduction settings that apply different noise reduction algorithms optimized for different conditions. Different combinations and types of noise require the operator to select and adjust the noise reduction system for best performance.

### 12.7.7 DSP Notch Filtering

An Automatic Notch Filter (ANF) is really the opposite of a NR filter. The auto-notch filter looks for the same correlated signals, but instead of preserving these signals, the algorithm attempts to remove these signals. The classic example for which an ANF is useful is when there is a birdie (spur) or undesired CW signal in the passband of a sideband signal. Because the CW signal or spur are much more correlated than the speech we are listening to, these signals are judged to be undesired and the filter deemphasizes them. In this way, the NR and ANF filters are cousins, doing the opposite of each other in support of their specific noise reduction goals.

- “VHF and UHF CW Beacons” by Michael Sapp, WA3TTS
- “A 2-Meter Transmitter for Fox Hunting” by Mark Spencer, WA8SME
- “Simple Frequency Doublers with High Performance” by Paul Wade, W1GHZ
- “A Microwave Controller” by Hamish Kellock, OH2GAQ

The following related items are included with the **Receiving** chapter supplements.

- “Amateur Radio Equipment Development — An Historical Perspective” by Joel Hallas, W1ZR
- Selected SDR: Simplified columns in *QEX* by Ray Mack, W5IFS W5IFS

# Transmitting

Transmitters — the companion to the receivers discussed in the previous chapter. As with receiver design, the analog heterodyne architecture that has dominated for so many years is being challenged and displaced by SDR techniques. Nevertheless, many of the same functions are required, regardless of whether they are implemented in analog electronics or digitally by software. As such, each function is discussed from both the traditional analog perspective and from the SDR perspective where material is available. Subsequent editions will continue to evolve as practices change and standardize on new approaches.

Included in this edition are helpful discussions on microphone selection and audio optimization by Jim Brown, K9YC, and a set of analog audio signal processing circuits by Jim Tonne, W4ENE. Sections on SDR implementations of basic functions are taken from SDR: Simplified columns in *QEX* by Ray Mack, W5IFS and from material contributed by Steve Hicks, N5AC. Material for the section on PIN Diode RF Switching was contributed by Hans Summers, GØUPL.

The RF power stages of a transmitter are still firmly in the analog camp although design has greatly simplified through integrated circuits and amplifier modules. Circuits for power levels above 100 W (at HF) are covered in the **RF Power Amplifiers** chapter. The **DSP and SDR Fundamentals** chapter has more information on digital techniques and architectures.

Projects included with previous editions have been collected into a set of projects in the online supplemental information accompanying this book.

Transmitter technology has advanced in a parallel process similar to that of the technology of receivers. While transmitters are composed of many of the same named blocks as those used in receivers, it's important to keep in mind that there are significant differences. An RF amplifier in a receiver may deal with amplifying picowatts while one in a transmitter may output up to kilowatts. While the circuits may even look similar, the size of the components, especially cooling systems and power supplies, may differ significantly in scale. Still, many of the same principles apply.

Transmitters also make use of many of the same functional blocks as receivers, such as filters and mixers. You will find additional material on these functions covered in the **Receiving** chapter. Oscillators are covered in the **Oscillators and Synthesizers** chapter. Elements of these functions that are pertinent to transmitter design are covered in this chapter but not duplicated.

Transmitters (and transceivers) using vacuum tubes and solid-state matching circuits are likely to present hazardous voltages. At higher power levels RF exposure issues must be considered — review the **Safety** chapter for more information. Techniques for transmitter measurement are covered in the **Test Equipment and Measurements** chapter.

## 13.1 Characterizing Transmitters

### 13.1.1 FCC Rules

A survey of the FCC rules in Part 97 shows that most of them are about transmitted signals! Thus, amateurs should have a clear idea of what required their transmitters are expected to satisfy.

There are two important definitions that FCC Part 97 applies to amateur signals (also known as *emissions*):

97.3(a)(8) *Bandwidth*. The width of a frequency band outside of which the mean power of the transmitted signal is attenuated at least 26 dB below the mean power of the transmitted signal within the band. (See Figure 3.16 later in this chapter.)

97.3(a)(43) *Spurious emission*. An emission, or frequencies outside the necessary bandwidth of a transmission, the level of which may be reduced without affecting the information being transmitted.

There are also some important definitions in Part 2.1031 – 2.1060 that apply to all wireless services:

2.202 *Bandwidths*.

(a) *Occupied bandwidth*. The frequency bandwidth such that, below its lower and above its upper frequency limits, the mean powers radiated are each equal to 0.5 percent of the total mean power radiated by a given emission.

(b) *Necessary bandwidth*. For a given class of emission, the minimum value of the occupied bandwidth sufficient to ensure the transmission of information at the rate and with the quality required for the system employed, under specified conditions. Emissions useful for the good functioning of the receiving equipment as, for example, the emission corresponding to the carrier of reduced carrier systems, shall be included in the necessary bandwidth.

The measurement of bandwidth (and other characteristics) is covered by Part 2.1031-2.1060.

Part 97, Subpart D, sets forth a number of technical standards for signals. Part 97.307 — Emission Standards covers all of the signal characteristics from signal quality through symbol rates. Part 97.313 covers transmitter power limits by band. Parts 97.315 and 97.317 set the standards for certification of external RF power amplifiers.

The FCC rules are easily accessible online via the ARRL website at [www.arrl.org/part-97-amateur-radio](http://www.arrl.org/part-97-amateur-radio) and so are not reproduced here.

### 13.1.2 Performance Measurements

The ARRL Lab has created a series of standardized tests for product review and compliance testing. The entire test program for receivers and transmitters is described in the book *Amateur Radio Transceiver Performance Testing* by Bob Allison, WB1GCM, ARRL Lab Staff Engineer. Important sections are summarized here. The book also addresses a number of other significant parameters that affect various elements of on-the-air performance. The chapter **Test Measurements and Equipment** also discusses transceiver performance.

#### EMISSION STANDARDS

A spurious signal is any signal (unwanted) other than the intended (fundamental) transmitted signal. Any oscillator will create unwanted products, such as spurs (spurious emissions) and harmonics (multiples of the fundamental frequency). Some consider harmonics to be spurious emissions but they are addressed separately in this book.

Spurs are usually found near or around the fundamental frequency. They can be reduced

with appropriate circuit design and, to some extent, with filtering. Harmonics are suppressed to an acceptable level with the use of band-pass filters. An “acceptable level” is one that will not create interference on two times the fundamental frequency (second harmonic), three times the fundamental frequency (third harmonic), and so on.

The single most important standard any transceiver operating in the amateur bands must meet is the FCC Part 97 rules for emissions. According to Part 97.307(d) and 97.307(e), an HF transceiver’s emissions must have at least 43 dB of spurious emission and harmonic suppression below 30 MHz. For 30 MHz through 225 MHz, the spurious and harmonic suppression must be 60 dB. (Emission designators are discussed in the **Modulation** chapter.)

#### CARRIER AND SIDEBAND SUPPRESSION

While there are no FCC specifications for suppression of the carrier and unwanted sideband for SSB signals, the ARRL Lab has established 60 dB of suppression as good practice. 50 dB of suppression is considered a minimum acceptable level.

#### INTERMODULATION DISTORTION (IMD)

Spurious emissions caused by IMD are definitely of concern, even though they might satisfy the rules on signal bandwidth. For today’s transceivers, a third-order product measurement of 30 dB below PEP is typical, 35 dB is considered good, and 25 dB below PEP is mediocre. A clean signal with the lower possible IMD products should be a key consideration for purchasing or operating a transceiver. It is also important to remember

that even the best transmitter can be misadjusted to put out an excessively wide signal that creates a lot of interference.

**Figures 13.1** and **13.2** show a typical example of a signal with good IMD performance (Figure 13.1) and an unacceptably wide signal (Figure 13.2). The signal in Figure 13.1 has acceptable 3rd-order IMD products and the higher-order products diminish rapidly farther from the main signal. The signal in Figure 13.2, however, has mediocre performance for the 3rd-order products and the higher-order products are far too high out to  $\pm 6$  kHz from the carrier frequency. This signal would interfere with at least two SSB contacts to each side of it.

#### CW KEYING

The shape of a transmitter’s keying waveform impacts the quality and effectiveness of its transmissions. By observing the keying waveform, it is possible to assess whether it has characteristics that will affect the quality of the transmitted signal and its impact on adjacent signals.

There are two primary signatures of problems that can be detected by observing the shape of the keyed waveform. The first is *overshoot* in which the transmitter sends a short high-power transient at the beginning of a transmission (see **Figure 13.3**). This is caused by the power control subsystem not reacting properly to the rapid change in output power. The transient can cause an amplifier’s power protection circuitry to activate or trip. It can also cause a key click on adjacent channels. The system at fault can be the ALC system, a software problem, or some other internal power control mechanism.

The second signature is too-rapid rise and fall times or abrupt edges and corners of the

Figure 13.1 — Two-tone IMD test results for a good transmitted signal. The 3rd-order products are close to 40 dB below peak power.

Figure 13.2 — Third-order IMD products are acceptable at 32 dB below PEP but the higher-order products are unacceptably high.

Figure 13.3 — A transient at the leading edge of a keying waveform.

Figure 13.4 — Abrupt, nearly vertical rising and falling edges of "hard" keying.

Figure 13.5 — A transmitter with a relatively low composite noise profile. This transmitter is unlikely to cause significant interference on adjacent channels or other bands.

followed by "off" or stand-by periods of the same or greater duration. The term "Amateur Service" covers other applications where operation is of an infrequent or highly intermittent nature, as well as the use of tubes in "amateur" transmitters. ICAS ratings generally are considerably higher than CCS ratings.

Although the ability of a tube to produce greater output power is usually accompanied by a reduction in tube life, the equipment designer may decide that a small tube operated at its ICAS ratings meets the requirements better than a larger tube operated within CCS ratings.

*Intermittent Mobile Service (IMS)* covers applications in which very high power output for short periods is required from equipment of the smallest practical size and weight. Tube ratings for IMS service are based on the premise that transmitter "on" periods do not exceed 15 seconds each, and are followed by "off" periods of at least 60 seconds duration. In equipment tests, however, maximum "on" periods of not more than 5 minutes each followed by "off" periods of at least 5 minutes are permissible, provided the total "on" time of such test periods does not exceed 10 hours during the life of the tube. Although tubes operated under IMS ratings may have a life of only about 100 hours, the use of these ratings is economically justified where high power must be obtained intermittently from very small tubes.

If equipment is specified as meeting Continuous Commercial Service requirements, that is exactly how the equipment or device is certified to perform. Very few amateur transmitters or amplifiers, however, are operated that way and if they had to meet the CCS level of service, would be quite expensive.

### 13.1.3 CCS, ICAS, and IMS Ratings

Amateur equipment is usually advertised as being rated at some level of ICAS service. There are several related types of operating service. From the RCA Transmitting Tubes manual (TT-4, 1956), the following definitions are obtained:

*Continuous Commercial Service (CCS)* covers applications involving continuous tube operation in which maximum dependability and long tube life are the primary considerations.

*Intermittent Commercial and Amateur Service (ICAS)* covers applications in which high tube output is a more important consideration than long tube life. The term "Intermittent Commercial" in this title applies to types of service in which the operating or "on" periods do not exceed 5 minutes each, and are

envelope as shown in Figure 13.4. There may also be discontinuities or artifacts present during the rising and falling edges of the waveform. These create distortion products that extend well beyond the CW signal's necessary bandwidth as key clicks that cause interference to adjacent channels.

### COMPOSITE (PHASE) NOISE

Composite noise is composed of both amplitude and phase noise on the transmitted signal. We are concerned with noise present from 100 Hz to 1 MHz from the carrier frequency of the signal. (See Figure 13.5) Composite noise can raise the noise floor of adjacent channels and in severe cases, across an entire band or on multiple bands. (See the discussions on phase noise in this chapter and in the **Transceiver Design Topics** chapter.)

ICAS, on the other hand, is just a name for the type of service the equipment is expected to provide. The description is intended to apply to use in which the equipment is operated with a 50% duty cycle having equal “on” and “off” periods of 5 minutes or less. Terms like “ICAS 50%” have no standard meaning. That could refer to the original ICAS definition or it could mean a period of 50% duty

cycle operation followed by an equal period of no operation at all. The safest choice is to ask the manufacturer directly for their interpretation of ICAS or any similar rating and not assume anything.

Regardless of which rating is used, the intent is to describe the conditions under which the equipment (or devices) may be operated and still be expected to meet the

performance specifications. Typically, devices are *de-rated* from their maximum ratings in order to meet the performance specifications but there are many other considerations to take into account when the equipment is designed. For example, equipment designed to operate at a high ambient temperature would have to be de-rated more than equipment operated at a lower temperature.

## 13.2 Transmitter Architecture

In the following section, “in-band” refers to signal frequencies within the bandwidth of the desired signal. For example, for an upper sideband voice signal with a carrier frequency of 14.200 MHz, frequencies of approximately 14.2003 to 14.203 would be considered in-band. Out-of-band refers to frequencies outside this range, such as on adjacent channels.

### 13.2.1 Upconverting Heterodyne Architecture

Figure 13.6 shows a traditional superhet-

erodyne architecture for transceivers in which the sideband filter, some amplifiers, and other filters are shared between transmit and receive modes through the use of extensive switching. A limitation of that architecture is that it is difficult to provide operation on frequencies near the first IF. The typical transceiver designer selected a first IF frequency away from the desired operating frequencies and proceeded on that basis.

New amateur bands at 30, 17, and 12 meters were approved at the 1979 ITU World Administrative Radio Conference. The dif-

ficulties of managing image rejection on the new bands and the desire for continuous receiver coverage of LF, MF and HF bands (general-coverage receive) required a significant change in the architecture of receivers and transceivers. Thus, the upconverting architecture discussed in the **Receiving** chapter became popular in the 1980s and, with a few notable exceptions, became almost universal in commercial products over the following decade.

The solution was to move to the upconverting architecture shown in **Figure 13.7**. By

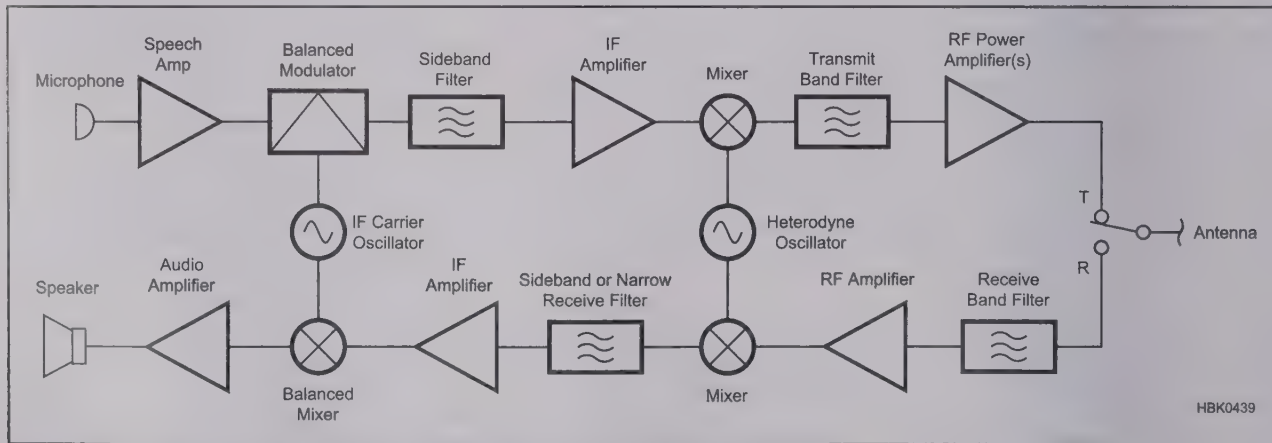

Figure 13.6 — Block diagram of a simple SSB transceiver sharing oscillator frequencies.

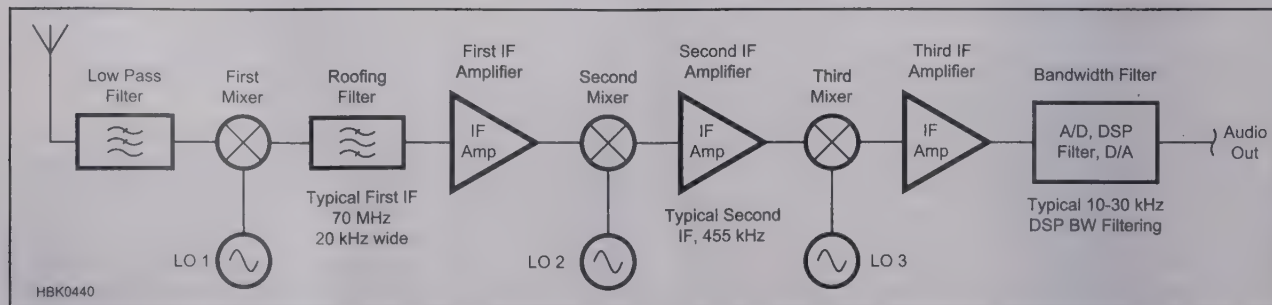

Figure 13.7 — Simplified block diagram of upconverting general coverage transceiver, receiver section shown.

selecting a first IF well above the highest receive frequency, the first local oscillator can cover the entire receive range without any gaps. With the 70 MHz IF shown, the full range from 0 to 30 MHz can be covered by an LO covering 70 to 100 MHz, less than a 1.5:1 range, making it easy to implement with modern PLL or DDS technology. Note that the high IF makes image rejection very easy and, rather than the usual tuned band-pass front end, we can use more universal low-pass filtering. The low-pass filter is generally shared with the transmit side and designed with octave cutoff frequencies to reduce transmitter harmonic content. A typical set of HF transceiver low-pass filter cut-off frequencies would be 1, 2, 4, 8, 16 and 32 MHz.

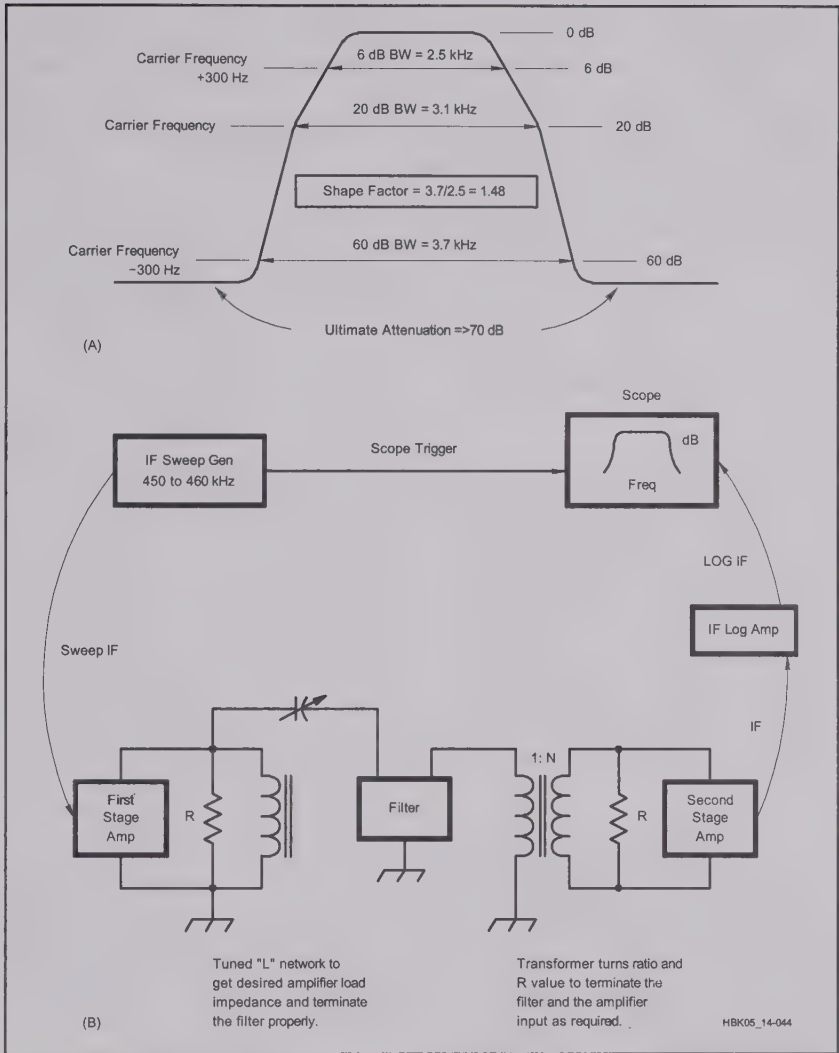

This architecture offers significant benefits. By merely changing the control system programming, any frequency range or ranges can be provided with no change to the architecture or hardware implementation. Unlike the more traditional transceiver architecture (Figure 13.6), continuous receive frequency coverage over the range is actually easier to provide than to not provide, offering a marketing advantage for those who also like to do shortwave or broadcast listening.

**IF FILTERS**

The desired IF filter response is shown in Figure 13.8A. The reduction of the carrier frequency is augmented by the filter response. It is common to specify that the filter response be down 20 dB at the carrier frequency. Rejection of the opposite sideband should (hopefully) be 60 dB, starting at 300 Hz below the carrier frequency, which is the 300-Hz point on the opposite sideband. The ultimate attenuation should be at least 70 dB. This would represent a very good specification for a high quality transmitter. The filter passband should be as flat as possible (with passband ripple less than 1 dB or so).

Special filters, designated as USB or LSB, are designed with a steeper roll-off on the carrier frequency side, in order to improve rejection of the carrier and opposite sideband. Mechanical filters are available that do this. Crystal-ladder filters (see the **Analog and Digital Filtering** chapter) are frequently called “single-sideband” filters because they also have this property. The steep skirt can be on the low side or the high side, depending on whether the crystals are across the signal path or in series with the signal path, respectively.

Filters require special attention to their terminations. The networks that interface the filter with surrounding circuits should be accurate and stable over temperature. They should be easy to adjust. One very good way to adjust them is to build a narrow-band sweep

**Figure 13.8 — At (A), desired response of a SSB IF filter. At (B), one method of terminating a mechanical filter that allows easy and accurate tuning adjustment and also a possible test setup for performing the adjustments.**

generator and look at the output IF envelope with a logarithmic amplifier, as indicated in Figure 13.8B. There are three goals:

- The driver stage must see the desired load impedance.
- The stage after the filter must see the desired source (generator) impedance.
- The filter must be properly terminated at both ends.

Lack of any of these conditions will result in loss of specified filter response. Figure 13.8B shows two typical approaches. This kind of setup is a very good way to make sure the filters and other circuitry are working properly.

Finally, overdriven filters (such as crystal or mechanical filters) can become nonlinear and generate distortion. Thus it is necessary

to stay within the manufacturer’s specifications. Magnetic core materials used in the tuning networks must be sufficiently linear at the signal levels encountered. They should be tested for IMD separately.

**IF Linearity and Noise**

Figure 13.9 indicates that after the last SSB filter, whether it is just after the SSB modulator or after the IF clipper, subsequent BPFs are considerably wider. For example, the 70 MHz crystal filter may be 15 to 30 kHz wide. This means that there is a “gray region” in the transmitter in which out-of-band IMD that is generated in the IF amplifiers and mixers can cause adjacent-channel interference.

A possible exception, not shown in Figure 13.9, is that there may be an intermediate IF

in the 10 MHz region that also contains a narrow filter.

The implication is that special attention must be paid to the linearity of these circuits. It's the designer's job to make sure that distortion in this gray area is much less than distortion generated by the PA and also less than the phase noise generated by the final mixer. Recall also that the total IMD generated in the exciter stages is the result of several amplifier and mixer stages in cascade; therefore, each element in the chain must have at least 40 to 50 dB IMD quality. The various drive levels should be chosen to guarantee this. This requirement for multistage linearity is one of the main technical and cost burdens of the SSB mode.

Of interest also in the gray region are additive white, thermal and excess noises originating in the first IF amplifier after the SSB filter and highly magnified on their way to the output. This noise can be comparable to the phase noise level if the phase noise is low, as it is in a high-quality radio. Recall also that phase noise is at its worst on modulation peaks, but additive noise may be (and often is) present even when there is no modulation. This is a frequent problem in co-located transmitting and receiving environments. Many

transmitter designs do not have the benefit of the narrow filter at 70 MHz, so the amplified noise can extend over a much wider frequency range.

### TRANSMIT MIXER LINEARITY AND NOISE

The last IF and the last mixer LO in Figure 13.9 are selected so that, as much as possible, harmonic IMD products are far enough away from the operating frequency that they fall outside the passband of the low-pass filters and are highly attenuated. This is difficult to accomplish over the transmitter's entire frequency range. It helps to use a high-level mixer and a low enough signal level to minimize those products that are unavoidable. Low-order crossovers that cannot be sufficiently reduced are unacceptable, however; the designer must go back to the drawing board.

### 13.2.2 SDR Transmitter Architecture

SDR transmitter architecture looks a lot like the SDR receiver architecture as described in the **DSP and SDR Fundamentals** and **Receiving** chapters "turned around." For

example, the FFT can be reused as its own inverse to translate back and forth between the time and frequency domains. I/Q modulation looks very much like I/Q demodulation. Substitute a DAC for the ADC to change digital to analog and vice versa. Digital filters just need a data stream and enough clock speed to handle the throughput.

The main question is one of providing enough computing resources and deciding where to make the jump from analog to digital. As the speed and resolution of data converters increases while the cost plummets, the transition between the analog and digital realms is moving ever closer to the antenna. Commercial mainstream transceiver designs being introduced in 2017 are no longer based on the traditional analog superheterodyne architecture. It is only a matter of time before the superheterodyne becomes a legacy technology.

Superheterodyne techniques are still used at points in the signal path, however. **Figure 13.10** shows the progression of transmitter architectures from all-superheterodyne through direct-sampled. If you think they look like the SDR receiver architectures of Figures 8.3 through 8.6 in the **DSP and SDR Fundamentals** chapter, you're right. They

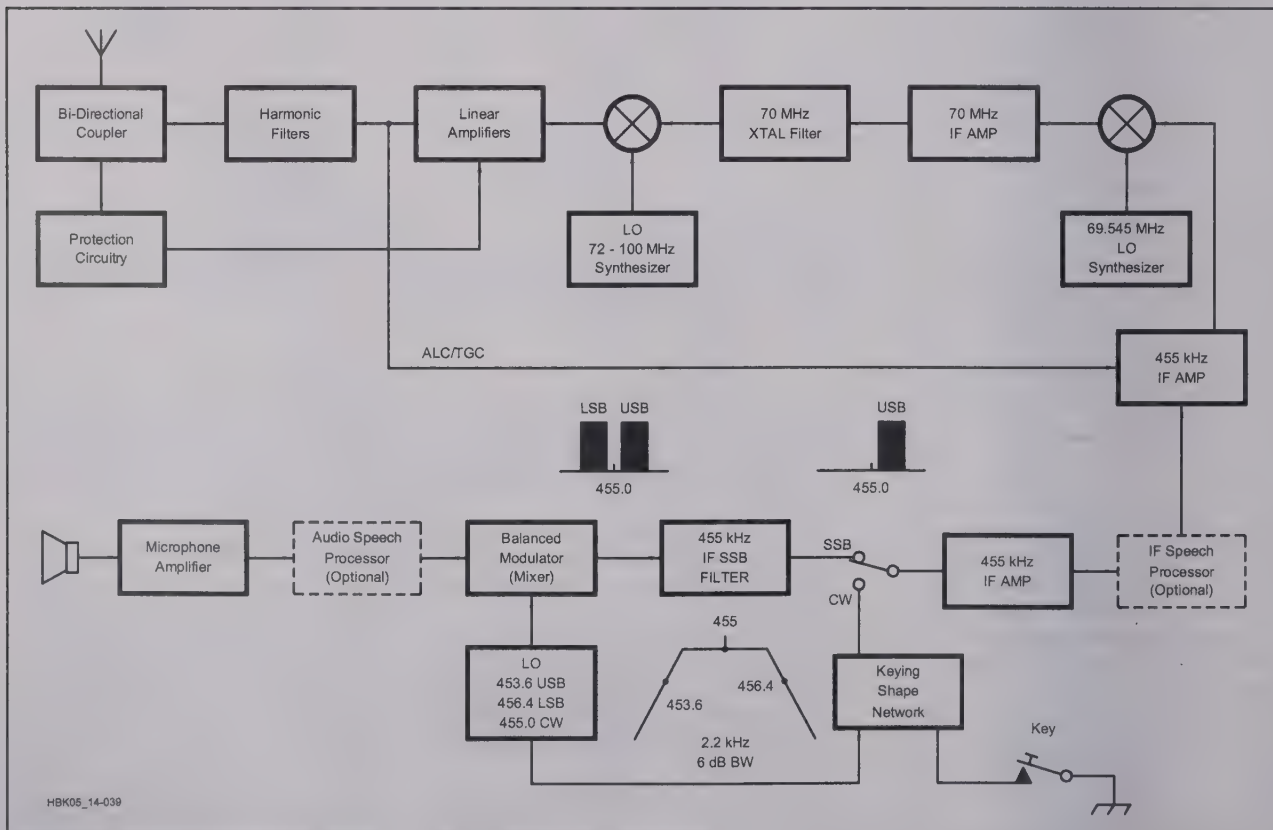

Figure 13.9 — Block diagram of an upconversion SSB/CW transmitter.

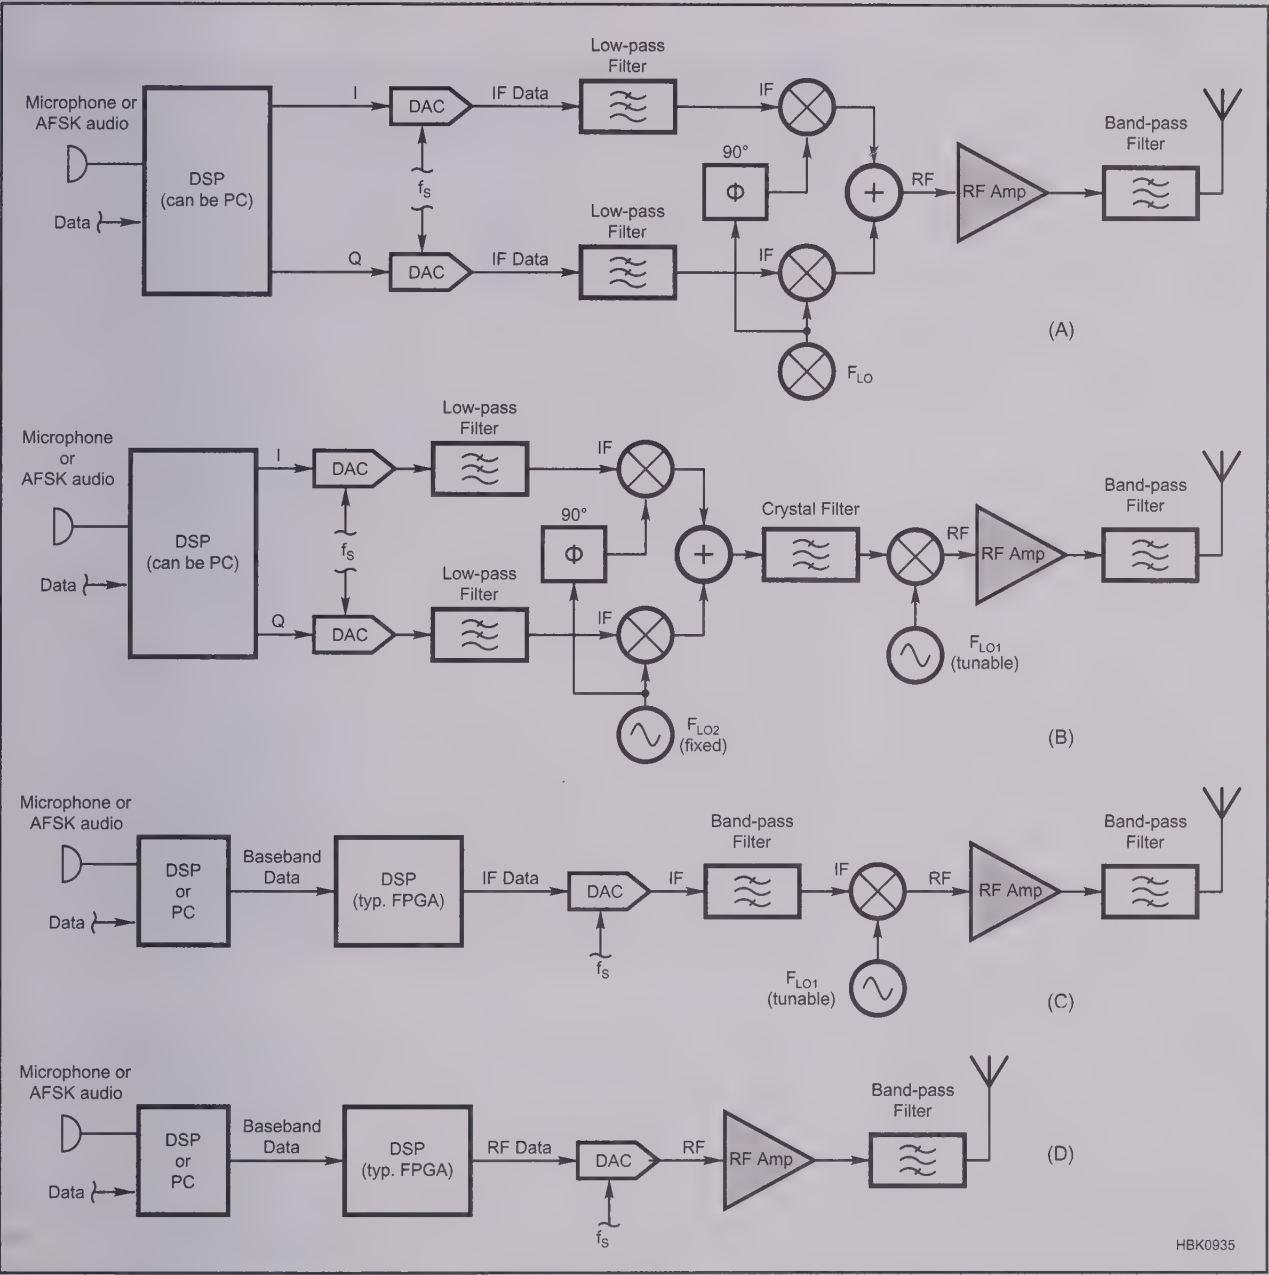

Figure 13.10 — Several SDR transmitter architectures. Direct-from-baseband (A), Hybrid superhet/SDR combination (B), Hybrid DSP-at-IF (C), Direct-sampled (D).

are essentially the same processes used for receiving but converting signals to RF instead of vice versa. (See the **Receiving** chapter for a discussion of the architecture pros and cons.) All of these architectures are in use by amateurs in homebuilt and commercial equipment today.

In any specific transceiver, the receiver and architectures are complementary in that they make use of the same DSP components and

convert between analog and digital at roughly the same point in the signal path. The architecture is largely driven by the cost and availability of the data converters and the FPGA or similar DSP computing devices. (Some transceivers are based on generic FPGA parts while others make use of specialized DSP or graphics processors.) Tradeoffs involved with the various architectures are discussed in the **Transceiver Design Topics** chapter.

SDR technology is evolving rapidly so it is premature to make blanket statements about expected levels of performance. The best approach is to read the *QST* Product Reviews, review comparisons such as by Rob Sherwood, NC0B ([www.sherweng.com/table.html](http://www.sherweng.com/table.html)) and Jim Brown, K9YC ([k9yc.com/publish.html](http://k9yc.com/publish.html)), ask experienced operators for their opinions, and then try the equipment for yourself!

HBK0935

# 13.3 Modulators

Previous editions of the *Handbook* covered modulators in a general treatment of mixers. Much of that discussion is now included in the **Receiving** chapter where you can find more detailed information on mixer operation.

## 13.3.1 Amplitude Modulators

You can see how an AM signal is constructed as illustrated in **Figure 13.11**. Figure 13.11A shows the carrier, and the sidebands from a modulating tone are shown in 13.11B and 13.11C. The waveform of an AM signal appears to vary the carrier amplitude but this is not the case. The varying envelope of the AM signal results from the signal's three components — the carrier and the two sidebands — adding together. As the components reinforce and cancel each other, their sum (which appears as the envelope) rises and falls.

If you look closely, you can see that the waveforms in Figures 13.11B and 13.11C have slightly different frequencies than the carrier. If the two sidebands are added together, the signal of Figure 13.11D is produced. This is what the two sidebands look like as waveforms without the carrier. This is a *double-sideband, suppressed carrier* (DSBSC).

When the carrier signal is added, the full AM signal is produced in Figure 13.11D. When all of the signals are in-phase, the resulting signal has its maximum amplitude. When all of the signals are out of phase, the resulting signal goes to zero. If the carrier's phase is used as our reference, the phase of each sideband can be viewed as slipping behind (lower sideband) or moving ahead (upper sideband) of the carrier. The sidebands are out of phase with each other at the frequency of the tone so the resulting envelope reproduces the modulating tone's sine wave.

In the transmitter, the SSB modulator must suppress both the carrier and the unwanted sideband. Carrier suppression is normally accomplished with a *balanced modulator*, a

**Figure 13.11** — At A is an unmodulated carrier. If the upper (B) and lower (C) sidebands are added together a double-sideband suppressed carrier (DSBSC) signal results (D). If each sideband has half the amplitude of the carrier, then the combination of the carrier with the two sidebands results in a 100%-modulated AM signal (E). Whenever the two sidebands are out of phase with the carrier, the three signals sum to zero. Whenever the two sidebands are in phase with the carrier, the resulting signal has twice the amplitude of the unmodulated carrier.

## Mixer Math: Amplitude Modulation

We can easily allow the carrier to be part of the mixer along with the sidebands merely by adding enough *dc level shift* into the information we want to mix so that its waveform never goes negative. In the sidebar "Mixer Math: Mixing as Multiplication" in the **Receiving** chapter, mixer math was kept relatively simple by setting the peak voltage of the input signals directly equal to their sine values. Each input signal's peak voltage therefore varies between +1 and -1, so all we need to do to keep our modulating-signal term (provided with a subscript *m* to reflect its role as the modulating or information waveform) from going negative is add 1 to it. Identifying the carrier term with a subscript *c*, we can write

$$\text{AM signal} = (1 + m \sin 2\pi f_m t) \sin 2\pi f_c t \tag{A}$$

Notice that the modulation ( $2\pi f_m t$ ) term has company in the form of a coefficient, *m*. This variable expresses the modulating signal's varying amplitude — variations that ultimately result in amplitude modulation. Expanding the equation gives us:

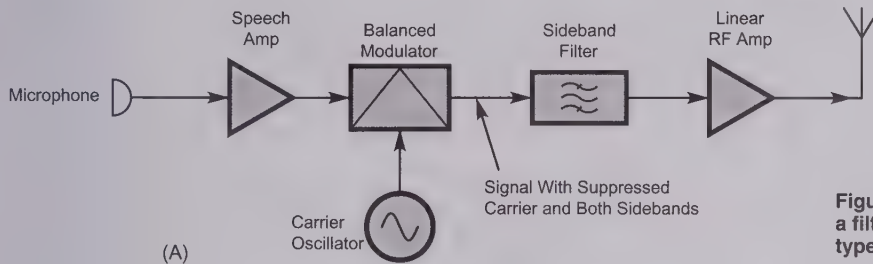

$$\text{AM signal} = \sin 2\pi f_c t + \frac{1}{2} m \cos (2\pi f_c - 2\pi f_m) t - \frac{1}{2} m \cos (2\pi f_c + 2\pi f_m) t \tag{B}$$

The modulator's output now includes the carrier ( $\sin 2\pi f_c t$ ) in addition to sum and difference products that vary in strength according to *m*. According to the conventions of talking about modulation, we call the sum product, which comes out at a frequency higher than that of the carrier, the *upper sideband (USB)*, and the difference product, which comes out a frequency lower than that of the carrier, the *lower sideband (LSB)*.

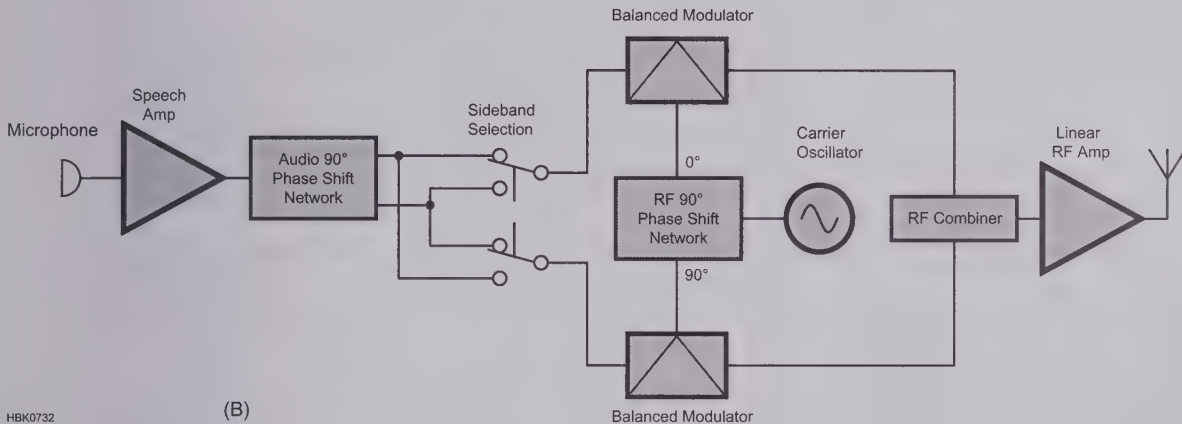

### Why We Call It Amplitude Modulation

This process is called *amplitude modulation* because the complex waveform consisting of the sum of the sidebands and carrier varies with the information signal's magnitude (*m*). Concepts long used to illustrate AM's mechanism may mislead us into thinking that the *carrier* varies in strength with modulation, but careful study of the equation above shows that this doesn't happen. The carrier,  $\sin 2\pi f_c t$ , goes into the modulator as a sinusoid with an unvarying maximum value of |1|. The modulator multiplies the carrier by the dc level (+1) that we added to the information signal ( $m \sin 2\pi f_m t$ ). Multiplying  $\sin 2\pi f_c t$  by 1 merely returns  $\sin 2\pi f_c t$ . Thus, the carrier's amplitude does not vary as a result of amplitude modulation.

Levels do not include splitter/combiner insertion loss.

HBK05\_11-034

**Figure 13.13** — Generating full-carrier AM with a diode DBM. A practical modulator using this technique is described in *Experimental Methods in RF Design*.

Another method to generate single sideband is called the *phasing method*. See Figure 13.12B. Using trigonometry, it can be shown mathematically that the sum of the signals from two balanced modulators, each fed with audio signals and RF carriers that are  $90^\circ$  out of phase, consists of one sideband only. The other sideband is suppressed. The output can be switched between LSB and USB simply by reversing the polarity of one of the inputs, which changes the phase by  $180^\circ$ . The phasing method eliminates the need for an expensive crystal filter following the modulator or, in the case of a transceiver, the need to switch the crystal filter between the transmitter and receiver sections. In addition, the audio quality is generally better because it eliminates the poor phase dispersion that is characteristic of most crystal filters. Using analog techniques, designing and building an audio phase-shift network that accurately maintained a  $90^\circ$  differential over a decade-wide frequency band (300 Hz to 3000 Hz) was rather complicated. With modern DSP techniques, the task is much easier.

## BALANCED MODULATORS

A balanced modulator is a mixer. Briefly, the IF frequency LO (455 kHz in the example of Figure 13.9) translates the audio frequencies up to a pair of IF frequencies — the LO plus the audio frequency and the LO minus the audio frequency. The balance from the

type of mixer whose output contains the sum and difference frequencies of the two input signals (the modulating signal and the carrier) but not the input signals themselves. There are several ways to eliminate the unwanted sideband, but the most common, shown in **Figure**

**13.12A**, is to pass the output of the balanced mixer through a crystal filter that passes the wanted sideband while filtering out the unwanted one. This is convenient in a transceiver since the same filter can be used in the receiver by means of a transmit-receive switch.

LO port to the IF output causes the LO frequency to be suppressed by 30 to 40 dB. Adjustments are provided to improve the LO null.

The filter method of SSB generation uses an IF band-pass filter to pass one of the sidebands and block the other. In Figure 13.9 the filter is centered at 455.0 kHz. The LO is offset to 453.6 kHz or 456.4 kHz so that the upper sideband or the lower sideband (respectively) can pass through the filter. This creates a problem for the other LOs in the radio, because they must now be properly offset so that the final transmit output's carrier (suppressed) frequency coincides with the frequency readout on the front panel of the radio.

Various schemes have been used to create the necessary LO offsets. One method uses two crystals for the 69.545 MHz LO that can be selected. In synthesized radios, the programming of the microprocessor controls the various LOs. Some synthesized radios use two IF filters at two different frequencies, one for USB and one for LSB, and a 455.0 kHz LO, as shown in Figure 13.9. These radios can be designed to transmit two independent sidebands (ISB) resulting in two separate channels in the spectrum space of the usual AM channel.

The data sheets for balanced modulators and mixers specify the maximum level of audio for a given LO level. Higher audio levels create excessive IMD. The IF filter following the modulator removes higher-order IMD products that are outside its passband but the in-band IMD products should be at least 40 dB below each of two equal test tones. Speech clipping (AF or IF) can degrade this to 10 dB or so, but in the absence of speech processing the signal should be clean, in-band.

### AMPLITUDE MODULATION WITH A DBM

We can generate DSB, suppressed-carrier AM with a DBM (double balanced mixer) by feeding the carrier to its RF port and the modulating signal to the IF port. (See the **Receiving** chapter for a detailed discussion of the DBM.) This is a classical *balanced modulator*, and the result — sidebands at radio frequencies corresponding to the carrier signal plus audio and the RF signal minus audio — emerges from the DBM's LO port. If we also want to transmit some carrier along with the sidebands, we can dc-bias the IF port (with a current of 10 to 20 mA) to upset the mixer's balance and keep its diodes from turning all the way off. (This technique is sometimes used for generating CW with a balanced modulator otherwise intended to generate DSB as part of an SSB-generation process.) **Figure 13.13** shows a more elegant approach to generating full-carrier AM with a DBM.

As we saw earlier when considering the many faces of AM, two DBMs, used in conjunction with carrier and audio phasing, can be used to generate SSB, suppressed-carrier AM. Likewise, two DBMs can be used with RF and LO phasing as an image-reject mixer.

### AN MC1496P BALANCED MODULATOR

Although it predates the SA602/612, Freescale's MC1496 Gilbert cell multiplier remains a viable option for product detection and balanced modulator service. It has been around for decades and is still one of the best and least expensive. **Figure 13.14** is a typical balanced modulator circuit using the MC1496. The circuit of **Figure 13.15** includes an MC1496-based balanced modulator that is capable of carrier suppression greater than 50 dB. Per its description in Hayward, Campbell, and Larkin's *Experimental Methods in RF Design*, its output with audio drive should be kept to about -20 dBm with this circuit. LO drive should be 200 to 500 mV P-P.

### SDR SSB GENERATORS

(This section is taken from the SDR: Simplified column by Ray Mack, W5IFS in the September/October 2012 issue of *QEX*.) The structure of this SDR SSB generator software is the same as if it were implemented in analog hardware. **Figure 13.16** shows the block diagram of the system. The program operates in a serial fashion: first an audio baseband filter limits the audio to a band of 300 Hz to 3 kHz. Second, the DDS phase step

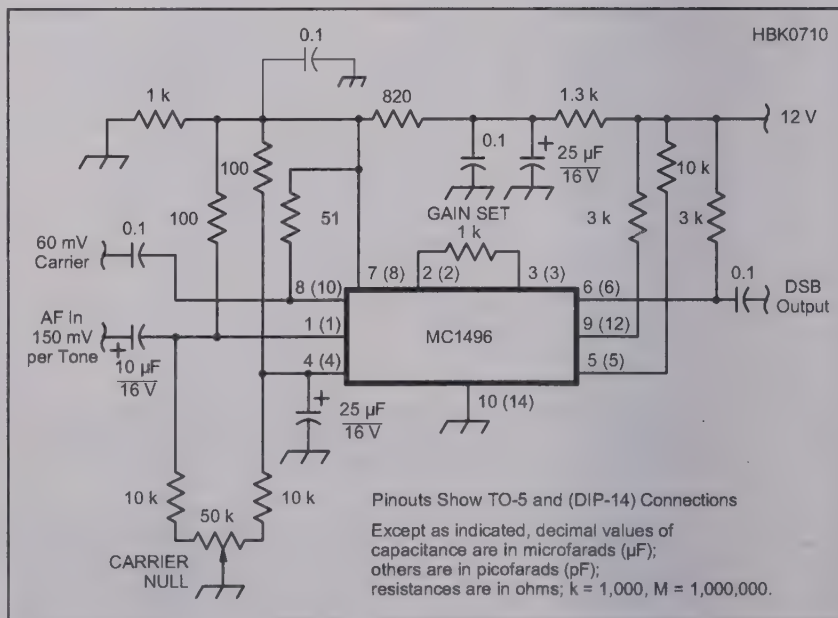

value to determine the carrier frequency is computed. Following that is the multiplication for the balanced mixer. Finally the undesired sideband is removed. Once the single sideband signal has been created, up-conversion is used to translate it to RF.

The audio band-pass filter response is only useful with 200 taps or more (See **Figure 13.17**). At 100 taps the rejection is only on the order of 12 dB below 100 Hz. Likewise, the opposite sideband filter requires on the order of 700 to 1000 taps to give approximately 60 dB of opposite sideband suppression. The large number of taps also makes the skirts very steep, so that we can use the filter to also further reduce any carrier feed-through. **Figure 13.18** illustrates how steep the skirts can be. If the low-frequency carrier is at 18 kHz, carrier suppression is approximately 52 dB and the unwanted sideband more than that.

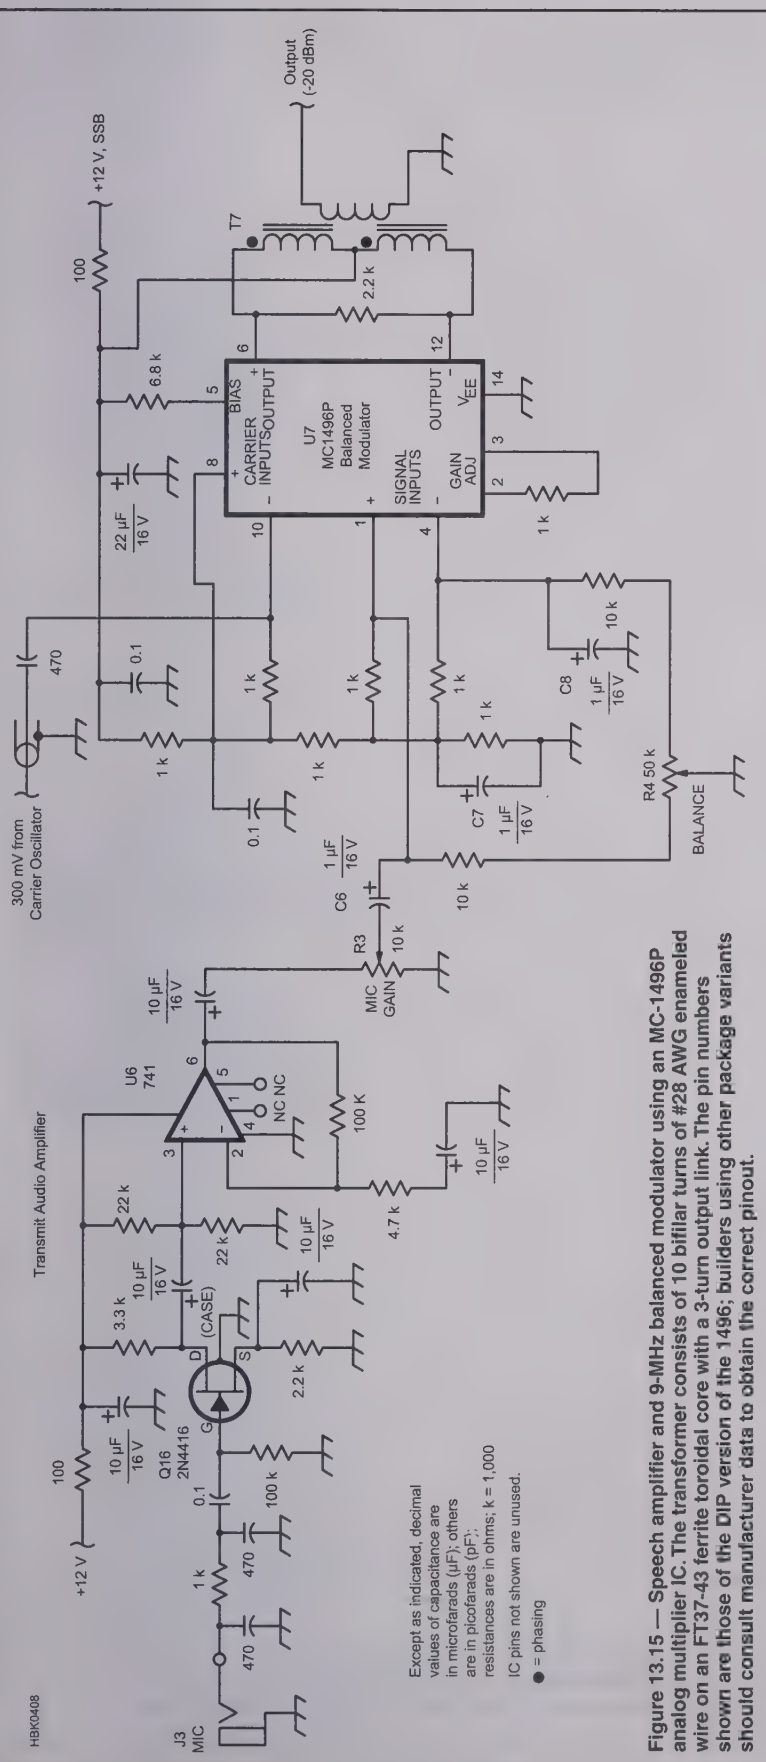

One alternative to reduce taps required in the audio filter is to simply use a dc block in the analog portion of the audio chain to set a lower boundary on the frequency. The response will be zero at 0 Hz and rise very rapidly to the frequency we set. This reduces the need for a sharp cutoff in DSP.

The close-in rejection of audio above 3 kHz is 45 dB or more with the 200-tap filter. Additionally, there is almost no energy above 3 kHz in the human voice, so energy in that region will likely be at least 60 dB below the lower frequencies after filtering.

Limiting the higher frequencies allows the use of a 6 kHz wide sideband selection filter instead of the normal 3 kHz filter to get bet-

**Figure 13.14** — An IC balanced modulator circuit using the MC1496 IC. The resistor between pins 2 and 3 sets the subsystem gain.

**Figure 13.15** — Speech amplifier and 9-MHz balanced modulator using an MC-1496P analog multiplier IC. The transformer consists of #28 AWG enameled wire on an FT37-43 ferrite toroidal core with a 3-turn output link. The pin numbers shown are those of the DIP version of the 1496; builders using other package variants should consult manufacturer data to obtain the correct pinout.

ter skirt response. A low-pass or high-pass filter would also work and give approximately the same skirt response, but we want to be sure to eliminate any residual energy at baseband in the case of a lower sideband transmission. The wider bandwidth limits the lower frequency for our carrier. We want the carrier frequency to be as high as possible in order to limit image response when we up-convert to our final RF signal.

There is a practical limit with respect to the number of taps in the filters. Each tap requires one multiply-accumulate operation, which is a MAC in the DSP world. (MAC also means Media Access Control to a networking hardware person!) The DSP is capable of one MAC for each MHz of clock frequency for each portion of the hardware chain. If voice is digitized at a 48 kHz sample rate, a transmitter filter with 200 taps for audio and 1000 taps for sideband selection will need 57.6 MMACs to do its job. (See the **Receiving** chapter note from KA9Q regarding fast convolution to implement the filter method as a more efficient method if the hardware can support it.) In addition, a large number of taps can create latency. In this case, for a 48 kHz sample stream, 1000 taps represents 20 msec. Depending on how the SDR is implemented, this could add to overall microphone-to-RF latency.

## OVERMODULATION

Since the information we transmit using AM shows up entirely as energy in its sidebands, it follows that the more energetic we make the sidebands, the more information energy will be available for an AM receiver to “recover” when it demodulates the signal. Even in an ideal modulator, there’s a practical limit to how strong we can make an AM signal’s sidebands relative to its carrier, however. Beyond that limit, we severely distort the waveform we want to translate into radio form.

We reach AM’s distortion-free modulation limit when the sum of the sidebands and carrier at the modulator output *just reaches zero* at the modulating wave-form’s most negative peak (**Figure 13.19**). We call this condition *100% modulation*, and it occurs when  $m$  in equation A in the sidebar “Mixer Math: Amplitude Modulation” equals 1. (We enumerate *modulation percentage* in values from 0 to 100%. The lower the number, the less information energy is in the sidebands. You may also see modulation enumerated in terms of a *modulation factor* from 0 to 1, which directly equals  $m$ ; a modulation factor of 1 is the same as 100% modulation.) Equation B in the sidebar shows that each sideband’s voltage is half that of the carrier. Power varies as the square of voltage, so the power in each sideband of a 100%-modulated signal is therefore  $(\frac{1}{2})^2$  times, or  $\frac{1}{4}$ , that of the carrier.

Figure 13.16 — This block diagram shows the software SSB transmit generator using the filter method.

Figure 13.17 — The 200-tap baseband filter response.

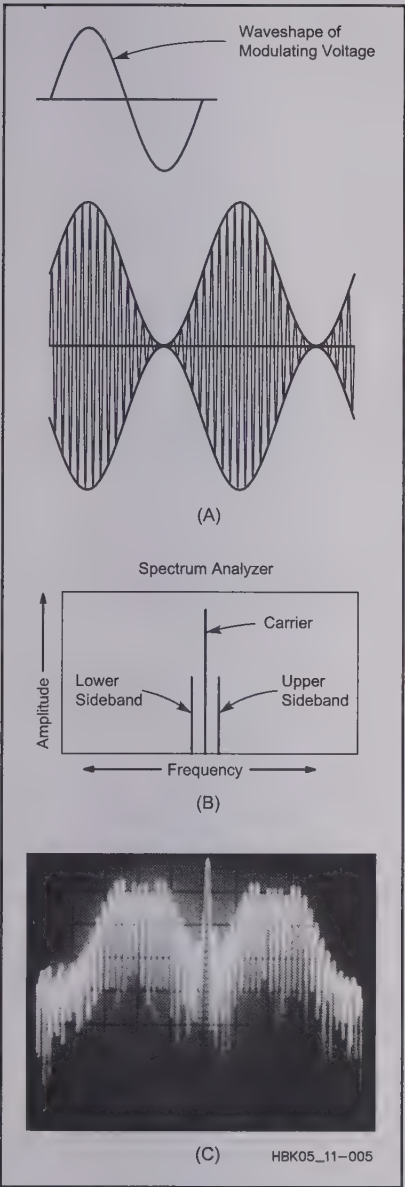

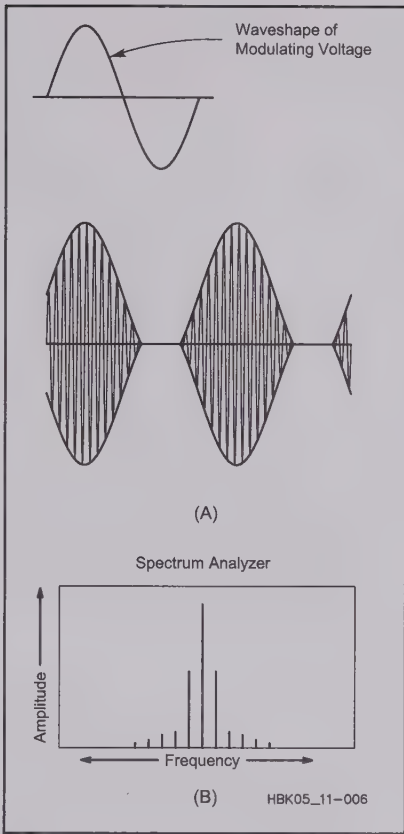

Figure 13.18 — The response of a 700-tap filter, showing a wider frequency view. The filter is 6 kHz wide to allow for a steep skirt on the carrier side. The 6 dB cutoff point is set at 300 Hz away from the low-frequency carrier, which is at 18,000 Hz (see text).

**Figure 13.19** — Graphed in terms of amplitude versus time (A), the envelope of a properly modulated AM signal exactly mirrors the shape of its modulating waveform, which is a sine wave in this example. This AM signal is modulated as fully as it can be — 100% — because its envelope just touches zero on the modulating wave's negative peaks. Graphing the same AM signal in terms of amplitude versus frequency (B) reveals its three spectral components: Carrier, upper sideband and lower sideband. B shows sidebands as single-frequency components because the modulating waveform is a sine wave. With a complex modulating waveform, the modulator's sum and difference products really do show up as bands on either side of the carrier (C).

**Figure 13.20** — Negative-going overmodulation of an AM transmitter results in a modulation envelope (A) that doesn't faithfully mirror the modulating waveform. This distortion creates additional sideband components that broaden the transmitted signal (B). Positive-going modulation beyond 100% is used by some AM broadcasters in conjunction with negative-peak limiting to increase "talk power" without causing negative overmodulation.

A transmitter capable of 100% modulation when operating at a carrier power of 100 W therefore puts out a 150-W signal at 100% modulation, 50 W of which is attributable to the sidebands. (The peak envelope power [PEP] output of a double-sideband, full-carrier AM transmitter at 100% modulation is four times its carrier PEP. This is why our solid-state, "100-W" MF/HF transceivers are usually rated for no more than about 25 W carrier output at 100% amplitude modulation.)

One-hundred-percent negative modulation is a brick-wall limit because an amplitude modulator can't reduce its output to less than zero. Trying to increase negative modulation beyond the 100% point results in *overmodulation* (Figure 13.20), in which the modulation envelope no longer mirrors the shape of the modulating wave (Figure 13.20A). A

**Figure 13.21** — An ideal AM transmitter exhibits a straight-line relationship (A) between its instantaneous envelope amplitude and the instantaneous amplitude of its modulating signal. Distortion, and thus an unnecessarily wide signal, results if the transmitter cannot respond linearly across the modulating signal's full amplitude range (B).

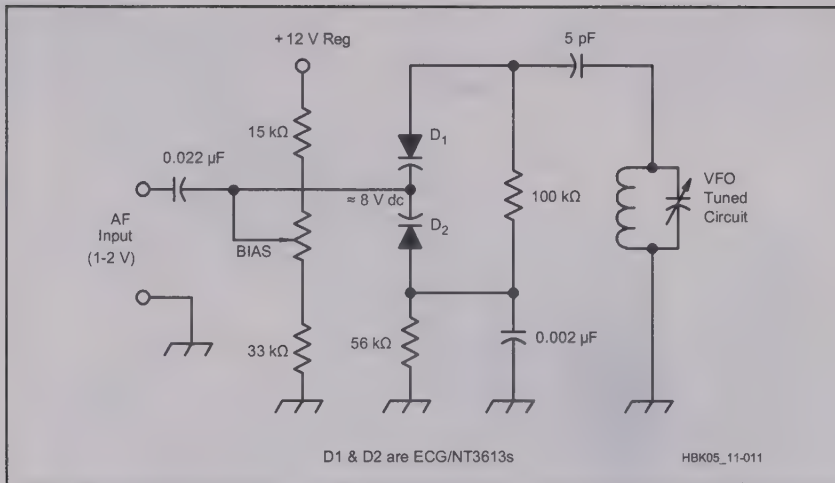

negatively overmodulated wave contains more energy than it did at 100% modulation, but some of the added energy now exists as harmonics of the modulating waveform (Figure 13.20B). This distortion makes the modulated signal take up more spectrum space than it needs. In voice operation, overmodulation commonly happens only on syllabic peaks, making the distortion products sound like transient noise we refer to as *splatter*.

**MODULATION LINEARITY**

If we increase an amplitude modulator's modulating-signal input by a given percentage, we expect a proportional modulation increase in the modulated signal. We expect good *modulation linearity*. Suboptimal amplitude modulator design may not allow this, however. Above some modulation percentage, a modulator may fail to increase modulation in proportion to an increase in its input signal (Figure 13.21). Distortion, and thus an unnecessarily wide signal, results.

**13.3.2 Angle Modulators**

Amplitude modulation served as our first means of translating information into radio form because it could be implemented as simply as turning an electric noise generator on and off. (A spark transmitter consisted of little more than this.) By the 1930s, we had begun experimenting with translating information into radio form and back again by modulating a radio wave's angular velocity (frequency or phase) instead of its overall amplitude. The result of this process is *frequency modulation (FM)* or *phase modulation (PM)*, both of which are often grouped

**Figure 13.22** — One or more tuning diodes can serve as the variable reactance in a reactance modulator. This HF reactance modulator circuit uses two diodes in series to ensure that the tuned circuit's RF-voltage swing cannot bias the diodes into conduction. D1 and D2 are "30-volt" tuning diodes that exhibit a capacitance of 22 pF at a bias voltage of 4. The BIAS control sets the point on the diode's voltage-versus-capacitance characteristic around which the modulating waveform swings.

under the name *angle modulation* because of their underlying principle.

A change in a carrier's frequency or phase for the purpose of modulation is called *deviation*. An FM signal deviates according to the amplitude of its modulating waveform, inde-

pendently of the modulating waveform's frequency; the higher the modulating wave's amplitude, the greater the deviation. A PM signal deviates according to the amplitude *and frequency* of its modulating waveform; the higher the modulating wave's amplitude

**Figure 13.23** — A series reactance modulator acts as a variable shunt around a reactance — in this case, a 47-pF capacitor — through which the carrier passes.

*and/or frequency*, the greater the deviation. See the sidebar, "Mixer Math: Angle Modulation" for a numerical description of these processes.

If you vary a reactance in or associated with an oscillator's frequency-determining element(s), you vary the oscillator's frequency. If you vary the tuning of a tuned circuit through which a signal passes, you vary the signal's phase. A circuit that does this is called a *reactance modulator*, and can be little more than a tuning diode or two connected to a tuned circuit in an oscillator or amplifier (**Figure 13.22**). Varying a reactance through which the signal passes (**Figure 13.23**) is another way of doing the same thing.

The difference between FM and PM depends solely on how, and not how much, deviation occurs. A modulator that causes deviation in proportion to the modulating wave's amplitude and frequency is a phase modulator. A modulator that causes deviation only in proportion to the modulating signal's amplitude is a frequency modulator.

## ANGLE MODULATION SIDEBANDS

Although angle modulation produces uncountable sum and difference products, most of them are vanishingly weak in practical systems. They emerge from the modulator spaced from the average ("resting," unmodulated) carrier frequency by integer multiples of the modulating frequency (**Figure 13.24**). The strength of the sidebands relative to the carrier, and the strength and phase of the carrier itself, vary with the degree of modulation — the modulation index. (The *overall* amplitude of an angle-modulated signal does not change with modulation, however; when energy goes out of the carrier, it shows up in the sidebands, and vice versa.) In practice, we operate angle-modulated transmitters at modulation indexes that make all but a few of their infinite sidebands small in amplitude.

## Mixer Math: Angle Modulation

An angle-modulated signal can be mathematically represented as

$$f_c(t) = \cos(2\pi f_c t + m \sin(2\pi f_m t))$$

$$= \cos(2\pi f_c t) \cos(m \sin(2\pi f_m t)) - \sin(2\pi f_c t) \sin(m \sin(2\pi f_m t))$$

In this equation, we see the carrier frequency ( $2\pi f_c t$ ) and modulating signal ( $\sin 2\pi f_m t$ ) as in equation A shown in the sidebar Mixer Math: Amplitude Modulation. We again see the modulating signal associated with a coefficient,  $m$ , which relates to degree of modulation. (In the AM equation,  $m$  is the modulation factor; in the angle-modulation equation,  $m$  is the *modulation index* and, for FM, equals the deviation divided by the modulating frequency.) We see that angle-modulation occurs as the cosine of the sum of the carrier frequency ( $2\pi f_c t$ ) and the modulating signal ( $\sin 2\pi f_m t$ ) times the modulation index ( $m$ ). In its expanded form, we see the appearance of sidebands above and below the carrier frequency.

Angle modulation is a multiplicative process, so, like AM, it creates sidebands on both sides of the carrier. Unlike AM, however, angle modulation creates an *infinite* number of sidebands on either side of the carrier! This occurs as a direct result of modulating the carrier's angular velocity, to which its frequency and phase directly relate. If we continuously vary a wave's angular velocity according to another periodic wave's cyclical amplitude variations, the rate at which the modulated wave repeats *its* cycle — its frequency — passes through an infinite number of values. (How many individual amplitude points are there in one cycle of the modulating wave? An infinite number. How many corresponding discrete frequency or phase values does the corresponding angle-modulated wave pass through as the modulating signal completes a cycle? An infinite number!) In AM, the carrier frequency stays at one value, so AM produces two sidebands — the sum of its carrier's unchanging frequency value and the modulating frequency, and the difference between the carrier's unchanging frequency value and the modulating frequency. In angle modulation, the modulating wave shifts the frequency or phase of the carrier through an infinite number of different frequency or phase values, resulting in an infinite number of sum and difference products.

**Figure 13.24** — Angle-modulation produces a carrier and an infinite number of upper and lower sidebands spaced from the average (“resting,” unmodulated) carrier frequency by integer multiples of the modulating frequency. (This drawing is a simplification because it only shows relatively strong, close-in sideband pairs; space constraints prevent us from extending it to infinity.) The relative amplitudes of the sideband pairs and carrier vary with modulation index,  $m$ .

(A mathematical tool called *Bessel functions* helps determine the relative strength of the carrier and sidebands according to modulation index. The **Modulation** chapter includes a graph to illustrate this relationship.) Selectivity in transmitter and receiver circuitry further modify this relationship, especially for sidebands far from the carrier.

### BIPHASE-SHIFT KEYING (BPSK) MODULATION WITH A DBM

Back in our discussion of square-wave mixing, we saw how multiplying a switching mixer’s linear input with a square wave causes a  $180^\circ$  phase shift during the negative part of the square wave’s cycle. As **Figure 13.25** shows, we can use this effect to produce *biphase-shift keying (BPSK)*, a digital system that conveys data by means of carrier phase reversals. A related system, *quadrature phase-shift keying (QPSK)* uses two DBMs and phasing to convey data by phase-shifting a carrier in  $90^\circ$  increments.

**Figure 13.25** — Mixing a carrier with a square wave generates biphase-shift keying (BPSK), in which the carrier phase is shifted  $180^\circ$  for data transmission. In practice, as in this drawing, the carrier and data signals are phase-coherent so the mixer switches only at carrier zero crossings.

### DEVIATION AND FREQUENCY MULTIPLICATION

Maintaining modulation linearity is just as important in angle modulation as it is in AM, because unwanted distortion is always our enemy. A given angle-modulator circuit can frequency- or phase-shift a carrier only so much before the shift stops occurring in strict proportion to the amplitude (or, in PM, the amplitude and frequency) of the modulating signal.

If we want more deviation than an angle modulator can linearly achieve, we can operate the modulator at a suitable sub-harmonic — submultiple — of the desired frequency, and process the modulated signal through a series of *frequency multipliers* to bring it up to the desired frequency. The deviation also increases by the overall multiplication factor, relieving the modulator of having to do it all directly. A given FM or PM radio design may achieve its final output frequency through a combination of mixing (frequency shift, no deviation change) and frequency multiplication (frequency shift *and* deviation change).

#### “TRUE FM”

Something we covered a bit earlier bears closer study: “An FM signal deviates according to the amplitude of its modulating waveform, independently of the modulating waveform’s frequency; the higher the modulating wave’s amplitude, the greater the deviation. A PM signal deviates according to

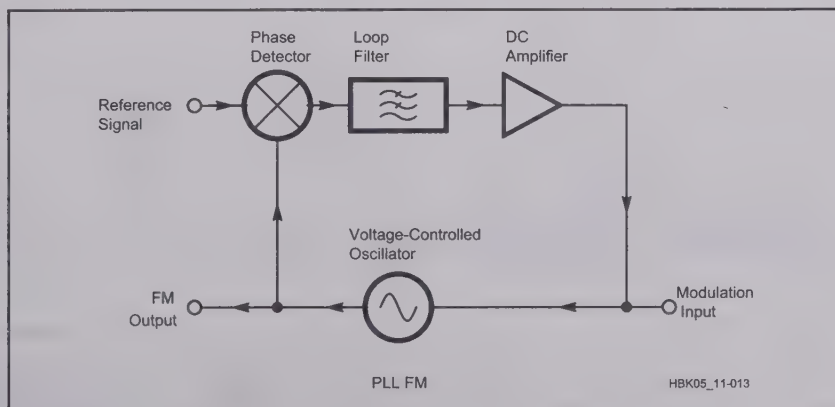

the amplitude *and* frequency of its modulating waveform; the higher the modulating wave’s amplitude *and/or* frequency, the greater the deviation.”

The practical upshot of this excerpt is that we can use a phase modulator to generate FM. All we need to do is run a PM transmitter’s modulating signal through a low-pass filter that (ideally) halves the signal’s amplitude for each doubling of frequency (a reduction of “6 dB per octave,” as we sometimes see such responses characterized) to compensate for its phase modulator’s “more deviation with higher frequencies” characteristic. The result is an FM, not PM, signal. FM achieved with a phase modulator is sometimes called *indirect FM* as opposed to the *direct FM* we get from a frequency modulator.

We sometimes see claims that one piece of gear is better than another solely because it generates “true FM” as opposed to indirect FM. We can debunk such claims by keeping in mind that direct and indirect FM *sound exactly alike in a receiver* when performed correctly.

### CONVEYING DC LEVELS WITH ANGLE MODULATION

Depending on the nature of the modulation source, there is a practical difference between a frequency modulator and a phase modulator. Answering two questions can tell us whether this difference matters: Does our modulating signal contain a dc level or not? If so, do we

**Figure 13.26** — Frequency modulation using a phase-locked loop (PLL).

need to accurately preserve that dc level through our radio communication link for successful communication? If both answers are *yes*, we must choose our hardware and/or information-encoding approach carefully, because a frequency modulator can convey dc-level shifts in its modulating waveform, while a phase modulator, which responds only to instantaneous changes in frequency and phase, cannot.

Consider what happens when we want to frequency-modulate a phase-locked-loop-synthesized transmitted signal. **Figure 13.26** shows the block diagram of a PLL frequency modulator. Normally, we modulate a PLL's VCO because it's the easy thing to do. As long as our modulating frequency results in frequency excursions too fast for the PLL to follow and correct — that is, as long as our modulating frequency is outside the PLL's *loop bandwidth* — we achieve the FM we seek. Trying to modulate a dc level by push-

ing the VCO to a particular frequency and holding it there fails, however, because a PLL's loop response includes dc. The loop, therefore, detects the modulation's dc component as a correctable error and "fixes" it. FMing a PLL's VCO therefore can't buy us the dc response "true FM" is supposed to allow.

We can dc-modulate a PLL modulator, but we must do so by modulating the frequency of the loop *reference*. The PLL then adjusts the VCO to adapt to the changed reference, and our dc level gets through. In this case, the modulating frequency must be *within* the loop bandwidth — which dc certainly is — or the VCO won't be corrected to track the shift.

### SDR ANGLE MODULATORS

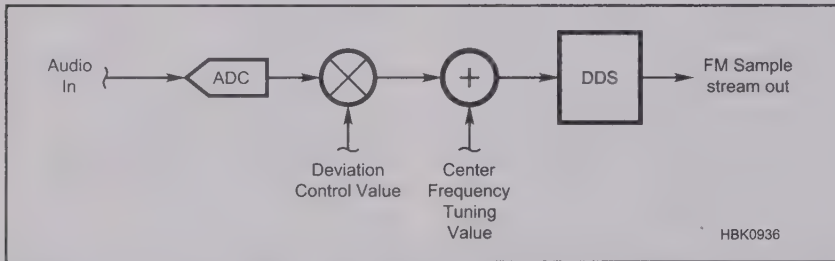

**Figure 13.27** shows the block diagram of an FM transmitter using DSP to produce the carrier, and using addition to create true FM

from the audio input. An FM signal can be generated directly through the DDS by simply adding or subtracting a small value that corresponds to the audio voltage to the tuning value used for the DDS accumulator. The frequency deviation is adjusted by controlling the gain applied to the audio signal. This method produces true frequency modulation. If the audio signal is used to control the phase accumulation of the DDS, the result is PM.

Angle modulation can also be produced using I/Q modulation as in **Figure 13.28**. A DSB-SC (double-sideband, suppressed-carrier) signal is produced by a balanced modulator or DSP multiplier (see SDR SSB Generators earlier in this chapter). The DSB-SC signal is then added to the carrier signal with a 90° phase difference. The result is a PM signal.

Frequency modulation requires that an integrator (low-pass filter) be applied to the modulating signal. This is because frequency is the time-derivative of phase. By applying the integrated signal to a phase modulator, FM is produced with a deviation that does not depend on signal amplitude — only frequency.

Because of the low-pass filter, speech is usually given a high-frequency boost by a high-pass pre-emphasis network. A corresponding de-emphasis (low-pass) network must be applied to the recovered modulation in the receiver to restore the original modulating signal's frequency response. This improves intelligibility and signal-to-noise ratio of the received audio.

**Figure 13.27** — Creating FM by controlling the frequency of a DDS signal source. By controlling the phase step instead of the frequency, PM would be created.

**Figure 13.28** — Two methods of using I/Q modulation to produce angle-modulated signals. The block diagram includes a DSB generator (Figure 13.16) with the additional step of mixing (multiplying) the DSB signal with a phase-shifted carrier signal to produce PM (A) or FM (B). FM requires applying an integrator (low-pass filter) to the modulating signal so that output frequency depends only on the amplitude of the modulating signal and not its frequency.

# 13.4 Transmitting CW

Earlier in this chapter, the importance of shaping the time envelope of the keying pulse of an on-off keyed transmitter is discussed. There are serious ramifications of not paying close attention to this design parameter. The optimum shape of a transmitter envelope should approach the form of a sinusoid raised to a power with a tradeoff between occupied bandwidth and overlap between the successive pulses. This can be accomplished either through filtering of the pulse waveform before modulation in a linear transmitter, or through direct generation of the pulse shape using DSP.

The differences between well-designed and poor pulse shaping can perhaps be best described by looking at some results. The following figures are from recent *QST* product reviews of commercial multimode 100 W HF transceivers. **Figure 13.29** shows the CW keying waveform of a transmitter with good spectrum control. The top trace is the key closure, with the start of the first contact closure on the left edge at 60 WPM using full break-in. Below it is the nicely rounded RF envelope. **Figure 13.30** shows the resultant signal spectrum. Note that the signal amplitude is about 80 dB down at a spacing of  $\pm 1$  kHz, with a floor of  $-90$  dB over the 10 kHz shown. **Figures 13.31** and **13.32** are similar data taken from a different manufacturer's transceiver. Note the sharp corners of the RF envelope, as well as the time it takes for the first "dit" to be developed. The resulting spectrum is not even down 40 dB at  $\pm 1$  kHz and shows a floor that doesn't quite make  $-60$  dB over the 10 kHz range. It's easy to see the problems that the latter transmitter will cause to receivers trying to listen to a weak signal near its operating frequency. The unwanted components of the signal are heard on adjacent channels as sharp clicks when the signal is turned on and off, called *key clicks*. Note that even the best-shaped keying waveform in a linear transmitter will become sharp with a wide spectrum if it is used to drive a stage such as an external power amplifier beyond its linear range. This generally results in clipping or limiting with subsequent removal of the rounded corners on the envelope. Trying to get the last few dB of power out of a transmitter can often result in this sort of unintended signal impairment.

## 13.4.1 CW Operation

**Figure 13.33A** closely resembles what we see when a properly adjusted CW transmitter sends a string of dots. Keying a carrier on and off produces a wave that varies in amplitude and has double (upper and lower) sidebands that vary in spectral composition according

**Figure 13.29** — The CW keying waveform of a transmitter with good spectrum control. The top trace is the key closure, with the start of the first contact closure on the left edge at 60 WPM using full break-in. Below that is the nicely rounded RF envelope.

**Figure 13.31** — The CW keying waveform of a transmitter with poor spectrum control. The top trace is the key closure, with the start of the first contact closure on the left edge at 60 WPM using full break-in. Note the sharp corners of the RF envelope that result in excessive bandwidth products.

**Figure 13.30** — The resultant signal spectrum from the keying shown in **Figure 13.29**. Note that the signal amplitude is about 80 dB down at a spacing of  $\pm 1$  kHz, with a floor of  $-90$  dB over the 10 kHz shown.

**Figure 13.32** — The resultant signal spectrum from the keying shown in **Figure 13.31**. The resulting spectrum is not even down 40 dB at  $\pm 1$  kHz and shows a floor that doesn't quite make 60 dB below the carrier across the 10 kHz.

**Figure 13.33** — Waveshaping in a CW transmitter often causes a CW signal's RF envelope (lower trace in the amplitude-versus-time display at A) to contain less harmonic energy than the abrupt transitions of its key closure waveform (upper trace in A) suggest should be the case. B, an amplitude-versus-frequency display, shows that even a properly shaped CW signal has many sideband components.

to the duration and envelope shape of the on-off transitions. The emission mode we call CW is therefore a form of AM. The concepts of modulation percentage and overmodulation are usually not applied to generating an on-off-keyed Morse signal, however. This is related to how we copy CW by ear, and the fact that, in CW radio communication, we usually don't translate the received signal all the way back into its original pre-modulator (*baseband*) form, as a closer look at the process reveals.

In CW transmission, we usually open and close a keying line to make dc transitions that turn the transmitted carrier on and off. See Figure 13.33B. CW reception usually does not entirely reverse this process, however. Instead of demodulating a CW signal all the way back to its baseband self — a shifting dc level — we want the presences and absences of its carrier to create long and short audio tones. Because the carrier is RF and not AF, we must mix it with a locally generated RF signal — from a *beat-frequency oscillator (BFO)* — that's close enough in frequency to produce a difference signal at AF (this BFO can, of course, also be inserted at an IF stage). What goes into our transmitter as shifting dc comes out of our receiver as tone bursts of dot and dash duration.

It so happens that we always need to hear one or more harmonics of the fundamental keying waveform for the code to sound sufficiently crisp. If the transmitted signal will be subject to fading caused by varying propagation — a safe assumption for any long-distance radio communication — we can *harden* our keying by making the transmitter's output rise and fall more quickly. This puts more energy into keying sidebands and makes the signal more copyable in the presence of fading — in particular, *selective fading*, which linearly distorts a modulated signal's complex waveform and randomly changes the sidebands' strength and phase relative to the carrier and each other. The appropriate keying hardness also depends on the keying speed. The faster the keying in WPM, the faster the on-off times — the harder the keying — must be for the signal to remain ear- and machine-readable through noise and fading.

Instead of thinking of this process in terms of modulation percentage, we just ensure that a CW transmitter produces sufficient keying-sideband energy for solid reception. Practical CW transmitters usually do not do their keying with a modulator stage as such. Instead, one or more stages are turned on and off to modulate the carrier with Morse, with rise and fall times set by *R* and *C* values associated with the stages' keying and/or power supply values. A transmitter's CW *waveshaping* is therefore usually hardwired to values appropriate for reasonably high-speed sending (35 to 55 WPM or so) in the presence of fading.

However, some transceivers allow the user to vary keying hardness at will as a menu option. Rise and fall times of 1 to 5 ms are common; 5-ms rise and fall times equate to a keying speed of 36 WPM in the presence of fading and 60 WPM if fading is absent.

The faster a CW transmitter's output changes between zero and maximum, the more bandwidth its carrier and sidebands occupy. See Figure 13.33B. Making a CW signal's keying too hard is therefore spectrum-wasteful and inconsiderate of other stations because it makes the signal wider than it needs to be. Keying sidebands that are stronger and wider than necessary are traditionally called *clicks* because of what they sound like on the air.

Radiotelegraph or CW operation can be easily obtained from the transmitter architecture design shown in Figure 13.9. For CW operation, a carrier is generated at the center of the SSB filter passband. There are two ways to make this carrier available. One way is to unbalance the balanced modulator so that the LO can pass through. Each kind of

balanced modulator circuit has its own method of doing this. The approach chosen in Figure 13.9 is to go around the modulator and the SSB filter.

A shaping network controls the envelope of the IF signal to accomplish two things: control the shape of the Morse code character in a way that limits wideband spectrum emissions that can cause interference, and make the Morse code signal easy and pleasant to copy.

### 13.4.2 RF Envelope Shaping

On-off keying (CW) is a special kind of low-level amplitude modulation (a low signal-level stage is turned on and off). It is special because the sideband power is subtracted from the carrier power, and not provided by a separate "modulator" circuit, as in high-level AM. It creates a spectrum around the carrier frequency whose amplitude and bandwidth are influenced by the rates of signal amplitude rise and fall and by the curvature of the keyed waveform. For additional infor-

Figure 13.34 — Keying speed versus rise and fall times versus bandwidth for fading and nonfading communications circuits. For example, for transmitter output waveform rise and fall times of approximately 6 ms, draw a horizontal line from 6.0 ms on the rise and fall times scale to the bandwidth line. Then draw a vertical line to the occupied bandwidth scale at the bottom of the graph. In this case the bandwidth is about 130 Hz. Also extend the 6.0 ms horizontal line to the K = 3 line for a nonfading circuit. Finally draw a vertical line from the K = 3 line to the WPM axis. The 6 ms rise and fall time should be suitable for keying speeds up to about 50 WPM in this example.

mation see the article by Sabin on IF signal processing in the References section of this chapter.

Now look at **Figure 13.34**. The vertical axis is labeled Rise and Fall Times (ms). For a rise/fall time of 6 ms (between the 10% and 90% values) go horizontally to the line marked Bandwidth. A -20 dB bandwidth of roughly 120 Hz is indicated on the lower horizontal axis. Continuing to the K = 5 and K = 3 lines, the upper horizontal axis suggests code speeds of 30 WPM and 50 WPM respectively.

These code speeds can be accommodated by the rise and fall times displayed on the vertical axis. For code speeds greater than these the Morse code characters become "soft" sounding and difficult to copy, especially under less-than-ideal propagation conditions.

The ITU Classification of Emission Standards for determining necessary bandwidths of signals uses a value of 0.8 for the conversion between baud and WPM and suggests a typical value for K of 5 on an HF

channel where the signal is subjected to fading. The bandwidth for a 13 WPM signal would then be:

$$BW = WPM \times 0.8 \times 5 = 10.4 \times 5 = 52 \text{ Hz}$$

For a narrow spectrum and freedom from adjacent channel interference, a further requirement is that the spectrum must fall off very rapidly beyond the -20 dB bandwidth indicated in Figure 13.34. A sensitive narrow-band CW receiver that is tuned to an adjacent channel that is only 1 or 2 kHz away can detect keying sidebands that are 80 to 100 dB below the key-down level of a strong CW signal.

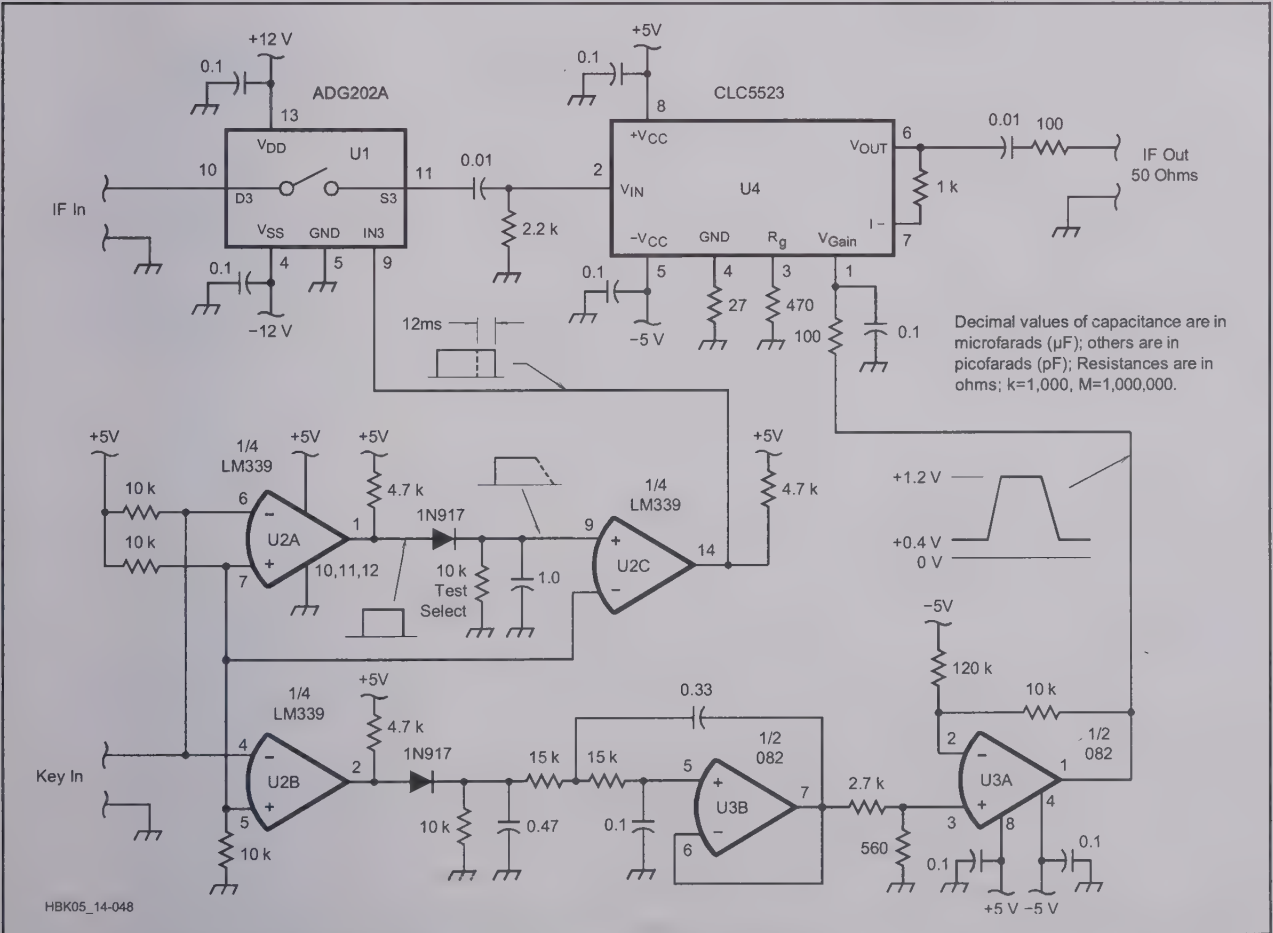

An additional consideration is that during key-up a residual signal, called *backwave*, should not be noticeable in a nearby receiver. A backwave level at least 90 dB below the key-down carrier is a desirable goal.

Microprocessor-controlled transceivers manufactured today control CW keying rise- and fall-time through software. The operator generally accesses the keying shape parameter through a menu selection and adjustment

process. Three to four ms is a typical value for most transceivers that balances crisp keying characteristics against excessive off-channel artifacts. See *QST* Product Reviews for waveforms and discussions of rise- and fall-time settings.

Homebrew equipment usually relies on analog circuitry to control keying waveforms. **Figure 13.35** is the schematic of one waveshaping circuit that has been used successfully. A Sallen-Key third-order op amp low-pass filter (0.1 dB Chebyshev response) shapes the keying waveform, produces the rate of rise and fall and also softens the leading and trailing corners just the right amount. The key closure activates the CMOS switch, U1, which turns on the 455-kHz IF signal. At the key-up time, the input to the wave-shaping filter is turned off, but the IF signal switch remains closed for an additional 12 ms.

The keying waveform is applied to the gain control pin of a CLC5523 amplifier IC. This device, like nearly all gain-control amplifiers, has a *logarithmic* control of gain; therefore some experimental "tweaking" of the capac-

**Figure 13.35** — This schematic diagram shows a CW waveshaping and keying circuit suitable for use with an SSB/CW transmitter such as is shown in Figure 13.9.

Figure 13.36 — At (A) is the oscilloscope display of the CW waveshaping and keying circuit output. The top trace is the IF keying signal applied to S1 of Figure 13.35. The bottom trace is the transmitter output RF spectrum. At (B) is a SPICE simulation of the waveshaping network. When this signal is applied to the logarithmic control characteristic of the CLC5523 amplifier, the RF envelope is modified slightly to the form shown in A.

itor values was used to get the result shown in Figure 13.36A. The top trace shows the on/off operation of the IF switch, U1. The signal is turned on shortly before the rise of the keying pulse begins and remains on for about 12 ms after the keying pulse is turned off, so that the waveform falls smoothly to a very low value. The result is an excellent spectrum and an almost complete absence of backwave. Compare this to the factory transmitter waveshapes shown in Figures 13.29 and 13.31. The bottom trace shows the resulting keyed RF output waveshape. It has an excellent spectrum, as verified by critical listening tests. The thumps and clicks that are found in some CW transmitters are virtually absent. The rise and fall intervals have a waveshape that is approximately a cosine. Spread-spectrum frequency-hop waveforms have used this approach to minimize wideband interference.

Figure 13.36B is an accurate SPICE simulation of the wave shaping circuit output before the signal is processed by the CLC5523 amplifier. To assist in adjusting the circuit, create a steady stream of 40 ms dots that can be seen on an RF oscilloscope that is looking at the final PA output envelope. It is important to make sure that the excellent waveshape is not degraded on its way to the transmitter output. Single-sideband linear power amplifiers are well suited for a CW transmitter, but they must stay within their linear range, and the backwave problem must be resolved.

When evaluating the spectrum of an incoming CW signal during on-the-air operations, a poor receiver design can contribute problems caused by its vulnerability to a strong but clean adjacent channel signal. Clicks, thumps, front end overload, reciprocal mixing, and other issues can be created in the receiver. It is important to put the blame where it really belongs.

### 13.4.3 Break-In CW Operation

Most current 100 W class HF transceivers use high-speed relays (with the relay actually following the CW keying) or solid-state PIN diodes to implement full break-in CW. Some RF power amplifiers use high-speed vacuum relays for the TR switching function. See the section on TR Switching later in this chapter for more information about circuits to perform this function. Two projects for adding QSK switching to linear amplifiers are included in the Station Accessories chapter.

The term *semi-break-in* is used to designate a CW switching system in which closing the key initiates transmission, but switching back to receive happens between words, not between individual dits. Some operators find this less distracting than full break-in, and it is easier to implement with less-expensive relays for the TR switching.

## 13.5 Transmitting AM and SSB

### 13.5.1 Amplitude-Modulated Full-Carrier Voice Transmission

A popular form of voice amplitude modulation is called *high-level amplitude modulation*. It is generated by mixing (or modulating) an RF carrier with an audio signal. Figure 13.37 shows the conceptual view of this. Figure 13.38 is a more detailed view of how such a voice transmitter would actually be implemented. The upper portion is the RF channel and the lower portion is the audio frequency or AF channel, usually called the *modulator*. The modulator is nothing more than an audio amplifier designed to be fed

from a microphone and with an output designed to match the anode or collector impedance of the final RF amplifier stage.

The output power of the modulator is

Figure 13.37 — Block diagram of a conceptual AM transmitter.

applied in series with the dc supply of the output stage (only) of the RF channel of the transmitter. The level of the voice peaks needs to be just enough to vary the supply to the RF amplifier collector between zero volts, on negative peaks, and twice the normal supply voltage on positive voice peaks. This usually requires an AF amplifier with about half the average power output as the dc input power (product of dc collector or plate voltage times the current) of the final RF amplifier stage.

The output signal, called *full-carrier double-sideband AM*, occupies a frequency spectrum as shown in Figure 13.39. The spectrum shown would be that of a standard broadcast station with an audio passband from 50 Hz

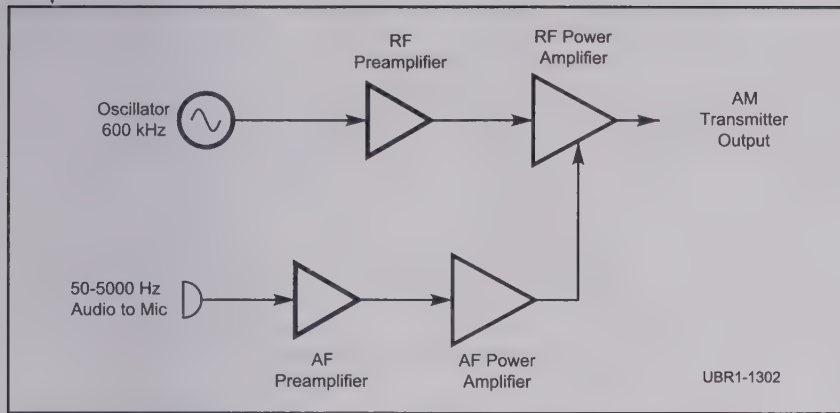

Figure 13.38 — Block diagram of a 600 kHz AM broadcast transmitter.

Figure 13.39 — The range of spectrum used by a 600 kHz AM broadcast signal showing sidebands above and below a carrier at 600 kHz.

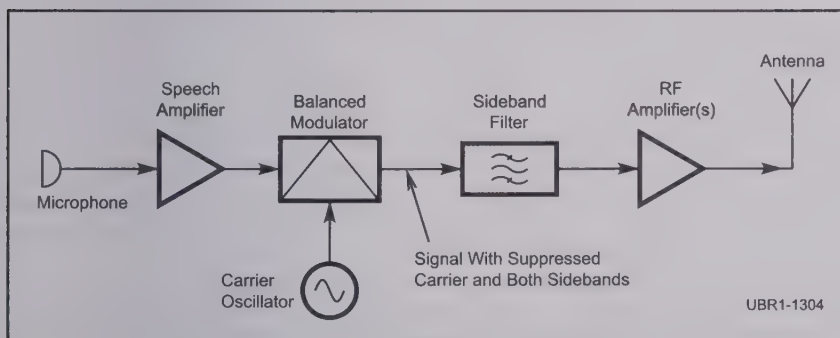

Figure 13.40 — Block diagram of a filter type single-sideband suppressed-carrier (SSB) transmitter.

to 5 kHz. Note that the resulting channel width is twice the highest audio frequency transmitted. If the audio bandwidth were limited to typical “telephone quality speech” of 300 to 3300 Hz, the resulting bandwidth would be reduced to 6.6 kHz. Note also that while a perfect multiplication process would result in just two sidebands and no carrier,

this implementation actually provides the sum of the carrier and the sidebands from the product terms. (See the **Receiving** chapter for the mathematical description of signal multiplication.)

Full-carrier double-sideband AM is used in fewer and fewer applications. The spectral and power efficiency are significantly lower

than single sideband (SSB), and the equipment becomes quite costly as power is increased. The primary application is in broadcasting — largely because AM transmissions can be received on the simplest and least expensive of receivers. With a single transmitter and thousands of receivers, the overall system cost may be less and the audience larger than for systems that use more efficient modulation techniques. While the PEP output of an AM transmitter is four times the carrier power, none of the carrier power is necessary to carry the information, as we will discuss in the next section.

### 13.5.2 Single-Sideband Suppressed-Carrier Transmission

The two sidebands of a standard AM transmitter carry (inverted) copies of the same information, and the carrier carries essentially no information. We can more efficiently transmit the information with just one of the sidebands and no carrier. In so doing, we use somewhat less than half the bandwidth, a scarce resource, and also consume much less transmitter power by not transmitting the carrier and the second sideband.

#### SSB — THE FILTER METHOD

The block diagram of a simple single-sideband suppressed-carrier (SSB) transmitter is shown in **Figure 13.40**. This transmitter uses a balanced mixer as a *balanced modulator* to generate a double sideband suppressed carrier signal without a carrier. That signal is then sent through a filter designed to pass just one (either one, by agreement with the receiving station) of the sidebands.

Depending on whether the sideband above or below the carrier frequency is selected, the signal is called *upper sideband (USB)* or *lower sideband (LSB)*, respectively. The resulting SSB signal is amplified to the desired power level and we have an SSB transmitter. Amateur practice is to use USB above 10 MHz and LSB on lower frequencies. The exception is 60 meter channels, on which amateurs are required to use USB for data and voice signals.

While a transmitter of the type in **Figure 13.40** with all processing at the desired transmit frequency will work, the configuration is not often used. Instead, the carrier oscillator and sideband filter are often at an intermediate frequency that is heterodyned to the operating frequency as shown in **Figure 13.41**. The reason is that the sideband filter is a complex narrow-band filter and most manufacturers would rather not have to supply a new filter design every time a transmitter is ordered for a new frequency. Many SSB trans-

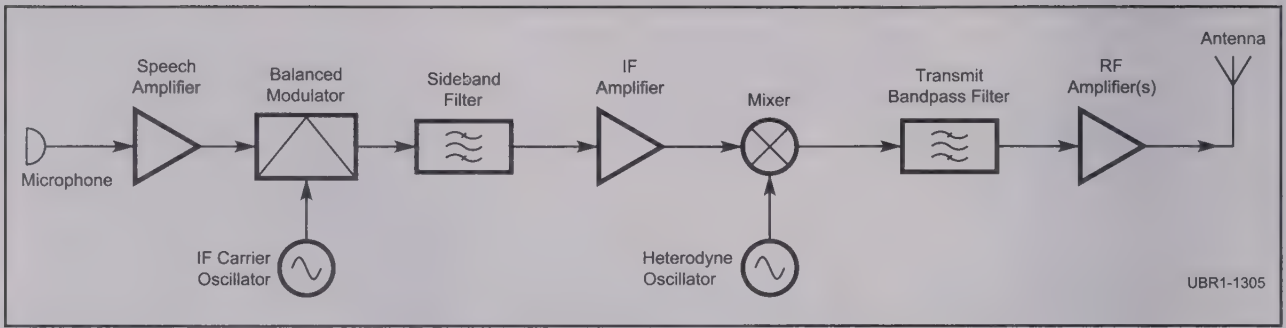

Figure 13.41 — Block diagram of a heterodyne filter-type SSB transmitter for multiple frequency operation.

mitters can operate on different bands as well, so this avoids the cost of additional mixers, oscillators and expensive filters.

Note that the block diagram of our SSB transmitter bears a striking resemblance to the diagram of a superheterodyne receiver except that the signal path is reversed to begin with information and produce an RF signal. The same kind of image rejection requirements for intermediate frequency selection that were design constraints for the superhet receiver applies here as well.

The filter method can be implemented by analog circuitry, using high-quality crystal filters to remove the unwanted sideband and a carefully adjusted balanced modulator to eliminate the carrier. An SDR can also implement the filter method by using very sharp DSP filters at a low frequency (carrier frequency less than 100 kHz) and then up-converting the signal to the desired RF frequency. As DSP hardware continues to improve in speed, this method should continue to grow in popularity

### SSB — THE PHASING METHOD

Most current transmitters use the method of SSB generation shown in Figure 13.40 to generate the SSB signal. That is the *filter method*, but really occurs in two steps — first a balanced modulator is used to generate sidebands and eliminate the carrier, then a filter is used to eliminate the undesired sideband, and often to improve carrier suppression as well.

The *phasing method* of SSB generation is exactly the same as the image-rejecting mixer described in the **Receiving** chapter. This uses two balanced modulators and a phase-shift network for both the audio and RF carrier signals to produce the upper sideband signal as shown in **Figure 13.42A**. By a shift in the sign of either of the phase-shift networks, the opposite sideband can be generated. This method trades a few phase-shift networks and an extra balanced modulator for the sharp sideband filter of the filter method.

While it looks deceptively simple, a limitation is in the construction of an analog phase-

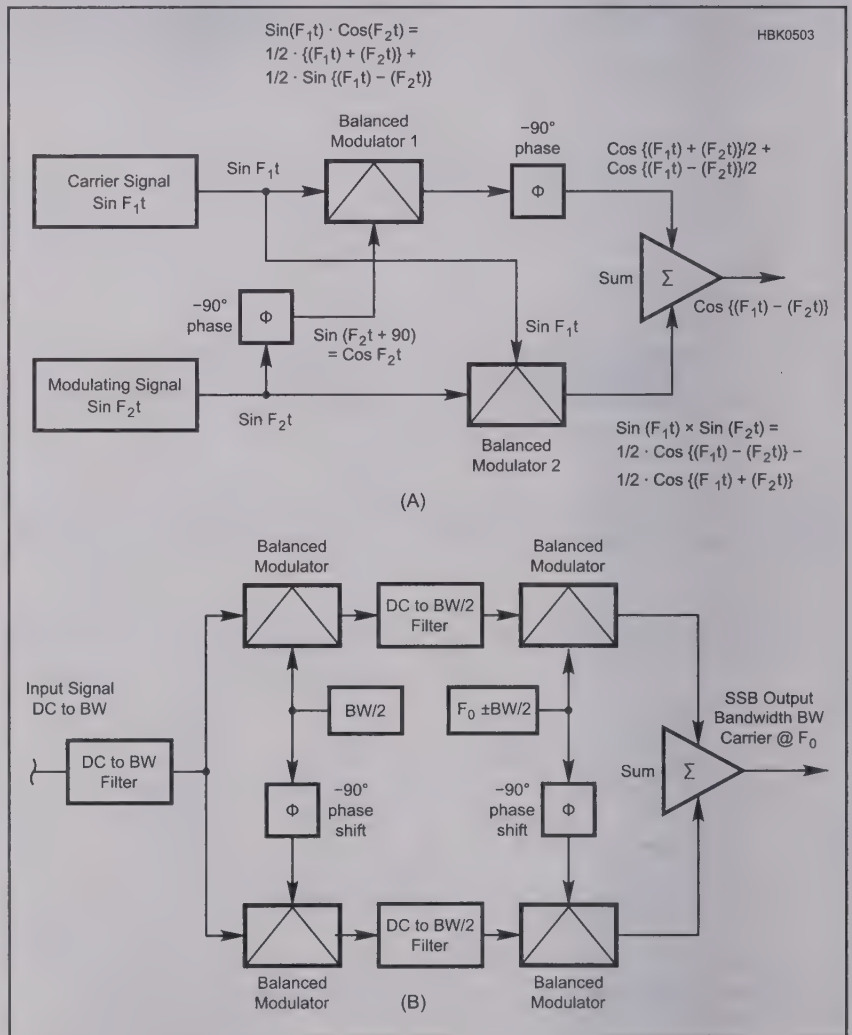

Figure 13.42 — Block diagram of (A) phasing type and (B) Weaver method SSB generators for single-frequency operation.

shift network that will have a constant 90° phase shift over the whole audio range. Errors in phase shift result in less than full carrier and sideband suppression. Nonetheless, there have been some successful examples offered

over the years.

The 90° phase shift network is also known as a Hilbert transformer after the mathematical operation it performs. Difficult to implement well in analog form, the phase shift is

straightforward to implement digitally. That makes the phasing method a good choice for SSB generation by an SDR transmitter.

### SSB — THE WEAVER METHOD

Taking the phasing method one step further, the Weaver method solves the problem of requiring phase-shift networks that must be aligned across the entire audio range. Instead, the Weaver method, shown in Figure 13.42B, first mixes one copy of the message

(shown with a bandwidth of dc to BW Hz) with an in-band signal at BW/2 Hz and another copy with a signal at BW/2 Hz that is phase-shifted by  $-90^\circ$ . Instead of phase-shifting the message, only the signal at BW/2 Hz must be phase-shifted — a much simpler task!

The output of each balanced modulator is filtered, leaving only components from dc to BW/2. These signals are then input to a second pair of balanced modulators with a more

conventional LO signal at the carrier frequency,  $f_0$ , offset by +BW/2 for USB and -BW/2 for LSB. The output of the balanced modulators is summed to produce the final SSB signal.

The Weaver method is difficult to implement in analog circuitry, but is well-suited to digital signal processing systems. The Weaver method has become common in DSP-based equipment that generates the SSB signal digitally.

## 13.6 Transmitting Angle Modulation

### 13.6.1 Angle-Modulated Transmitters

Transmitters using frequency modulation (FM) or phase modulation (PM) are generally grouped into the category of *angle modulation* since the resulting signals are often indistinguishable. An instantaneous change in either frequency or phase can create identical signals, even though the method of modulating the signal is somewhat different. To generate an FM signal, we need an oscillator whose frequency can be changed by the modulating signal.

We can make use of an oscillator whose frequency can be changed by a “tuning voltage.” If we apply a voice signal to the TUNING VOLTAGE connection point, we will change the frequency with the amplitude and frequency of the applied modulating signal, resulting in an FM signal.

The phase of a signal can be varied by changing the values of an R-C phase-shift network. One way to accomplish phase modulation is to have an active element shift the

Figure 13.43 — Simple FET-based phase modulator circuit.

phase and generate a PM signal. In Figure 13.43, the drain current through the field-effect transistor is varied with the applied modulating signal, varying the phase shift at the stage’s output. Because the effective load on the stage is changed, the carrier is also

amplitude-modulated and must be run through an FM receiver-type limiter in order to remove the amplitude variations.

### FREQUENCY MODULATION TRANSMITTER DESIGN

Frequency modulation is widely used as the voice mode on VHF for repeater and other point-to-point communications. Figure 13.44 shows the phase-modulation method, also known as *indirect FM*, as used in many FM transmitters. It is the most widely used approach to FM. Phase modulation is performed at a low frequency, say 455 kHz. Prior to the phase modulator, speech filtering and processing perform four functions:

1. Convert phase modulation to frequency modulation (see below).
2. Apply pre-emphasis (high-pass filtering) to the speech audio higher speech frequencies for improved signal-to-noise ratio after deemphasis (low-pass filtering) of the received audio.
3. Perform speech processing to emphasize

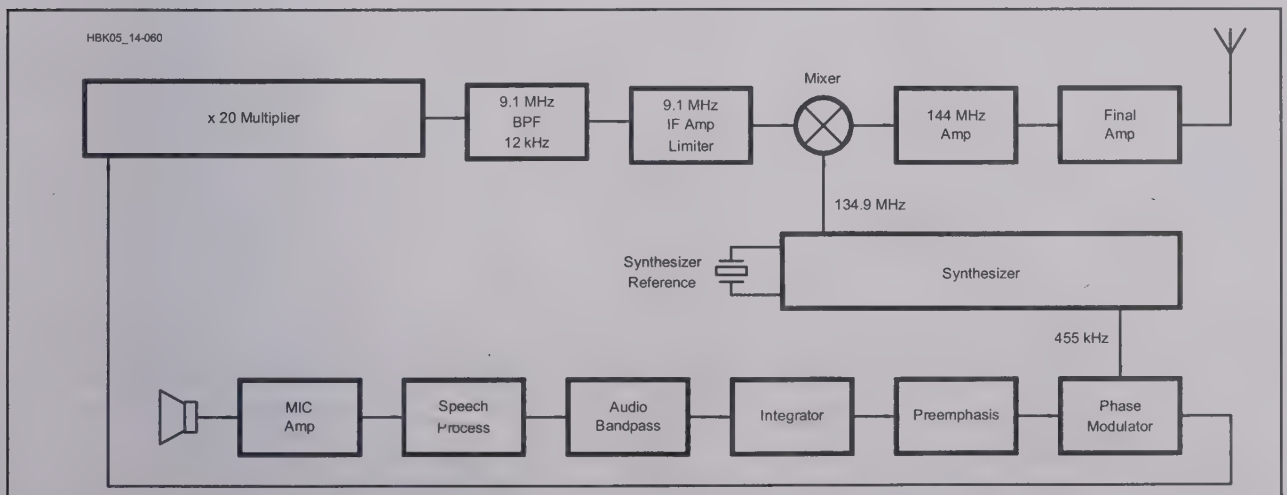

Figure 13.44 — Block diagram of a VHF/UHF NBFM transmitter using the indirect FM (phase modulation) method.

the weaker speech components.

4. Compensate for the microphone's frequency response and possibly also the operator's voice characteristics.

Multiplier stages then move the signal to some desired higher IF and also multiply the frequency deviation to the desired final value. If the FM deviation generated in the 455 kHz modulator is 250 Hz, the deviation at 9.1 MHz is  $20 \times 250$ , or 5 kHz.

### 13.6.2 Frequency Multipliers

Frequency multipliers are frequently used in FM transmitters as a way to increase the deviation along with the carrier frequency. They are composed of devices that exhibit high levels of harmonic distortion, usually an undesired output product. In this case the desired harmonic is selected and enhanced through filtering. The following examples show the way this can be done, both with amplifiers and with passive diode circuits. (Additional discussion of frequency multipliers can be found in Chapter 5.4 of *Experimental Methods in RF Design* and in the "VHF Signal Sources" article by Rick Campbell, KK7B which is included in this book's downloadable supplemental content.)

A passive multiplier using diodes is shown in **Figure 13.45A**. The full-wave rectifier circuit can be recognized, except that the dc component is shorted to ground. If the fundamental frequency ac input is  $1.0 V_{RMS}$ , the second harmonic is  $0.42 V_{RMS}$  or 8 dB below the input, including some small diode losses. This value is found by calculating the Fourier series coefficients for the full-wave-rectified sine wave, as shown in many textbooks.

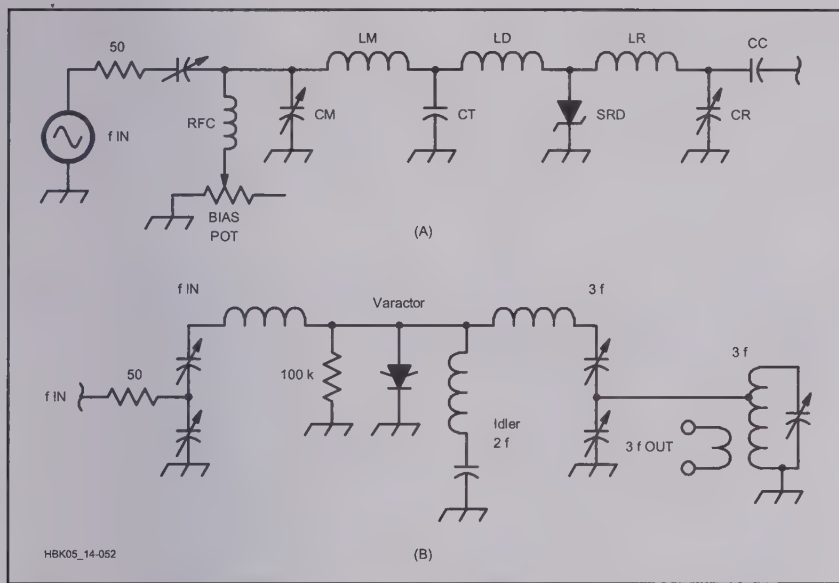

Transistor and vacuum-tube frequency multipliers operate on the following principle: if a sine wave input causes the plate/collector/drain current to be distorted (not a sine wave) then harmonics of the input are generated. If an output resonant circuit is tuned to a harmonic, the output at the harmonic is emphasized and other frequencies are attenuated. For a particular harmonic the current pulse should be distorted in a way that maximizes that harmonic. For example, for a doubler the current pulse should look like a half-wave rectified sine wave ( $180^\circ$  of conduction). A transistor with Class B bias would be a good choice. For a tripler, use  $120^\circ$  of conduction (Class C).

An FET, biased at a certain point, is very nearly a *square-law* device as described in the **Electrical Fundamentals** chapter. That is, the drain-current change is proportional to the square of the gate-voltage change. It is then an efficient frequency doubler that also de-emphasizes the fundamental.

A push-push doubler is shown in Figure 13.45B. The FETs are biased in the square-

**Figure 13.45 — Frequency multipliers. A: diode doubler. B: push-push doubler using JFETs. C: single-ended multiplier using a BJT. D: push-pull tripler using BJTs.**

**Figure 13.46 — Specialized diode frequency multipliers. A: step-recovery diode multiplier. B: varactor diode multiplier.**

law region and the BALANCE potentiometer minimizes the fundamental frequency. Note that the gates are in push-pull and the drains are in parallel. This causes second harmonics to add in-phase at the output and fundamental components to cancel.

Figure 13.45C shows an example of a single-ended doubler using a bipolar transistor. The efficiency of a doubler of this type is typically 50%, that of a tripler 33%, and of a quadrupler 25%. Harmonics other than the one to which the output tank is tuned will appear in the output unless effective band-pass filtering is applied. The collector tap on L1 is placed at the point that offers the best compromise between power output and spectral purity.

A push-pull tripler is shown in Figure 13.45D. The input and output are both push-pull. The balance potentiometer minimizes even harmonics. Note that the transistors have no bias voltage in the base circuit; this places the transistors in Class C for efficient third-harmonic production. Choose an input drive level that maximizes harmonic output.

The step recovery diode (SRD) shown in **Figure 13.46A** is an excellent device for harmonic generation, especially at microwave frequencies. The basic idea of the SRD is as follows: When the diode is forward conducting, a charge is stored in the diode's diffusion capacitance, and if the diode is quickly reverse-biased, the stored charge is very suddenly released into an LC harmonic-tuned circuit. The circuit is also called a "comb generator" because of the large number of

harmonics that are generated. (The spectral display looks like a comb.) A phase-locked loop (PLL) can then lock onto the desired harmonic.

A varactor diode can also be used as a multiplier. **Figure 13.46B** shows an example. This circuit depends on the fact that the capacitance of a varactor changes with the instantaneous value of the voltage across it, in this case the RF excitation voltage. This is a nonlinear process that generates harmonic currents through the diode. Power levels up to 25 W can be generated in this manner.

Following frequency multiplication, a second conversion to the final output frequency is performed. Prior to this final translation, IF band-pass filtering is performed in order to minimize adjacent channel interference that might be caused by excessive frequency deviation. This filter needs good phase linearity to assure that the FM sidebands maintain the correct phase relationships. If this is not done, an AM component is introduced to the signal, which can cause nonlinear distortion problems in the PA stages. The final frequency translation retains a constant value of FM deviation for any value of the output signal frequency.

The IF/RF amplifiers can be nonlinear Class C amplifiers because the signal in each amplifier contains, at any one instant, only a single value of instantaneous frequency and not multiple simultaneous frequencies whose relationship must be preserved as in SSB. These amplifiers are not sources of IMD, so they need not be "linear." The sidebands that

appear in the output are a result only of the FM process. (The spectrum of an FM signal is described by Bessel functions.)

In phase modulation, the frequency deviation is directly proportional to the frequency of the audio signal. (In FM, the deviation is proportional to the audio signal's amplitude.) To make deviation independent of the audio frequency, an audio-frequency response that rolls off at 6 dB per octave is needed. An op-amp low-pass circuit in the audio amplifier accomplishes this function. This process converts phase modulation to frequency modulation.

In addition, audio speech processing helps to maintain a constant value of speech amplitude, and therefore constant IF deviation, with respect to audio speech levels. Pre-emphasis of speech frequencies (a 6 dB per octave high-pass response from 300 to 3000 Hz) is commonly used to improve the signal-to-noise ratio at the receive end. Analysis shows that this is especially effective in FM systems when the corresponding de-emphasis (complementary low-pass response) is used at the receiver. (See reference for Schwartz.) By increasing the amplitude of the higher audio frequencies before transmission and then reducing them in the receiver, high-frequency audio noise from the demodulation process is also reduced, resulting in a "flat" audio response with lower hiss and high-frequency noise.

An IF limiter stage may be used to ensure that any amplitude changes that are created during the modulation process are removed. The indirect-FM method allows complete frequency synthesis to be used in all the transmitter local oscillators (LOs), so that the channelization of the output frequency is very accurate. The IF and RF amplifier stages are operated in a highly efficient Class-C mode, which is helpful in portable equipment operating on small internal batteries.

FM is more tolerant of frequency misalignments between the transmitter and receiver than is SSB. In commercial SSB communication systems, this problem is solved by transmitting a *pilot carrier* with an amplitude 10 or 12 dB below the full PEP output level. The receiver is then phase-locked to this pilot carrier. The pilot carrier is also used for squelch and AGC purposes. A short-duration "memory" feature in the receiver bridges across brief pilot-carrier dropouts, caused by multipath nulls.

In a "direct FM" transmitter, a high-frequency (say, 9 MHz or so) crystal oscillator is frequency-modulated by varying the voltage on a varactor diode. The audio is pre-emphasized and processed ahead of the frequency modulator as for indirect-FM.

# 13.7 Effects of Transmitted Noise

With receiver sensitivity, selectivity, and linearity having reached extraordinary levels of performance, a reduction in transmitted spurious emissions is clearly in the best interests of all amateurs. It does us no good to spend time and effort creating an exceptional receiver if the channel is filled with transmitted noise and distortion products! (See the article by Grebenkemper in the Reference section.)

In heterodyne transmitters the last mixer and the amplifiers after it are wideband circuits, limited only by the harmonic filters and by any selectivity that may be in the antenna system. Wide-band phase noise transferred onto the transmitted modulation by the last LO (almost always a synthesizer of some kind) can extend over a wide frequency range; therefore LO cleanliness is always a matter of great concern.

The amplifiers after this mixer are also sources of wide-band “white” or additive noise. This noise can be transmitted even during times when there is no modulation, and it can be a source of local interference. To reduce this noise, use a high-level mixer with as much signal output as possible, and make the noise figure of the first amplifier stage after the mixer as low as possible.

SDR transmitters may not have analog mixers but they certainly have data converters and many processes that generate phase noise through clock jitter, non-linear data conversion, and other causes, even rounding errors! The result — heard on the air as transmitted noise — causes the same problems as noise generated by an analog transmitter. **Figure 13.47** is a collection of composite noise (phase noise) and CW keying sideband noise from several current transceivers evaluated by the ARRL Lab during product review assessments. The data is from a single band (14 MHz) and does not represent either the best or worst performance. This chart was initially created in 2014 from that data by Jim Brown, K9YC, to compare the noise performance of several transceivers. (The FT1000MP Mark V Field legacy spectrum shows the improved performance available today.) The data points on the graph represent noise peaks from the measured noise spectra. For the CW sideband noise data, a comparison of averaged and smoothed data is available in K9YC's online paper referenced at the end of this section. The paper also includes data for several older transceiver models.

There is quite a bit of difference between the various models as described in the *QST* Product Reviews. The variation shows why it is important for amateurs to pay attention to noise performance specifications, espe-

cially if they plan on operating in the crowded HF bands. With many transceivers now offering upgradable firmware, amateurs are strongly encouraged to install the latest version. This will improve performance on both receive and transmit, as well as help all of us

transmit cleaner signals on the air.

Transmitted noise plays the same role in interference as receiver phase noise. The two are ultimately additive and interference becomes a “weakest link” problem in that poor noise performance of the receiver or the

## Noise Consideration for Antenna Layout

By Steve Hicks, N5AC

Transmitted noise is a point to consider when laying out the antennas at a multi-transmitter site like Field Day or a contest station. For every 10 dB stronger any given signal appears in the receiver, another 10 dB improvement in phase noise performance is required to ensure interference-free operation. A poor antenna layout that produces very strong signals in receivers when local transmitters are operating can render even the best phase noise performance receivers inoperable. George Cutsogeorge, W2VJN's book *Managing Interstation Interference* (available from Inrad ([www.inrad.net](http://www.inrad.net))) is an excellent reference for station planning and interference mitigation techniques.

**Figure 13.47** — Transmitted composite noise (A) and keying sidebands (B) from a selection of representative modern transmitters measured by the ARRL Lab. These graphs are based on ARRL Lab test data published in *QST* Product Reviews, following graphs originally created by Jim Brown, K9YC

transmitter can be the culprit in an interference problem. While both amplitude and phase noise contribute to transmitted composite noise, most of the noise contribution is phase noise from the various oscillators and clock signals in the transceiver. (The effects of receiver phase noise are addressed in the **Receiving** chapter.)

In a multiple-transmitter operation such as Field Day or a contest station, a single radio with poor transmitted noise performance can render all of the receivers at the site useless. Similarly, a receiver with poor phase noise performance can suffer from interference issues regardless of how good the performance of co-located transmitters is. In situations where multiple radios are brought to a

single location for a joint operation, transmit phase noise is typically more strongly scrutinized since a single poor performer in the transmit phase noise arena can render the whole operation a failure.

Transmitted noise is not just a problem when multiple stations are at one site. Poor noise performance at full power can have an adverse effect on other stations for miles around. In competitive environments, noise from a closely-spaced strong signal can render adjacent channels nearly unusable. Under normal circumstances, transmitted noise raises the noise floor everywhere there is propagation. After decades of receiver improvement, it is important for amateurs to pay closer attention to transmitted noise performance.

The ARRL Lab measures transmitted noise as part of Product Reviews for *QST* magazine. These tests are described in the **Test Measurements and Equipment** chapter and in the book *Amateur Radio Transceiver Performance Testing* by Bob Allison, WB1GCM, ARRL Lab Staff Engineer. Individual transceiver performance is documented in the *QST* Product Review. In addition to creating Figure 13.47, Jim Brown, K9YC has compiled the information from these reviews in an online paper, “Comparison of ARRL Lab Data for Selected Transceivers” which is available at [k9yc.com/publish.html](http://k9yc.com/publish.html). Figure 13.47 is typical of the many figures in the paper comparing various noise measurements.

## 13.8 Microphones and Speech Processing

### 13.8.1 Frequency Content of Speech

Human speech has content from about 100 Hz to 8 kHz, but only the energy between about 400 Hz and 4 kHz contributes to speech intelligibility. Vocal content below 400 Hz provides “body” to the voice (great for singers and radio announcers), but that low frequency output of the microphone also contains breath pops, room noise, microphone handling noise, wind noise, and reverberation. This low frequency energy can easily be as much as half of the power picked up by the microphone, but it contributes nothing to communications, so it wastes transmitter power.

Likewise, speech content above 3 kHz provides “presence” and helps communications a bit, but the added bandwidth adds noise (and QRM to and from other stations). Most SSB transmitting filters are 2.7 kHz wide, so a well-adjusted radio will align those filters so that they pass audio between 400 Hz and 3.1 kHz. A few radios allow the user to adjust this setting via a configuration menu.

These bandwidth limits for speech communications were established in the earliest days of long distance telephony — they allow what’s necessary, but nothing extra. Over more than a century, they have allowed more and more conversations to be packed into less and less bandwidth.

Thus, our first rule is to minimize any part of the audio signal below about 400 Hz, and to not waste bandwidth transmitting sound above 3 kHz. We have several controls over this. First, we can choose a microphone without excess low frequency response. See

“Choosing a Microphone” later in this section. Many transceivers provide menu settings to tailor the audio frequency response. Study the manual to understand and choose settings for your radio.

Some newer transceivers make it even easier to tailor the frequency response — they have a built-in octave-band equalizer covering the speech range. (An octave is a 2:1 frequency step). Each band can be set for up to 18 dB of boost or cut in 1 dB steps. A good starting point for most microphones and voices is maximum cut of the three lowest bands (50, 100, 200 Hz), and 3–6 dB cut of the fourth band (400 Hz) leaving all other bands set flat (no boost or cut). Some microphone or voices may benefit from a bit more cut at 400 Hz or from 3-6 dB of cut or boost in the two highest bands. Save these adjustments for when you have a trained listener to advise you.

### 13.8.2 Dynamics Processing

The loudness of speech varies over a wide range as we speak, sometimes by as much as 20 dB. The audio section of our transmitter must be adjusted so that we never overmodulate, which causes interference on adjacent frequencies (splatter), but keeping audio level as close as practical to 100% modulation makes our signal louder at the other end. Modern transceivers include peak limiters to prevent overmodulation on loudness peaks and compressors to increase the audio gain for quieter parts of speech. When well-designed and carefully adjusted, these circuits work well, increasing our “talk power,” but

when badly adjusted, cause transmitted audio to be distorted, mushy, dull, and hard to understand.

The strength of sound falls off with distance from the source by inverse square law, just as RF field strength falls off with distance from the antenna. Doubling (or halving) the distance between microphone and mouth causes loudness to change by 6 dB. A boom microphone attached to a headset helps maintain more constant level by keeping the microphone element at a fixed distance.

To adjust these circuits, first set equalization as in the previous section, then set microphone gain so that normal speech causes near 100% modulation with compression disabled. Then set the transceiver display to show compression and adjust compression (or processing) to provide about 10 dB gain reduction on voice peaks. While radios can be set for more compression, few sound very good with more than 10 dB, and too much compression can make speech hard to copy. (On some transceivers, compression may be called “processing.”) The combined effect of equalization to eliminate speech content below 400 Hz and using 10 dB of compression is about 13 dB, which is equivalent to multiplying transmitter power by a factor 20!

### 13.8.3 Types of Microphones

Most common microphones in the amateur station are one of two basic types:

*Dynamic microphones* operate on the same principle as a loudspeaker, (a coil mounted to a diaphragm is moved by varying magnetic field that surrounds it makes air vibrate) but

in reverse (vibration moves a diaphragm in the microphone, generating a voltage in the coil as it moves within the magnetic field). A loudspeaker works pretty well as a microphone, and has been used that way for more than half a century in intercom systems.

**Electret condenser microphones** are very different — the diaphragm is one plate of a capacitor; a voltage is applied between the two plates (the other being fixed). The source impedance is quite high (megohms), and must be transformed to a lower impedance by a FET follower built into the microphone (so that what it feeds doesn't load down the microphone). The electret capsule is pre-polarized, but the FET follower needs a small positive voltage fed through a load resistor to operate. This is referred to as *bias voltage* and it is applied to the output of the microphone: 8 V dc through a 5.6 k $\Omega$  resistor is typical. (Note that if bias voltage is applied to a dynamic microphone element, the result will be muffled, low-volume audio. If the radio's microphone connection supplies bias voltage, a series blocking capacitor of 0.1 to 1  $\mu$ F should be used to remove the bias voltage.)

Both electrets and dynamic microphones are available with an *omnidirectional* pattern (picks up equally in all directions) or a *cardioid* pattern (picks up better in front of the microphone with a null to the rear). Cardioids can be thought of as "half space" microphones, meaning they pick up sounds from anywhere in front of the microphone but reject sound from all directions to the rear.

Cardioid microphones have an important characteristic called *proximity effect*, which is a very strong bass boost for sound sources very close to the microphone. In addition to making voices "bass heavy," proximity effect magnifies breath pops, wind noise, and handling noise. Virtually all microphones used in live sound are cardioids, and those intended for use by singers have a strong low frequency rolloff that partially compensates proximity effect. Although cardioids reduce room noise pickup, proximity effect generally makes them a poor choice in the ham shack. A microphone designed for radio communications is a better choice.

Cardioids work on the principle of acoustic cancellation between sound reaching the element via front and rear openings of the microphone housing. (Omnidirectional microphones have a single opening). Proximity effect is the result of that process and there being a single front opening and a single rear opening.

An important variation of the cardioid microphone is built with extra openings spaced along the length of the handle, which greatly reduces proximity effect. The ElectroVoice (EV) 664 and 666 were the first popular microphones of this type, which are

called "variable-D" (for the variable distant openings), as opposed to "single-D" cardioids with a single rear opening. If you're looking for a good used pro-quality microphone for your ham station, the variable-D EV RE10, 11, 15, 16, 18, 20, and 27, and the Shure SM53 and SM54 are great choices. All but the RE16, 20, and 27 are long discontinued, but dynamic microphones last indefinitely as long as they are not badly mistreated, so buying used from a trustworthy source is a good option.

An omnidirectional microphone, whether dynamic or an electret, or one of the variable-D models listed above, are the best choice for ham radio. They have no proximity effect, so can be used close to the mouth. This minimizes breath pops, while still being close enough to minimize room noise. The soft foam supplied with many microphones is intended to reduce breath pops.

### MICROPHONE EQUALIZATION

Beginning in the late 1950s, Shure introduced the model 440, the first microphone designed specifically for SSB transmission. The modern version is the 444D. These are omni-directional mics with the recommended equalization built in — low frequency response rolling off below 400 Hz and a pronounced peak around 3 kHz that compensates for some of the loss in the SSB transmit filter. These are excellent sounding microphones and are primarily desktop models. Most microphones in the Heil line use the same concepts.

### 13.8.4 Using a Professional or PC Microphone

Pro microphones are balanced and are designed to feed balanced inputs using shielded, twisted pair cables, while ham microphones and rigs use unbalanced wiring. Pro electret microphones cannot easily be used with ham gear (because of the method used to power the balanced microphone's FET follower output stage).

Pro dynamic microphones work well and are easy to connect with ham gear. Their 3-pin XL-connector comes wired for balanced circuits — Pin 1 is the shield, Pins 2 and 3 carry the signal. To connect them to your ham rig with shielded twisted pair, wire the shield to the shell of the microphone connector and connect the signal pair to MIC and MIC RETURN (or MIC GND).

Alternatively, with coaxial cable between the microphone and the radio, wire the cable shield to pin 1 and 3 at the microphone and the center conductor to pin 2. At the radio's microphone connector, wire the center conductor to the radio's MIC input and wire the cable shield both to MIC RETURN and to the connector shell.

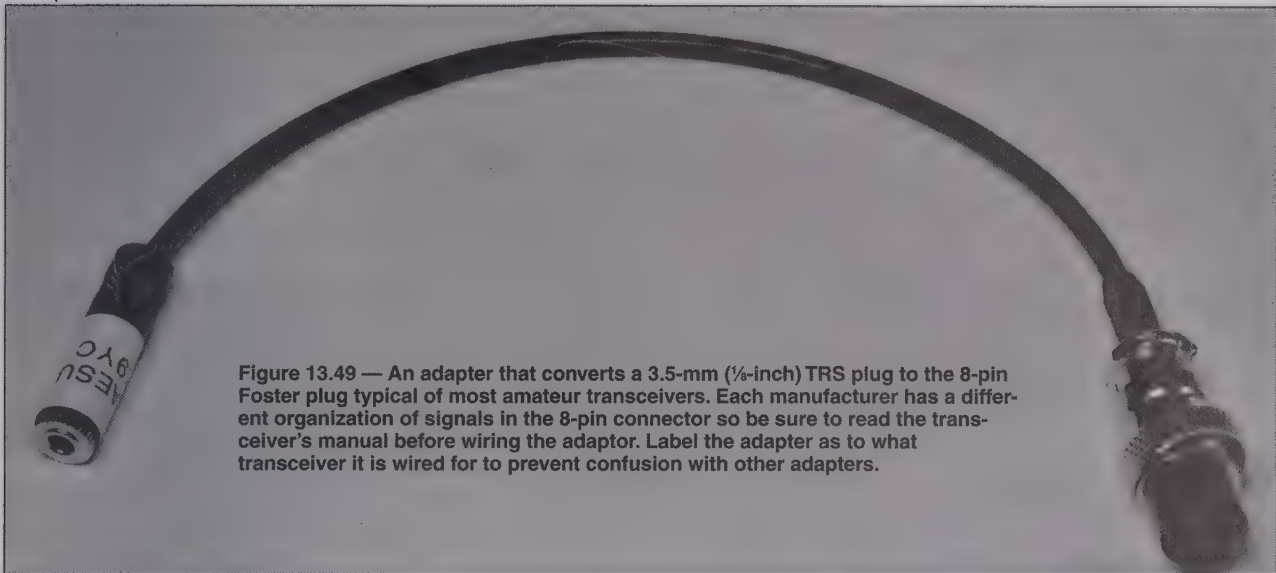

Pro microphones generally have uniform

("flat") frequency response. They have more bass response than communications microphones and lack the boost around 3 kHz, so they generally require more equalization. The low frequency rolloff in audio circuits is set by the time constant of interstage coupling capacitors and their resistive load. Using a smaller value capacitor raises the -3dB frequency ( $X_C = R$ ) producing a gentle low frequency rolloff (6 dB/octave). In transmitters that lack an equalizer, raising the -3dB frequency to 1-2 kHz (by reducing those time constants) can provide much of the equalization needed to make a pro microphone produce good communications audio.

Headsets with a microphone attached made for use with computers work well with ham transceivers. **Figure 13.48** illustrates good placement that minimizes breath pops and allows an occasional sip of water or coffee. Most of these microphones are electrets with both headphones and microphone wired to 3.5-mm ( $\frac{1}{8}$ -inch) phone plugs (also known as TRS or tip-ring-sleeve plugs). Almost any of these headsets will work with ham transceivers, but some are far more comfortable than others. The Yamaha CM500 and Koss SB-45 and CS-100 are popular with contesters and DXers. All that is needed is a cable adapter to a Foster plug (the round 8-pin connector used on most transceivers) to mate with the 8-pin microphone connector on transceivers that lack a 3.5 mm microphone jack.

**Figure 13.48** — Using a computer-style headset electret boom microphone. Place the microphone far enough from your mouth to avoid picking up excessive noise from breathing and pops from speech. Balance the placement for normal speech levels while minimizing pickup of room and fan noise. On-the-air testing is important to account for your station circumstances and speaking style.

**Figure 13.49** — An adapter that converts a 3.5-mm (1/8-inch) TRS plug to the 8-pin Foster plug typical of most amateur transceivers. Each manufacturer has a different organization of signals in the 8-pin connector so be sure to read the transceiver's manual before wiring the adaptor. Label the adapter as to what transceiver it is wired for to prevent confusion with other adapters.

Adapters for RJ-45 microphone connectors are also available. **Figure 13.49** shows a typical adapter you can build yourself.

To make the adapter, you'll need a cable-mount plug to mate with your radio and a female 1/8-in TRS jack to mate with the TRS plug on the headset. Check the manual for your transceiver for wiring of the microphone connector and label the adapter.

To connect the microphone to the radio, run a single-conductor shielded cable (such as mini-coax or braid-shielded audio cable) from the tip of the TRS jack to the microphone input pin of the Foster plug, connecting the cable shield to the sleeve of the TRS jack and the shell of the Foster plug.

Nearly all modern radios supply bias voltage in the range of 8 V on one pin of the microphone connector; wire a 5.6 kΩ resistor between that pin and the MIC pin. This resistor can have a very low power rating, so it's usually possible to fit it inside the Foster plug. Buy Foster plugs from ham vendors; female TRS jacks can be bought from pro audio vendors such as Full Compass and Sweetwater. (Neutrik part number NYS240BG is typical.)

### 13.8.5 Optimizing Your Microphone Audio

Summarizing the steps to optimize audio for communications:

- 1) Set your radio to minimize audio content below 400 Hz and above 3.2 kHz.
- 2) Keep the distance between microphone and mouth as constant as possible. A boom microphone attached to a headset solves this problem.
- 3) Get audio gains set right: adjust the mic input of the radio (or of the computer), the

## Computer Audio Formats

### Bits and Kilobits Per Second

The number of bits in a digital system (called the bit depth) sets the limit for its maximum dynamic range. An ideal 16-bit system would provide 96 dB of dynamic range (the difference between the highest and lowest instantaneous voltage that it can accurately reproduce). The dynamic range of real products is a few dB less. Each additional bit doubles the range of voltage that can be reproduced, and double (or half) the voltage is a change of 6 dB. Thus, a 12-bit system should be capable of a few dB less than 72 dB dynamic range.

The bit rate of a digital system, expressed in kilobits/sec (kbps), sets the limit for its audio bandwidth, which is 90% of half the numerical value, in kHz. Thus, a 48 kHz system can provide about 22 kHz audio bandwidth. When a sound card is used as part of a spectrum display, the maximum displayed bandwidth in kHz is equal to the maximum bit rate in kbps. Most computer sound cards and sound recording software can operate at standard sample rates and bit depth less than their maximum value, and most software that uses a computer sound system can vary these settings either automatically or as desired by the user.

The size of a sound file depends both on its bit depth and bit rate. A 12-bit sound file recorded at 12 kbps provides audio bandwidth of about 5 kHz with about 70 dB of dynamic range, and is a good choice for use in Amateur Radio. Uncompressed sound files recorded in this format require about 16 kB on a hard drive for each second of recording time for each channel of audio recorded.

### Audio Data Compression

Audio and video signals in digital form can be compressed to reduce both the bandwidth needed to transmit them and the size of files needed to contain them. Compression systems like MP3 use smart algorithms to approximate the audio by leaving out parts of the waveform that the ear/brain is unlikely to miss. On playback, the system guesses at what parts were left out and adds them back in. Such systems are referred to as lossy compression because they do not provide a perfect copy of the original digital signal. Lossless systems like the ZIP or FLAC (Free Lossless Audio.Codec) formats, do provide an exact copy of the original. ZIP provides very little compression of uncompressed sound files, but FLAC can reduce file size by about one half.

While file compression can save space on a hard drive, it takes time for the compression and de-compression algorithms to operate. MP3 compression is a great choice for recording a QSO, but a poor choice for recording messages for playback during a contest. MP3 compression can reduce file size (and transmission bandwidth) by 75-95% (that is, files and bandwidth between 5% and 25% of their uncompressed size).

USB sound cards designed for semi-pro audio users and even for gamers are usually good performers. They are often significantly better than the sound cards built into computers, especially laptops. An inferior quality sound card can degrade the decoding capability of software for digital modes. Some semi-pro units have LEDs to indicate safe signal levels — for example, green for good level, red for overload (also called "digital clip").

output gain of the computer sound card, and/or the line input of the radio.

4) Set processing for an indicated 10 dB on voice peaks.

5) Resist the urge to turn up mic gain or compression — once levels have been set as described here, turning it up louder makes your voice sound *worse*, not better.

You should also make sure the transmitter RF controls are set properly:

6) Tune the RF power amp carefully.

7) Don't overdrive the RF amp, and don't use ALC to set TX power.

8) If your radio requires a nominal 13.8 V dc power supply, make sure the supply is as close to 14 V as possible.

### 13.8.6 Setting Levels for Digital Modes

#### SETTING SOUND CARD INPUT LEVEL

This is important to achieving maximum signal-to-noise performance. For units with a digital clip indicator (see the sidebar), simply turn up the input gain until the red light flashes with the loudest signals, then back it off slightly so that it never flashes. Then set the digital gain in your encode/decode software as directed by the manual.

#### SETTING SOUND CARD OUTPUT LEVEL

It is just as important to avoid transmitting a distorted or overmodulated signal. There are three steps, all of which are important: (1) making the output of the computer clean, (2) not overdriving the radio's audio input stage, and (3) setting the audio input gain in the radio. There are (at least) four good ways to set output level from the computer, depending on what test equipment is available.

The first method uses an oscilloscope connected to the output of the sound card (in this case, the USB interface) that feeds the radio. Set the sweep so that you see clearly defined sine waves that make up the signal from the digital program (RTTY, PSK, WSJT modes, and so on) in transmit mode. Because these modulation schemes include multiple frequencies, you probably won't get the display to sync. Increase the output level until you see squaring at the top of the sine waves or "spiky" digital distortion, then reduce the output level by half the voltage.

The second method uses an audio spectrum analyzer connected to the output of the sound card. With the digital program in transmit mode and output level set fairly low, note the spectrum lines. With JT65, you should see only the tones that you would see on the WSJT-X or JT65-HF display, roughly 200 Hz wide. With RTTY, you should see only two tones spaced by 170 Hz. With JT9

or PSK, you should only see a single tone. Now, increase levels until you begin to see additional lines spread out from the normal tones. These additional lines are distortion products, and will cause QRM. Note the *difference* in strength (in dB) between the signal tones and the distortion, then gradually increase output level until you see the difference become smaller (which indicates that the percentage distortion is rising). Now, back off the output level until the difference is larger (the distortion is much less). With proper adjustment, the distortion products should be at least 40 dB below the tones.

The third method uses an audio voltmeter connected to the output of the sound card. With the digital program in transmit mode, start with very low output, and gradually increase it until you no longer see voltage increasing, then back off the output level to one-half the maximum measured voltage.

The fourth method uses your ears and headphones connected to the output of the sound card. Start with the output of the sound card set low, gradually increasing it until you hear harshness or sharpness in the tones. That harshness is the distortion products. Now, reduce the output of the sound card until the tones sound half as loud. This works because a change of 6-10 dB is perceived as half (or twice) as loud.

#### FEEDING COMPUTER AUDIO TO THE RADIO

To avoid overdriving the radio's audio input, feed the computer sound card to the radio's LINE IN input (if there is one). In older rigs, this may be labeled as a phone patch input, or for use with a hardware RTTY interface.

If the rig has no line input, you'll need to feed the microphone input through a simple voltage divider (often called a "pad" — see the sidebar) so that you don't overload the microphone preamp. All it takes is two resistors, one in series with the audio path, and one in parallel with the input of the radio. 20 dB (a 10:1 voltage divider) of attenuation should be enough for most radios, and calls for a 10:1 ratio between the two resistors. The values are not critical, but 10 k $\Omega$  for the series resistor and 1 k $\Omega$  for the parallel resistor, or 4.7 k $\Omega$  and 470  $\Omega$  are good choices. Low-wattage resistors may be used here, and can fit within the connectors of the patch cable between the computer and the radio if you use the right connector. RCA and 1/8-inch connectors made by Switchcraft have the most space inside them. Neutrik is also a good brand.

With all of these methods, adjust the input gain control of your radio according to the user manual for the radio for transmitting digital modes. Always make sure that any

processing in the radio is turned off.

As a final check, ask another amateur who is receiving your signal fairly well to look carefully for sidebands in the received waterfall display (first making sure that the noise blanker is turned off, and that you are not overloading the receiver).

### Microphone Pads

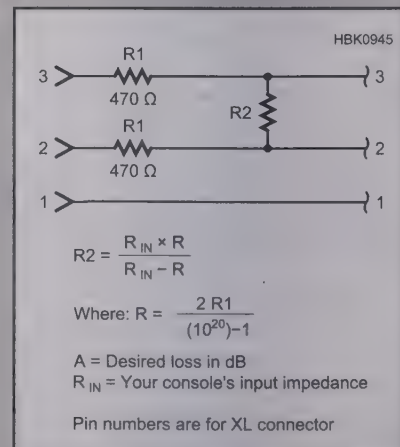

(The following material was contributed by Ethan Winer. More design information is available on his website: [ethanwiner.com/gadgets.html](http://ethanwiner.com/gadgets.html).)

The balanced microphone attenuator or *pad* shown in **Figure 13.A1**, is about as basic a circuit as you're likely to encounter. But finding the optimum resistor values can be a challenge for the beginner, and a time consuming nuisance for the more advanced.

**Figure 13.A2** shows the same general configuration, except this circuit yields a low-end rolloff beginning at a frequency dictated by the resistor and capacitor values. Notice that the designation "R1" does not appear in this diagram. The same component numbering is used throughout the figures to make the formulas easier to understand. Also note that the low-cut circuit in **Figure 2** will not pass bias voltage (also known as *phantom power* in professional audio).

Exchanging the capacitors and resistor in **Figure 13.A2** results in a high-frequency loss (**Figure 13.A3**), while adding an inductor allows adjusting the midrange response for boosting presence or controlling sibilance (**Figures 13.A4A** and **13.A4B**).

One problem with inductors is their inherent series resistance, which is

**Figure 13.A1** — Basic microphone attenuation pad.

## 13.8.7 Speech Amplification and Processing

### AUDIO SIGNAL LEVELS

The output level of most modern microphones ranges from about 10 mV to a few hundred mV when used close to the mouth. Microphone inputs are designed to accept signals in this range and are likely to be over-

inevitable due to the wire they're made from. The smaller (physically) a given inductor is built, the higher the resistance since the wire must be a smaller diameter. The Mouser 43LH and 43LJ series inductors minimize this by winding the wire around a ferrite core. At low currents the ferrite core does a

great job of increasing the inductance without requiring as many turns of wire, which keeps the series resistance relatively low. Also, these coils are encapsulated in a rugged phenolic case which eliminates the danger of damaging the hair-thin wires during assembly.

### IMPEDANCE IN AUDIO CIRCUITS

Since solid-state electronics became standard, audio circuits are no longer impedance-

matched. Instead, audio circuits are voltage-matched. *Output* circuits have a low source impedance, typically around 100 Ω for pro line level, 300 Ω for consumer line level, and around 200 Ω for most modern microphones. Audio *input* circuits have a high input impedance, typically 10 kΩ for pro line level inputs, 50 kΩ for consumer line level inputs, and at least 1 MΩ for microphone inputs.

loaded by stronger signals. In addition to microphone inputs, most ham equipment also features line-in inputs that are designed to accept signals between about 100 mV and 2 V.

For the midrange networks shown in this sidebar you can expect to alter the response by about 4 or 5 dB, though this can be varied by adjusting R2 up or down in value. With the high- and low-end rolloffs, the cutoff slope is 6 dB per octave beyond the chosen frequency. This rolloff rate is hard to change because additional capacitors and resistors would be needed. That not only complicates the design, but also reduces the signal level overall.

### Construction Notes

The pads can be constructed in the usual metal enclosures. Note that the S3FM connector assembly made by Switchcraft — a 3.5-inch tube fitted with a male XL (or XLR) at one end and a female at the other — has enough room in the middle to build a mike pad, low-end rolloff network, polarity reverser, or any number of other useful little gadgets.

With space generally at a premium in any small enclosure, you must use the smallest components you can find. For microphone-level signals you can use 1/8-watt resistors. Another space saver is to use low-voltage capacitors. When the component values are large, such as the low-frequency rolloff, tantalum capacitors are the best choice and you may be able to find ultra-miniature types rated as low as 6 or even 3 V. Tantalums cost more than standard electrolytics, but they are smaller and generally higher quality.

Use shrink-fit sleeving over all of the components or otherwise ensure that the components don't short out to one another. The S3FM comes with a plastic-coated cardboard tube that lines the inside of the case, and this prevents any wires from touching the grounded case. Clear shrink tubing lets you see what parts are inside — a definite advantage if you have to take it apart for repair or just to see what's in there. Avoid black electrical tape for insulation; not only can't you see through it, but after a while it can turn into a sticky mess that's difficult to unwrap. Draw the schematic on a small piece of paper, and roll it up to serve as the outer insulation.

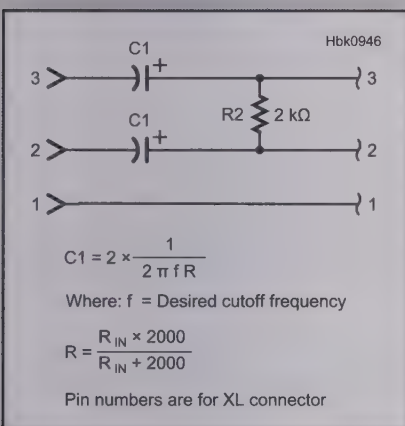

Figure 13.A2 — Low-frequency rolloff pad.

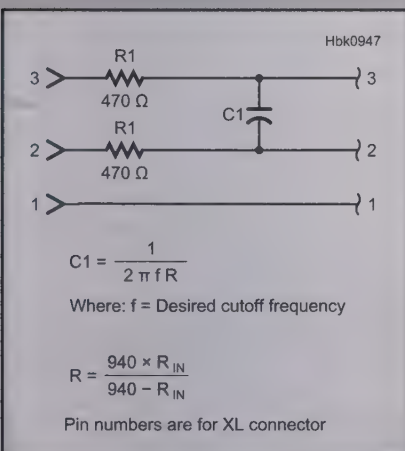

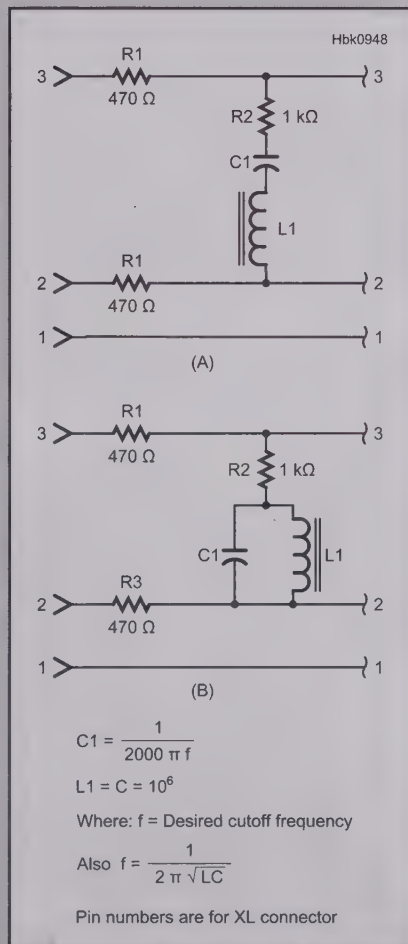

Figure 13.A3 — High-frequency rolloff pad.

Figures 13.A4 — Midrange cut (A) and boost (B) pads.

Thanks to these impedance relationships, very little current flows in microphone and line circuits. Output stages are constant voltage sources, so they can easily drive multiple inputs in parallel. While output circuits are usually *rated* for a 600  $\Omega$  load, loading them with 600  $\Omega$  degrades their performance.

Loudspeaker amplifiers are different, in that they *do* provide power. They are still constant voltage sources, and those that drive loudspeakers typically have output impedance of a few tens of milliohms, designed to drive loads in the range of 4-16  $\Omega$ . Since they are constant voltage sources, they will deliver four times more power into a 4- $\Omega$  load than into a 16- $\Omega$  load. The ratio of load impedance to source impedance is the *damping factor*.

Headphone amplifiers also supply power but a lot less of it. Headphones range in impedance from 8  $\Omega$  to more than 600  $\Omega$ , and most will be pretty loud with only a few volts drive. Most headphone amplifiers can drive more than one pair of headphones in parallel. Most headphone amplifiers have a resistor in series with their output so that they are not damaged when a plug is not inserted properly.

Computer sound cards have stereo *outputs* designed to drive headphones and line level inputs. The sound cards built into many laptop computers have only a mono *input*, often designed only for microphone levels. Most outboard sound cards, and better built-in sound cards, provide both a mono microphone

and a stereo line input, or a single stereo input that can be switched to microphone or line level via the computer's operating system or the software that uses the audio signal.

## SPEECH PROCESSING

Transmitters generally require audio signals in the volt region and it will be found advantageous to shape the frequency response prior to transmission. ("Amplified" microphones are outside this discussion.) Before being applied to the modulator circuits in the transmitter the audio signal is applied to a clipper or compressor for amplitude control. Such circuits along with their associated filtering increase the average value of signal level into the transmitter and so make the signal sound louder and define the occupied bandwidth.

## PREAMPLIFIER

The output of the microphone is amplified and its frequency response shaped in a preamplifier as shown in **Figure 13.50**. R4 allows coarse gain adjustment and it can be a 100 k $\Omega$  potentiometer if various microphones are to be accommodated. The low-pass filter has a flat response out to about 3 kHz, including a peak of several dB at 2500 Hz (discussed below). The filters work in concert with the following treble peaking circuit to produce a response very suitable for communications as shown in **Figure 13.51**. The magnitude of

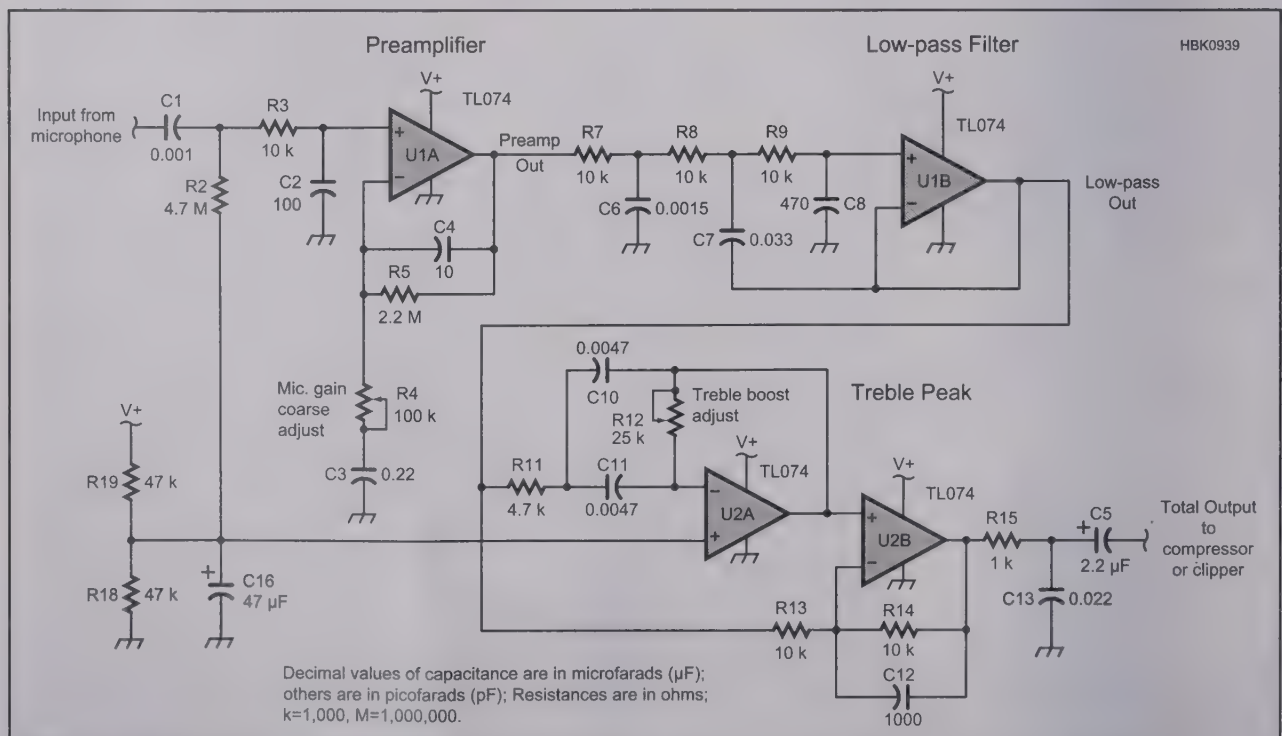

the peak at 2500 Hz may be adjusted by simply changing the value of R12. This treble peaking circuit only affects speech signals in the 2500 Hz region.

The response as shown has a rise of 15 dB at 2500 Hz relative to 400 Hz but is nevertheless down 30 dB at 10 kHz. Very low frequencies have been rolled off. The output of the preamplifier is applied to a level control and then to a clipper or compressor for level control.

## CLIPPER

After the speech signal has been increased in level and the basic response has been shaped, it may be applied to a clipper to increase its average volume level. At this point it must be pointed out that clipping must be used with great care if the transmitter is operating in the single-sideband mode. SSB transmitters cannot handle clipped waveforms gracefully. Clipping can always be used to catch occasional overshoots resulting from sluggish AGC systems, as an example, but in SSB systems should not be used as a routine method of volume maximization. However, clipping can be used in AM systems with great effect. A clipper followed by a low-pass filter sets the occupied bandwidth of the transmitter, assuming the following stages are operating cleanly.

**Figure 13.52** shows the schematic of a speech clipper with its associated filtering.

**Figure 13.50** — Schematic of a microphone preamplifier with a gain stage, a low-pass filter and a treble peaking stage.

The “preclip” filters are optional but recommended. The “postclip” low-pass filter is a mandatory requirement to limit the transmitted bandwidth.

The 200 Hz high-pass filter ahead of the clipper greatly reduces low-frequency inter-

modulation distortion. The 3 kHz low-pass filter ahead of the clipper prevents high-frequency audio (sibilants) from being clipped and similarly causing high-frequency intermodulation distortion.

This circuit uses an over-driven op-amp as

a clipper. Its sensitivity may be changed by changing the value of R8. The output is reduced by a factor of two (R11 and R12) so the following low-pass filter can handle the signal in a linear mode.

This filter has a sharp cutoff which would ordinarily have overshoots in its transient response when a clipped waveform is applied to its input. This can result in overmodulation, but it has been modified to have a step in its frequency response with the result that the overshoots have been turned into “undershoots” and so are rendered harmless. The overall response of the filtering in this block including the high-pass and both low-pass filters is shown in Figure 13.53.

### AUDIO COMPRESSOR

Another way to increase the average modulation level is to use automatic gain control (AGC) or a compressor. Such a circuit is shown in Figure 13.54. Compressors can be used for any mode of speech transmission. Compression should *never* be used with digital modes using AFSK modulation.

On the output of the op-amp are two LEDs in parallel but with opposite polarities. Audio voltages of either polarity illuminate a photoconductor causing its resistance to decrease. The photoconductor will then adjust the gain of the associated op-amp circuit. As audio levels increase, the LEDs illuminate the photoconductor more, reducing its resistance.

Figure 13.51 — Frequency response at various points within the speech amplifier.

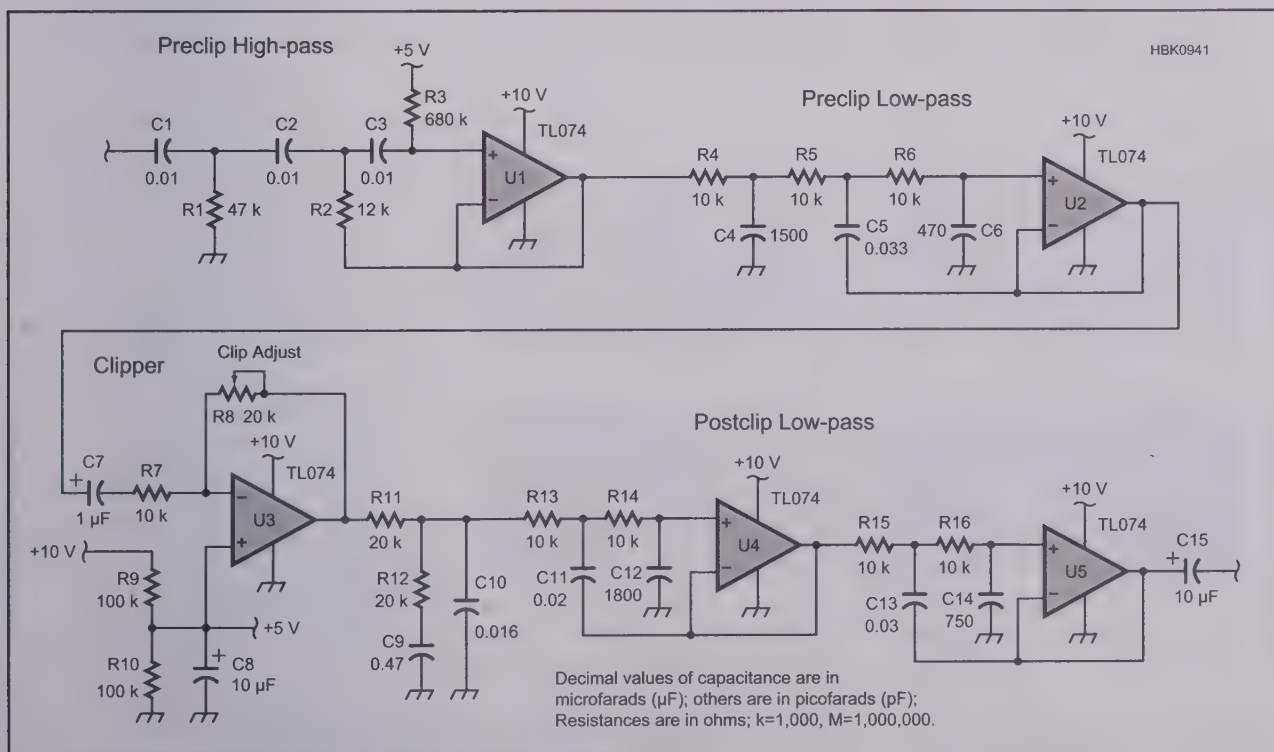

Figure 13.52 — Schematic of the speech clipper and its associated filtering.

Figure 13.53 — Overall response of the clipper-filtering block.

This causes the photoconductors to reduce the circuit gain, maintaining a constant audio output level. A second photoconductor monitors the illumination and so shows the degree of compression. The photoconductors (Luna PDV-P8101 or equivalent) are mounted directly on top of the white LEDs (Cree C503D-WAN-CCBEB152 or equivalent). This is shown in the inset for Figure 13.54.

This circuit responds to signal level increases within 2 or 3 milliseconds. After a

transient, it increases the gain back to normal in less than 100 milliseconds. The result is a very high average modulation level with far lower distortion than a clipper. Some signal overshoots will escape while gain reduction is underway but time-wise, on a percentage basis, they are quite small. If this block of circuitry is followed by a clipper to catch the overshoots then even those small overshoots will be of no concern.

The pre-clip high-pass and pre-clip low-

pass filters shown in the clipper block may be used in the compressor; they were not shown here. If used, they must be on the input to the compressor.

### IF SPEECH CLIPPER

Audio clipper speech processors can generate a considerable amount of in-band harmonics and IMD (involving different simultaneously occurring speech frequencies). The total distortion detracts somewhat from speech intelligibility. IF clippers (also known as RF speech processors) overcome most of these problems, especially the Hilbert Transform problem. (See Şabin and Schoenike in the References section.)

Figure 13.55A is a schematic diagram of a 455 kHz IF clipper using high-frequency op-amps. 20 dB of gain precedes the diode clippers. A second amplifier establishes the desired output level. The clipping produces a wide band of IMD products close to the IF frequency. Harmonics of the IF frequency are easily rejected by subsequent selectivity. “Close-in” IMD distortion products are band-limited by the 2.5 kHz wide IF filter so that out-of-band splatter is eliminated. The in-band IMD products are at least 10 dB below the speech tones.

Figure 13.55B shows a block diagram of an adaptation of the above system to an audio in-audio out configuration that can be inserted into the mic input of any transmitter to provide the benefits of RF speech processing. These are sometimes offered as aftermarket accessories.

Figure 13.56 shows oscilloscope pictures

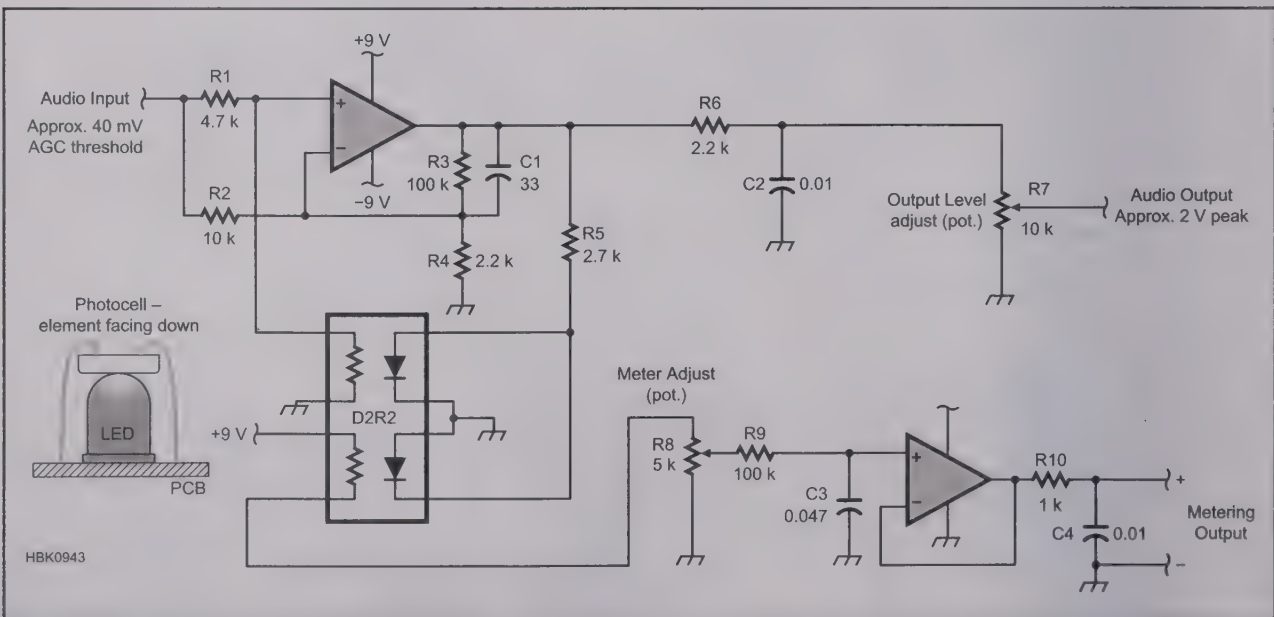

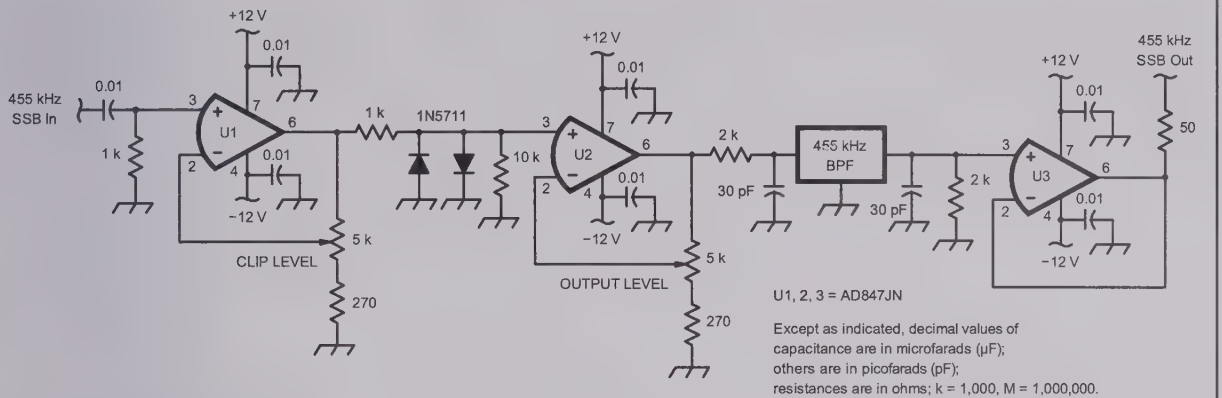

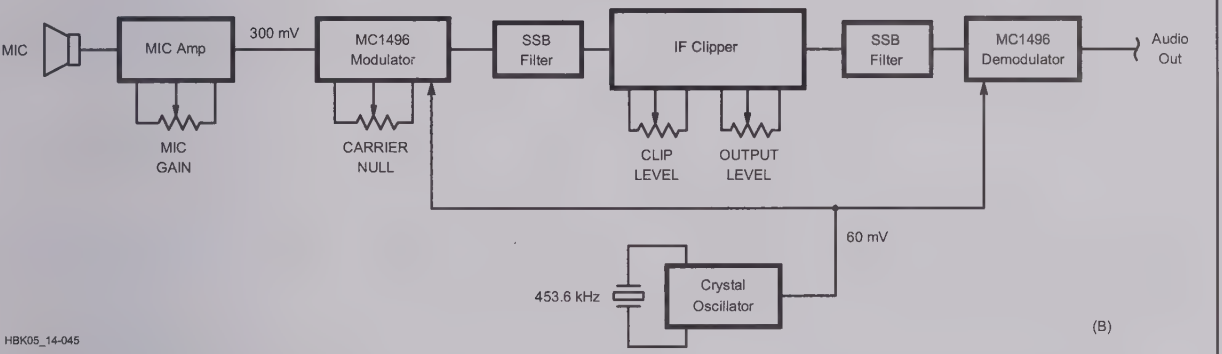

Figure 13.54 — Compressor circuit based on LEDs shining on photoconductors (cadmium sulfide photocells). See the text for a description of how to fabricate D2R2.

(A)

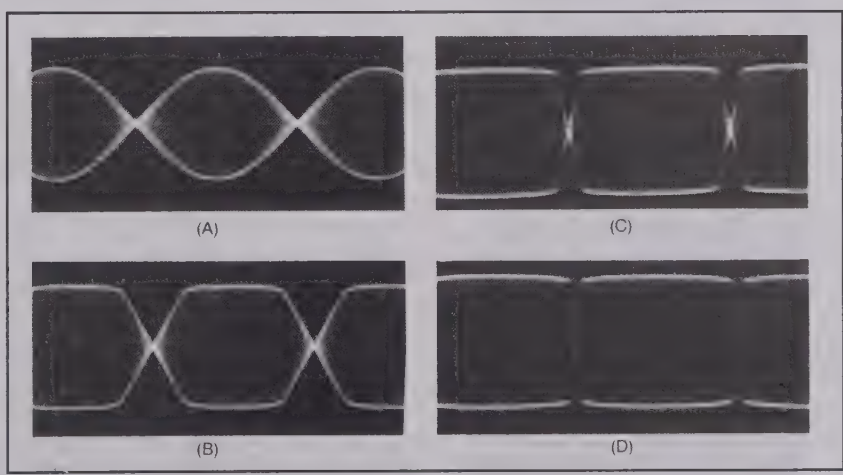

(B)

**Figure 13.55 — IF speech clipping.** At (A), schematic diagram of a 455 kHz IF clipper using high-frequency op amps. At (B) block diagram of an adaptation of the above system to an audio in-audio out configuration.

of an IF clipped two-tone signal at various levels of clipping. The level of clipping in a radio can be estimated by comparing with these photos. Listening tests verify that the IMD does not sound nearly as bad as harmonic distortion. In fact, processed speech sounds relatively clean and crisp. Tests also verify that speech intelligibility in a noise background is improved by 8 dB. (See the article on RF clippers by Sabin in the References section.)

The reapeaking effect from band-pass filtering the clipped IF signal occurs, and must be accounted for when adjusting the output level. A two-tone audio test signal or a speech signal should be used. The ALC circuitry (discussed later) will reduce the IF gain to prevent splattering in the power amplifiers. If the IF filter is of high quality and if subsequent amplifiers are clean, the transmitted signal is of very high quality and is very effective in noisy situations and often also in pile-ups.

The extra IF gain implies that the IF signal entering the clipper must be free of noise,

**Figure 13.56 — Two-tone envelope patterns with various degrees of RF clipping.** All envelope patterns are formed using tones of 600 and 1000 Hz. At A, clipping threshold; B, 5 dB of clipping; C, 10 dB of clipping; D, 15 dB of clipping.

hum and spurious products. The cleanup filter also helps reduce the carrier frequency, which is outside the passband.

An electrically identical approach to the IF clipper can be achieved at audio frequencies. If the audio signal is translated to, say 455 kHz, processed as described and trans-

lated back to audio, all the desirable effects of IF clipping are retained. This output then plugs into the transmitter's microphone jack. Figure 13.55B shows the basic method. The mic amplifier and the MC1496 circuits have been previously shown and the clipper circuit can be the same as in Figure 13.55A.

The interesting operating principle in all of these examples is that the characteristics of the IF clipped (or equivalent) speech signal do not change during frequency translation, even if translated down to audio and then back up to IF in a balanced modulator.

## 13.9 Voice Operation

### 13.9.1 Push-To-Talk for Voice

Another advance in amateur station switching followed longstanding practices of aircraft and mobile voice operators who had other things to contend with besides radio switches. Microphones in those services included built-in switches to activate TR switching. Called push-to-talk (PTT), this function is perhaps the most self-explanatory description in our acronym studded environment.

Relays controlled the various switching functions when the operator pressed the PTT switch. Some top-of-the-line transmitters of the period included at least some of the relays internally and had a socket designed for PTT microphones. **Figure 13.57** is a view of the

ubiquitous Astatic D-104 microphone with PTT stand, produced from the 1930s to 2004, and still popular at flea markets and auction sites. PTT operation allowed the operator to be out of reach of the radio equipment while operating, permitting “easy chair” operation for the first time.

Modern transceivers include some form of PTT (or “one switch operation”). Relays, diodes, transistors and other components seamlessly handle myriad transmit-receive changeover functions inside the transceiver. Most transceivers have additional provisions for manually activating PTT via a front-panel switch. And many have one or more jacks for external PTT control via foot switches, computer interfaces or other devices.

### 13.9.2 Voice-Operated Transmit-Receive Switching (VOX)

How about break-in for voice operators? SSB operation enabled the development of voice operated transmit/receive switching, or VOX. During VOX operation, speaking into the microphone causes the station to switch from receive to transmit; a pause in speaking results in switching back to receive mode. Although VOX technology can work with AM or FM, rapidly turning the carrier signal on and off to follow speech does not provide the smooth operation possible with SSB. (During SSB transmission, no carrier or signal is sent while the operator is silent.)

#### VOX OPERATION

VOX is built into current HF SSB transceivers. In most, but not all, cases they also provide for PTT operation, with switches or menu settings to switch among the various control methods. Some operators prefer VOX, some prefer PTT and some switch back and forth depending on the operating environment.

VOX controls are often considered to be in the “set and forget” category and thus may be controlled by a software menu or by controls on the rear panel, under the top lid or behind an access panel. The following sec-

tions discuss the operation and adjustment of radio controls associated with VOX operation. Check your transceiver's operating manual for the specifics for your radio.

Before adjusting your radio's VOX controls, it's important to understand how your particular mic operates. If it has no PTT switch, you can go on to the next section! Some mics with PTT switches turn off the audio signal if the PTT switch is released, while some just open the control contacts. If your mic does the former, you will need to lock the PTT switch closed, have a different mic for VOX, or possibly modify the internal mic connections to make it operate with the VOX. If no audio is provided to the VOX control circuit, it will never activate. If the mic came with your radio, or from its manufacturer, you can probably find out in the radio or mic manual.

#### VOX Gain

**Figure 13.58** shows some typical transceiver VOX controls. The VOX gain setting determines how loud speech must be to initiate switchover, called “tripping the VOX.” With a dummy load on the radio, experiment with the setting and see what happens. You should be able to advance it so far that it switches with your breathing. That is obviously too sensitive or you will have to hold your breath while receiving! If not sensitive enough, it may cause the transmitter to switch

**Figure 13.57** — A classic Astatic D-104 mic with PTT stand.

**Figure 13.58** — The function of VOX controls is described in the text. They require adjustment for different types of operating, so front-panel knobs make the most convenient control arrangement. In some radios, VOX settings are adjusted through the menu system.

off during softly spoken syllables. Notice that the setting depends on how close you are to the microphone, as well as how loud you talk. A headset-type microphone (a “boom set”) has an advantage here in that you can set the microphone distance the same every time you use it.

The optimum setting is one that switches to transmit whenever you start talking, but isn’t so sensitive that it switches when the microphone picks up other sounds, such as a cooling fan turning on or normal household noises.

### VOX Delay

As soon as you stop talking, the radio can switch back to receive. Generally, if that happens too quickly, it will switch back and forth between syllables, causing a lot of extra and distracting relay clatter. The VOX delay control determines how long the radio stays in the transmit position once you stop talking. If set too short, it can be annoying. If set too

long, you may find that you miss a response to a question because the other station started talking while you were still waiting to switch over.

You may find that different delay settings work well for different types of operation. For example, in a contest the responses come quickly and a short delay is good. For casual conversation, longer delays may be appropriate. Again, experiment with these settings with your radio connected to a dummy load.

### Anti-VOX

This is a control with a name that may mystify you at first glance! While you are receiving, your loudspeaker is also talking to your microphone — and tripping your VOX — even if you aren’t! Early VOX users often needed to use headphones to avoid this problem. Someone finally figured out that if a sample of the speaker’s audio signal were fed back to the mic input, out-of-phase and at the appropriate amplitude, the signal from the

speaker could be cancelled out and would not cause the VOX circuit to activate the transmitter. The ANTI-VOX (called ANTI-TRIP in the photo) controls the amplitude of the sampled speaker audio, while the phase is set by the transceiver design.

As you tune in signals on your receiver with the audio output going to the speaker, you may find that the VOX triggers from time to time. This will depend on how far you turn up the volume, which way the speaker is pointed and how far it is from the mic. You should be able to set the anti-VOX so that the speaker doesn’t trip the VOX during normal operation.

Generally, setting anti-VOX to higher values allows the speaker audio to be louder without activating the VOX circuit. Keep in mind that once you find a good setting, it may need to be changed if you relocate your microphone or speaker. With most radios, you should find a spot to set the speaker, microphone and anti-VOX so that the speaker can be used without difficulty.

## 13.10 Transmitter Power Stages

The functions described so far that process input data and information and result in a signal on the desired output radio frequency generally occur at a low level. The one exception is full-carrier AM, in which the modulation is classically applied to the final amplification stage. More modern linear transmitter systems generate AM in the same way as SSB at low levels, typically between 1 mW and 1 W.

### 13.10.1 Types of Power Amplifiers

The **RF Power Amplifiers** chapter provides a detailed view of power amplifiers; however, we will take a quick peek here to set the stage for the following discussions. Amplifiers use dc power applied to active devices in order to increase the power or level of signals. As will all real devices, they introduce some distortion in the process, and are generally limited by the level of distortion products. Power amplifiers can be constructed using either solid-state devices or vacuum tubes as the active device. At higher powers, typically above a few hundred watts, vacuum tubes are more frequently found, although there is a clear trend toward solid state at all amateur power levels.

Independent of the device, amplifiers are divided into classes based on the fraction of

the input cycle over which they conduct. A sinusoidal output signal is provided either by the *flywheel* action of a resonant circuit or by other devices contributing in turn. The usual amplifier classes are summarized in **Table 13.1**. Moving from Class A toward Class C, the amplifiers become progressively less linear but more efficient. The amplifiers with a YES in the LINEAR column thus are not all equally linear however A, AB or Class B amplifiers can be suitable for operation in a linear transmitter chain. Class C amplifiers can be used only for amplification of signals that do not have modulation information contained in the amplitude, other than on-off keyed signals. Thus class C amplifiers are useful for amplification of sinusoids, CW, FM, or as the nonlinear stage at which high-level AM modulation is employed.

Recent developments in switching-type amplifiers and in single-band matching network design have created several additional classes. Class D is a switchmode amplifier most often used for high-efficiency audio amplification. Class E and F use tuned output networks that let the amplifying device act like a switch but prevent high voltage and high current at the same time. Class G is similar to a Class B amplifier, but switches between two voltage levels to reduce power dissipation at low signal levels. Class I uses two devices driven with complementary pulse

**Table 13.1**  
Characteristics of Transceiver Power Amplifier Classes

Values are typical

Class	Conduction	Linear	Efficiency
A	360°	Yes	30%
AB	270°	Yes	55%
B	180°	Yes	65%
C	90°	No	74%

duty cycles to cancel harmonics and follow the input waveform. Class S is a variation on Class D, and Class T uses DSP to optimize pulse widths in a Class D amplifier for better performance. More information on amplifier classes is available in the online tutorial “Amplifier Classes” at [www.electronicstutorials.es/amplifier/amplifier-classes.html](http://www.electronicstutorials.es/amplifier/amplifier-classes.html). See also the references at the end of this chapter for Rosu and for Silver.

### 13.10.2 Linear Amplifiers

While transmitters at power levels of 1 mW to 1 W have been successfully used for communication across many portions of the spectrum, most communications systems operate with more success at higher powers. The low level stage is usually referred to as an exciter,

while higher power is provided by one or more linear amplifier stages as shown in **Figure 13.59**.

The power levels shown at the various points in Figure 13.59 are fairly typical for a high powered amateur station. The 1500 W PEP output represents the legal limit for US amateurs in most bands (200 W PEP on 30 meters and 100 W ERP on the 60 meter channels are notable exceptions). The first amplifier block may contain more than one stage, while the final output amplifier is often composed of multiple parallel active devices.

Typical power supply requirements for the amplifier stages are noted for a number of reasons. First, while power is rarely an issue at the exciter level, often it is a significant issue at the power levels shown for the amplifiers. The power supplies represent a large portion of the cost and weight of the system as the power increases. Some manufacturers are beginning to use switching-type power supplies for high-power amplifiers, resulting in a major reduction in size and weight.

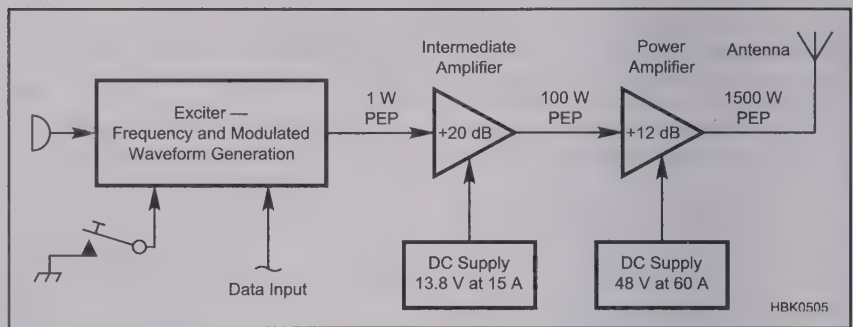

Note also that a gross amplifier efficiency of about 50% is assumed for the amplifiers, taking into account ancillary subsystems as well as the inefficiency of the active devices in linear mode. The 50% that doesn't result in actual RF output is radiated as heat from the amplifier and must be removed from the amplifier as it is generated to avoid component damage. This represents another cost and weight factor that increases rapidly with power level.

The voltages shown for the supplies are those typical of modern solid state amplifiers. While virtually all commercial equipment now includes solid state amplifiers at the 100 W level, vacuum tube active devices are frequently found at higher levels, although the trend is clearly moving toward solid state. Vacuum tube amplifiers typically operate at voltages in the 2 to 4 kV range, requiring stringent measures be taken to avoid arcing across components. In addition, vacuum tube amplifiers typically dissipate up to 100 W of filament power that must be added to the power supply and heat dissipation planning.

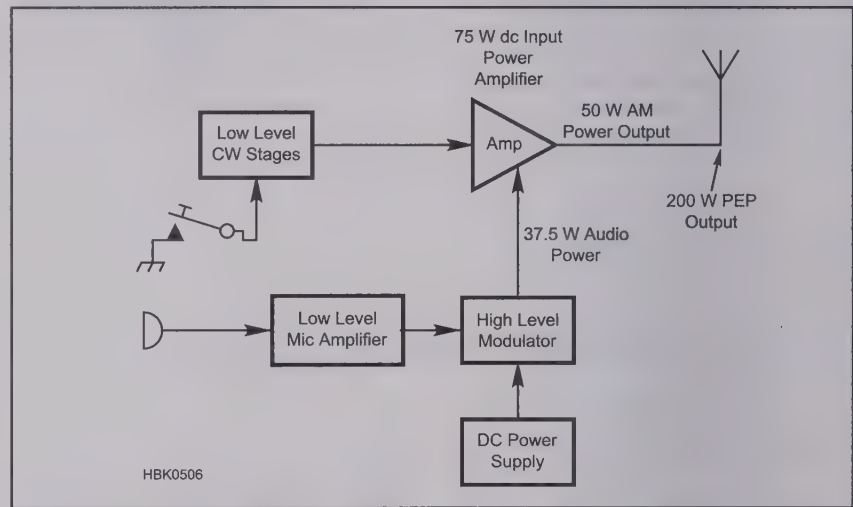

### 13.10.3 Nonlinear Amplifiers

Nonlinear transmitters are somewhat different in architecture than the linear systems discussed previously. The configuration of a high-level AM modulated transmitter is shown in **Figure 13.60**. Note that none of the upper RF stages (the "RF chain") need to be particularly linear. The final stage must be nonlinear to have the modulation applied. Thus the RF stages can be the more power-efficient Class C amplifiers if desired.

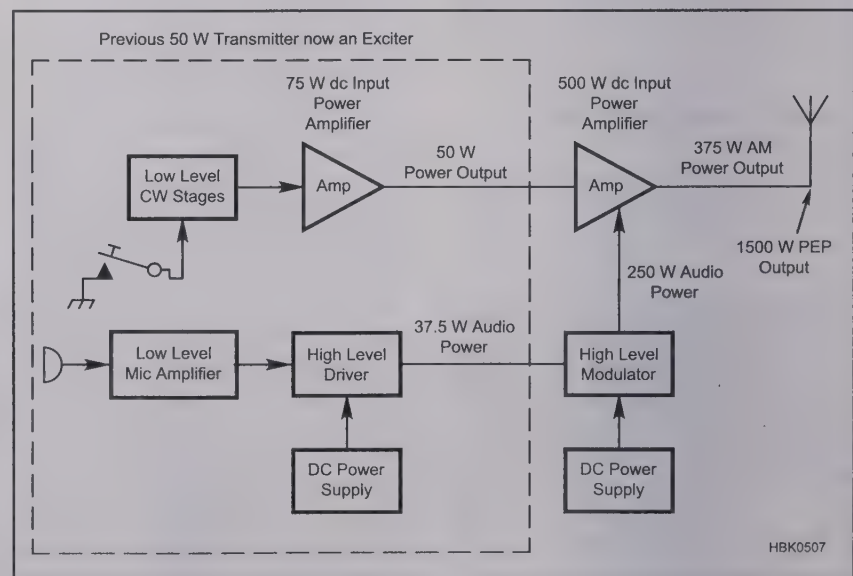

There are some observations to be made here. Note that the RF chain is putting out the full carrier power whenever in transmit

**Figure 13.59** — Block diagram of a solid-state linear transmitter chain with multiple amplifier stages.

**Figure 13.60** — Block diagram of a high level AM modulated transmitter.

**Figure 13.61** — Block diagram of a high level AM modulated transmitter with added output stage.

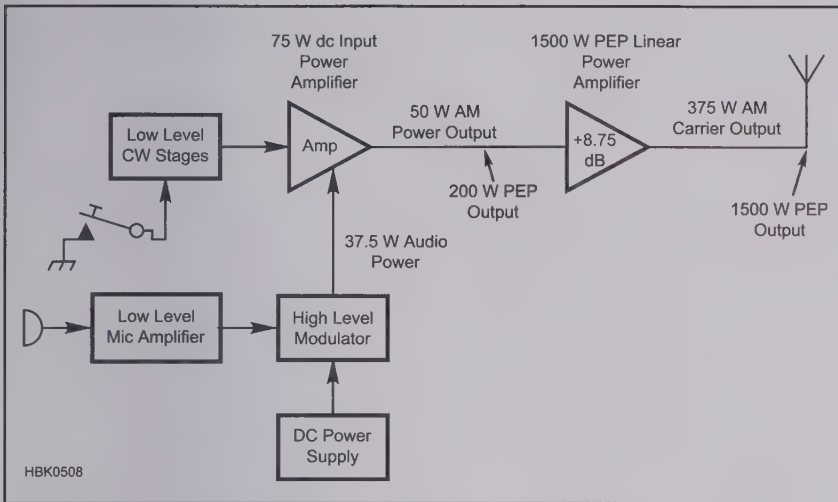

Figure 13.62 — Block diagram of a hybrid nonlinear/linear AM transmission system.

mode, requiring a 100% duty cycle for power and amplifier components, unlike the SSB systems discussed previously. This imposes a considerable weight and cost burden on the power supply system. Note also that the PEP output of a 100% modulated AM system is equal to four times the carrier power.

The typical arrangement to increase the power of such a system is to add not only an RF amplifier stage capable of handling the desired power, but also to add additional audio power amplification to fully modulate the final RF stage. For 100% high-level plate modulation, an audio power equal to half the dc input power (plate voltage times plate current of a vacuum tube amplifier) needs to be provided. This arrangement is shown in Figure 13.61. In the example shown, the lower level audio stages are provided by those of the previous 50 W transmitter, now serving as an exciter for the power amplifier and as a driver for the modulating stage. This was frequently provided for in some transmitters of the AM era, notably the popular E. F. Johnson Ranger series, which provided special taps on its modulation transformer for use as a driver for higher-power systems.

It is worth mentioning that in those days the FCC US amateur power limit was expressed in terms of dc input to the final stage and was limited to 1000 W, rather than the 1500 W PEP output now specified. A fully modulated 1000 W dc input AM transmitter would likely have a carrier output of 750 W or 3000 W PEP — 3 dB above our current limit. If you end up with that classic Collins KW-1 transmitter, throttle it back to make it last and stay out of trouble!

### 13.10.4 Hybrid Amplifiers

Another alternative that is convenient with

current equipment is to use an AM transmitter with a linear amplifier. This can be successful if the relationship that  $PEP = 4 \times$  Carrier Power is maintained. Figure 13.62 shows a 1500 W PEP output linear amplifier following a typical 50 W AM transmitter. In this example, the amplifier would be adjusted to provide a 375 W carrier output with no modulation applied to the exciter. During voice peaks the output seen on a special PEP meter, or using an oscilloscope, should be 1500 W PEP.

Note that during AM operation, the amplifier is producing a higher average power than it would without the carrier being present, as in SSB mode. The duty cycle specification of the amplifier should be checked to be sure it can handle the heavier load. If the amplifier has an RTTY rating, it should be safe to run an AM carrier at 66% of the RTTY output, following the required on and off time intervals.

### 13.10.5 Automatic Level Control (ALC)

The purpose of ALC is to prevent the various stages in the transmitter from being overdriven. Over-drive can generate too much out-of-band distortion or cause excessive power dissipation, either in the amplifiers or in the power supply. ALC does this by sampling the peak amplitude of the modulation (the envelope variations) of the output signal and then developing a dc gain-control voltage that is applied to an early amplifier stage, as suggested in Figure 13.9.

ALC is usually derived from the last stage in a transmitter. This ensures that this last stage will be protected from overload. However, other stages prior to the last stage may not be as well protected; they may generate excessive distortion. It is possible to derive a composite ALC from more than one stage in a way that would prevent this problem. But designers usually prefer to design earlier stages conservatively enough so that, given a temperature range and component tolerances, the last stage can be the one source of ALC. The gain control is applied to an early stage so that all stages are aided by the gain reduction.

Note that ALC should be minimally active with most digital mode transmissions. The modulation of these signals requires linear amplification to preserve the waveform shape and minimize distortion products. ALC action creates distortion as it alters the power level of the signal. Adjust the radio drive levels so that the ALC is at its minimum level of activity — usually shown as the lower bar of a multi-segment LCD meter or a needle position just above zero. (The same caution applies to any form of audio or speech processing if the digital signal is generated by audio tones applied to the transmitter's microphone input.)

Figure 13.63 shows how a dual directional

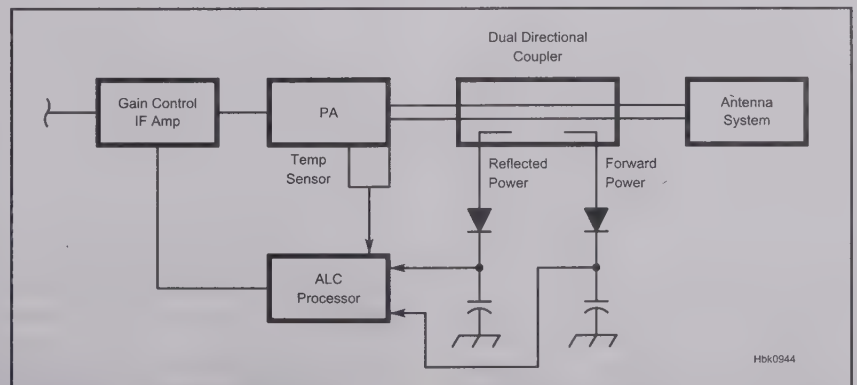

Figure 13.63 — An ALC protection method for a solid-state transmitter using a directional coupler to sense power level.

coupler can be used to provide ALC for a solid-state power amplifier (PA). The basic idea is to protect the PA transistors from excessive SWR and dissipation by monitoring both the forward power and the reflected power.

### 13.10.6 Transmit-Receive (TR) Switching

As the complexity of a transceiver increases, switching between receive and transmit becomes quite complex. In commercially built equipment, this function is usually controlled by a microprocessor that manages any necessary sequencing and interlock functions that would require an excessive amount of circuitry to implement with discrete components. For an example of just how complex TR switching could be in an advanced transceiver, look at the schematic for any modern mid-level or top-of-the-line solid-state transceiver.

Nevertheless, the basic functions of TR switching are well within scope for the amateur building a transceiver. Understanding TR switching will also assist in troubleshoot-

ing a more complex commercial radio.

### QRP TR SWITCHING

Numerous schemes are popular for switching an antenna between transmitter and receiver functions. But these schemes tend to get in the way when one is developing both simple receivers and low-power transmitters, perhaps as separate projects. A simple relay-based TR scheme is then preferred and is presented here. In this system, used in the MkII Updated Universal QRP Transmitter by Wes Hayward, W7ZOI (see the full article in this book's online supplemental information), the TR relay not only switches the antenna from the receiver to the transmitter, but disconnects the headphones from the receiver and attaches them to a sidetone oscillator that is keyed with the transmitter.

The circuitry that does most of the switching is shown in Figure 13.64. A key closure discharges capacitor C1. R2, the 1 k $\Omega$  resistor in series with C1, limits the discharge current. Key closure causes Q6 to saturate, causing Q7 to also saturate, turning the relay on. The relay picked for this example has a 700  $\Omega$ , 12 V coil with a measured 4 ms pull-in time.

If full break-in TR switching is required, a high-speed reed relay can be used. KE2QJ provided circuits that can be adapted for internal use in a home-built transceiver, although the original purpose was to integrate a stand-alone receiver with a transceiver and linear amplifier. His full article is available in this book's downloadable supplemental information. The References also include an excellent online paper by W8ZR on adding a high-speed vacuum relay QSK switch for full legal-limit QSK operation.

If you already have a receiver and transmitter and want to integrate them under the control of a separate TR switch, the K8IQY "Magic Box" ([www.4sqr.com/MagicBox.php](http://www.4sqr.com/MagicBox.php)) incorporates a number of useful features. This is a microprocessor-controlled design that can handle up to 10 W of transmitter power, switches at up to 50 WPM, and includes an audio sidetone output, as well. Although the kit is no longer offered, complete documentation is available online, including schematics and design information. The design could be extended to handle more transmit power with heavier components and the appropriate circuit changes.

## AMPLIFIER-TRANSCIVER TR SWITCHING

Amateur transceivers intended for use with external amplifiers have a KEY OUT output. This is usually a contact closure while in transmit mode intended to connect to a corresponding KEY IN input on the external amplifier. Check the transceiver and amplifier manuals to find out what they are called on your equipment. A diagram of the proper cabling to connect the transceiver and amplifier will be provided in the manual. Amplifiers may also have an output signal that can be used to inhibit RF output from the transceiver until TR switching is complete and the amplifier is ready to operate. This avoids “hot switching” when the transceiver output is active while the amplifier’s TR switch is still changing state.

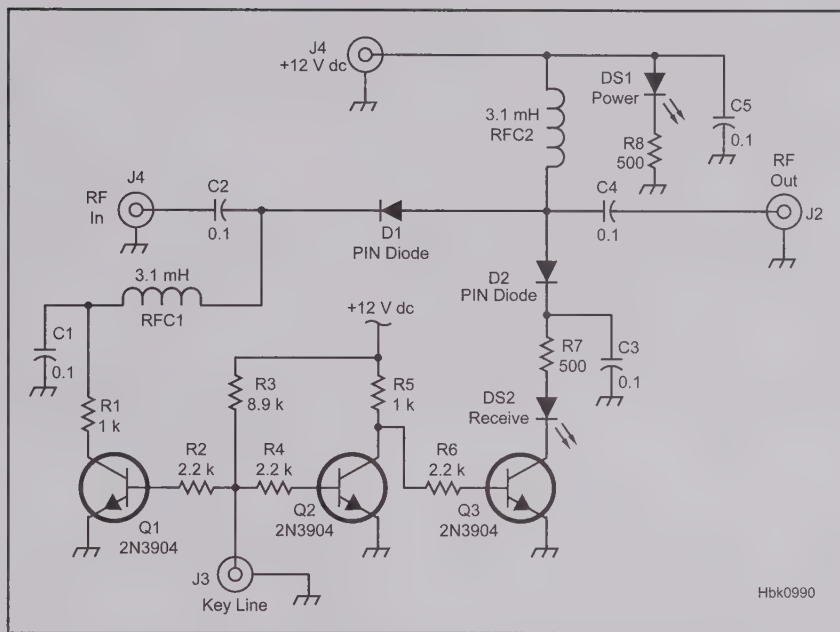

Check the ratings to find out how much voltage and current the transceiver can safely switch, whether by a relay or a solid-state device. Many transceivers have both with the solid-state output used for high-speed switching or full break-in (QSK). Although most amplifiers are compatible with the switching capabilities of current transceivers, the voltage and/or current required to switch the relays in an older linear amplifier may exceed the ratings.

If your amplifier manual doesn’t say what the switching voltage is, you can find out with a multimeter or DMM. Set the meter to read voltage of 250 V dc or higher. Connect the positive meter probe to amplifier key jack’s center conductor, and connect the negative meter probe to the chassis ground (or the other key jack terminal if it’s not grounded). This will tell you what the open circuit voltage is on the amplifier key jack. You may need to try a lower voltage range or switch to read ac voltage.

Now set the meter to read current. Start with a range that can read 1 A dc, and with the leads connected as before, you should hear the amplifier relay close and observe the current needed to operate the TR relay or circuit. Adjust the meter range, if needed, to get an accurate reading.

These two levels, voltage and current, are what the transceiver will be asked to switch. If *either* reading is higher than the transceiver specification, do not connect the transceiver and amplifier together. Doing so will likely damage your transceiver. You will need a simple interface circuit to handle the amplifier’s switching voltage and current.

The simple, low-cost relay circuit shown in **Figure 13.65** can be used to key an older amplifier with a modern transceiver. It offers an added benefit: Another potential use of the transceiver KEY OUT jack is to switch to a separate low-noise receive antenna on the lower bands. While most high-end trans-

ceivers have a separate receive-only antenna connection built in, many transceivers don’t. If you don’t need one of the extra functions, just omit that connection.

### 13.10.7 PIN Diode RF Switching

Many current transceivers and amplifiers use PIN diodes for RF switching. They switch very quickly (as fast as nanoseconds) and do not wear out. They can be destroyed through excess reverse voltage or average forward current, requiring more protection than a simple pair of relay contacts. If high-speed, transparent break-in or digital mode operation is required, the PIN diode is the practical choice. Two practical papers available on-line with a lot of information about PIN diode use are recommended to learn more about switch design — see the References for Huff and Summers. Two industry papers on using PIN diodes are also referenced from Microsemi and Skyworks as well as a general paper by Rosu on RF switches using PIN diodes.

#### BASIC PIN DIODE OPERATION

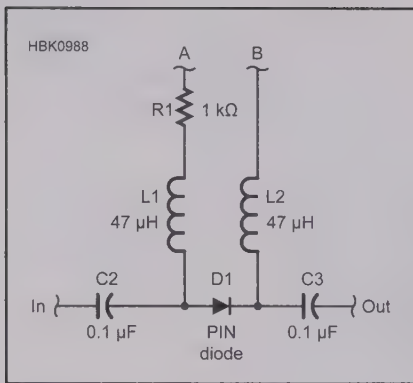

A PIN diode is a diode with a wide undoped “intrinsic semiconductor” region between the

usual P-type and N-type doped semiconductor layers of a regular diode (See the discussion of PIN diodes in the **Circuits and Components** chapter.) The PIN diode’s wide intrinsic layer acts as a storage reservoir for charge. When forward bias current is flowing, the intrinsic layer fills up with electrons. When the diode is reverse biased, it takes time for the stored electrons to empty out of the intrinsic layer. At high enough frequencies, the time available is too short and the diode never “turns off”. It remains conducting through the whole RF cycle.

PIN diodes behave like variable resistances. The resistance is determined by the amount of dc forward bias current. They are near-perfect variable resistors which add very little distortion to the signal. For switching, all we want is either a very low resistance (ON), or a very high resistance (OFF).

- To switch the PIN diode OFF, apply a large reverse bias voltage. The voltage should be higher than the peak voltage of the RF being switched. That means high voltage is required for the switch to withstand high power RF voltages when it is turned off.

- To switch the PIN diode ON, apply a forward bias current; the more current, the lower the insertion loss.

**Figure 13.66** — The basic PIN diode RF switch. See text.

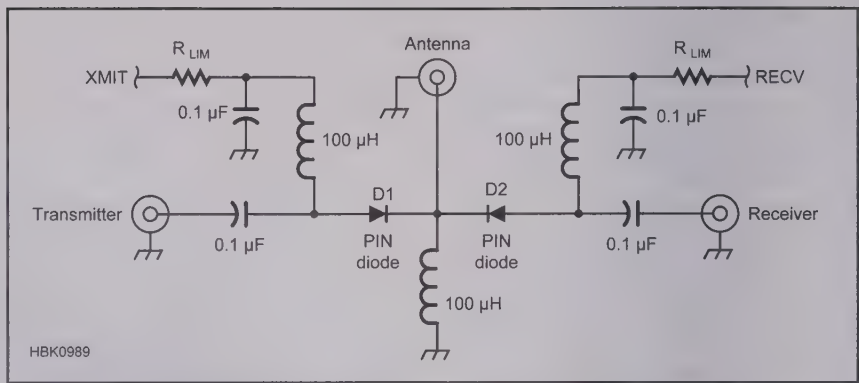

The basic element of the PIN diode switch is shown in **Figure 13.66**. The input RF signal passes through C2, then D1, and finally C3 to the output. (RF can flow in either direction — the left-to-right convention is followed here for convenience.) The dc blocking capacitors C2 and C3 are necessary to isolate the dc bias for D1. For the HF range, a 0.1 μF capacitor is satisfactory, with a reactance of approximately 1 Ω at 1.8 MHz. Remember that the capacitor will have to carry all of the RF current so a low-loss, low-inductance type is required for transmitting applications. L1 and L2 are RF chokes that prevent RF from getting into the bias source and switching circuits. At 1.8 MHz, the reactance of 47 μH is over 500 Ω and should be sufficient in a 50 Ω system.

To switch on D1, we apply a forward bias current through D1. For this, we set A to the supply voltage (assumed to be +12 V here) and B to ground. The current flows through the diode, limited by R1. Neglecting the diode's forward voltage, a 1 kΩ resistor results in  $12 / 1000 = 12$  mA. This is typical for low-power designs. Higher-power PIN diodes require more bias current to minimize insertion loss.

To switch off D1, we apply a reverse bias voltage by setting A to 0 V and B to the supply voltage. The reverse bias voltage must be higher than the peak voltage of the applied RF with some margin. The reverse voltage must also be high enough that when the diode is off there is enough isolation for the circuit requirements. Complex PIN diode switches can achieve several tens of dB of isolation. 30 dB is typical of single-diode switches like this one.

### BASIC SPDT PIN DIODE SWITCH

The switch in **Figure 13.66** is a SPDT switch and RF current can flow through it in either direction when the PIN diode is forward biased. The switch in **Figure 13.67** is a SPDT switch with the antenna port connected to the

**Figure 13.67** — A simple SPDT PIN diode RF TR switch to connect either a transmitter or receiver to an antenna. See text for design information.

switch common point. The diodes are turned on alternately to connect either the transmitter or the receiver to the antenna, but not both at the same time. This is a typical PIN diode TR switch.

When the XMIT signal is ON (a positive voltage), PIN diode D1 is forward biased and conducting RF while D2 is reverse biased and non-conducting. The transmitter is connected to the antenna and the receiver input path is open-circuited. When the RECV signal is ON, the situation is reversed and the receiver is connected to the antenna and the transmitter path open-circuited. The circuit's user must ensure that both XMIT and RECV cannot be on at the same time.

Depending on the type of diode being used, isolation between the transmitter and receiver ports will be about 30 dB at 28 MHz and as much as 60 dB at 1.8 MHz if careful construction techniques are followed. If additional isolation is required, multiple diode sections can be added in series or a shunt diode added as in the next section.

The value of  $R_{LIM}$  and the dc resistance of the 100 μH RF chokes limit diode current. Typical PIN diodes require 10 to 20 mA of forward bias to reach insertion loss of 0.1 dB at HF. The choice of diode will determine the amount of forward bias current required.

To perform PIN diode switching at high power levels, considerably more details are involved in the design. The online paper by Garland should be studied to learn more about use of PIN diodes at full legal limit power levels.

### SERIES-SHUNT PIN DIODE SWITCH

If the transmitter is connected to the antenna at all times while the receiver is switched in and out, the series-shunt circuit of **Figure 13.68** can be used. This circuit was designed by KE2QJ and its complete operation is described in the article included with the downloadable supplemental information. When the receiver is to be connected to the antenna

(RF In), series diode D1 is forward biased on and bias is removed from shunt diode D2. (It is not reverse biased.) When the transmitter is keyed (Key Line shorted to ground), forward bias is removed from series diode D1 and shunt diode D2 is forward biased on, connecting the receiver input to ground through C3. The designer reports isolation between the transmitter/antenna and receiver ports to be between 43 and 53 dB depending on bias current level.

### REVERSE BIAS

To switch a PIN diode completely off, the reverse bias must be larger than the peak voltage of the applied RF. For a given power level, P, and impedance, Z:

$$V_{PK} = 1.414 V_{RMS} = 1.414 \sqrt{P \times Z}$$

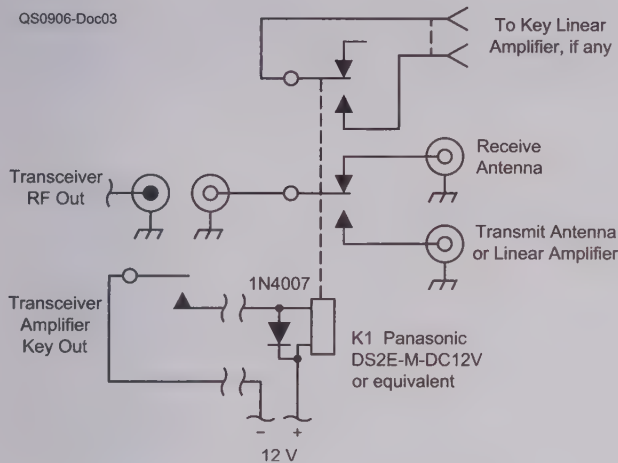

At P = 10 W,  $V_{PK} = 32$  V; at P = 100 W,  $V_{PK} = 100$  V; and at P = 1.5 kW,  $V_{PK} = 387$  V. This assumes SWR = 1:1. At higher SWR, the voltage at the output of a transmitter or amplifier will be higher. (See the **Transmission Lines** chapter.)

The current requirements for reverse bias voltage are very low, consisting of the diode reverse leakage current and any leakage through switching transistors. For two examples of how reverse bias voltage is obtained, see the Reference entries for Summers and Huff. A small dc-to-dc converter is another possible choice.

### USING 1N4007 RECTIFIERS AS PIN DIODES

PIN diodes tend to be expensive items. However, the 1N4007 rectifier diode has a peak inverse voltage (PIV) rating of 1000 V. In order to achieve this very high PIV rating, its internal construction is very similar to a "real" PIN diode. Hence the 1N4007 is often referred to as the "Poor man's PIN diode."

Since the 1N4007 is sold as a power rec-

**Figure 13.68** — Schematic of an external circuit that allows a modern transceiver to key a linear amplifier with TR switch voltage or current requirements that exceed the transceiver's ratings. As a bonus, it can also be used to allow reception from a low-noise receiving antenna.

tifier, its RF characteristics are not highly repeatable and its resistance is not linearly controllable. Nevertheless, to act like an ON/OFF switch across the HF range, the 1N4007 costs just a few cents and functions as well as a PIN diode designed for the same application and ratings. See the References for Huff and Summers for more information about 1N4007 performance in this application.

A properly used 1N4007 should not im-

pact the dynamic range or third-order intercept point, IP3 in the receiver. An excellent set of measurements by IN30TD confirms the 1N4007 is suitable for use at HF as a switching diode. ([www.qsl.net/in30td/electronics/PIN\\_diodes/PIN\\_diodes.html](http://www.qsl.net/in30td/electronics/PIN_diodes/PIN_diodes.html) and [www.qsl.net/in30td/electronics/PIN\\_diodes/1N4007](http://www.qsl.net/in30td/electronics/PIN_diodes/1N4007)). His broad conclusions are that a properly biased 1N4007 at HF (1.8 to 30 MHz) has the following characteristics:

- “ON” insertion loss less of than 0.1 dB for 10 mA forward bias current
- “OFF” isolation of at least 30 dB (at 30 MHz)
- IP3 > +50 dBm

Thus, the use of 1N4007 PIN diode switches should result in very little loss of transmitter output power, very little loss of sensitivity on receive, and will not degrade the excellent IP3 (and dynamic range) modern receivers.

# Transceiver Design Topics

This chapter is intended to capture system-level concerns that deal with integrating the functions of receiving and transmitting into an effective transceiver. It is anticipated that this chapter will grow as more material becomes available along with the expansion of SDR technology in Amateur Radio. Innovations in digital systems and networks by amateurs will also find an initial home in this *Handbook* chapter. Since the topics are not expected to overlap, reference sections will be created for each topic if appropriate.

This edition's chapter primarily includes high-level material on SDR design. Steve Hicks, N5AC, contributed the sections on signal chains and interfaces. John Petrich, W7FU, updated the introductory material on *GNU Radio* and expanded the list of reference materials. The additional short introduction to FPGA data engines is based on the series of *QEX* columns "Hands-On SDR" by Scotty Cowling, WA2DFI.

Material on transverters was contributed by Paul Wade, W1GHZ, and Wayne Overbeck, N6NB. Material on adding panadapters to older radios was contributed by Ed Krome, K9EK.

There is a great deal of material that doesn't fit neatly into the categories of receiving, transmitting, DSP/SDR fundamentals, or any of the major radio functions. This information is still required, however, to integrate all of the functions into a single package — the transceiver. There are questions of architecture, interfaces, development tools, and many other topics that must be addressed to build an effective transceiver or communications system. That is the purpose of this general-purpose chapter, to create a home in the *Handbook* for material that would be inappropriate for a chapter focused on a particular aspect of the radios themselves. Amateur Radio is poised at the threshold of great innovation and change — it's a bright future!

## 14.1 Signal Chains in SDR Transceivers

In an SDR, most work in both transmit and receive signal processing is performed in a computing or processing element that operates on digital samples. **Figure 14.1** shows a simplistic diagram of a transceiver setup for phone operation. Looking first at the transmit side of the radio, the analog microphone audio is converted to digital samples in an analog to digital converter (ADC). These digital samples are passed to the processing element where they enter the *transmit signal chain*. The transmit signal chain typically has a series of functional blocks that perform various functions on the signal including the modulator. While it is possible to use a purely digital exciter, most radios then pass the digital samples into a digital to analog converter (DAC) which turns the digital signal back into analog form. The resulting analog signal is amplified by an RF power amplifier and transmitted through the antenna.

In the receiver, the direction of flow is the opposite: analog RF data enters through the antenna and is turned into digital signals in an ADC. This data is passed to the receive *signal chain* where it is filtered, demodulated and processed into a signal we can hear. In some digital modes, such as RTTY, the demodulated signals are filtered and turned directly into digital symbols without ever being turned back into analog. For modes that we are expected to hear, the digital samples are sent into a codec where a DAC turns them back into analog for playback through headphones, speakers, or via a line-level output.

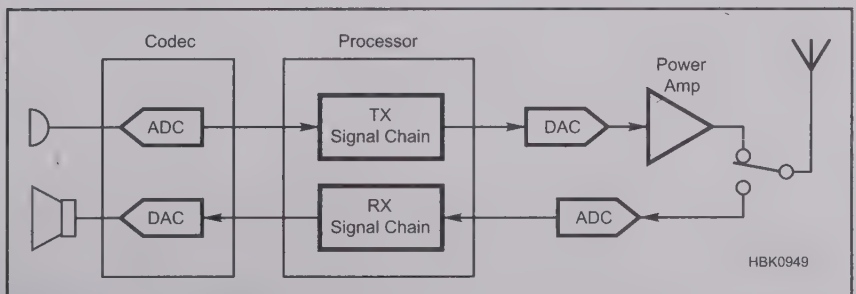

Figure 14.1 — A high-level block diagram of an SDR transceiver configured for phone operation.

The transmit signal chain and receive signal chain are at the heart of an SDR. Let's take a closer look at how they operate.

### 14.1.1 Receive Signal Chain

Most receivers will capture more digital samples than are needed for a single receiver. This can happen for many reasons. For example, we might have a wideband sampling receiver that captures a substantial portion of the spectrum and places several receivers in that spectrum. In this case, each individual narrowband receiver only requires a portion of the captured data. When we use the term narrowband receiver, we're talking about a receiver that will be used to demodulate signals in a 50-20,000 Hz slice of the RF spectrum. In another example, the receiver might be designed using an analog or digital mixing technique that reduces the bandwidth to an "audio" range (such as 0-192 kHz). The radio may preserve this larger bandwidth to plot a spectrum display, but will reduce it for narrowband receiver processing.

To understand the next steps, it's important to first understand the relationship between sampling rate and available bandwidth. Generally, in a sampled RF system we will either be using real or complex samples. (See the **DSP and SDR Fundamentals** chapter) *Real samples* will be used for audio input and output. Real samples consist of a single fixed or floating point number that represents each sample.

According to the Nyquist sampling theorem, we can represent at most one half of our sampling rate in bandwidth. For example, if we sample a microphone signal at 48 ksp/s (real samples), we can represent audio from 0-24 kHz. As a practical matter, the filters we use to process the audio will have a transition band that will further restrict this to something around 20 kHz.

If we sample using the in-phase and quadrature sampling (I/Q) commonly used in RF systems, then each sample consists of a pair of fixed or floating point numbers, one for I and one for Q. This is also commonly referred to as *complex sampling*. In a complex sampled system, sample speed and sampled bandwidth are equal, ignoring filter transition bands. For example, if the sample rate is 48 ksp/s (complex samples), the samples can represent almost of 48 kHz of RF spectrum (again accounting for filter transition bands). For a

better understanding of the reasons behind these general rules there are several excellent references including Richard Lyons' book *Understanding Digital Signal Processing* that can be consulted. (See the Reference sections of the **DSP and SDR Fundamentals**, **Receiving**, and **Transmitting** chapters for a comprehensive set of references rather than reproducing them in this chapter.)

In either situation, the primary need to reduce the bandwidth for the receiver signal chain is driven by the processing resources required to process the receiver signals. The more bandwidth that is captured digitally, the higher the sampling rate and consequently the more processing power required in our signal chain. If we plan to ultimately discard the extra bandwidth in a filter, then we are wasting valuable processing resources by processing a wider bandwidth than we ultimately need.

In any of these cases, our first step is generally to reduce the bandwidth of the incoming signals through decimation. (See the **DSP and SDR Fundamentals** chapter) By decimation, we reduce the number of samples in the receiver by combining multiple samples and producing an output that has fewer samples, but with more bits per sample (greater bit width). After decimation, the receiver will typically have a sampling rate of somewhere between 24 and 48 ksp/s. We will then process all elements of our signal chain at this rate. While this is not strictly necessary, it is the most convenient. If our sampling rate varies in each block of our signal chain, we will be constantly buffering and re-sampling, again wasting valuable time and computing resources.

A typical receiver signal chain is shown in **Figure 14.2**, again computing from right to left. (This is the same direction as signal flow in the block labeled "Receive Signal Chain" in Figure 14.1.) Each DSP block in the chain will take input samples, generally in a buffer or block of samples, process the samples using the algorithm for the block, and then pass the resulting samples to the next block. It is a requirement of the receive signal chain that all blocks are processed in less than the time it takes before another buffer of samples arrives.

What does this mean? Let's say that our system is running at 48 ksp/s and our sample buffers are 512 samples each. We will receive a new buffer every 10.67 ms. If we are not able to process the next sample buffer because we are still processing the last buffer we received,

then the buffers will stack up forming a queue of samples needing processing. Even worse, our DAC at the output of the signal chain has the responsibility for turning a stream of sample buffers into a continuous audio signal. If we "starve" it by not sending a buffer when it has exhausted the previous buffer, it will be forced to play empty audio or repeat previous buffers. If you've ever used digital electronics built this way, you've likely experienced the effects first-hand. Here are some examples of how other engineers dealt with a similar problem:

1. In XM satellite radio, when the satellite signal is briefly lost some satellite radios play "comfort noise," a low-level hiss that sounds like a normal AM or FM signal that has faded away. This noise is completely synthetic and doesn't represent any actual noise in the receiver. Since the source signal is digital, the receiver knows when the signal has faded and could easily play "blank audio," but it was probably judged that this sound would best convey to the consumer that the radio is working, but has lost a signal.

2. Many CD players, when starved for digital data from the disc due to a scratch and the inability to recover the signal, will replay the contents of the last digital buffer, resulting in a repetitive sound reminiscent of a skipping vinyl record player. This sound conveys to traditional (analog) vinyl users that there is a problem with the disc. (Data however, does not warp when left in the sunlight on a vehicle's back seat!)

It is, therefore, important to budget processing power to ensure all blocks can be processed in the time it takes to collect a new buffer. If our radio has more than one receiver, but a single processing element, our requirement will be to process all the DSP blocks for all receivers in the requisite time for a single buffer. While beyond the scope of this discussion, it's worth mentioning that multi-core processors, both symmetric and asymmetric, can provide a platform for some unique solutions that stagger or pipeline DSP blocks and receivers and allow spreading the processing requirements across different cores.

### PASS-BAND FILTER

Next, we filter the buffered data. The filter removes unneeded signals from the buffer, limiting it to just our bandwidth of interest, called the *receiver pass-band*. Since the samples entering the filter are 48 ksp/s of I/Q data, we start out with something on the order of 40 kHz of audio bandwidth. If we are using sideband, we're only typically interested in a bandwidth of 2-5 kHz. If we're using CW we might want to reduce the bandwidth down to 50-100 Hz. The filter achieves this reduction in bandwidth by employing DSP filtering techniques. (See the **Analog and Digital Filtering** chapter)

Figure 14.2 — Typical functional blocks that make up a receive signal chain.

The filter may need to accumulate several buffers of time-domain samples before performing the filter processing depending on how steep or sharp the filter skirts are required to be in order to create the filter's required shape factor. As mentioned previously, it is also required that once we have accumulated the requisite buffers, we must process the filter within the duration of our buffering. For example, if our buffer size is 512 samples and we are using an overlap-and-save FIR filter with 2048 taps, we will need to accumulate 2048 samples before processing the filter. After this, 1024 samples will be added to the filter for the next processing, since 1024 samples are saved from the last processing. In aggregate, we must be able to process this filter in under  $1024/48 \text{ kpsps} = 20.3 \text{ ms}$  of CPU time (including all other signal chain operations).

Filters used in receivers can be of many different topologies including finite impulse response (FIR) and infinite impulse response (IIR). Even within these two broad categories there are a plenty of additional variations that affect passband and stop-band ripple, phase distortion (detrimental to some digital modes), group delay, and other parameters. Also, this filter which is often called the *final filter* since it is the last filter before the signals are presented to the operator, will determine a significant part of the receiver latency (the delay between the input of an RF signal to the output of the data or audio). Why is this? The slower the sampling rate, the more impact collecting samples and filtering them will have on latency.

Some radios allow the operator to make tradeoffs in filter parameters, favoring low latency at one time and favoring the best filtering at another. A sizable FIR filter using 4096 taps will add roughly  $1.5 \times 4096 / 48 \text{ kpsps} = 128 \text{ ms}$  of latency. This is not a large amount for phone conversations, but would be significant for CW contesting.

One of the great triumphs of SDR is that we have eliminated our dependency on needing a collection of electronic or mechanical filters. We now have continuously variable filters that let us tailor our pass-band to meet our operating demands without worrying about the design cost or space for our old electronic and mechanical filter collection. In some radios, we can also adjust the taps in the filter to select better filter shape factor or lower latency as our operations dictate.

## DEMODULATOR

The demodulator performs the conversion of on-air signal to the baseband audio signal that we will be hearing. For example, with FM we must convert a fixed-amplitude carrier changing frequency according to the amplitude of the audio into a time-domain amplitude-varying signal that we can understand with our ears and brain. The output of

Figure 14.3 — Typical functional blocks that make up a transmit signal chain.

the demodulator is audio that we can hear and understand.

The demodulator block is selected based on the mode being used. When you change the mode of the radio on the front panel, you are switching one demodulator with another for the mode you have just selected. Of course, the filtering and noise mitigation techniques may vary by mode also, and so we may be switching other blocks in the DSP chain based on the requirements of each mode.

### 14.1.2 Transmit Signal Chain

For phone, the transmit signal chain will prepare spoken audio for transmission over the air. If our mode is CW or other digital modes, the transmit signal chain will be very different, perhaps just a single or a pair of software oscillators that produce the tones that we will send on air. Figure 14.3 shows a typical signal chain for phone transmission.

## GAIN

Depending on how the designer has implemented the ability to change output power in the radio, a gain stage may exist at the start of the signal chain that can be adjusted to raise or lower the power of the transmitter. This gain stage could be implemented at other places in the radio as well. A gain stage will multiply all samples in the buffer by an input level value, raising or lowering the level of all audio samples in the buffer.

## EQUALIZATION

In a software defined radio, it is easy to isolate frequency bands in an audio buffer and allow each band's relative power to be raised or lowered. This equalization function can be used to tailor a person's voice to produce the best sound on the receiving end. This function is known as equalization or simply EQ. The input to the equalization function is the relative increase or decrease for each band of interest. A typical equalizer panel with vertical sliders for each audio band is shown in Figure 14.4. At the output of the equalization stage, we have audio prepared for transmission, but it may exceed required output levels that have been set in the radio. For example, we may independently have set a maximum output power for the radio to prevent overshooting an amplifier input. This is where a clipper becomes useful.

Figure 14.4 — An equalizer control window showing the adjustments for each frequency band of interest.

## CLIPPER / ALC

A clipper may be employed to reduce the level of any signals that exceed required power levels. It generally does this by checking each sample in the buffer for the maximum allowable level and replacing any samples that exceed the threshold with a corresponding sample of the maximum level, thereby clipping the peak value of that sample.

While clipping can produce undesirable effects, it may be necessary to prevent the radio from operating outside the limits provided by the operator. Automatic level control (ALC) may also be used to reduce signal levels if a downstream amplifier provides voltage to the radio requesting a lowering of the levels.

Generally, a series of meter displays or values derived at different stages in the signal chain will provide the operator with information on undesired effects occurring within the signal chain. This allows the operator to make adjustments to correct any undesired effects. Since we have absolute control over the signal level by altering samples in the radio, it is generally better to set a maximum power out in the radio and allow the signal chain to make the appropriate adjustments than to rely on ALC to adjust the levels when they are too high for an amplifier.

An ALC subsystem that is too active can modulate the transmit signal. This results in distortion that could be prevented by adjusting the proper levels in the signal chain to start with. This is why many digital mode guidelines specify that the ALC system be switched off — to avoid unintentional distortion of the signal by power control systems.

## FILTER

Since our audio input may contain frequency components well above those required or that comply with good practices, a filter is employed to remove them. For normal SSB operation, we could set the filter to pass audio from 100 Hz–2.8 kHz. For Extended Signal Sideband (ESSB), we may set the filter to pass audio from 50 Hz–4 kHz or more. The transmit filter setting may also be set to comply with communication laws in the country where the transmission is occurring.

The filter will remove the unneeded frequency components of the signal before transmission using similar DSP techniques to those in the receive signal chain filter.

## MODULATOR

The modulator will then take the audio signal and create a modulated RF or IF signal required by the operating mode. The modulator takes care of placing the audio in the proper sideband for SSB, producing the carrier for AM and performing frequency modulation for FM. After modulation, the signal is ready to be transmitted.

## SUMMARY

Signal chains are the heart of the software defined radio. This overview provides the basics of how a signal chain is put together and the requirements on each of the DSP functions. A typical signal chain in an SDR may have many more blocks including blocks to meter samples, providing valuable feedback to the operator, more audio tailoring and filtering blocks, oscillators for in-air testing, speech compressors, and so on.

# 14.2 User Interfaces

Many years ago, the knob we used to tune our radios was often attached to a frequency indicator stenciled on a piece of plastic that would rotate into view as the knob was turned. The plastic marker displayed an offset into a band selected by a band switch. The strength of any incoming signal would be displayed on an S meter, a magnetic meter movement excited by the voltage from the AGC circuit. In the 1970s and 1980s, the *liquid crystal display* (LCD) and *light emitting diode* (LED) display came into popularity and most radio manufacturers adopted some form of display device that used LCD and/or LEDs. Both technologies were used to show frequency, mode selections, and simulated S meters without their mechanical counterparts.

These technologies of the past provided only minimal *situational awareness*. We only had a narrow view of the spectrum limited to the instruments at hand showing us the signal strength in our narrow receiver along with a

display of our current frequency. There was no way to see how many signals were on the band, how strong they were, whether the noise floor in the band was rising, or if we might just be listening where some local noise was causing us interference.

With *panadapters* now available on modern transceivers, we can see all the signals across the band. Finding a place to call CQ can be difficult when the bands are busy. With a panadapter, we can glance at the band and notice where there are gaps, quickly tune to an empty frequency, and call CQ. We can also instantly tell where the strong and weak signals are in the band. If we're looking for signals arriving at our location through particular propagation, we can search for signals that look alike or share the similar power levels.

The *waterfall display* provides the same information with a time-historical twist. In the waterfall we can see how signals and noise are changing over time. Imagine working a DX

pileup where a few hundred amateurs are all trying to work the same station. We can watch the DX station systematically contact every station and observe the operating patterns. We know where the DX station is listening because we can see each station in the pileup respond to the DX station as they are called. Observing this pattern, we now know where the DX will listen next and can simply drop our call in this location and make the contact. Those enjoying panadapters today lament: how did we survive without this capability?

The tools available today for gaining a situational awareness of the bands and our receiver have dramatically changed. Let's look at each of these tools in some more detail.

### 14.2.1 The Panadapter Display

The *panadapter*, or spectrum display, shown in **Figure 14.5** displays the amplitude

Figure 14.5 — A typical panadapter display showing a number of signals over about 18 kHz of the 40 meter CW segment.

of signals across a range of frequencies. The panadapter's design roots come from spectrum analyzers that were designed in the 1950s and 1960s. These instruments featured a swept receiver that tuned across the band. As the receiver tuned the band, the signal level in the receiver was captured and displayed. The resulting display is a graph with frequency on the x-axis and amplitude on the y-axis.

The spectrum analyzer has proven its worth in many areas from radio design and troubleshooting to the analysis of on-air interference problems. The almost-continuous view of the spectrum allows the operator to quickly understand the spectrum and act accordingly. A spectrum analyzer's controls allow alteration of the bandwidth of the sweep receiver, known as *resolution bandwidth (RBW)*, the *sweep rate* of the receiver, the total bandwidth displayed and other parameters. (See the **Test Measurements and Equipment** chapter for more details about spectrum analyzers.)

In the absence of a signal, the swept receiver would return the higher of the noise from the input port of the analyzer or the spectrum analyzer's noise floor. This noise floor visualized or painted is partly a function of the bandwidth of the sweep receiver itself: the wider the bandwidth, the more noise was input to the receiver and the higher the noise floor appears. If the noise floor visualized on the sweep was higher than signals of interest, the resolution bandwidth of the receiver could be lowered, reducing the noise let into the receiver and lowering the noise floor of the display.

In the absence of a signal and assuming evenly distributed noise, the noise floor will drop by 3 dB each time the resolution bandwidth is halved since the total noise in the receiver was cut in half by the bandwidth filter. Typically, as the display is "zoomed in" to show less bandwidth on the screen, the instrument will automatically reduce the receiver bandwidth in the sweep (resolution bandwidth) and the noise floor of the display will drop. The swept receiver approach to a spectrum display is used in radios designed in the early 2000s, such as the Icom 756 Pro-series.

The swept receiver design has some key drawbacks, though. First, time is required for the receiver to settle, a measurement to be taken, and the receiver tuned to the next frequency. This limits the speed at which the receiver can tune and often results in a slow "painting" of the display that lacks the full-motion look of modern panadapters.

The slower sweep rate reduces situational awareness. For example, imagine someone sitting sending a series of CW dits. In the swept design, the receiver will typically hear a signal or no signal as it passes the CW dit signal. We will either see a nice signal out of the noise—or nothing—depending on the timing of the dits in relation to our sweep receiver. With a modern panadapter refreshing many

times per second, we can see the signal rise and fall with the CW dits, giving us a clear view of what's going on.

The second drawback of the swept receiver design is the tradeoff between sweep speed and resolution bandwidth. As we reduce RBW to see more detail in the spectrum, the sweep rate must slow because the measurement takes longer; primarily because the narrower filter requires more time for signals to pass through and stabilize before the measurement takes place. The more detail we want to see, the slower our display updates, and the lower our situational awareness.

Today's transceiver panadapter displays are built on many of the same principles of the spectrum analyzer with one notable exception: today's receiver panadapters are almost always built from a Fast Fourier Transform or FFT (See the **DSP and SDR Fundamentals** chapter). The FFT accepts a wide bandwidth of time domain samples from an analog-to-digital converter and translates the time-domain signals into the frequency spectrum.

## PANADAPTER TYPES

There are two main panadapter types available in current amateur products; the *dependent* and *independent* panadapter. In a dependent panadapter design, the data for the panadapter is from the receiver's IF signal. In this scenario, the panadapter will always show the spectrum to either side of our received frequency which is shown in the center. For example, if the panadapter display spans 192 kHz, our receive frequency will be in the center and we will see 96 kHz of spectrum on either side of the receiver.

In contrast, an independent display operates independently of the receiver. The panadapter display frequencies can be moved and the received frequency can be moved without being in the center of the display. This allows showing a DX pileup with the DX station on the left, the pileup on the right and tune our transmitter across the pileup without shifting the spectrum display. Internally, this requires a separate receiver just for the panadapter that is tuned independent of the receiver(s) in the radio.

The FFT used to build the panadapter is always measured in *points* or *bins*, each of which is essentially a collection of receiver channels like our sweep receiver in the spectrum analyzer. The bins are spaced evenly across the range of frequencies output by the FFT. The bandwidth of each bin is determined by the total sampling width presented to the FFT divided by the number of FFT points. For example, if our input is 192 kilosamples per second (abbreviated ksp/s), and we use a 4096-point FFT, each bin of the FFT would represent a receiver that is  $192,000 / 4096 = 46.875$  Hz in width. In other words, each point in the display of our FFT represents the signal and noise heard by a receiver with a

bandwidth of about 47 Hz. In this way, you can think of the panadapter as a series of equally spaced S meters, laying on their sides continually showing the signal level in each of our FFT bins.

To compute an FFT for a panadapter, the FFT must first collect enough time-domain samples to fill the input registers of the FFT. Using the previous example, a 4096-point FFT required 4096 time-domain input samples in order to create a 4096-point frequency-domain output. For a receiver operating at 192 ksp/s, the time required to collect these samples is  $4096 / 192,000 = 21.3$  ms. After this time, the FFT can be computed and a *frame* can be displayed for the operator. The maximum possible frame rate for the display is the reciprocal of the time to fill the input. In this example,  $1/21.3\text{ms} = 46.875$  frames per second (46.875 Hz refresh or update rate). Note that this frame rate is exactly equal to the bin width of the FFT.

Considering a typical sideband signal with a bandwidth of 3 kHz, the panadapter just described would show  $3,000\text{ Hz} / 46.875\text{ Hz} = 64$  different points across the audio range of a received signal. Since a sideband signal is the audio in the operator's voice shifted in frequency to the RF spectrum, we can see the energy in the operator's voice at each of 64 different frequencies as the operator talks. Outside of the operator's intended transmit bandwidth we can also observe any RF that is transmitted unintentionally. This allows us to observe the cleanliness of signals on the band in significant detail.

**Figure 14.6** shows a transmitted SSB signal that is fairly clean, that has little RF outside of the transmitted band of interest, and **Figure 14.7** shows a significantly less clean signal displaying splatter caused by an improperly configured amplifier. This capability is particularly useful for assisting another amateur to diagnose a transmitter that has signal anomalies. The visual representation of their transmission can make quick work of identifying intermodulation distortion, splatter, and other problems.

For CW or narrowband digital mode operation, a panadapter with a higher resolution than 47 Hz is desired. There are two ways to achieve higher resolution:

1. An increase in the number of points in the FFT directly reduces the bandwidth of each FFT bin, both lowering the noise floor and increasing the resolution.
2. A reduction in the bandwidth of the samples presented from the ADC also directly affects the resolution. For example, if we simultaneously reduce the ADC bandwidth to 96ksp/s and increase the FFT to 8192 points, our bin size is now  $96,000 / 8192 = 11.7$  Hz, a reduction factor of four in the bin size. The noise floor of the narrower bin will decrease by 6 dB as well.

Figure 14.6 — A panadapter display showing a cleanly transmitted SSB signal.

Figure 14.7 — A panadapter display showing an SSB signal with splatter and other distortion products.

The resulting display shows higher resolution but this comes at a price. First, the frame rate of our FFT is now 11.7 frames per second. This is because we must now collect  $8192 / 96,000 = 85.3$  ms of data before calculating the FFT. Also, because the FFT is now based on a larger time period of data, fine temporal (moment-to-moment) details are lost in the display. For example, a 60 WPM CW signal is composed of 20 ms dits and 20 ms spaces between elements. A string of dits at this speed could be visible as individual pulses in our first FFT example, but would be somewhat lost in the new FFT since several transitions would occur during each FFT frame. This time limit tends to place practical limits on how fine-grained an FFT can be used in a panadapter. The other practical limit is computational complexity. As the number of points in the FFT is increased, more computing power is required to calculate the FFT that is the basis for the panadapter.

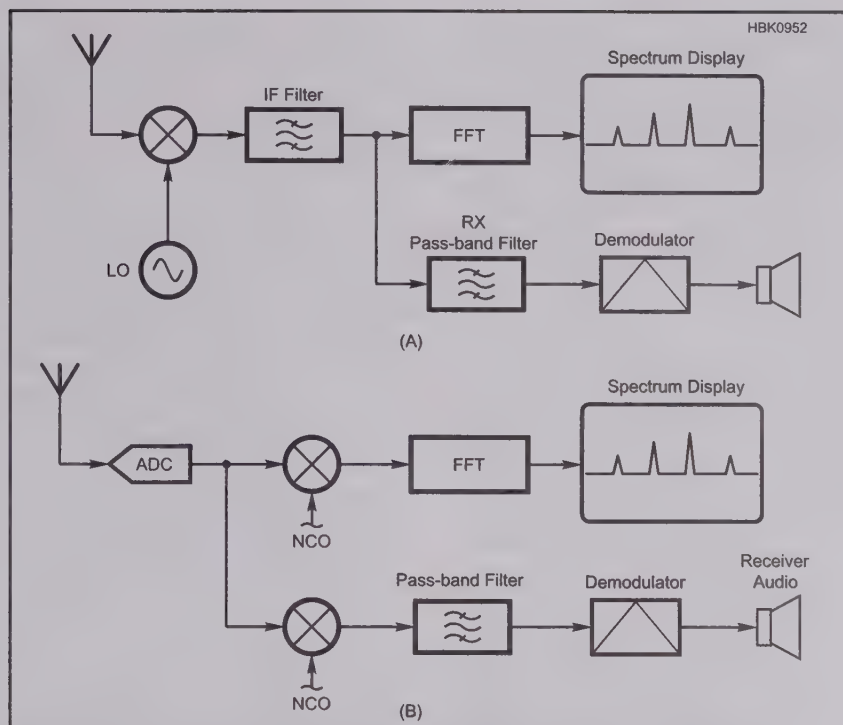

How far we might “zoom in” to a panadapter display is a function of what we want to observe. For SSB with signals approximately 3 kHz wide, we often want to observe many tens of kilohertz of spectrum to get a good view of other signals on the bands. In contrast, with CW we might only want to see a few kHz of bandwidth to determine the exact frequency of each CW signal. With two-tone FSK (RTTY) and PSK (PSK31) signals, it can be helpful to see both components clearly to aid in tuning, but not at such a fine resolution that the display operates slowly or incurs temporal distortion. A properly designed modern panadapter will allow us to make these tradeoffs to get the panadapter tuned “just right” to give us the view of the spectrum we need to help most in our operating mode.

## PANADAPTER CONSTRUCTION

There are several methods for building panadapter displays, but the two key pieces of a panadapter display are the receiver and the FFT. As mentioned earlier, dependent panadapters (Figure 14.8A) are derived from the same receiver we use to demodulate and copy stations we are trying to work. In this case, the primary decision is how wide to make the receiver (sampling rate) since this will determine the bandwidth of our panadapter.

In radio systems with dependent panadapters for which the processing of the receiver signal chain is performed on a PC, the designer must be careful to limit the panadapter bandwidth since all this data will need to be sent to the PC and processed using the PC’s main CPU. The dependent panadapter architecture was invented with *PowerSDR* and first shown on the original FlexRadio transceivers such as the FLEX-5000. This panadapter architecture is also used in the HPSDR and several other radios.

With the independent panadapter architec-

**Figure 14.8 — Panadapter architecture.** (A) Dependent architecture in which the panadapter and main receiver signal chain share common tuning and filtering mechanisms. The panadapter and receiver are tuned together. Dependent panadapters can be implemented both as superheterodyne and as direct sampling receivers. (B) shows an independent architecture in which the panadapter and receiver have their own signal chain. The panadapter and receiver can be tuned independently of each other.

**Figure 14.9 — Variable rate decimation.**

ture shown in Figure 14.8B, we see that the receiver and panadapters are separate. This architecture allows tuning the panadapter independently of the receiver and gives rise to more flexibility in setting up the panadapter display and receivers. The other key consideration is the rate of the sample stream from the receiver into the FFT. As discussed above, this affects the bin width of the display along with the refresh rate of the display. It also affects the amount of processing power required to process the raw data from the receiver. The wider the panadapter, the higher the sampling rate data is required to produce the display and the more computing power is required, assuming no loss of data.

To implement a “simple” panadapter display using the independent panadapter archi-

techure, we could use a signal receiver with a bandwidth of, say 1 MHz, running into a FFT with 16,384 FFT points (the FFT algorithm requires the number of bins to be a power of two, in this case  $2^{14}$ ). This would give us bin sizes of 61 Hz. If our radio display has, say, a horizontal width of 600 pixels we can implement a zoom-in and zoom-out feature by simply discarding or using a MAX function across bins we are consolidating into a single pixel. This type of display will also have a consistent noise floor, commensurate with a 61 Hz receiver bandwidth.

To implement a more advanced panadapter using the independent panadapter architecture, we could implement a variable rate decimation function as shown in Figure 14.9. The decimator or resampler can take in a sample

stream at one sample rate and output a stream at other rates. In this way, we can zoom-in and zoom-out by varying the decimation rate. For example, let's assume our input rate to the decimator is 1 Mbps. We could output 1 Mbps, 500 kbps, 250 kbps, and so on, down to any rate we needed. This data could then be input to the same FFT function.

The resulting FFT output frame rate will be the input sampling rate divided by the number of FFT points and will have a bin width equal to the sampling rate divided by the number of bins (assuming I/Q input data). This architecture is used in the FLEX-6000 Signature Series transceivers and requires substantially more computing resources than the simple implementation, but provides a more capable panadapter that can expand to many MHz of spectrum or zoom in to just a few kHz.

### PANADAPTER APPLICATIONS

The benefits of a panadapter can be wide-reaching. In the simplest of cases, the instantaneous view of the spectrum can quickly demonstrate where the band is and is not in use. Watching the band for just a few seconds gives the operator an idea for a good place to call CQ. It's always a good idea to check if the band is use before calling since only one side of a conversation may be audible from your QTH, but this same awareness of the band is difficult to achieve by spinning the dial.

When operating on microwave weak signal bands, it can be hard to find other signals. Rover (mobile) stations using crystal-controlled rigs in very cold or very hot weather may have drifted many kHz from their dial frequency due to the multiplicative effect of crystal error on higher bands and temperature changes in the rover. A panadapter makes quick work of locating these operators. A common methodology is to ask a rover to "send dashes" on a microwave band and then watch the waterfall for the tell-tale dashes to appear. Because signals deep into the 500 Hz noise floor can be seen on the waterfall display, we can see signals from stations before we can hear them and this can also be used to assist in pointing antennas. As a fixed station, we can tell the

rover operator on a liaison frequency to rotate his antennas as we watch the panadapter for a rise or fall of signal strength. Some panadapters have increased their FFT bins to  $2^{17}$  to reduce their bin size and allow them to see even further into the noise floor.

In contesting, there are often advantages to working stations in a particular order. For example, weaker stations that have reduced signals in the panadapter may be DX stations that would result in a multiplier. Stronger stations are easier to work and bagging these stations first might be a strategy worthy of consideration. In some sprint-style contests *running*, continually calling CQ on the band and working stations that respond to your CQ, is not permitted. Finding other stations quickly becomes paramount in this type of operating event. With a panadapter, finding stations quickly is simplified to looking for peaks in the panadapter display.

Interference in contests is a frequent problem and rapid identification and resolution of interference sources is important. An adjacent splattering station is obvious in a panadapter and can allow an operator to make a quick comment to the right station, asking for the other operator to check the transmitting equipment. In some situations, changing frequency may be required and again the panadapter can help locate where to move. From a competitive standpoint, having a panadapter is akin to having extra mirrors on a race car to see where other competitors are and what they are up to.

For panadapters displayed on a computer monitor, tuning can often be achieved by placing the a cursor on a signal or specific frequency and clicking. Quickly working stations in this manner bypasses the required tuning on traditional receivers. In this situation, the panadapter can provide a significant advantage. This is also true of panadapters on touch-screen devices where tuning can be accomplished by just tapping on a signal seen on the panadapter display.

Interference and noise are common in today's RF landscape. The panadapter offers the same capabilities of a spectrum analyzer by

showing instantaneous views of the spectrum to help with isolation and characterization of noise. Some noise is limited to a narrow range of frequencies while other noise sources may repeat on a specific frequency interval. Knowing the repeating frequency interval of a noise source or the similarities of the noise across the band can aid in diagnosis of the type of noise. Some types of noise drift over time while others remain fairly constant with time. Other noise is broadband and raises the noise floor of the entire band. All of these different characteristics of noise can be easily observed in a panadapter, giving the amateur a thorough view of the type of noise under investigation.

### 14.2.2 The Waterfall Display

The *waterfall* display is similar to the panadapter in that it has frequency along the x-axis. The y-axis in a waterfall is time rather than amplitude as shown in **Figure 14.10**. The waterfall display is typically created line-by-line, starting at the top of the display. A new line is added to the display with each unit of time and all previous lines of the display are shifted down one line. In this way, the waterfall shows what has happened in the spectrum over time. It is this flowing motion of the waterfall that gives the display its name since it gives the impression of a band of slowly falling water.

Let's build on the earlier analogy of a panadapter as equally spaced S meters lying on their sides. Similarly, the waterfall display can be envisioned as a series of panadapter frames, equally spaced in time and lying on their sides so we view them "from the top." What we see in the waterfall is color or intensity representing the height of the signal (amplitude) in the panadapter. Each line of the waterfall has either different colors or different intensities on each frequency that represent the signal level from the panadapter during that period of time. Typically, brighter or more intense colors represent stronger signals. By looking at the waterfall display, we can see the occupation of frequencies across the spectrum over time. The historical view of the waterfall can assist

Figure 14.10 — A waterfall display showing the same spectrum as the panadapter in Figure 14.5 with CW and digital signals. More recent data is at the top of the display and signal strength is indicated by brightness.

in locating a frequency that is either has been or has not been in use depending on the need.

Like its cousin the panadapter, waterfall displays are also calculated from an FFT, sometimes from the same data used to produce the panadapter. The waterfall also uses the same FFT bins and follows the same rules as the panadapter. The noise floor visible in the waterfall is determined by the bin size of the FFT. The narrower the bins in the FFT, the less noise in the bin and the more weak signals can be observed in the waterfall. In Amateur Radio, we generally refer to the noise floor as the noise observed in a receiver with a 500 Hz bandwidth. If our FFT bin width is 50 Hz, our noise floor would be 10 dB lower, calculated as  $10\log_{10}(500/50)$ . Similarly, a 5 Hz bin would have a noise floor 20 dB lower than for a 500 Hz receiver bandwidth. To see signals “below the noise floor” is a useful capability in both the panadapter and waterfall displays.

The historical view of a waterfall can provide an additional level of information not always visible in a panadapter. Using the same microwave operating example, assume that we are attempting to hear 10 GHz signal from a microwave rover with the dish antenna slightly off our bearing. A common technique is to ask the rover to send a series of slow CW dashes “please send dashes” using a VHF liaison frequency. By watching the noise floor in the waterfall carefully, we may be able to see a faint line representing those dashes. We can then ask the rover to rotate the dish one way or the other and see if the intensity increases. The final outcome would hopefully be to align the dish

where we can hear the rover.

Using an HF example, the waterfall can provide unique insight into the patterns used by a DXpedition station operator. Knowing these patterns and where the DX station is transmitting can help the DXer pick a frequency that is likely to be heard, and worked, by the DX station. For example, by observing the DX station working several stations across a pileup, the DXer can immediately put the information to use and “tailgate” the last contact hoping to work the DX entity before the listening frequency changes. Consistently locating the DX entity on a traditional receiver by spinning the dial is futile in comparison.

### COMBINING THE PANADAPTER AND WATERFALL

A common way to show both a panadapter and a waterfall display at the same time is to position the panadapter above the waterfall, both lining up in frequency so that a common frequency axis is used for both. In this way, we can see what’s happening now in the panadapter and what happened in the past in the waterfall.

A vast amount of information is presented to the operator with both displays present simultaneously. A short burst of noise heard in the receiver could be anything, but close examination of the panadapter and waterfall can show that it is a signal slowly moving across the spectrum (perhaps an ionosonde) or maybe it’s a spread-spectrum signal that is 10 kHz wide moving around the ham bands. The difference will be apparent looking at a wider view of the waterfall and seeing the

same signal move around the band. Most operators find that after using a panadapter and waterfall for a while they are not able to easily go back to using a radio without these features that enhance situational awareness.

### 14.2.3 User Control Interfaces

The front panel of the radio, referred to here as the *user interface* or simply, *interface*, provides for control, meters, status, frequency indicators and displays such as a panadapter and/or waterfall to visualize the spectrum. Typical controls allow for changing the frequency, mode, mode-specific settings and other features of the radio.

#### THICK CLIENTS

The SDR-1000, an amateur SDR designed by Gerald Youngblood, K5SDR, was featured in a 2002 series of *QEX* articles listed in the references for the *DSP and SDR Fundamentals* chapter. The SDR-1000 hardware did not have an interface itself, but relied instead on a computer program as its interface. This first SDR interface, *PowerSDR*, was designed to display the spectrum and control the radio. *PowerSDR* is not only the interface for the SDR-1000, it also performs all of the signal processing required to both modulate and demodulate audio and produce all of the spectrum and other displays in the software. This type of interface is known as a *thick client* in the computer industry. The term thick client is used when substantial work must be done in the client software. **Figure 14.11** shows how

HBK0954

Figure 14.11 — A block diagram of the SDR-1000 showing the main data flows for signal processing.

the signal processing software in *PowerSDR* works with the radio.

There are generally four streams of real-time data that flow between a thick client and the SDR hardware:

1) Receiver samples are time-domain samples collected by the SDR hardware. The hardware itself can be direct-sampling, a superheterodyne (followed by an ADC), or direct conversion. The samples sent to the software for processing are generally in the range of 48 kbps to 384 kbps. Since the samples are often sent as both in-phase and quadrature (I/Q) and are often 16-32 bits each, a 384 kbps stream can contain as much as 25 Mbps of data.

2) The receiver samples are tuned, demodulated, filtered and ultimately provided to the radio hardware for audio output, usually from headphones or speakers.

3) Microphone samples are captured in the radio hardware and sent to the software for processing and preparation for transmission.

4) Transmit samples are sent from the software back to the radio for transmission when the radio is transmitting.

Some radios require both the speakers and microphone to reside on the computer rather than the radio. In this case, both the speaker and microphone streams are generally not sent to and from the radio, respectively.

Once the interface software has the samples collected from the receiver, it can perform the DSP functions required to create the audio signal. (See the sections on Receive and Transmit Chains earlier in this chapter.)

Similarly, the transmit signal chain commonly has a modulator, filter and limiter. When the radio is transmitting CW or FSK, the SDR software generally synthesizes the waveforms for both of these modes directly without the need for many of the other transmit signal chain elements. For this reason, it is common for there to be a separate signal chain for each mode.

The thick client SDR interfaces such as *PowerSDR* place a higher demand on the computing hardware since many of the DSP functions are performed in the computer. There is also a stringent set of requirements around timing to ensure that the constant flow of samples on both the receive and transmit sides is not interrupted. If an interruption occurs on the receive side, it will result in audio dropouts. Interruptions on the transmit side can result in discontinuities in the transmit signal. Depending on the hardware involved, discontinuities in the transmit signal can result in high frequency components that cause the transmitted signal to reside outside of the desired transmit passband. There are advantages to the thick client architecture, specifically:

1) Since computing and software require-

ments for the radio itself are minimal, the radio hardware can be less expensive.

2) Software that runs on the PC is typically easier to develop, test and debug.

3) As PC hardware has continued to achieve higher price-performance ratios, more power for more capabilities can be added without changing the radio..

The thick client architecture is now common, due in a large part to the availability of open source *PowerSDR* and the ease of adapting it to other radios. More than one HPSDR radio has been designed using this architecture as have the ANAN radios, adapted from the HPSDR designs.

## THIN CLIENTS

In contrast to a thick client interface are *thin client* interfaces. In a thin client, all or most of the work required to modulate, demodulate and produce the displays for the radio is performed inside the radio hardware. The thin client is used, then, to display the interface and accept control commands which are passed to the radio for processing. An example of the thin client approach is the FLEX-6000 Signature Series radios by FlexRadio Systems.

In the FLEX-6000, all modulation, demodulation and radio control are performed in the radio in the *SmartSDR* software running under *Linux*. This reduces the performance requirements on the client system used for the interface. In turn, the interface can easily be run on cellular phones, tablet computers and other less expensive computing hardware. Key advantages of the thin client architecture are:

1) A wide array of computing hardware can serve as the interface due to the low computing demands.

2) Reduction of network bandwidth between the client and radio due to the process-

ing occurring in the radio. This allows remote operation over low-speed network interfaces making remote directly to a cell phone possible, for example.

3) The client software is considerable simpler since it is just responsible for display and control and can, therefore, be easily ported to new computing devices resulting in a wide array of available interfaces and interface platforms.

4) Availability of an applications programming interface (API) due to the necessity of an API for the client. This API can then be used by other amateur applications wishing to use the radio as a server or utility.

## 14.2.4 Panadapters for Older Radios

Panadapters can also be added to an older analog or analog-digital hybrid transceiver. The concept is straightforward; use an SDR receiver to monitor the radio's IF spectrum while the radio operates normally. The radio provides the front-end preselector, band-pass filtering, and initial IF filtering. The SDR and software displays signals in the IF passband. As the radio is tuned, signals move across the display. This is an example of *dependent architecture* as described in this section (see Figure 14.8). Panadapter software demodulates signals independently of the radio, so different signals can be monitored simultaneously on the radio and the panadapter.

Adding a panadapter to an older radio requires 1) an SDR device with display software that will cover the receiver's IF; and 2) a method of interfacing the SDR to the IF of the radio. SDR devices come in all capabilities and price ranges. The two most common and least expensive types are:

## Software for External Panadapters

Software for display and demodulation is dependent on SDR type and PC operating system. All listed titles below have versions available for multiple operating systems. The following packages support the Windows operating system:

- **HSDR:** ([hdsdr.de](http://hdsdr.de)) Powerful, many customizable features. Can record RF or AF on a timer. Mild learning curve. Widely used.
- **SDR Sharp:** Powerful. Easy to use. Lots of add-ons and customizations. The port driver *Zadig* (included with the distribution) is required for using *SDR#* with RTL-SDR. Specific instructions on how to properly load *SDR#* on the [RTL-SDR.com](http://RTL-SDR.com) website and must be followed exactly. ([sdrsharp.com](http://sdrsharp.com) redirects the browser to AirSpy website where *SDR#* software is available under downloads)
- **SDRRuno:** ([sdrplay.com](http://sdrplay.com)) Supports all *SDRplay* and other packages.
- **SDR Console:** ([sdr-radio.com](http://sdr-radio.com)) Extremely powerful, multiple windows. More advanced learning curve.
- **RTL-SDR:** ([rtl-sdr.com](http://rtl-sdr.com)) Supports the RTL2832+R820. Detailed installation instructions, much information.
- **Rocky:** ([dxatlas.com](http://dxatlas.com)) For SoftRock (or other I/Q type devices). Simple and works well.

Two packages for the Android operating system include *RF Analyzer* and *SDR Touch*. Both are designed for use with RTL-SDR connected to the Android device by an OTG ("On-The-Go") cable. More software is available from Google Play.

1) An external commutating mixer (also called a Tayloe mixer — see the Receiving chapter) such as a SoftRock. These use a fixed or variable LO to switch a multiplexer IC that samples the IF signal in quadrature (every 90 degrees). The result is a pair of audio frequency I and Q signals that are fed to a computer soundcard for the display and demodulation software.

Limited by the performance of inexpensive components and the requirement for an LO that usually runs at 4 times the IF, these are generally limited to a maximum IF frequency of 30 MHz. An additional limitation is the sample width and quality of the soundcard. Built-in PC soundcards are often limited to 48 kHz, so 24 kHz is the limit of the displayable RF bandwidth. Higher performance external or add-in soundcards are available with sample rates up to 192 kHz with 24-bit resolution.

2) USB “dongles” such as the FunCube Dongle Pro+, a USB plug-in with a 0.15 to 1900 MHz RF range and 192 kHz bandwidth. These have automatically selected internal RF filters and offer surprisingly good performance. Other popular types are SDRPlay, AirSpy and HackRF. For an IF higher than 25 MHz, the RTL2832U+R820 European TV tuner dongle, commonly called RTL-SDR, includes software that converts it into a 24 – 1700 MHz receiver of 2 MHz bandwidth and 8-bit resolution. These have no internal filtering but if applied properly, work OK for IF monitoring.

Interfacing to the IF requires modifications to the radio. Making the modifications to add the panadapter could void the warranty and can damage the radio if done incorrectly. Refer to a skilled transceiver technician if you are not comfortable making the necessary modifications on your own.

Adding an IF monitoring tap is not a simple task. Modern analog radios have low-impedance circuitry in the IF, so simply adding a 50- $\Omega$  device in parallel with the existing IF circuitry will be detrimental to stage gain and balance. Some SDR devices are known to

## SDR Panadapter Hardware

- JFET buffer amps from **SDR-Kits.net** and **huprf.com**
- Funcube: FCD Pro+ from **funcube-dongle.com**
- SDRplay: (**sdrplay.com**) Several versions available; 10 kHz to 2 GHz with up to 10 MHz bandwidth.
- Airspy: **airspy.com**
- HackRF: (**greatscottgadgets.com**) Frequencies to 6 GHz. Half duplex transceiver. Open source.
- RTL2832+R820 (**rtl-sdr.com**) Also called RTL-SDR. Available from Amazon, Nooelec, other sources.
- SoftRock: (**fivedash.com**) simple kits and pre-built.

generate switching noise from their input port where it is injected into the receiver's IF, affecting all signals received by the main radio.

There are several ways of tapping IF signal out of the radio. The radios for which it's easiest to add the panadapter have buffered IF outputs already built in. Examples include the Icom IC-R7000 receiver and Elecraft K2 and K3 transceivers. Simply connect the SDR device input to this output port. Some radios add a dc voltage to the IF output for supplying power to an external device. If the input of the SDR device you are using is dc-coupled, a dc blocking capacitor must be added. A value of 0.01  $\mu$ F will work in most cases. Use a ceramic capacitor with low lead inductance to minimize reactance at VHF and higher frequencies.

It may be possible to find a point in the IF signal path that is buffered. The Kenwood TS-430S and TS-700SP transceivers both have splitters and buffers in the IF path that feed separate FM demodulator circuits. (In these radios, a signal was always present at the buffer output, regardless of mode selected but that may not be true of all radios. Check

the in-depth User's or Service Manual for the transceiver.) An SDR connected to that point should have little effect on the overall receiver performance although dc blocking may still be required. Careful testing before and after adding the separate IF output is required.

Another widely used method of interfacing to tap into the IF with a high impedance buffer amplifier. An excellent design is available from SDR-Kits (**www.sdr-kits.net**) utilizing a JFET input buffer (100 k $\Omega$  input impedance) followed by a buffer amplifier and low-pass filter to drive the SDR device. These interfaces provide reverse isolation to keep SDR noise out of the IF chain. Information from the interface's original designer (G4HUP) is maintained on the SDR-Kits website.

It is also very useful to remove dc power or disable the IF output during transmit to prevent spurious audio noise and display artifacts during transmit. A source of dc in the radio that turns off during transmit or a control signal to enable and disable the IF output is useful. See the information from G4HUP on the SDR-Kits website for suggestions.

Examples of radios evaluated by the author include:

- Icom IC-R7000: An easy radio for adding a panadapter. The buffered 10.7 MHz IF is brought out to a jack on the back panel. No buffer amp required but adding a dc blocking capacitor is required.
- Kenwood TS-430S: 8.83 MHz IF. Worked well with SoftRock.
- Kenwood TS-700SP: A buffered path in the 10.7 MHz IF, similar to that in the TS-430S.
- Yaesu FT-817: No buffered path in the 68.33 MHz first IF so it requires a high-impedance buffer such as the G4HUP “PAT.” There is a version with a 70 MHz low-pass filter that removes artifacts before the following SDR. If the IF is tapped before the first IF bandpass filter, the SDR input bandwidth is approximately  $\pm 75$  kHz from the center operating frequency. After the first IF filter the SDR input has a bandwidth of  $\pm 10$  kHz.

## 14.3 Configuration and Control Interfaces

Computer control interfaces for radios play a key role in use of our radios beyond all but the simplest of operation. These interfaces allow us to check the status of our radios, change their settings, tune them and operate from a distance. Logging programs often use them during contests to automatically acquire frequency and other data for the contest log. In combination with logging programs, the interfaces can be used to automatically select antennas, turn rotators, and control other equipment in the station.

Each radio manufacturer has selected or designed an interface to work with their radios. Typically a manufacturer will use a common interface across their product lines. The user's manual and service manual contain complete information on the commands and data that are exchanged via the interface protocol.

### 14.3.1 Icom CI-V

Icom's control interface, CI-V, named as the fifth (V) Communications Interface (CI) is a serial "one-wire" protocol that uses the RS-232 electrical interface (generally with 5 V rather than the RS-232 standard  $\pm 12$  V), but allows multi-drop or multiple transceivers on a single CI-V communications line.

By using CSMA/CD (carrier sense, multiple access, collision detect), multiple radios can avoid using the communications interface at the same time, detecting when a collision occurs and retransmitting data. This is the same technique used in 10Base2 Ethernet in which coaxial cable was used and multiple computers used the same communications bus.

In CI-V, each radio has an address (which can be changed) and the computer can communicate with any of the radios on the CI-V bus. The CI-V protocol allows tuning the radio, changing modes, selecting memory channels, and other functions. CI-V generally treats the RS-232 data as bytes and references commands using their hexadecimal values. It is essentially a binary communications protocol. CI-V is also used in newer Ten-Tec radios, but with additional commands specific to Ten-Tec transceivers.

### 14.3.2 CAT (Computer Aided Transceiver) Interface

CAT is a control interface based on the RS-232 electrical standard. Most manufacturers such as Kenwood, Yaesu, Elecraft, and FlexRadio implement CAT via RS-232 or via a USB interface that emulates RS-232 signals. The protocol used by each manufacturer is proprietary to that line of equipment. Unlike CI-V, CAT is a point-to-point protocol meaning the expectation is that there is a single computer controlling a single radio on the line. CSMA/CD protocols are no longer required, but an additional communications port must be used for each radio. CAT is not a binary communications interface, but uses ASCII characters. As with CI-V, each radio implements only those commands that are meaningful to that radio.

With the advent of USB, many radios now make their CAT interfaces available over USB in the form of a USB communications port. When the USB cable is plugged into a computer, the USB protocol recognizes the device

as a communication port and adds a new port to the computer. In this way, many radios can be added to a single computer using a USB hub.

As Ethernet and the Internet have been added to our computing palette, CAT has been implemented over TCP/IP, an Internet standard communications protocol pair. For example, with the FLEX-6000's *SmartSDR* CAT program, a TCP/IP port can be added that responds to CAT commands. The base protocol remains the same, but the communications transport mechanism is TCP/IP over Ethernet rather than RS-232. This allows a relatively simple conversion for programs wishing to access radios over Ethernet rather than either RS-232 or USB.

FlexRadio Systems, although adopting CAT to allow for interoperability with legacy software such as existing loggers and digital mode programs, also added a new computer control interface, the *SmartSDR* API. CAT is restricted to commands relating to two variable frequency oscillators (VFO), typically called VFO A and VFO B. Since the FLEX-6000 can currently have up to eight slice receivers (synonymous with a VFO for the purposes of controlling the radio), the CAT standard could not sufficiently provide for control of the radio. The *SmartSDR* API is also based on ASCII commands and allows full control of the radio over a TCP/IP port or using a Microsoft *Windows* .NET DLL interface. FlexRadio's *SmartSDR* thin client running on a *Windows* PC achieves all of its display and control capabilities using the *SmartSDR* API.

## 14.4 SDR Design Tools

A description of how SDR works and the opportunities it presents are interesting but not of much use unless the reader can acquire and use the necessary tools to work with SDR technology. This section discusses *GNU Radio*, a popular software development environment for working with digital signal processing (DSP) and applying it to SDR. A short introduction to working with FPGA technology is also included. DSP software is key to working effectively with SDR at the level to which amateurs are accustomed with traditional analog technology and a soldering iron.

### 14.4.1 GNU Radio

#### INTRODUCTION TO *GNU RADIO*

The ability to create and work with software for SDR projects is a new skill for many

hams. Professional programmers have many options to pursue. For hams without a programming background, software packages are now available that create a gateway for ordinary hams to build custom DSP software. Software authoring has been vastly simplified. The software packages feature graphic user interfaces (GUI) and offer useful DSP functions in DSP source code libraries.

The ham experimenter has choices of graphically based DSP software packages: the proprietary packages, *Matlab / Simulink* by MathWorks and *LabVIEW* by National Instruments, or the open source *GNU Radio / GNU Radio Companion (GRC)* DSP library package. This section introduces the combination of *GNU Radio* and *GRC* package as a powerful, "ham friendly," development environment for SDR projects. The material

is based on a pair of *QEX* articles by John Petrich, W7FU (see the *GNU Radio* references) which are included in the online supplemental information for this book.

*GNU Radio* was conceived as a development tool intended for advanced educational programs, and commercial product development labs. With a little effort, hobbyists can use these tools as well. *GNU Radio* can be used as a simulation tool to study DSP without being connected to an SDR. *GNU Radio* can also be used to develop practical and operationally satisfying DSP software for SDR transmitters, receivers, and transceivers as well as test equipment.

To make DSP authoring accessible for all levels of users, the *GNU Radio* developers include the user option of *GNU Radio Companion (GRC)*. *GRC* is the graphical DSP li-

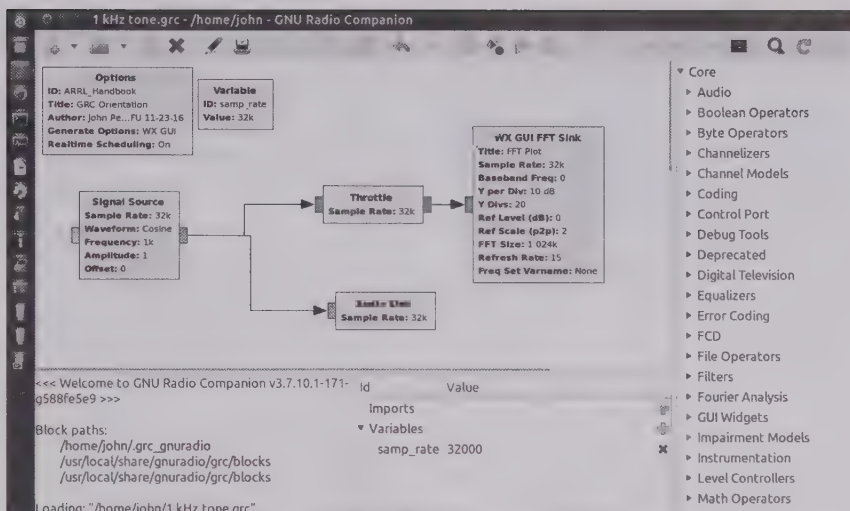

library interface, an integral part of *GNU Radio*. The foundational *GNU Radio* DSP library is accessed with character-based command line entries. *GRC* is a graphical overlay to the *GNU Radio* DSP library with the same full functionality as the command line approach. *GRC* emulates the command line entries and represents each DSP function as a graphical icon without command line entries. (For the sake of completeness, a very few of the *GRC* DSP parameters in are expressed as simple Python code commands. These Python commands are covered in the section **Learning Resources: DSP Competency and GNU Radio**)

An arrangement of DSP icons and digital data links is termed a *flow graph*. When executed, the *GRC* flow graph is compiled to a Python code file, which itself is a wrapper for C++ executable DSP code. This artful layered construction, like a set of nesting dolls, provides a high level, user friendly, graphical interface for DSP authoring with the speed and efficiency of lower level code for DSP process speed and efficiency. More information from the developers about the construction of this DSP library environment is available at [wiki.gnuradio.org/index.php/What\\_is\\_GNU\\_Radio%3F](http://wiki.gnuradio.org/index.php/What_is_GNU_Radio%3F)

### GNU RADIO AND THE GRC TOOL

*GRC*, the easy to use graphical interface, makes this DSP library particularly appealing. Reduced to the basics, the step-by-step design of a functional DSP begins with envisioning or drawing a block diagram pattern of a traditional analog signal processing circuit. Once the general signal processing pattern is conceived, select the desired DSP function(s) from the DSP library (filter, mixer, oscillator, amplifier, etc.), arrange the DSP function(s) as graphical blocks in the work screen according to the design pattern, connect the blocks with an appropriate type of data link, add the DSP parameters in each block, and execute the program. The details of constructing a DSP flow graph are covered in the **Success with GNU Radio Tools** section and in the on-line tutorials referenced in the section **Learning Resources: DSP Competency and GNU Radio**. The process is straightforward.

Let's examine the *GRC* work environment and flow graph composition at the highest level or block level. The *GRC* work environment consists of four parts: the work area, the control bar, the library, and the console. **Figure 14.12** illustrates the *GRC* user graphic user interface (GUI). The DSP is authored in the work area in the center of the GUI screen. The *GRC* control bar is located across the top of the work area. The *GNU Radio* DSP library runs along the right margin of the screen. The operating console is visible at the very bottom of the work environment and becomes active when a DSP function is executed.

**Figure 14.12** — The development window user interface for *GNU Radio* functional blocks.

**Figure 14.13** — The user interface window showing an operating 1 kHz audio tone FFT.

Centered in the work area are six DSP blocks which, in aggregate constitute a DSP flow graph. The flow graph implements, in DSP, a 1 kHz audio tone output to both an audio sink (computer speaker) and to an FFT panadapter display (on screen). **Figure 14.13** is the FFT display output once the flow graph has been executed. Note the signal spike is accurately centered at 1 kHz on the FFT display and the 1 kHz tone would be heard via the computer sound card.

Continuing to the parameter level, one step below the block level, each DSP library item is displayed as a rectangular shaped “block” with input / output ports. Each block must be “opened” with a mouse right-click to gain access to the parameter fields that define that DSP function. Each parameter has a field in

which the values are either added or selected from a menu.

**Figure 14.14** displays the parameter screen for a low-pass filter DSP block. Note how the digital data type (*FIR Type*), sample rate, filter bandwidth and filter shape, and other parameters can be selected or specified. Some parameter values are intuitive, direct carry-overs from analog design. For example, the bandwidth and shape factor parameters for a DSP filter block are specified in kHz in the same way an analog filter is specified. Other parameter values are not as intuitive and refer to parameters unique to DSP. Examples of these parameters are the DSP *Sample Rate* and *FIR Type* choices. More detail about the most commonly used DSP blocks and appropriate parameter choices are explained in

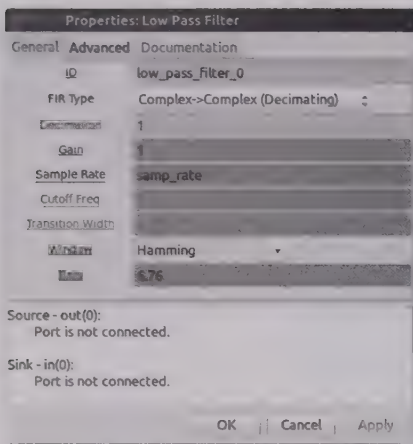

Figure 14.14 — A screen showing how parameters are managed for a typical DSP filter block.

greater detail in the section below, **The Rest of the Story: Basic DSP Theory Applied to a Flow Graph Segment.**

Figure 14.15 depicts the more complex flow graph of an SDR broadcast FM receiver. This flow graph uses an RTL-SDR as the receiver source. Other SDR receiver hardware can be substituted easily as explained in the section *GNU Radio, Radio Hardware, and UHD.*

The RTL-SDR is represented by the *RTL-SDR Source* block on the left. The *Audio Sink* on the right outputs the audio sound. The *WX GUI FFT Sink* in the center generates a panadapter display. The chain of DSP blocks in the center of the work screen perform the filtering and signal demodulation functions for this radio. Compare this flow graph with a block diagram for a simple analog FM receiver to appreciate the fundamental similarity. Figure 14.16 illustrates the operating receiver GUI that appears when the flow graph is executed. Shown are the radio tuning controls for frequency and audio output, and the FFT panadapter display.

### SUCCESS WITH GNU RADIO TOOLS

Just as success at woodworking comes from competency with woodworking tools, success with *GNU Radio* comes from learning and using its tools. Viewing a flow graph is the first step in learning the tools. Success with *GNU Radio* inevitably proceeds to DSP competency, as well.

An important part of success with *GNU Radio* comes from an organized and disciplined authoring approach. Lacking organization and discipline, flow graph construction can easily become a chaotic non-functional mess. This section describes one general disciplined approach. Following a description of the general approach, a detailed example flow

graph creates entry level DSP competency through flow graphs construction.

DSP competency for new users is not necessary for initial success. Many of the automatic default settings in *GRC* are adequate for entry level flow graphs. Ultimately, DSP competency comes from incrementally constructing more advanced DSPs with simple flow graphs.

### GENERAL APPROACH: THE FOUR STEPS TO FLOW GRAPH SUCCESS

The disciplined approach involves following a pattern of four basic steps. These basic steps are useful at getting started the first time with DSP flow graph construction and as an efficient approach to construct more advanced and complex flow graphs.

How does one begin a DSP flow graph using the *GNU Radio GRC* graphical interface? Four steps are required to construct any flow graph: the “block” step, the “parameter” step, the “logical interconnection” step, and the “DSP” step. Each step is explained below.

**Step 1 — the Blocks:** Arrange the appropriate DSP blocks from the *GRC* library to form a diagram of the desired circuit in the work area. See how the functional blocks are arranged in the example flow graph in the work area of Figure 14.17.

**Step 2 — the Parameters:** To perform the desired DSP function, each DSP block re-

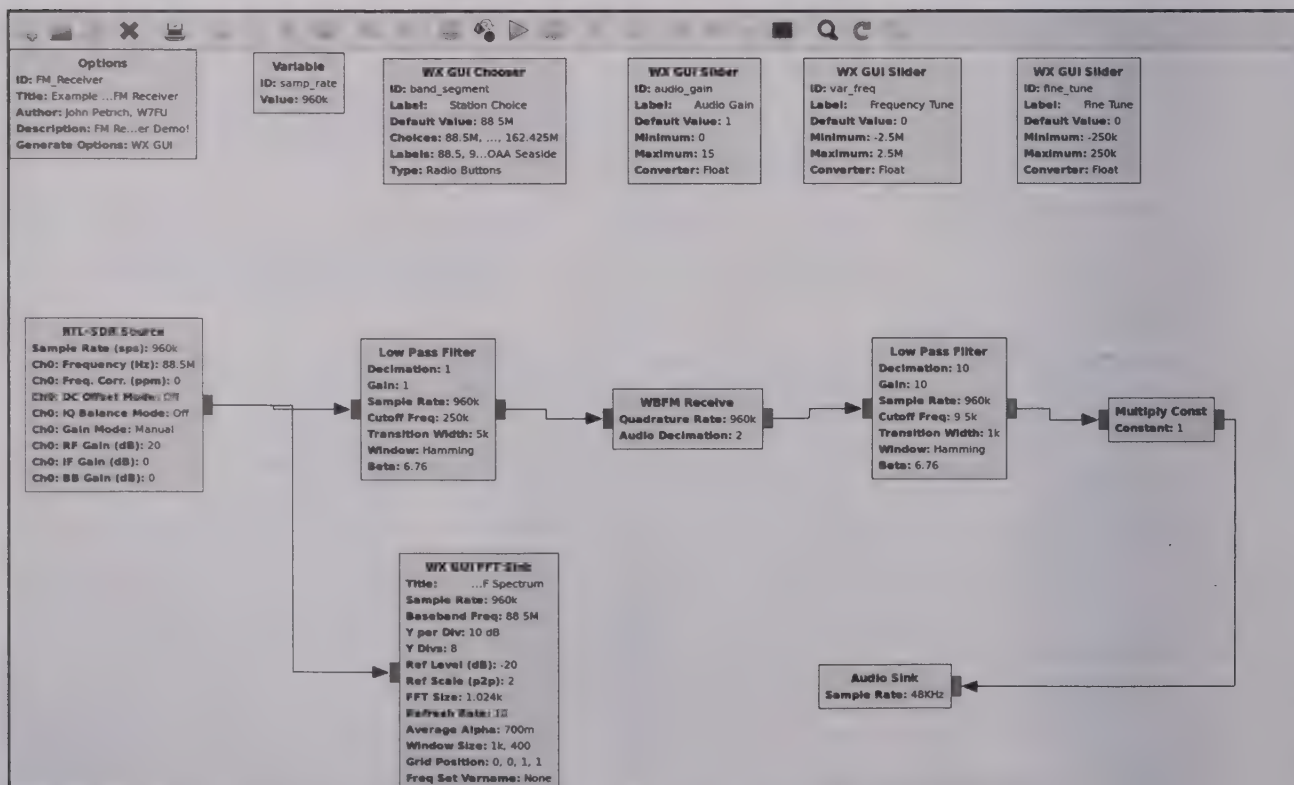

Figure 14.15 — Flow graph for a broadcast FM receiver showing the various function blocks involved.

Figure 14.16 — The user interface window for the operating FM broadcast receiver created from the flow graph in Figure 14.15.

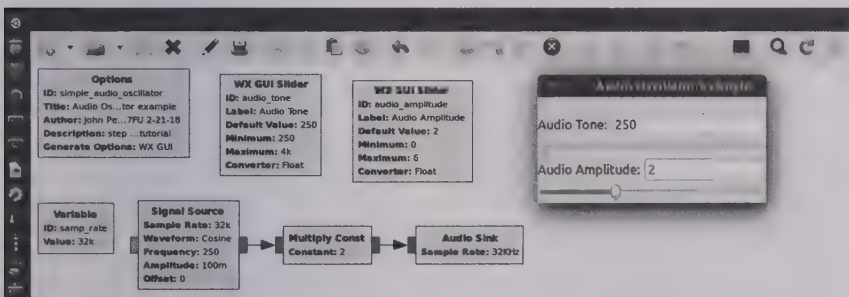

Figure 14.17 — The flow graph for the audio oscillator.

quires user-specified parameters. In the parameter step, right-click each block, select *Properties*, and enter the parameter values in the available fields. Each block in the flow graph diagram is opened in turn and the desired parameters are entered in each block. Typical parameters are familiar values such as gain, frequency, bandwidth, and so on, as well as some less familiar values such as *Sample Rate* and *Output Type*. The *Sample Rate* and *Output Type* parameter values are unique to DSP as discussed below. These DSP parameters are set by default in many flow graphs and automatically propagated into every DSP block. For one to meaningfully change these default parameters, a basic understanding of DSP theory is required as described in Step 4.

**Step 3 — the Logical Interconnections:** Each DSP block must be connected to the

other blocks by a data link arrow in a logical manner. The data links begin with the “input” or *Source* location in the flow graph end with the “output” or *Sink* in the flow graph.

**Step 4 — DSP Parameters:** It is in this fourth, and final step, that authoring a flow graph involves DSP issues. Let’s begin with the special *Variable* block located in the left-hand corner of the work area. That block is automatically present whenever *GRC* is opened for programming. The *Variable* block is the location for the base line *Sample Rate* parameter for each block in the DSP. The default parameter is 32,000 samples per second (SPS). That default parameter is automatically propagated to the *Sample Rate* field in each DSP block in the flow graph work area. The default *Sample Rate* value is a good starting place for many DSP flow graphs and can

be used as a default for many designs. Advanced DSP designs may require different sample rates and may require adjustments to the sample rate parameter in the DSP blocks.

Another default DSP parameter is the *Output Type* parameter for each DSP block. The default parameter is termed *Complex* or *I and Q*. This default parameter is useful for many, but not all radio-related DSPs. The flow graph example described below illustrates a flow graph where the default *Output Type* must be changed for the simple flow graph to function. (See the *Modulation* chapter for more information about complex signals and modulation.)

## FLOW GRAPH EXECUTION

In practice, the above outlined flow graph is created in the *work area* of the *GRC*. To operationalize the flow graph, select the *Execute flow graph* control (a green arrow on the screen) from the tool bar above the *work area*. After the software compiles, the DSP will spring to life. The operational GUI appears on the screen with the control functions displayed as displayed on the right side of the screen in Figure 14.17.

## SPECIFIC FLOW GRAPH EXAMPLE: SIMPLE SINGLE-TONE AUDIO OSCILLATOR

**Step 1 — the Blocks:** Figure 14.17 is a screen capture of the audio oscillator flow

graph. The operating GUI is superimposed on the right side of the figure. The operating GUI only appears only after the *Execute flow graph* is selected from the tool bar.

The flow graph blocks are selected from the library off the right-hand edge depicted in Figure 14.12 (not Figure 14.17) and placed in the work area. At a glance, the flow graph block diagram is constructed to look essentially the same as a traditional analog radio block diagram with the same components. The diagram and component content reflect standard signal processing practice. A traditional circuit block diagram for a simple sine wave oscillator with audio output would consist of series of blocks linked by lines; an oscillator block, a frequency control, an audio amplifier, an audio volume control, all connected one after the other, to an audio output block.

In this audio oscillator example, the signal processing pattern is the same for the traditional analog and the *GNU Radio* digital implementation. With a DSP, the interconnections between blocks are no longer signal links (wires in traditional circuits) but digital data links as we will see in Step 3 below.

**Step 2 — the Parameters:** Most of the parameters for each DSP block are visible in Figure 14.17. Examine the parameters of each block with a right-click on the block and select *Properties*. Right-click the *QT GUI Range* control block with the *ID audio\_tone* located at the top of the work space. This block is the control block for the oscillator frequency or audio tone. Note the block ID, *audio\_tone*, and the tone's tuning range from 250 Hz to 4 kHz in 1 Hz steps. This block connects to and controls the *Signal Source* DSP block output frequency which is the audio oscillator tone in this example.

The *ID audio\_tone* comprises the software link between the control block and the *Signal Source* DSP block. The term *audio\_tone* is entered into both the *Signal Source* frequency parameter field and the *QT GUI Range ID* field thereby connecting the two blocks in software.

In the same manner, the audio volume control is linked via software to the audio amplifier. Select *Properties* in the *QT GUI Range* control block with the *ID audio\_amplitude*. The multiplication values range from 0 to 10. These numbers are factors that tell the *Multiply Const* DSP block to multiply the digital data stream amplitude for audio volume control. The ID *audio\_amplitude*, denotes the software link to the *Multiply Const* DSP block. That ID is entered in the *constant* parameter field in the *Multiply Const* DSP block. The two blocks are linked in the same way as the audio tone frequency is linked to the audio oscillator. The *Sample Rate* value from the *Variable* block, 32k, is automatically propagated to the other DSP blocks but not to the two control blocks

**Step 3 — the Logical Interconnections:** To complete the basic DSP flow graph, each block is logically interconnected to the others. Additional attention to details are important in this step. Not appreciated in the screen capture is how the *Multiply Const* DSP block became configured to have only single input and single output ports. This block and many other blocks from the DSP library are pre-configured for multiple input and output ports. When placed in the *GRC* work area, pre-configured blocks from the library are re-configured for the desired number of ports to fit the flow graph. To reconfigure the number of ports, right-click the block, select *Properties*, and enter a value for the number of desired ports in the appropriate port parameter field. In this example, a value of 1 was entered in the *Input Port* field of the *Multiply Const* DSP block. Select OK, the window closes, and the block appears on screen ready to use with a single input and single output port.

Once the block ports are configured, the DSP blocks must be linked with the data stream. To form these data stream links, left-click on the output port of the *Signal Source* DSP block, followed by a left-click on the input port of the *Multiply Const* DSP block. A data link arrow appears, and those two blocks are digitally connected. The output of the *Multiply Const* DSP block connects in a similar manner to the input port of the *Audio Sink* DSP block.

The flow graph is almost complete. The two control blocks have no visible data link arrows. They are automatically connected via the software *ID* parameters described above. Next, we consider the DSP parameter step.

**Step 4 — DSP parameters:** The audio oscillator flow graph functions fine with the default *Sample Rate* parameter in conjunction with modern computer sound cards. No change is required for the *Sample Rate* parameter. The *Output Type* parameter is different and must be changed from the default setting for this flow graph to function.

The *Output Type* parameter for each DSP block is displayed in a drop-down menu, found by selecting *Properties* for that DSP block. The *Output Type* is also visually displayed in the flow graph by the color of the input and output port tabs on the blocks. (This color code is a useful bug fix hint with advanced DSP programming and not central for this description. The change in color is only visible when viewing the screen capture or flow graph on a computer screen.) The desired *Output Type* for this flow graph is "Float" (digital data using floating-point values). The *Output Type* parameter for each DSP block in this example must be the same: "Float." Right-click and select *Properties* for each DSP block in the flow graph, navigate to the *Output Type* parameter, and select "Float" from the drop-down menu. The two control

blocks don't require any DSP parameters.

Once all steps are completed, the flow graph is ready to be executed. Upon execution, a new GUI appears on the screen with the controls displayed. That GUI screen is superimposed in the upper right-hand corner of the screen capture in Figure 14.17. Listen for the 250 Hz audio tone in the speaker. Adjust the audio volume and audio frequency with the GUI controls. You can also experiment with adjusting the sample rate in the *Variable* block, or parameter values in any block and observe the effect these changes have on the operation of the flow graph. (The *GRC* flow graph for this example is included in the downloadable supplemental package for this book. The file, Chapter 14 - Audio Oscillator example.grc, can be executed in the *GNU Radio* application.)

### THE REST OF THE STORY: BASIC DSP THEORY APPLIED TO A FLOW GRAPH

To better understand this DSP flow graph example and to aid authoring more advanced DSP flowgraphs, basic information about the relationship of sample rate, data stream output type, and DSP is important. (See the **DSP and SDR Fundamentals** chapter for a detailed discussion of the analog/digital conversion process.)

Sampling is a foundational aspect of DSP. DSP comes into action in the A/D converter where an analog signal is converted to a digital data stream. The DSP acts to manipulate the series of data points which form a replica of the sinusoid signal as stream of digital data. The greater the number of samples, the more closely the replicated digital data corresponds to the original sinusoid signal. After digital processing, the digital data stream can be reconstructed to generate the familiar analog sound or radio signals with a D/A converter.

Connecting the sampling concept to a functioning flow graph, each DSP block in the flow graph must function with a compatible sample rate parameter. *GRC* automatically enters the default sample rate for each DSP block which is fine for many DSP processes. Advanced DSP techniques using *GNU Radio* and *GRC* call for a wide range of sample rate parameters beyond the default value. The sample rate parameters can also be individually adjusted for each DSP block in the flow graph. These sample rate changes are accomplished using *Resampler* DSP blocks. Sample rate adjustments within a single flow graph are termed "multi-rate" sampling and a common practice with advanced DSPs such as those for SDR applications.

Another foundational concept regarding DSP is to understand that the sole purpose of each DSP block is to mathematically manipulate the digital data stream. Fortunately, with *GNU Radio* and the *GRC* graphical approach

to programming, the user is not required to understand or program the underlying mathematics. The DSP functions in *GNU Radio* DSP library are preloaded with the necessary mathematical algorithms to perform their intended DSP function.

The data stream math algorithms are unique in each DSP block. The operation can be single purpose, such as for the *Multiply Constant* DSP block which functions as an amplifier or attenuator by simple multiplication of the digital data stream amplitude. Other DSP blocks provide filtering or mixing functions and frequently combinations of these functions. All operations are performed mathematically based on algorithms programmed by the developers into each DSP block.

Not only is the data stream manipulated in a mathematically determined manner, but the mathematical structure of the digital data stream has an impact on how a flow graph can function. Return to the flow graph in Figure 14.17 where the *Output Type* DSP parameter reflects the structure of the digital data stream that communicates among the DSP blocks. The mathematically processed digital data stream *Output Type* can be customized as necessary for advanced DSP processes.

As a practical matter, the default *Output Type* digital data structure for most *GNU Radio* DSP blocks are set by default to “Complex” or I and Q data. The default setting, “Complex,” is the preferred data type for many, if not most, ordinary radio related DSP applications. Some DSP flow graphs, such as those employing phasing techniques and the audio oscillator example in this case, require an *Output Type* that is different from the default “Complex.” (Some SDR hardware digital data output types are derived from different math conversions and require a non-default data stream structure conversion in the flow graph, as well.) In other words, one type of digital data stream doesn’t fit all. The *Output Type* data stream parameter can be quite specific for the some SDR hardware and quite specific for some DSP process. Mastering the details of *Output Type* for your flow graph constructions will come with more in-depth understanding of DSP fundamentals. For further information on sampling rate choices and *Output Type* digital data streams, review the information on the GNU Radio website.

## LEARNING RESOURCES: DSP COMPETENCY AND GNU RADIO

This introduction to *GNU Radio*, *GRC* and flow graph construction presents DSP at the high-level of blocks and parameters, consistent with *GNU Radios* high-level graphical environment. But that is only the beginning of a journey into the world of DSP. The **DSP and SDR Fundamentals** and the **Receiving** chapters contain much useful information about understanding DSP. That information

offers important background and context to more in-depth understanding of DSP to apply to *GNU Radio* although not specific to *GNU Radio*.

DSP competency is readily learned using *GNU Radio* as a tool for experiments and simulation. The online educational resources specific to *GNU Radio* are great learning resources. Detailed examples of DSP applications and parameter selection, awkward and sometimes confusing in a text format, are much more easily understood via online video tutorials. The Ettus Corporation-sponsored series of DSP tutorials ([files.ettus.com/tutorials/labs/Lab\\_1-5.pdf](http://files.ettus.com/tutorials/labs/Lab_1-5.pdf)) and the related video series ([www.youtube.com/playlist?list=PL618122BD66C8B3C4](http://www.youtube.com/playlist?list=PL618122BD66C8B3C4)) are highly recommended for this learning format.

For a more academic treatment of DSP consider both the **DSP and SDR Fundamentals** in this *Handbook* and the DSP texts by Richard Lyons. The Lyons texts provide a particularly “ham friendly,” intuitive, approach to understanding DSP. (See the *GNU Radio References* section.)

## INSTALLING GNU RADIO

The very first step for a new user is to review the *GNU Radio* web portal for authoritative information ([gnuradio.org/redmine/projects/gnuradio/wiki](http://gnuradio.org/redmine/projects/gnuradio/wiki)). The *GNU Radio* developers have published a rich source of detailed information to help the new user to get started using *GNU Radio*. From that portal page one can link to installation instructions, tutorials, latest news, and in-depth information about the software development process. Refer to it frequently, since the content changes with the ongoing software development.

To get started with *GNU Radio*, a particularly appealing option is to use the *GNU Radio Live SDR Environment* ([wiki.gnuradio.org/index.php/GNU\\_Radio\\_Live\\_SDR\\_Environment](http://wiki.gnuradio.org/index.php/GNU_Radio_Live_SDR_Environment)). The *Live Environment* allows the user to implement *GNU Radio* without installing *GNU Radio* on the computer hard drive. The latest versions of the *Ubuntu* operating system and *GNU Radio* software are downloaded from the Internet to a storage medium (for example, DVD or USB memory stick) as an executable file. Upon executing from the medium, the *Live Environment* opens in a complete *Ubuntu* operating system with *GNU Radio* application pre-installed. *GNU Radio* and *GRC* can be immediately executed to run at essentially full capability.

To install *GNU Radio* directly to a computer hard drive, installation from the official Source with the “*build-gnuradio script*” is far and away the most dependable and highly recommended approach ([wiki.gnuradio.org/index.php/InstallingGRFromSource](http://wiki.gnuradio.org/index.php/InstallingGRFromSource)). Installing *GNU Radio* from the Source with the *build-gnuradio* script automatically installs the most recent *GNU Radio* version,

all add ons, and the latest driver for compatible SDR hardware, the *Universal Hardware Driver (UHD)*. The *build-gnuradio* script is a preferred method for initial installation and subsequent updates of *GNU Radio* and UHD as needed. Step by step “ham friendly” help with the installation process is also available at [www.w7fu.com](http://www.w7fu.com)

## GETTING THE MOST OUT OF GNU RADIO

Support for *GNU Radio* is available on-line via the “discuss-gnuradio” message reflector. ([lists.gnu.org/mailman/listinfo/discuss-gnuradio](http://lists.gnu.org/mailman/listinfo/discuss-gnuradio)) Questions can be posted on the reflector and the *GNU Radio* developers respond via email. The reflector is very active and a rich source of information.

The most efficient and user-friendly approach to get full benefit of what *GNU Radio* has to offer is to implement *GNU Radio* in the Linux *Ubuntu* operating system. The *GNU Radio* developers develop and maintain *GNU Radio* in *Ubuntu*. Potential cross-platform bugs and incompatibilities are avoided by adopting the same *Ubuntu* operating system that the developers use. *GNU Radio* is reported to operate on Windows and Mac OSX, but there are challenges with full implementation with these operating systems which make them best avoided by beginners.

Computer users unfamiliar with Linux operating systems shouldn’t be intimidated by using the *Linux Ubuntu* operating system. *Ubuntu* has the look and feel and straight forward ease of use as MS Windows. The *Ubuntu* operating system is open source, downloadable via the internet, and can easily be installed in a separate hard drive partition if necessary. Installing *Ubuntu* via the internet is straight forward and quick. The official *Ubuntu* website provides the latest downloadable *Ubuntu* versions and instructions for using *Ubuntu*. ([www.ubuntu.com/download/desktop](http://www.ubuntu.com/download/desktop))

*GNU Radio* is a dynamic application with version updates on an irregular but frequent basis. It is important to keep abreast of the changes via the web portal and learn to update the application re-using the *build-gnuradio* script as necessary. Follow the “Latest news” for updates and other information ([gnuradio.org/redmine/projects/gnuradio/wiki](http://gnuradio.org/redmine/projects/gnuradio/wiki)).

For serious DSP authoring and most SDR projects, avoid installing the Linux “distribution” versions of *GNU Radio*. The “distribution” versions of *GNU Radio* are built into the *Ubuntu* operating version at the time of that operating system release. These “distribution” versions can be installed easily from within the *Ubuntu* version. Because *GNU Radio* is built into the *Ubuntu* version at the time of initial release, these *GNU Radio* versions are typically out of date, have outdated *UHD* drivers, and are installed differently within the file

system from the versions downloaded from the official Source. The UHD might not work with newer SDR hardware. Updating and adding DSP blocks to, distribution, versions is not possible. For all of these reasons it is best to avoid installing a “distribution” version of *GNU Radio* instead install a full installation of the current *GNU Radio* version.

A capable computer is necessary to use *GNU Radio* to its full real-time DSP potential. The developers recommend a dual-core CPU at the i3 level or above to users. Single-core and early dual-core CPUs lack the speed and capacity for many ham DSP designs.

### GNU RADIO, RADIO HARDWARE, AND UHD

To implement real-time SDR radio projects with *GNU Radio*, it is necessary to use compatible SDR hardware. The *Universal Hardware Driver (UHD)* is a dedicated software package to interface *GNU Radio* and compatible SDR hardware. Of late, there have appeared a new generation of SDRs that interface with a multi-layered PPA system of *GNU Radio* packages or a suite of applications. The documentation for compatible hardware will refer to the *GNU Radio UHD* capability or to a PPA *GNU Radio* package. Given the popularity of *GNU Radio* with the DSP developer community, *UHD* or the *GNU Radio* PPA is commonly specified for modern SDR hardware.

The latest version of *UHD* is installed automatically whenever *GNU Radio* is installed via the *build-gnuradio* script from Source. The *GNU Radio* PPA requires a separate and additional installation. The ever-expanding list of compatible hardware is published at [wiki.gnuradio.org/index.php/Hardware](http://wiki.gnuradio.org/index.php/Hardware). Searches of the internet and close reading of the specifications can sometimes find *UHD*-compatible SDR hardware that hasn't yet reached the official list.

### 14.4.2 FPGA Data Engines

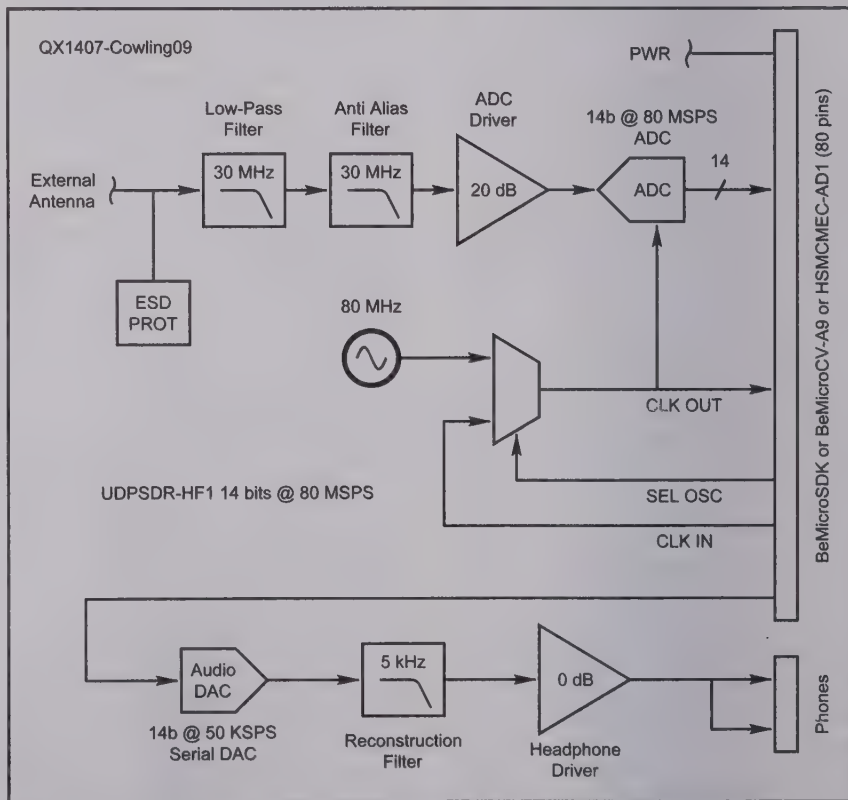

What actually implements the DSP functional blocks referenced in the previous chapters? In the early days of amateur SDR and DSP, the only suitable hardware platform with a reasonable cost was a high-end PC or specialized DSP or graphics processing microprocessors (microcontroller units – MCU). These are still used today but after some years in transition, amateur SDR is largely implemented by FPGAs — Field-Programmable Gate Arrays.

An MCU executes instructions from a pre-defined instruction set in sequential order; the hardware is fixed, but the sequence of instructions is programmable. An FPGA, on the other hand, has no fixed instruction set or sequence of instructions, operates on data in parallel and has programmable logic and interconnections. Software defined radio (SDR) implementations benefit greatly from the FPGA parallel hardware architecture since they can be configured to implement the required math operations directly in hardware, at very high speed. FPGA ICs are now

available inexpensively and with a sufficient number of gates (in the 10s of 1000s) to implement high-performance SDR functions.

The FPGA as typically used by non-professional developers is part of a general-purpose computing unit, also known as a *data engine*. Support ICs are included in the package to allow the developer to interact with the FPGA and program it. Other data ports are available, depending on what applications the data engine is designed to handle. When combined with external RF hardware and either an on-board user interface or the ability to stream data to an external user interface, the result is an effective SDR development environment. An example is shown in **Figure 14.18** which combines the SDRStick receiver and transmitter with a BEMICROCV-A9 data engine. An Ethernet port provides enough bandwidth to implement the user interface and display on a PC. This is a thin-client implementation as described in the previous section on User Interfaces.

In a series of Hands-On SDR columns in *QEX* magazine beginning in 2014, Scotty Cowling, WA2DFI, described several data engines and the software development environment needed to program the FPGAs. Several of the key columns dealing with FPGA development are included with the online supplemental information for this book.

**Figure 14.18** — An SDR development system based on the BEMICROCV-A9 data engine and separate SDRStick receive and transmit modules.

# 14.5 Transverters

The material in this section is largely taken from material provided by Paul Wade, W1GHZ, and Wayne Overbeck, N6NB. Along with downloadable materials in the supplemental information package, the print and online articles in the references provide much more detail and technical depth.

Transverters allow an HF or VHF transceiver to operate on a band it doesn't support by converting both the transmitted and received signal. As a result, the full features of the transceiver are available on the converted band. At one time, building and installing transverters presented a serious challenge for all but the most experienced and technically adept amateurs, but today's off-the-shelf transverters are almost as easy to install as a commercial transceiver. For those who prefer the challenge of building their own transverters from kits or from scratch, those options offer a real sense of accomplishment, as well.

Non-repeater operation on the VHF/UHF/microwave bands is usually CW or SSB, requiring a multimode transceiver. (FT8, JT65, and similar digital modes use the SSB or SSB DATA features.) Some transceivers cover 6 meters, 2 meters, and 70 cm in addition to HF. Although some VHF/UHF transceivers such as the TS-2000 and IC-9700 cover 23 cm (1296 MHz), multimode radios that cover 222–225 MHz, 33 cm (902 MHz) and the bands above 2.3 GHz are not available as of early 2020. Wideband SDR receivers that cover from VHF through several GHz are widely available, but companion transmitters are just starting to become available. That limits the equipment choices to surplus equipment that can be modified — and transverters.

Similarly, for the amateur MF and LF bands at 630 meters (472–479 kHz) and 2200 meters (136 kHz), commercial transceivers covering these bands are uncommon. Surplus equipment can be adapted to amateur use, but availability is quite variable and the equipment is likely to be designed for operation on fixed channels. As a result, transverters are likely to be used on those bands for the foreseeable future.

Commercial transverters such as those in **Figure 14.19** are available as finished packages for 6 meters, 2 meters, 222 MHz, 432 MHz, 902 MHz, 1296 MHz, 2304 MHz, 3456 MHz, 5760 MHz, and 10 GHz. Recently, transverters have also become available for much higher frequency bands, including 24 GHz, 47 GHz and 76 GHz. Manufacturers that offer complete transverters include DB6NT ([shop.kuhne-electronic.com](http://shop.kuhne-electronic.com)); Down East Microwave ([www.downeastmicrowave.com](http://www.downeastmicrowave.com)); Q5 Signal ([www.q5signal.com](http://www.q5signal.com)); and SG-Lab ([www.sg-lab.com](http://www.sg-lab.com)). A number of small shops also produce kits or finished prod-

**Figure 14.19** — The Q5 Signal 222 MHz transverter (28 MHz IF) is shown at A. At B is the SG-Lab 2.3 GHz transverter (430 MHz IF) and at C is the Kuhne MKU 24 G3 transverter for 24 GHz (432 MHz IF).

(C)

ucts as single PC boards that can be mounted in an enclosure and integrated into a system. For the kits and single-board products, an internet search may turn up vendors.

Becoming a member of a VHF+ club is also a good way to find used and surplus equipment along with information about vendors and their products. These groups are typically great for mentoring and technical advice on transverters, as well as tips on operating.

### 14.5.1 Transverter Basics

A transverter is both a receive converter and a transmit converter for a conventional HF or VHF transceiver, usually operating on 10 meters or 2 meters. The HF/VHF transceiver acts similarly to the intermediate frequency (IF) sections of a conventional superheterodyne radio and is referred to as the *IF radio*. For those using a full-featured commercial transceiver, the various receive and transmit functions are also available on the converted band, creating a high-performance VHF/UHF/microwave (or MF/LF) transceiver. Some transceivers also have the ability to display the converted frequency so that the operator does not have to convert the lower frequency display to the higher band. (From this point on, discussion will assume the transverter is supporting a VHF/UHF/microwave band.)

An IF radio operating on the 28 MHz or 144 MHz band will cover either 2 or 4 MHz of the band that is being converted if the operator tunes from 28 to 30 MHz or 144 to 148 MHz. That is adequate to cover the entire weak signal portion of a VHF/UHF/microwave band. However, the amateur bands above 400 MHz

are much wider than the 10 meter and 2 meter bands, so the entire band will not be covered. For FM repeater coverage of 432, 902, or 1296 MHz, a dedicated mobile or handheld FM transceiver is needed, since FM activity may cover a span of 20 MHz or more.

The 28 MHz band is commonly used as an IF for 50 MHz, 70 MHz (in Europe), and 144 MHz transverters, and sometimes for transverters on higher bands. The most common IF band for the higher bands is 144 MHz. For transverters on higher bands, 432 MHz is becoming more popular as an IF both to provide coverage of more of the band and to achieve better technical performance.

Even older transceivers and single-band 10 meter and 11 meter transceivers can provide reasonably good performance as IF radios. Low-power transceivers such as the Yaesu FT-817/818 are widely used because most transverters are now designed for up to 5 W of IF drive, nicely matching the output power of such transceivers.

### 14.5.2 Integrating a Transverter with a Transceiver

Figure 14.20 shows the two most common ways of connecting a transverter and transceiver IF radio. Some transceivers have dedicated low-level transmit outputs as in Figure 14.20A, often available through an auxiliary connector, that can be connected directly to a transverter regardless of the power available at the main antenna connector. (A dummy load may have to be connected during transverter operation.)

If the transverter is rated to handle the power, a simpler approach is to turn the transceiver output power down to 5 W and connect its antenna connector to the IF port on the transverter that handles both transmit and receive signal paths. The transverter internally switches the IF port between the transmit and receive sections of the transverter. Most modern transverters have built-in attenuators that can handle up to 5 W of transmitter power from the transceiver. That's one reason why 5-W transceivers are so popular for use with transverters. This method is shown in Figure 14.20B. Of course, the operator has to remember to reduce the transmitter power of a higher power transceiver from the full output to 5 W when switching from "straight through" operation on 10 meters or 2 meters to transverter operation. Be aware that some transceivers transmit a full-power transient at the beginning of a transmission before the ALC system can control the output power. If this is the case, turning the power down manually is probably a poor option. Table 14.1 shows some values for attenuators you can build to reduce transmit power.

If the transverter does not have the option to operate directly with the transceiver's main RF port, a TX/RX switch is required. Switching is controlled either by RF sensing or by the transceiver's transmit control line, such as a grounded PTT line or a positive-true TX on signal. Performing switching control through the IF radio's RF port does eliminate one cable and connector set.

Optional preamps and power amplifiers may be mounted directly at the antenna for best performance. Because feed line losses are so high at microwave frequencies, many amateurs mount transverters and amplifiers in a weatherproof enclosure at the antenna and only send the IF signals, dc power, and any control lines from the transceiver.

Transverter users must also consider frequency stability, especially on the microwave bands. Most transverters are now designed to accept a highly stable 10 MHz "reference signal" from a *GPS-disciplined oscillator* or a *rubidium oscillator* (see the **Oscillators and Synthesizers** chapter). Commercial transverters usually have built-in local oscillators (LO) that are designed to be fairly stable. However, the best LO circuits will drift several kilohertz or more on microwave bands during warmup. Even after a long warmup, an internal LO may drift too much for modern digital modes. Most amateurs who want good performance will add an external GPSDO or Rubidium reference to "lock" their transverters on the correct frequency. One outboard reference signal can be fed into a distribution amplifier to serve several transverters.

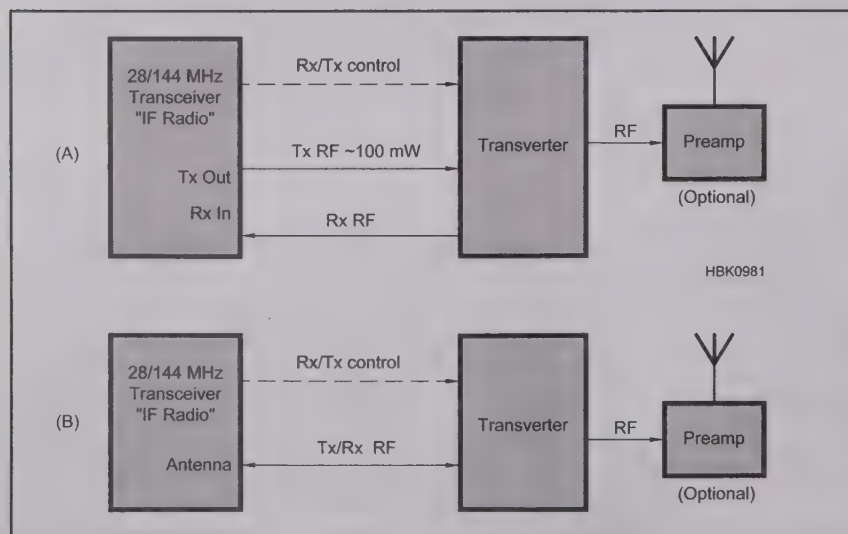

Figure 14.20 — The illustration at A shows a transceiver with receiver input and separate low- power transmit output connections. At B, the RF path is through a direct connection to the transceiver's main antenna connector, requiring the RF power output to be reduced to 5 W for most modern transverters.

**Table 14.1**  
**Attenuator Component Values**

IF Power	10 W	6W	½ – 3 W	< 250 mW
First attenuator	23 dB	20 dB	18 dB	6 dB
R1	50 @ 8W	50 @ 4W	50 @ 2W	50
R2	27 * 4	43 * 4	56 * 4	100
R3	1.5k * 4	1k * 4	560 * 3 or 750 * 4	39
R4	56	62	62	150

NOTES:

\*4 means four resistors in parallel; \* 3 means three resistors in parallel

See Figure 14.25 for the attenuator schematic

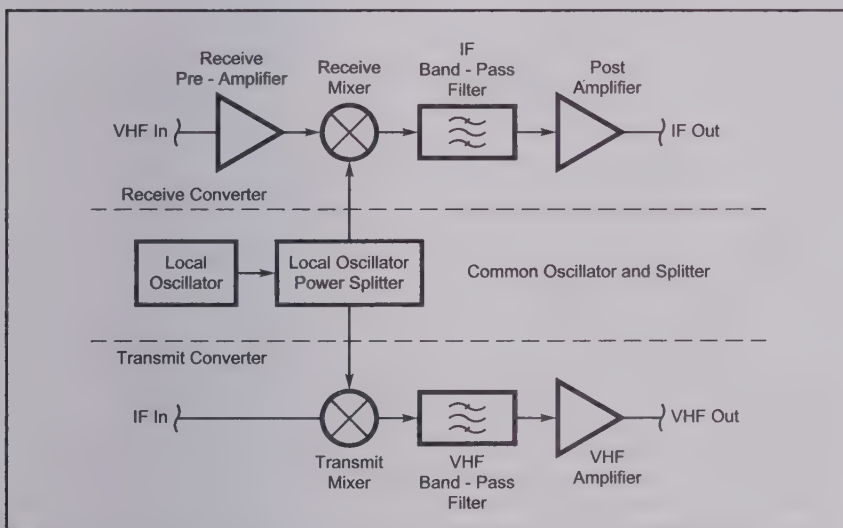

All resistances are in ohms and all resistors are ¼ W unless noted otherwise

### 14.5.3 Basic Transverter Structure

Most radio amateurs now buy commercial transverters and install them as just described. This section is for those who wish to understand the inner workings of their transverters — or perhaps wish to build their own transverters.

The block diagrams of two typical transverter structures are shown in **Figure 14.21** and **14.22**. The transverter in Figure 14.21

has separate receive and transmit paths. A low-level output, typically 100 mW (20 dBm) or less, from the IF radio (labeled IF IN) is mixed with the transceiver's LO. The desired VHF mixing product is selected with the VHF band-pass filter and amplified by one or more low-power amplifier modules or ICs. This architecture requires the IF radio to supply a separate receiver input (typically labeled RX IN) and low-power transmit output (usually referred to as a "transverter output.")

**Figure 14.21** — Block diagram for a typical transverter. The upper chain is the receiving converter and the lower chain is the transmitting converter.

In Figure 14.22, the transceiver uses only a single *bilateral* mixer that converts signals flowing in either direction as transmit or receive. This allows the IF transceiver to operate as it normally does, with its internal transmit-receive (TR) switching routing signals. In the case of the 222 MHz transceiver, it is operating on the 24 MHz band. The transceiver output power must be attenuated or turned down to an acceptable level to avoid damaging the transverter's input circuits.

### 14.5.4 Mixers

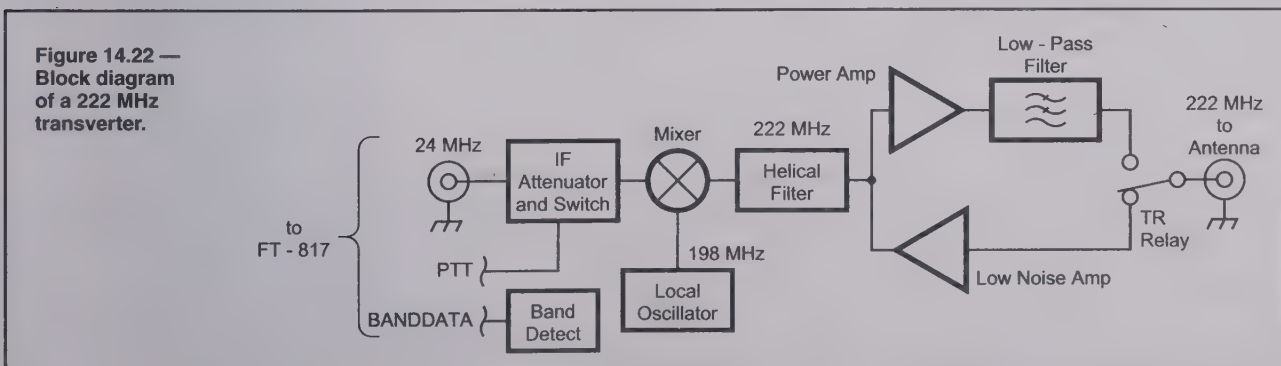

The heart of a transverter is a mixer, sometimes called a "frequency mixer" or a "frequency changer," a nonlinear device that combines two signals at different input frequencies to produce new frequencies at the mixer output. These new output frequencies are the sum and difference of the original input frequencies. Mixers are discussed in detail in this book's **Receiving** chapter.

In the 222 MHz transverter of Figure 14.22, the mixer combines input signals with a 198 MHz local oscillator. To transmit, a 24-MHz signal is applied at the IF port from the transceiver; the sum frequency is 222 MHz, which is amplified and sent to the antenna. To receive, 222 MHz signals from the antenna combine with the local oscillator and the difference frequency, 24 MHz, is sent to the IF port on the 12 meter band.

A common choice for a transverter mixer is an inexpensive, double-balanced diode mixer. A high-level version will provide for better dynamic range (see the **Receiving** chapter). A wide dynamic range is important for rejecting out-of-band signals from other services, particularly TV, FM, and commercial/public safety signals, which are often present at the elevated locations common for portable operating.

### 14.5.5 Preamplifiers

Double-balanced mixers typically have a relatively high noise figure, so it is almost always necessary to use a low-noise preamp ahead of the mixer. The preamp can be a dis-

**Figure 14.22** — Block diagram of a 222 MHz transverter.

crete semiconductor circuit, or an MMIC RF amplifier can be used. If a preamp is used, a band-pass filter should be used at the input. (See the **Receiving** chapter for more information on preamps, including some discrete component design references.) A wide-band preamp design useful up to 1296 MHz is provided in this book's downloadable supplemental information. (See "Universal MMIC Preamp" by Paul Wade, W1GHZ)

External preamplifiers are often mounted directly at the antenna with power supplied via the main feed line. An RF sensing circuit or a separate control line from the transceiver or transverter is required to route transmit RF around the preamplifier. Some transverters can be mounted at the antenna, as well, and may include a preamplifier. Both techniques improve the noise figure (see the **Receiving** chapter) of the receiving chain and also reduce the antenna system cost by allowing less-expensive coax to be used.

### 14.5.6 Filters

Transverters typically use a filter before and after the mixer. Comb filters, helical filters, and lumped LC filters are all used to provide band-pass responses. A low-pass filter is generally sufficient for the IF input and output since the IF radio's filters will be used. Another low-pass filter at the output of the transverter power amplifier path reduces harmonics. A band-pass filter at the antenna port can serve the same function and keeps spurious signals from being transmitted on the air. It also helps prevent overload or intermodulation from strong out-of-band signals on receive.

Regardless of filter type, both filters and mixers are much better behaved when they are terminated in a load impedance that is constant over a wide bandwidth. Filters also behave better when their inputs and outputs are terminated by the impedance for which they were designed. A 3-dB pad made up of chip resistors at filter and mixer inputs and outputs allows each to achieve a reasonable impedance match, which makes both circuits perform more predictably.

Filter designs are available in the **Analog and Digital Filtering** chapter or can be designed using the *ELSIE* software package that is included with this book's download-

able supplemental information. If amplifier modules are used, some models are less stable with capacitor-input filters, so the inductor-input designs are recommended.

Microstrip line and cavity filters are most often used in amateur microwave transverters. Microstrip line filters consist of patterns of printed circuits that are frequency selective. Cavity filters are usually constructed from small plumbing parts that are soldered to circuit boards and then tuned with setscrews. Waveguide filters are also used, most notably at 10 GHz and higher. These consist of a piece of waveguide with metal rods and irises inserted. Tuning is performed with screws.

If portable operation is planned at hilltop sites where commercial or government transmitters are in operation, you should consider using external band-pass filters to reject the extremely strong signals that will be present. Be aware that noise from these transmitters (and possibly intermodulation products) may be quite strong compared to weaker amateur signals.

### 14.5.7 Local Oscillator

A good local oscillator (LO) is usually the hardest part of any transverter design. It must provide a clean signal, because any undesired frequencies generated by the LO can become a source of "birdies" in the receiver. It must also be stable and have low phase noise. Low phase noise is important, as a noisy local oscillator will raise the noise floor of the receiver, particularly in the presence of strong undesired signals, either out-of-band or in-band. Above 50 MHz, the interesting signals are usually the weak ones, so a low noise floor gets them in the log.

A crystal oscillator is the most obvious LO solution (see the **Oscillators and Synthesizers** chapter). Good crystals have become more expensive and harder to find, except those made for frequencies used in computer hardware — those are cheap and produced in high volumes. Oscillator modules are the usual choice, having all of the circuitry optimized for the crystal and temperature stability. Packaged oscillators don't have any provisions for frequency adjustment, but because they are inexpensive, several can be ordered and the module closest to the desired frequency used.

In addition, many wide-band SDR transceivers also have transverter outputs that can operate over a wide range of frequencies, allowing more choices for the LO frequency.

The oscillator frequency is usually not high enough to use directly so it must be multiplied. **Figure 14.23** shows a typical scheme for generating a 10 GHz signal from a VHF crystal oscillator. For this oscillator to be reasonably temperature stable, a temperature stabilized miniature oven is usually used. After warming a simple ovenized 200 MHz oscillator stays within a few tenths of a hertz over the time that typical contacts are made. The 200-MHz oscillator is multiplied by approximately 50 to achieve an LO for a 10.386 GHz radio. One hertz of variation in the crystal oscillator will result in about 50 Hz change at 10 GHz, a noticeable change that may cause problems on some digital modes. If the LO is to drive an 80 GHz or 145 GHz radio, the sensitivity to drift is ten times more critical. (See K7MDL's "Multiband Microwave Local Oscillator" paper in the References at the end of this section for an approach to developing a stable signal source that is designed for transverter operation.)

While multiplier circuits can be difficult to design and adjust, the oscillator modules used for digital circuits have a square wave output. These oscillators have very fast rise and fall times, so they are rich in odd harmonics. Separating a third or fifth harmonic with a narrow filter or diplexer and amplifying with an MMIC produces satisfactory output.

Microwave LOs in commercial and scientific converters are usually phase locked oscillators or PLOs. These items cost over a thousand dollars if purchased new. However, these PLO "bricks" are sometimes available at flea markets and auction sources at low cost. The negatives of using a surplus PLO include the effort to retune them, acquisition of a special crystal, greater weight and the need for -20 V at 1 A of power that most do not require. The positives include excellent phase noise, great stability after warm up at low cost. Synthesized LO modules with low phase noise are also available, such as the *digiLO* from [g5systems.com](http://g5systems.com). Most of these can also be locked to a GPS-disciplined 10 MHz reference for very accurate and stable frequency control.

Figure 14.23 — A local oscillator multiplier chain for a 10 GHz transverter.

A high-stability TCXO is highly recommended in the IF radio for use with transverters. For the microwave bands, LO oscillator and microphonics can be a problem. It is important to keep the IF radio and the transverter at a constant temperature and avoid vibration. As noted earlier, most modern transverters have a provision for an external frequency reference that will lock the transverter on frequency with an accuracy of plus or minus only a few hertz even at 10 GHz.

## 14.5.8 Transceiver Power Output Control

Assuming your transceiver can be set to output  $\frac{1}{2}$  W or less, perhaps through a dedicated transverter output port, ordinary  $\frac{1}{4}$  W resistors can be used as an input attenuator which may be fixed or variable. Be sure to test a resistor design before using it between a transceiver and transverter. In the 222 MHz transverter shown in Figure 14.22, two resistors are used in series; one fixed and one variable. PIN diodes are used to bypass a variable attenuator on receive but a smaller fixed attenuator is left in the line to protect the receiver in case of a switching failure.

Most modern commercial transverters have built-in attenuators so they can handle the full output power of a 5-W transceiver. If your transverter outputs 100 W, however, it's up to you to remember to turn the power down every time you switch from straight-through or 2-meter operation to transverter operation. If you forget to reduce the power in the heat of battle to try to work a new multiplier, you may not only miss the multiplier but also damage the input circuitry of your transverter and yourself up for a costly repair.

Another option for power control is to use an external dc voltage to control the transceiver's ALC function. For most transverters, a negative dc voltage applied to the ALC input can reduce the output power to nearly 50%. The ALC input is a high-impedance input so little current is required. **Figure 14.24** shows a simple circuit that will work on most transverters. The Inverting DC-DC converter project in the downloadable supplemental information for the **Power Sources** chapter will also work and can be connected to the radio's power supply.

## 14.5.9 Power Amplification

Transverter modules commercially available as kits have an output of 10 to 100 mW (0 to 20 dBm) and usually require additional amplification to be able to fully drive a standard solid-state amplifier to the 10 to 50 W level. RF amplifier modules designed for commercial service are available to amplify low-level signals to useful power levels.

**Figure 14.24** — Negative voltage ALC power control circuit. Note the battery polarity and chassis connection. The 0.01  $\mu\text{F}$  capacitor filters out any RF that might be present and the 1 k $\Omega$  resistor limits current into the ALC input.

The power level at the output of a mixer/buffer might be as low as 100  $\mu\text{W}$  ( $-10$  dBm) and must be increased to develop useful output power levels. MMICs are an easy and inexpensive way to raise the power level to 20–100 mW ( $+13$  dBm to  $+20$  dBm) required to drive higher power devices or modules. Gain at and above UHF has become much less expensive in recent years due to consumer devices operating at these frequencies.

Hybrid modular amplifiers can be used to easily reach the 10–25 W level. While they seem a bit expensive, they are easy to use and usually the only other components required are a few capacitors and chokes. Higher power modules require more current and heat-sinking, increasing the size and weight of the transverter. Amplifier modules made by Mitsubishi/Toshiba ([www.mitsubishielectric.com/semiconductors/products/hf/sirf-powermod/index.html](http://www.mitsubishielectric.com/semiconductors/products/hf/sirf-powermod/index.html)) are very common in amateur VHF/UHF FM transverters and can also be used for transverters. Remember that the module must be capable of linear operation for use with SSB and AFSK modulation. Vendors such as RF Parts ([www.rfparts.com](http://www.rfparts.com)) can supply modules in small quantities. (Also see the RF Power Amplifier Modules listing in the **Component Data and References** chapter.)

## 14.5.10 TR Switching and Sequencers

Just as in a transceiver, the transmit-receive (TR) functions must be switched at the appropriate time. The simplest approach is to use a relay activated by the transceiver's PTT circuit to switch the input and output circuits. If the timing of the PTT and RF output from the transceiver are well-behaved, and some protective attenuation is provided at the receiver connections, this approach may work fine.

However, applying RF from a transmitter before the receive circuits have been disconnected can destroy a sensitive receive preamplifier or mixer. Many commercial

transverters can transmit power immediately upon being activated, before any external circuits can switch from transmit to receive. The unwanted power can burn out mixers and preamps, as well as coaxial relays that are not meant to hot-switch RF power — it doesn't take much power to damage a relay contact while it is switching. Another common problem is that some transverters output a high-power transient until the ALC loop regains control of the transmitter power. This is addressed by using a sequencer. Several manufacturers such as Kuhne Electronic sell highly reliable sequencers for a modest price to address these problems. If you use one of these and carefully follow the directions, you should be fine.

Another pitfall in the TR switching process is caused by the relay itself. The coil that activates a relay may send a powerful voltage spike back into the transverter when it is de-energized, with devastating consequences for the low-level circuitry. Read the instructions from the transverter manufacturer carefully. If it says to add a protective diode across the relay coil, follow those instructions literally, observing the recommended polarity. (A small bypass capacitor across the diode will keep it from generating harmonics of any RF that is present.) If it doesn't say to take that precaution, consider doing it anyway.

Some approaches involve trying to delay the transceiver output, either by intercepting the PTT line from the microphone or keying devices or by controlling a Transmitter Inhibit input to the transceiver. Both of these approaches work well, but need additional connections to the transceiver, are model-specific, and present additional points of possible failure.

A simpler approach is to have a single connection from transceiver to transverter, with PTT voltage added to the IF transceiver output feed line. A microcontroller can then monitor the switching operation. The article "A Smart Fool-resistant Conditional Sequencer" by Paul Wade, W1GHZ (see this book's downloadable supplemental information for the complete article) describes the Arduino-based controller (an Arduino Pro Trinket) suitable for adaptation to many transverter circuits. For example, an RF sensor can detect any transmitted power and switches the input circuit to a safe state to absorb unwanted power until the sequencer finishes all switching.

In **Figure 14.25**, the PIN diode switching circuit is controlled by the signal lines TXE (Transmit Enable) and RXD (Receive Disable). Both controlling signals for the PIN switch are asserted High. To receive, both are de-asserted. RXD is asserted, but not TXE, for the SAFE state, and then TXE is asserted along with RXD to transmit. TXE should never be asserted without RXD, a combina-

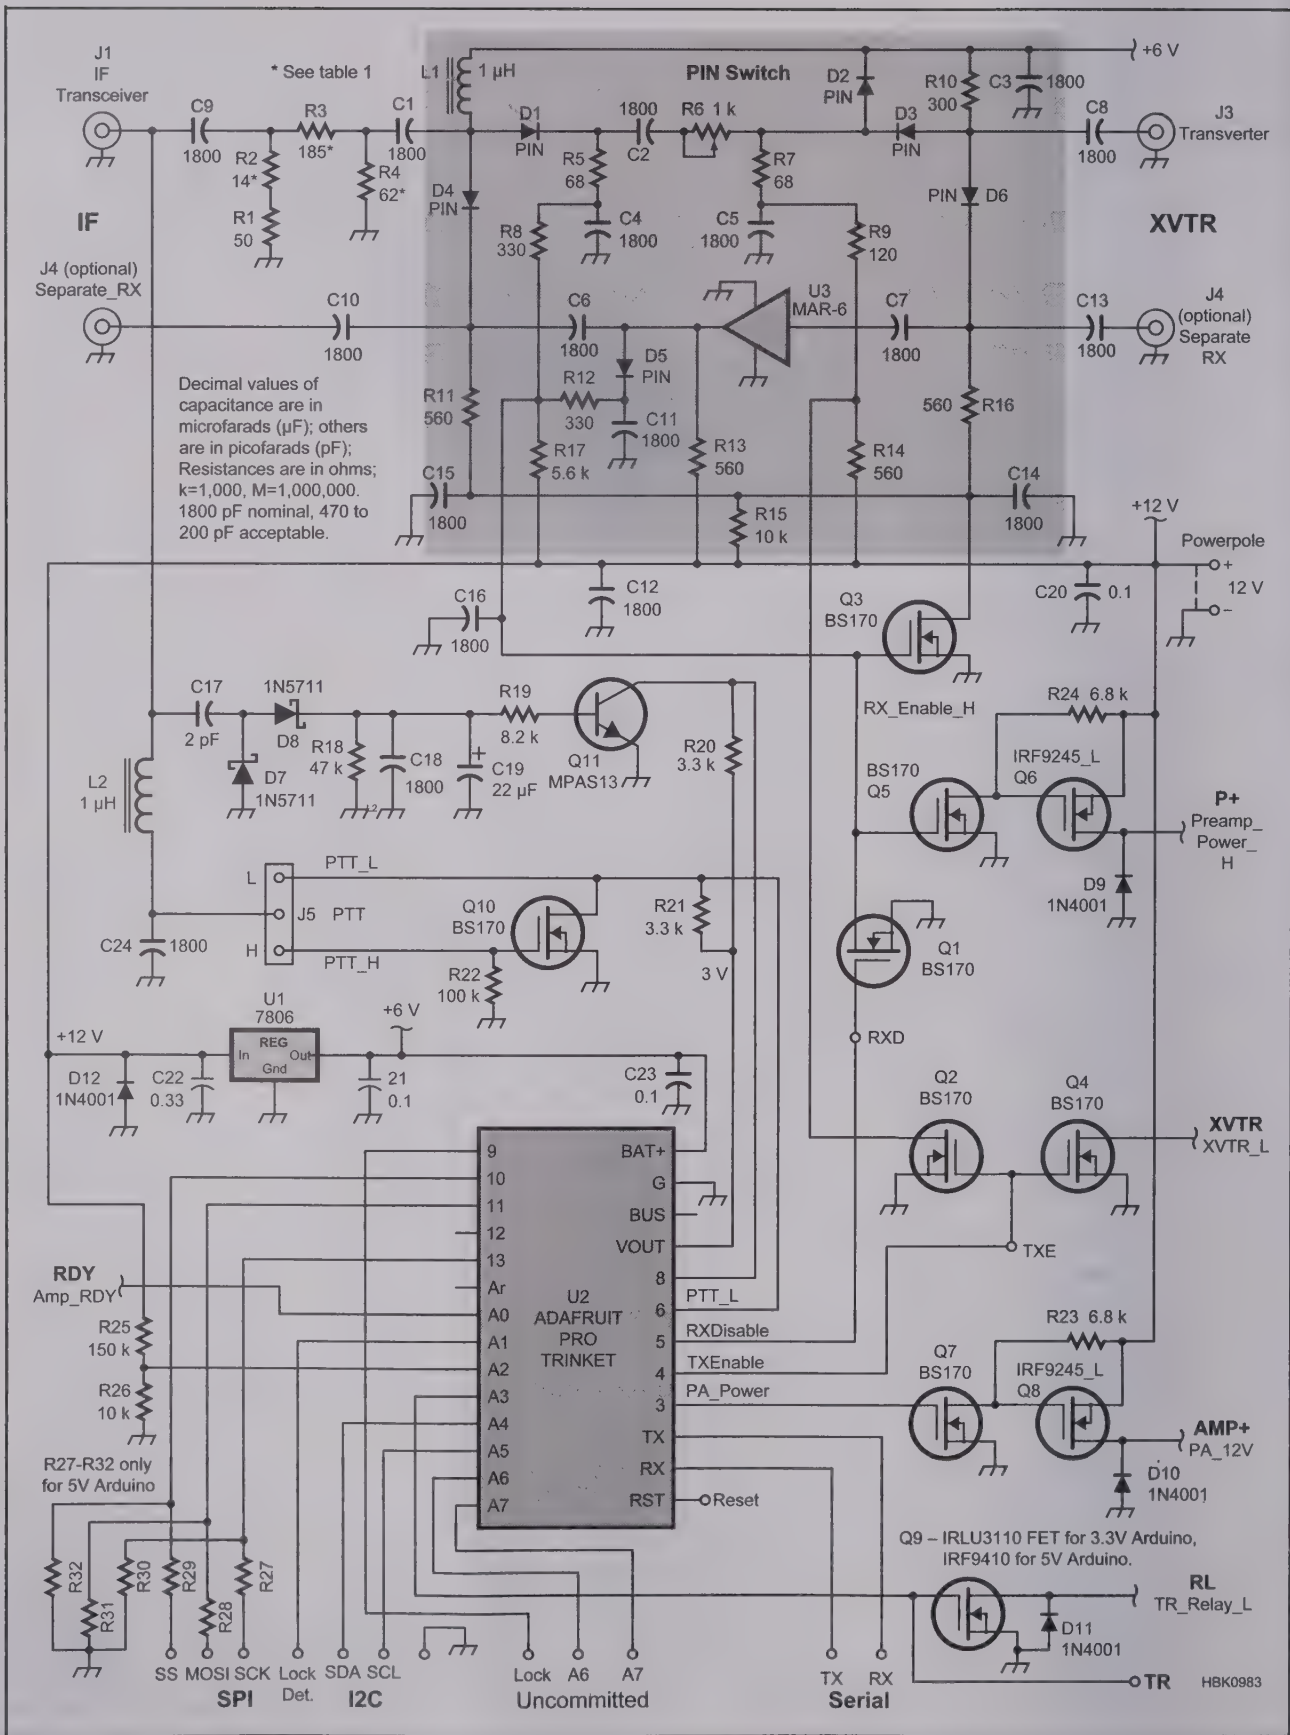

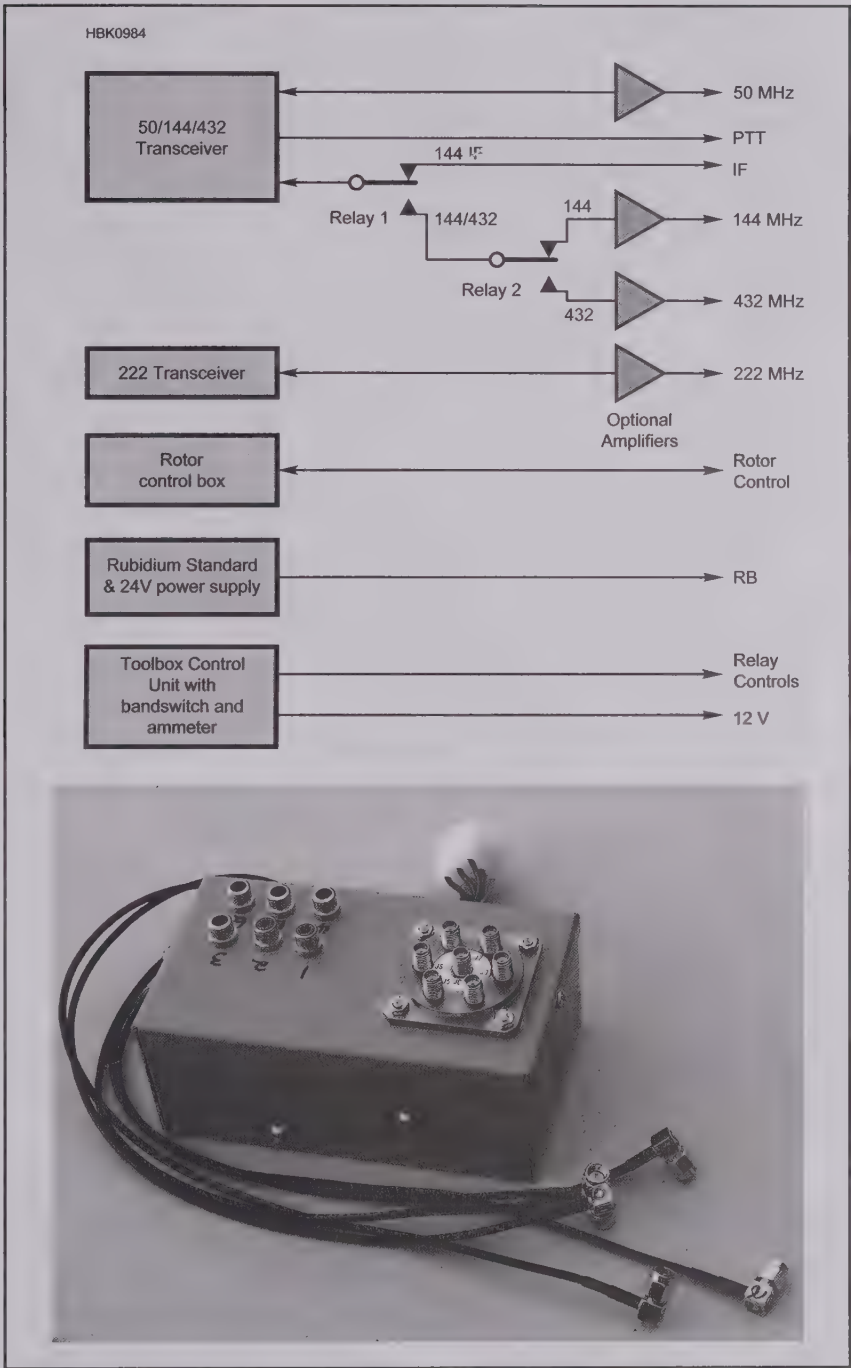

Figure 14.25 — A processor-controlled sequencer. The PIN switch circuitry at the top is controlled by the Arduino processor through the TXE (Transmit Enable) and RXD (Receive Disable) control lines.

tion that would enable both transmitter and receiver simultaneously.

### 14.5.11 Transverter Systems

Building a separate transverter for each band has been the norm for decades, but recent technological advances are making multiband transverters possible. For example, Down East Microwave is in the final pre-production stages (as of November 2019) of producing a six-band transverter covering 902, 1296, 2304, 3456, 5760, and 10368 MHz requiring only a single 144-MHz IF radio. Wideband SDR-based radios are also becoming available, moving transceiver performance to the UHF and microwave bands, with transverter opportunities extending into the millimeter-wave spectrum.

Another approach is taken by Wayne Overbeck, N6NB, in creating his “Ten-Band Toolbox Transverter” system designed for roving in VHF+ contests. (The full article describing the transverter system is available online, see the References list at the end of this section.) The system consists of two packages: an IF radio and control unit which goes inside the vehicle (see Figure 14.26) and a transverter package designed for mounting on top of

Figure 14.26 — Control unit for multiband transverter system by N6NB. The switch enclosure goes inside the toolbox or other microwave equipment box. It switches the IF, PTT line, and rubidium standard reference signal through the six bands from 902 MHz to 10 GHz.

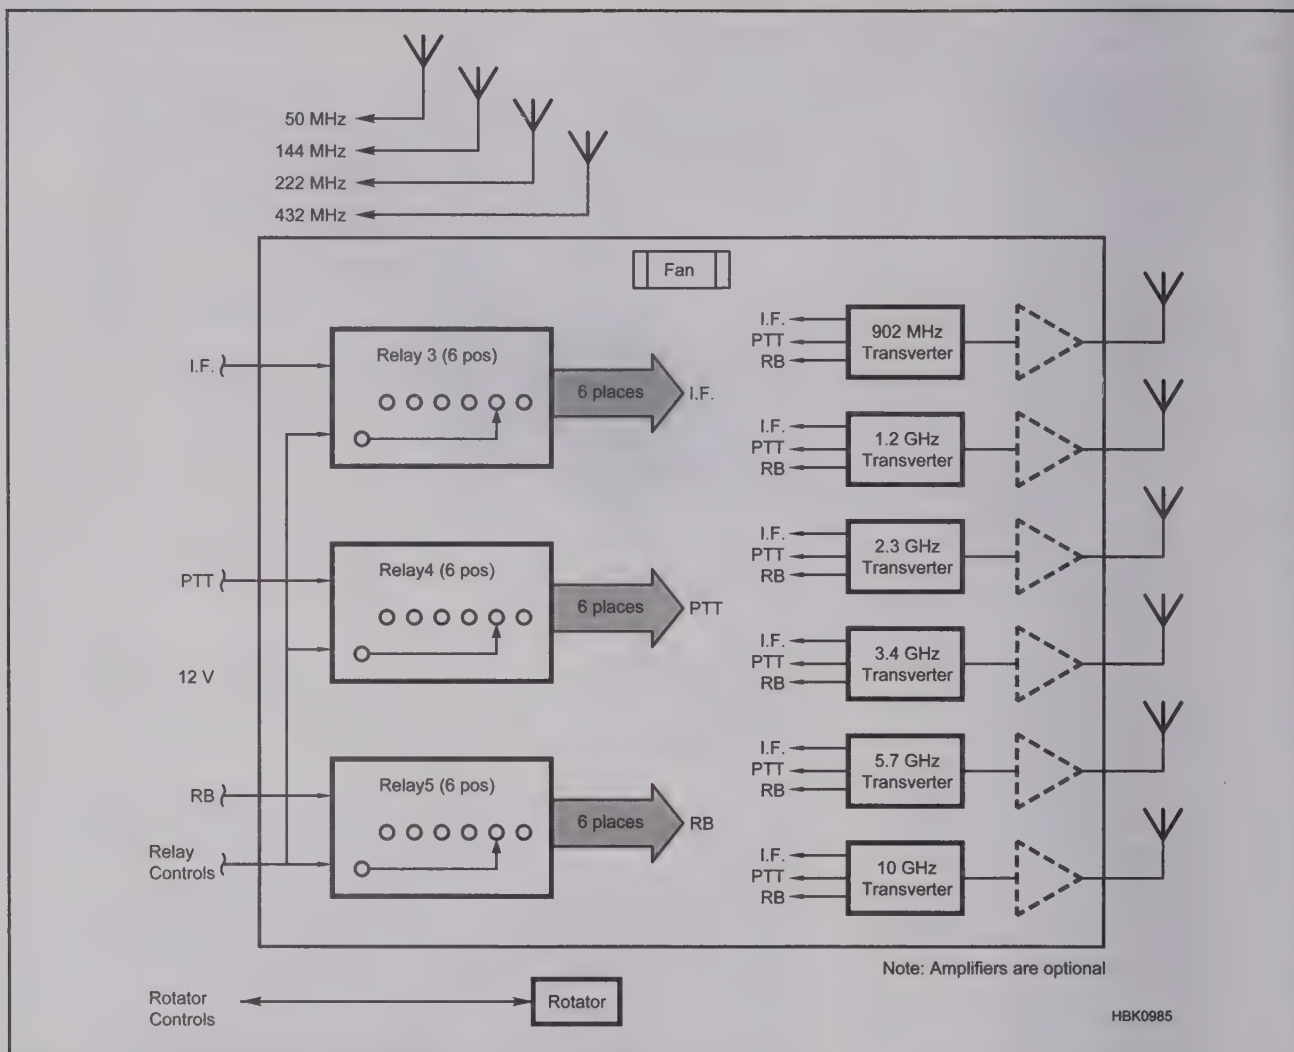

Figure 14.27 — Block diagram of integrated transverter package.

the vehicle, Figures 14.27 and 14.28. The transverter package is integrated with antennas so that the whole package is easy to install and remove.

This package can be used as a fixed or mobile/rover station and covers all bands from 50 MHz to 10 GHz with a single transceiver and a group of transverters. A 6-position or 8-position rotary switch is mounted in a small box to serve as a band switch. One set of its

contacts is used to switch the PTT control line (the TR switching line) between transverters. Another set of contacts switches a dc voltage (usually either 12 V or 28 V) to control a 6-position SMA relay (available on the surplus market) that routes the 144 MHz IF signals between transverters. The result is a multiband station with rapid single-knob band switching.

If additional switch positions are available,

the relay can also be configured to transfer the IF radio's output directly to an antenna for straight-through operation on 144 or 432 MHz. Sometimes a 222 MHz transverter is also connected to this package, although that often requires switching the IF rig from 144 MHz to 28 MHz, the usual IF for a 222 MHz transverter. That's why many VHF operators have a separate transceiver and transverter for 222 MHz.

Figure 14.28 — Seven transverter packages designed to be mounted on the roof of the vehicle with antennas attached.

# Digital Protocols and Modes

Amateur Radio operators are creating new digital modes to communicate both as “chat-style” keyboard-to-keyboard operation or using packetized network-compatible protocols. Many new protocols can be entirely implemented using software and a computer sound card, making tools for experimentation and implementation available worldwide via the Internet. New SDR technology will allow digital protocols and modes to be implemented directly without an intervening audio modulation/demodulation step. It is an exciting period for Amateur Radio with frequent innovations and improvements.

This chapter will focus on the protocols for transferring various data types, focusing on the processes by which data is encoded, compressed and error checked, packaged and exchanged. Joe Taylor, K1JT, and Steve Franke, K9AN, updated the sections on *WSJT-X* modes FT8, FT4, and MSK144. Modulation methods are covered in the **Modulation** chapter, and the **Digital Communications** chapter available with the online supplemental material discusses the practical considerations of operating using these modes.

There is a broad array of digital modes to service various needs with more coming. The most basic modes simply encode text data for transmission in a keyboard-to-keyboard chat-type environment. These modes may or may not include any mechanism for error detection or correction. The second class of modes are generally more robust and support more sophisticated data types by structuring the data sent and including additional error-correction information to properly reconstruct the data at the receiving end. The third class of modes discussed will be networking modes with protocols often the same or similar to versions used on the Internet and computer networks.

## 15.1 Digital “Modes”

The ITU uses *Emission Designators* to define a “mode” as demonstrated in the **Modulation** chapter. These designators include the bandwidth, modulation type and information being sent. This system works well to describe the physical characteristics of the modulation, but digital modes create some ambiguity because the type of information sent could be text, image or even the audio of a CW session. As an example, an FM data transmission of 20K0F3D could transmit spoken audio (like FM 20K0F3E or 2K5J3E) or a CW signal (like 150H0A1A). These designators don’t help identify the type of data supported by a particular mode, the speed that data can be sent, if it’s error-corrected, or how well it might perform in hostile band conditions. Digital modes have more characteristics that define them and there are often many variations on a single mode that are optimized for different conditions. We’ll need to look at the specifics of these unique characteristics to be able to determine which digital modes offer the best combination of features for any given application.

### 15.1.1 Symbols, Baud, Bits and Bandwidth

The basic performance measure of a digital mode is the *data rate*. This can be measured a number of ways and is often confused. Each change of state on a transmission medium defines a *symbol* and the *symbol rate* is also known as *baud*. (While commonly used, “baud rate” is redundant because “baud” is already defined as the rate of symbols/second.) Modulating a carrier increases the frequency range, or bandwidth, it occupies. The FCC currently limits digital modes by symbol rate on the various bands as an indirect (but easily measurable) means of controlling bandwidth.

The *bit rate* is the product of the *symbol rate* and the number of bits encoded in each symbol. In a simple two-state system like an RS-232 interface, the bit rate will be the same as baud. More complex waveforms can represent more than two states with a single symbol so the bit rate will be higher than the baud. For each additional bit encoded in a symbol, the number of states of the carrier doubles. This makes each state less distinct from the others, which in turn makes it more difficult for the receiver to detect each symbol correctly in the presence of noise. A V.34 modem may transmit symbols at a baud rate of 3420 baud and each symbol can represent up to 10 discrete states or bits, resulting in a *gross (or raw) bit rate* of 3420 baud × 10 or 34,200 bits per second (bit/s). Framing bits and other overhead reduce the *net bit rate* to 33,800 bit/s.

Bits per second is abbreviated here as *bit/s* for clarity but is also often seen as *bps*. Bits per second is useful when looking at the protocol but is less helpful determining how long it

**Table 15.1**  
**Data Rate Symbols and Multipliers**

Name	Symbol	Multiplier
kilobit per second	kbit/s or kbps	1000 or 10 <sup>3</sup>
Megabit per second	Mbit/s or Mbps	1,000,000 or 10 <sup>6</sup>
Gigabit per second	Gbit/s or Gbps	1,000,000,000 or 10 <sup>9</sup>

takes to transmit a specific size file because the number of bits consumed by overhead is often unknown. A more useful measure for calculating transmission times is *bytes per second* or *Bps* (note the capitalization). Although there are only eight bits per byte, with the addition of start and stop bits, the difference between bps and Bps is often tenfold. Since the net bit rate takes the fixed overhead into account, Bytes per second can be calculated as  $\text{bps}_{\text{net}}/8$ . Higher data rates can be expressed with their metric multipliers as shown in **Table 15.1**.

Digital modes constantly balance the relationship between symbol rate, bit rate, bandwidth and the effect of noise. The Shannon-Hartley theorem demonstrates the maximum channel capacity in the presence of Gaussian white noise and was discussed in the **Modulation** chapter in the Channel Capacity section. This theorem describes how an increased symbol rate will require an increase in bandwidth and how a reduced signal-to-noise ratio (SNR) will reduce the potential *throughput* of the channel.

### 15.1.2 Error Detection and Correction

Voice modes require the operator to manually request a repeat of any information required but not understood. Using proper phonetics makes the information more easily understood but takes longer to transmit. If 100% accuracy is required, it may be necessary for the receiver to repeat the entire message back to the sender for verification. Computers can't necessarily distinguish between valuable and unnecessary data or identify likely errors but they offer other options to detect and correct errors.

#### ERROR DETECTION

The first requirement of any accurate system is to be able to detect when an error has occurred. The simplest method is *parity*. With 7-bit ASCII data, it was common to transmit an additional 8th parity bit to each character. The parity bit was added to make the total number of 1 bits odd or even. The binary representation for an ASCII letter Z is 1011010. Sent as seven bits with even parity, the parity bit would be 0 because there are already an even number of 1 bits and the result would be 0101 1010. The limitation of parity is that it only works with an odd number of

bit inversions. If the last two bits were flipped to 01011001 (the ASCII letter Y), it would still pass the parity check because it still has an even number of bits. Parity is also rarely used on 8-bit data so it cannot be used when transferring binary data files.

*Checksum* is a method similar to the "check" value in an NTS message. It is generally a single byte (8-bit) value appended to the end of a packet or frame of data. It is calculated by adding all the values in the packet and taking the least significant (most unique) byte. This is a simple operation for even basic processors to perform quickly but can also be easily misled. If two errors occur in the packet of equal amounts in the opposite direction (A becomes B and Z becomes Y), the checksum value will still be accurate and the packet will be accepted as error-free.

*Cyclic redundancy check (CRC)* is similar to checksum but uses a more sophisticated formula for calculating the check value of a packet. The formula most closely resembles long division, where the quotient is thrown away and the remainder is used. It is also common for CRC values to be more than a single byte, making the value more unique and likely to identify an error. Although other error detection systems are currently in use, CRC is the most common.

#### ERROR CORRECTION

There are two basic ways to design a protocol for an error correcting system: *automatic repeat request (ARQ)* and *forward error correction (FEC)*. With ARQ the transmitter sends the data packet with an error detection code, which the receiver uses to check for errors. The receiver will request retransmission of packets with errors or sends an acknowledgement (ACK) of correctly received data, and the transmitter re-sends anything not acknowledged within a reasonable period of time.

With forward error correction (FEC), the transmitter encodes the data with an *error-correcting code (ECC)* and sends the encoded message. The receiver is not required to send any messages back to the transmitter. The receiver decodes what it receives into the "most likely" data. The codes are designed so that it would take an "unreasonable" amount of noise to trick the receiver into misinterpreting the data. It is possible to combine the two, so that minor errors are corrected without retransmission, and major errors are detected

and a retransmission requested. The combination is called *hybrid automatic repeat request (hybrid ARQ)*.

There are many error correcting (ECC) algorithms available. Extended lay coding is used on blocks of ALE data, for example, as described in the section on G-TOR. In addition to the ability to detect and correct errors in the data packets, a modulation scheme allows sending multiple data streams and interleaving the data in a way that a noise burst will disrupt the data at different points.

### 15.1.3 Data Representation

When comparing digital modes, it is important to understand how the data is conveyed. There are inherent limitations in the method chosen. PSK31 might seem a good choice for sending data over HF links because it performs well, but it was only designed for text (not 8-bit data) and has no inherent error correction. It is certainly possible to use a modulation scheme to send 8-bit data and error correction to create a new mode. This would maintain the weak signal performance but the speed will suffer from the increased overhead. Similarly, a digital photo sent using analog SSTV software may only take minutes to send, but over VHF packet it could take 10 minutes, despite the higher speed of a packet system. This doesn't mean SSTV is more efficient. Analog SSTV systems generally transmit lower resolution images with error correction. Over good local links, a VHF packet system will be able to deliver perfect images faster or of higher quality.

#### TEXT REPRESENTATIONS

Morse code is well known as an early code used to send text data over a wire, then over the air. Each letter/number or symbol is represented with a varying length code with more common letters having shorter codes. This early *varicode* system is very efficient and minimizes the number of state changes required to send a message.

The Baudot code (pronounced "bah-oh") was invented by Émile Baudot and the predecessor to the character set currently known more accurately as International Telegraph Alphabet No 2 (ITA2). This code used for radioteletype communications contains five bits with start and stop pulses. This only allows for 2<sup>5</sup> or 32 possible characters to be sent, which is not enough for 26 letters plus numbers and characters. To resolve this, ITA2 uses a LTRS code to select a table of upper case (only) letters and a FLS code to select a table of numbers, punctuation and special symbols. The code is defined in the ITA2 codes table with the downloaded supplemental content.

Early computers used a wide variety of

abetic codes until the early 1960s until the advent of the American Standard Code for Information Interchange or ASCII (pronounced "SS-key"). At that point many computers standardized on this character set to allow simple transfer of data between machines. ASCII is a 7-bit code which allows for 2<sup>7</sup> = 128 characters. It was designed without the *control characters* used by Baudot for more reliable transmissions and the letters appear in English alphabetical order for easy sorting. The code can be reduced to only six bits and still carry numbers and uppercase letters. Current FCC regulations provide that amateur use of ASCII conform to ASCII as defined in ANSI standard X3.4-1977. The international counterparts are ISO 646-1983 and International Alphabet No. 5 (IA5) as published in ITU-T Recommendation V.3. A table of ASCII characters is presented as "ASCII Character Set" with the downloadable supplemental content.

ASCII has been modified and initially extended to eight bits, allowing the addition of foreign characters or line segments. The different extended versions were often referred to as *code pages*. The IBMPC supported code page 437 which offers line segments, and English *Windows* natively supports code page 437 with additional foreign characters and symbols. All of these extended code pages include the same first 128 ASCII characters for backward compatibility. In the early 1990s efforts were made to support more languages directly and *Unicode* was created. Unicode generally requires 16 bits per character and can represent nearly any language.

More recent schemes use varicode, where the most common characters are given shorter codes (see [en.wikipedia.org/wiki/Prefix\\_code](http://en.wikipedia.org/wiki/Prefix_code)). Varicode is used in PSK31 and MFSK to reduce the number of bits in a message. Although the PSK31 varicode contains all 128 ASCII characters, lower-case letters contain fewer bits and can be sent more quickly. Tables of PSK and MFSK varicode characters are included with the downloadable supplemental content.

## IMAGE DATA REPRESENTATIONS

Images are generally broken into two basic types, *raster* and *vector*. Raster or *bitmap* images are simply rows of colored points known as *pixels* (picture elements). Vector images are a set of drawing primitives or instructions. These instructions define shapes, placement, size and color. Similar coding is used with letters to command the pens to create the desired image.

Bitmap images can be stored at various *color depths* or bits per pixel indicating how many colors can be represented. Common *color depths* are 1-bit (2 colors), 4-bit (16 colors), 8-bit (256 colors), 16-bit (65,536 colors) also called *high color* and 24-bit (16

**Table 15.2**  
**Typical Audio Formats**

Audio Format	Bits per Sample	Dynamic Range	Maximum Frequency	kbytes per Minute
44.1 kHz stereo	16	98	22,050 kHz	10,584
22 kHz mono	16	98	11 kHz	2,640
8 kHz mono	8	50	4 kHz	960

million also called *true color*). True color is most commonly used with digital cameras and conveniently provides eight bits of resolution each for the red, green and blue colors. Newer scanners and other systems will often generate 30-bit (2<sup>30</sup> colors) and 36-bit (2<sup>36</sup> colors). Images with 4- and 8-bit color can store more accurate images than might be obvious because they include a *palette* where each of their 16 or 256 colors respectively are chosen from a palette of 16 million. This palette is stored in the file which works well for simple images. The GIF format only supports 256 colors (8-bit) with a palette and lossless compression.

Digital photographs are raster images at a specific resolution and color depth. A typical low resolution digital camera image would be 640×480 pixels with 24-bit color. The 24-bit color indicated for each pixel requires three bytes to store (24 bits / 8 bits per byte) and can represent one of a possible 2<sup>24</sup> or 16,777,216 colors with eight bits each for red, green and blue intensities. The raw (uncompressed) storage requirement for this image would be 640×480×3 or 921,600 bytes. This relatively low resolution image would require significant time to transmit over a slow link.

Vector images are generally created with drawing or CAD packages and can offer significant detail while remaining quite small. Because vector files are simply drawn at the desired resolution, there is no degradation of the image if the size is changed and the storage requirements remain the same at any resolution. Typical drawing primitives include lines and polylines, polygons, circles and ellipses, Bézier curves and text. Even computer font technologies such as TrueType create each letter from Bézier curves allowing for flawless scaling to any size and resolution on a screen or printer.

Raster images can be resized by dropping or adding pixels or changing the color depth. The 640×480×24-bit color image mentioned above could be reduced to 320×240×16-bit color with a raw size of 153,600 bytes — a significant saving over the 921,600 byte original. If the image is intended for screen display and doesn't require significant detail, that size may be appropriate. If the image is printed full sized on a typical 300 dpi (dots per inch) printer, each pixel in the photo will explode to nearly 100 dots on the printer and appear very blocky or pixilated.

## AUDIO DATA REPRESENTATIONS

Like images, audio can be stored as a sampled waveform or in some type of primitive format. Storing a sampled waveform is the most versatile but can also require substantial storage capacity. MIDI (musical instrument digital interface, pronounced "MID-ee") is a common music format that stores instrument, note, tempo and intensity information as a musical score. There are also voice coding techniques that store speech as *allophones* (basic human speech sounds).

As with images, storage of primitives can save storage space (and transmission times) but they are not as rich as a high quality sampled waveform. Unfortunately, the 44,100 Hz 16-bit sample rate of an audio compact disc (CD) requires 176,400 bytes to store each second and 10,584,000 bytes for each minute of stereo audio.

The Nyquist-Shannon sampling theorem states that perfect reconstruction of a signal is possible when the sampling frequency is at least twice the maximum frequency of the signal being sampled. With its 44,100 Hz sample rate, CD audio is limited to a maximum frequency response of 22,050 Hz. If only voice-quality is desired, the sample rate can easily be dropped to 8000 Hz providing a maximum 4000 Hz frequency response. (See the **DSP and SDR Fundamentals** chapter for more information on sampling.)

The *bit depth* (number of bits used to represent each sample) of an audio signal will determine the theoretical dynamic range or signal-to-noise ratio (SNR). This is expressed with the formula SNR = (1.761 + 6.0206 × bits) dB. A dynamic range of 40 dB is adequate for the perception of human speech. **Table 15.2** compares the audio quality of various formats with the storage (or transmission) requirements.

## VIDEO DATA REPRESENTATIONS

The most basic video format simply stores a series of images for playback. Video can place huge demand on storage and bandwidth because 30 frames per second is a common rate for smooth-appearing video. Rates as low as 15 frames per second can still be considered "full-motion" but will appear jerky and even this rate requires substantial storage. Primitive formats are less common for video

but animation systems like Adobe *Flash* are often found on the web.

## 15.1.4 Compression Techniques

There are a large variety of compression algorithms available to reduce the size of data stored or sent over a transmission medium. Many techniques are targeted at specific types of data (text, audio, images or video). These compression techniques can be broken into two major categories: *lossless compression* and *lossy compression*. Lossless algorithms are important for compressing data that must arrive perfectly intact but offer a smaller compression ratio than lossy techniques. Programs, documents, databases, spreadsheets would all be corrupted and made worthless if a lossy compression technique were used.

Images, audio and video are good candidates for lossy compression schemes with their substantially higher compression rates. As the name implies, a lossy compression scheme deliberately omits or simplifies that data to be able to represent it efficiently. The human eye and ear can easily interpolate missing information and it simply appears to be of lower quality.

Compression of a real-time stream of data such as audio or video is performed by software or firmware *codecs* (from *coder-decoder*). Codecs provide the real-time encoding or decoding of the audio or video stream. Many codecs are proprietary and have licensing requirements. Codecs can be implemented as operating system or application plug-ins or even as digital ICs, as with the P25 IMBE and D-STAR AMBE codecs.

There are also specifically designed low bit-rate codecs for voice that are more accurately called *vocoders*. Vocoders are optimized for voice characteristics and can encode it extremely efficiently. Conversely, they cannot effectively process non-voice signals. This is easily demonstrated with a mobile phone by listening to music through a voice connection, such as when a call is placed on hold. Mobile phones use highly efficient vocoders to minimize the bandwidth of each voice channel which allows more channels per tower. This also means that non-voice sounds such as music or mechanical sounds are not well reproduced.

Good vocoders are extremely valuable and vigorously guarded by their patent holders. This has made it difficult for amateurs to experiment with digital voice techniques. David Rowe, VK5DGR, worked for several years on a project called CODEC2. This is a very effective open source vocoder made available at the end of 2012. It has been incorporated into the *FDMDV* software and there has been extensive testing and tuning

made on the HF bands. More information about the project can be found at [www.rowatel.com](http://www.rowatel.com). Digital voice is discussed elsewhere in this chapter.

## LOSSLESS COMPRESSION TECHNIQUES

One of the earliest lossless compression schemes is known as *Huffman coding*. Huffman coding creates a tree of commonly used data values and gives the most common values a lower bit count. Varicode is based on this mechanism. In 1984, Terry Welch released code with improvements to a scheme from Abraham Lempel and Jacob Ziv, commonly referred to as *LZW* (Lempel-Ziv-Welch). The Lempel-Ziv algorithm and variants are the basis for most current compression programs and is used in the GIF and optionally TIFF graphic formats. *LZW* operates similarly to Huffman coding but with greater efficiency.

The actual amount of compression achieved will depend on how redundant the data is and the size of the data being compressed. Large files will achieve greater compression rates because the common data combinations will be seen more frequently. Simple text and documents can often see 25% compression rates. Spreadsheets and databases generally consist of many empty cells and can often achieve nearly 50% compression. Graphic and video compression will vary greatly depending on the complexity of the image. Simple images with solid backgrounds will compress well where complex images with little recurring data will see little benefit. Similarly, music will compress poorly but spoken audio with little background noise may see reasonable compression rates.

*Run length encoding (RLE)* is a very simple scheme supported on bitmap graphics (*Windows* BMP files). Each value in the file is a color value and “run length” specifying how many of the next pixels will be that color. It works well on simple files but can make a file larger if the image is too complex.

It is important to note that compressing a previously compressed file will often yield a larger file because it simply creates more overhead in the file. There is occasionally some minor benefit if two different compression algorithms are used. It is not possible to compress the same file repeatedly and expect any significant benefit. Modern compression software does offer the additional benefit of being able to compress groups of files or even whole directory structures into a single file for transmission.

The compression mechanisms mentioned above allow files to be compressed prior to transmission but there are also mechanisms that allow near real-time compression of the transmitted data. V.92 modems implement a LZJH adaptive compression scheme called V.44 that can average 15% better through-

put over the wire. Winlink uses a compression scheme called B2F and sees an average 44% improvement in performance since most Winlink data is uncompressed previously. Many online services offer “Web Accelerators” that also compress data going over the wire to achieve better performance. There is a slight delay (latency) as a result of the compression but over a slow link, the additional latency is minimal compared to the performance gain.

## LOSSY COMPRESSION SCHEMES

Lossy compression schemes depend on the human brain to “recover” or simply ignore the missing data. Since audio, image and video data have unique characteristics as perceived by the brain, each of these data types has unique compression algorithms. New compression schemes are developed constantly to achieve high compression rates while maintaining the highest quality. Often a particular file format actually supports multiple compression schemes or is available in different versions as better methods are developed. In-depth discussion of each of these algorithms is beyond the scope of this book but there are some important issues to consider when looking at these compression methods.

### Lossy Audio Compression

Audio compression is based on the psychoacoustic model that describes which part of a digital audio signal can be removed or substantially reduced without affecting the perceived quality of the sound. Lossy audio compression schemes can typically reduce the size of the file 10- or 12-fold with little loss in quality. The most common formats currently are MP3, WMA, AAC, Ogg Vorbis and ATRAC.

### Lossy Image Compression

The Joint Photographic Experts Group developed the JPEG format (pronounced “JAY-peg”) in 1992 and it has become the primary format used for lossy compression of digital images. It is a scalable compression scheme allowing the user to determine the level of compression/quality of the image. Compression rates of 10-fold are common with good quality and can be over 100-fold with substantially reduced quality. The JPEG format tends to enhance edges and substantially compress fields of similar color. It is not well suited when multiple edits will be required because each copy will have generational loss and therefore reduced quality.

### Lossy Video Compression

Because of the massive amount of data required for video compression it is almost always distributed with a lossy compression scheme. Lossless compression is only used

editing to eliminate generational loss. Video support on a computer is generally complemented with a codec that allows encoding and decoding the video stream. Video files are containers that can often support more than one video format and the specific format information is contained in the file. When the

file is opened, this format information is read and the appropriate codec is activated and fed into the data stream to be decoded.

The most common current codecs are H.261 (video conferencing), MPEG-1 (used in video CDs), MPEG-2 (DVD Video), H.263 (video conferencing), MPEG-4, DivX, Xvid,

H.264, Sorenson 3 (used by *QuickTime*), WMV (Microsoft), VC-1, RealVideo (RealNetworks) and Cinepak.

The basic mechanism of video compression is to encode a high quality "key-frame" that could be a JPEG image as a starting image. Successive video frames or "inter-

## FLDIGI

By Ken Humbertson, W0KAH, and Jeff Coval, AC0SC

You may have heard of the free digital mode software *fldigi* by David H. Freese Jr., W1HKJ. It is very popular for use in emergency communications, for example, because of its multimode capabilities and its ability to work with a companion program *flmsg* that generates standard message forms to be transmitted using *fldigi*. The software supports more than 34 modes (as of early 2013) as well as variations of tones, bandwidth, baud rates, number of bits, and other variations for many modes. Versions of *fldigi* are available for Linux/Free-BSD, Windows XP/V2K/NT/Vista/Win7, and OS X. See [www.w1hkj.com](http://www.w1hkj.com) for information on downloading the files.

If you have a computer with a sound card and microphone, you can begin using *fldigi* to receive with no additional hardware. A quick example would be to tune to 14.070 MHz or 21.070 MHz USB during the day. Set the radio speaker volume to a normal listening level. Start *fldigi* on the computer with sound card and microphone connected and you should see a waterfall display similar to **Figure 15.A** (left).

If your rig has computer control capability, *fldigi* can likely interface with it to display frequency and mode, as well as control the radio from the program.

In **Figure 15.A**, an ICOM IC-7000 is controlled by *fldigi* and thus shows the current operating frequency and mode of 21.070 MHz USB, the QSO frequency of 21071.511 (kHz) (in the windows at the upper left corner), and the current mode of BPSK31 (lower left corner).

When you see multiple signals in the waterfall, *fldigi* will decode whichever one you choose when you place the mouse cursor over a signal of interest and line up the two vertical red lines on your screen with the sides of the signal, as shown near 1500 Hz. When you change modes or bandwidths within a mode, the spacing of the red lines will adjust to the new bandwidth. **Figure 15.B** (right) shows that by selecting RTTY-45 under the OP MODE tab, you will notice that the red line spacing increases to match the familiar RTTY tone shift of 170 Hz. Simply place the two red lines over the signal you wish to decode and the program does the rest.

**Figure 15.B** shows a decoded ARRL digital bulletin from January 2, 2013. While the examples show BPSK31 and RTTY, there are many operating modes to choose from, including CW.

Actions in *fldigi* are performed by action buttons that invoke *macros* — text scripts that control the program. For example, to call CQ use the mouse to click on an unoccupied spot in the waterfall display. This shifts the

modulating tones of the signal to that offset within your receive bandwidth. Click the CQ action button on the *fldigi* display. The transmitted text is displayed in red above the waterfall display. When the text is finished, *fldigi* will return to receive mode. The tutorial "Beginner's Guide to Fldigi" at [www.w1hkj.com/beginners.html](http://www.w1hkj.com/beginners.html) is recommended and the program has an extensive Help file.

The program can be used with an internal sound card or external sound card adapter such as the Tigertronics Signalink USB ([www.tigertronics.com](http://www.tigertronics.com)) or West Mountain Radio Rigblaster series ([www.westmountainradio.com](http://www.westmountainradio.com)). Setting up a sound card to use *fldigi* may require manipulation of the audio device configuration for your computer's operating system. Follow the instructions in the *fldigi* manuals and the manufacturer's manuals if you are using an external adapter. A digital data interface that allows you to connect the sound card to your rig's microphone input is recommended. (See the **Assembling a Station** chapter and the **Digital Communications** chapter with the online supplemental content.

*Fldigi* is frequently updated to include new modes that are being developed. The program is a user-friendly way to become active on the digital modes, a rapidly expanding aspect of Amateur Radio.

**Figure 15.A**

**Figure 15.B**

frames” contain only changes to the previous frame. After some number of frames, it is necessary to use another key-frame and start over with inter-frames. The resolution of the images, frame rate and compression quality determine the size of the video file.

### BIT RATE COMPARISON

Table 15.3 provides an indication of minimum bit rates required to transmit audio and video such that the average listener would not perceive them significantly worse than the standard shown.

**Table 15.3**  
**Audio and Video Bit Rates**

<i>Audio</i>	
8 kbit/s	Telephone quality audio (using speech codecs)
32 kbit/s	AM broadcast quality (using MP3)
96 kbit/s	FM broadcast quality (using MP3)
224-320 kbit/s	Near-CD quality, indistinguishable to the average listener (using MP3)
<i>Video</i>	
16 kbit/s	Videophone quality (minimum for “talking head”)
128-384 kbit/s	Business videoconference system quality
1.25 Mbit/s	VCD (video compact disk) quality
5 Mbit/s	DVD quality
10.5 Mbit/s	Actual DVD video bit rate

### 15.1.5 Compression vs. Encryption

There is some confusion about compression being a form of encryption. It is true that a text file after compression can no longer be read unless uncompressed with the appropriate algorithm. In the United States the FCC defines encryption in part 97.113 as “mes-

sages encoded for the purpose of obscuring their meaning.” Compressing a file with ZIP or RAR (common file compression methods) and transmitting it over the air is simply an efficient use of spectrum and time and is not intended to “obscure its meaning.”

As amateur digital modes interact more with Internet-based services, the issue arises

because many of these services utilize encryption of various types. Banks and other retailers may encrypt their entire transactions to insure confidentiality of personal data. Other systems as benign as e-mail may simply encrypt passwords to properly authenticate users. The FCC has offered no additional guidance on these issues.

## 15.2 Unstructured Digital Modes

The first group of modes we’ll examine are generally considered “sound card modes” for keyboard-to-keyboard communications. Because each of these modes is optimized for a specific purpose by blending multiple features, they often defy simple categorization.

### 15.2.1 Radioteletype (RTTY)

*Radioteletype (RTTY)* consists of a *frequency shift keyed (FSK)* signal that is modulated between two carrier frequencies, called the *mark* frequency and the *space* frequency. The protocol for amateur RTTY calls for the mark carrier frequency to be the higher of the two in the RF spectrum. The difference between the mark and space frequencies is called the *FSK shift*, usually 170 Hz for an amateur RTTY signal.

At the conventional data speed of 60 WPM, binary information modulates the FSK signal at 22 ms per bit, or equivalent to 45.45 baud. Characters are encoded into binary 5-bit Baudot coded data. Each character is individually synchronized by adding a start bit before the 5-bit code and by appending the code with a stop bit. The start bit has the same duration as the data bits, but the stop bit can be anywhere between 22 to 44 ms in duration. The stop bit is transmitted as a mark carrier, and the RTTY signal “rests” at this state until a new character comes along. If the number of stop bits is set to two, the RTTY signal will send a minimum of 44 ms of mark carrier before the next start bit is sent. A start bit is sent as a space carrier. A zero in the Baudot code is sent as a space signal and a one is sent as a

mark signal. Figure 15.1 shows the character D sent by RTTY.

### BAUDOT CODE

The Baudot code (see the downloadable supplemental content) is a 5-bit code; thus, it is capable of encoding only 32 unique characters. Since the combination of alphabets, decimal numbers and common punctuations exceeds 32, the Baudot code is created as two sets of tables. One table is called the LTRS Shift, and consists mainly of alphabetic characters. The second table is called the FIGS Shift, and consists mainly of decimal numerals and punctuation marks. Two unique Baudot characters called LTRS and FIGS are used by the sender to command the decoder to switch between these two tables.

Mechanical teletypewriter keyboards have two keys to send the LTRS and FIGS charac-

ters. The two keys behave much like the caps lock key on a modern typewriter keyboard. Instead of locking the keyboard of a typewriter to upper case shift or lower case shift, the two teletypewriter keys lock the state of the teletypewriter into the LTRS table or the FIGS table. LTRS and FIGS, among some other characters such as the space character, appear in both LTRS and FIGS tables so that you can send LTRS, FIGS and shift no matter which table the encoder is using.

To send the letter Q, you need to first make sure that the decoder is currently using the LTRS table, and then send the Baudot code-word for Q, 17 (hexadecimal or “hex” value). If the same hex 17 is received when the decoder is in the FIGS shift, the number 1 will be decoded instead of the Q. Modern software does away with the need for the operator to manually send the LTRS and FIGS codes.

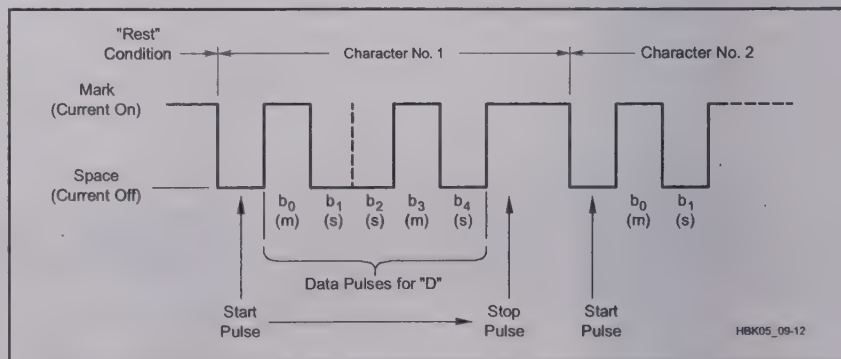

Figure 15.1 — The character “D” sent via RTTY.

When the operator sends a character from the LTRS table, the software first checks to make sure that the previous character had also used a character from the LTRS table; if not, the software will first send a LTRS character.

Noise can often cause the LTRS or FIGS character to be incorrectly received. This will cause subsequent characters to decode into the wrong Baudot character, until a correct LTRS or FIGS is received (see also USOS below). Instead of asking that the message be repeated by the sender, a trick that many RTTY operators use is to observe that on a standard QWERTY keyboard, the Q key is below the 1 key in the row above it, the W key is below the 2 key, and so on. Q and W happen to share the same Baudot code; V and 2 share the same Baudot code, and so forth. Given this visual aid, a printed UE can easily be interpreted by context to 73 and 00 interpreted as 599.

If the sender uses one stop bit, an RTTY character consists of a total of seven bits after adding the start and stop bits. If the sender uses 1.5 stop bits, each RTTY character has a total length of 7.5 bits. The least significant bit of the Baudot code follows the start bit of a character.

## INVERTED SIGNALS

There are times when the sender does not comply with the RTTY standard and reverses the mark and space order in the spectrum. This is often called an “inverted” signal or reverse shift.” Most RTTY modulators and demodulators have a provision to reverse the shift of an inverted signal.

## DEMODULATION AND DECODING

The most common way to decode an RTTY signal is to use a single sideband (SSB) receiver to first translate the two FSK carriers into two audio tones. If the carriers are 170 Hz apart, the two audio tones (called the *tone pair*) will also be 170 Hz apart. The RTTY demodulator, in the form of a terminal unit (TU) or a software modem (modulator-demodulator), then works to discriminate between the two audio tones. Some packet NCs (terminal node controllers) can be made to function as RTTY demodulators, but often they do not work as well under poor signal-to-noise conditions because their filters are matched to packet radio FSK shifts and baud rate instead of to RTTY shift and baud rate.

As long as the tone pair separation is 170 Hz, the frequencies of the two audio tones can be quite arbitrary. Many TUs and modems are constructed to handle a range of tone pairs. A reception uses a lower sideband (LSB) receiver, the higher mark carrier will become the lower of the two audio tones. If upper sideband (USB) is used, the mark carrier will remain the higher of the tone pair. It is common to use 2125 Hz as the mark tone and 2295 Hz as a space tone. Since the mark tone (2125

Hz) is lower in frequency, the receiver will be set to LSB. In general, modem tone pairs can be “reversed” (see the Inverted Signals section), so either an LSB or a USB receiver can be used. Moreover, the tone pairs of many modems, especially software modems, can be moved to place them where narrowband filters are available on the receiver.

In the past, audio FSK demodulators were built using high-Q audio filters followed by a “slicer” to determine if the signal from the mark filter is stronger or weaker than the signal that comes out of the space filter. To counter selective fading, where ionospheric propagation can cause the mark carrier to become stronger or weaker than the space carrier, the slicer’s threshold can be designed to adapt to the imbalance. Once “sliced” into a bi-level signal, the binary stream is passed to the decoder where start bit detection circuitry determines where to extract the 5-bit character data. That data is then passed to the Baudot decoder, which uses the current LTRS or FIGS state to determine the decoded character. The mark and space transmitted carriers do not overlap, although this can occur after they pass through certain HF propagation conditions. Sophisticated demodulators can account for this distortion.

A software modem performs the same functions as a hardware terminal unit, except that the software modems can apply more sophisticated mathematics that would be too expensive to implement in hardware. Modern desktop computers have more than enough processing speed to implement an RTTY demodulator. Software modems first convert the audio signal into a sequence of binary numbers using an analog-to-digital converter which is usually part of an audio chip set either on the motherboard or sound card. Everything from that point on uses numerical algorithms to implement the demodulation processes.

## FSK VS AFSK MODULATION

An RTTY signal is usually generated as an F1B or F2B emission. F1B is implemented by directly shifting an RF carrier between the two (mark and space) frequencies. This method of generating FSK is often called *direct FSK*, or *true FSK*, or simply FSK. F2B is implemented by shifting between two audio tones, instead of two RF carriers. The resultant audio is then sent to an SSB transmitter to become two RF carriers. This method of first generating an audio FSK signal and then modulating an SSB transmitter to achieve the same FSK spectrum is usually called AFSK (audio frequency shift keying).

AFSK can be generated by using either an upper sideband (USB) transmitter or a lower sideband (LSB) transmitter. With a USB transmitter, the mark tone must be the *higher* of the two audio tones in the audio FSK sig-

nal. The USB modulator will then place the corresponding mark carrier at the higher of the two FSK carrier frequencies. When LSB transmission is used, the mark tone must be the *lower* of the two audio tones in the audio FSK signal. The LSB modulator will then place the corresponding mark carrier at the higher of the two FSK carrier frequencies. As when receiving, the actual audio tones are of no importance. The important part of AFSK is to have the two audio tones separated by 170 Hz, and have the pair properly flipped to match the choice of USB or LSB transmission. (See the **Modulation** chapter for more information on USB and LSB modulation and the relationship between modulating frequency and transmitted signal frequency.)

When using AFSK with older transceivers, it is wise to choose a high tone pair so that harmonic by-products fall outside the passband of the transmitter. Because of this, a popular tone pair is 2125 Hz/2295 Hz. Most transceivers will pass both tones and also have good suppression of the harmonics of the two tones. Not all transceivers that have an FSK input are FSK transmitters. Some transceivers will take the FSK keying input and modulate an internal AFSK generator, which is then used to modulate an SSB transmitter. In this case, the transmitter is really operating as an F2B emitter. This mode of operation is often called “keyed AFSK.”

## “SPOTTING” AN RTTY SIGNAL

By convention, RTTY signals are identified by the frequency of the mark carrier on the RF spectrum. “Spotting” the suppressed carrier frequency dial of an SSB receiver is useless for someone else unless they also know whether the spotter is using upper or lower sideband and what tone pair the spotter’s demodulator is using. The mark and space carriers are the only two constants, so the amateur RTTY standard is to spot the frequency of the mark carrier.

## DIDDLE CHARACTERS

In between the stop bit of a preceding character and the start bit of the next character, the RTTY signal stays at the mark frequency. When the RTTY decoder is in this “rest” state, a mark-to-space transition tells a decoder that the start of a new character has arrived. Noise that causes a start bit to be misidentified can cause the RTTY decoder to fall out of sync. After losing sync, the decoder will use subsequent data bits to help it identify the location of the next potential start bit.

Since all mark-to-space transitions are potential locations of the leading edge of a start bit, this can cause multiple characters to be incorrectly decoded until proper synchronization is again achieved. This “character slippage” can be minimized somewhat by not allowing the RTTY signal to rest for longer

than its stop bit duration. An idle or *diddle character* (so called because of the sound of the demodulated audio from an idle RTTY signal sending the idle characters) is inserted immediately after a stop bit when the operator is not actively typing. The idle character is a non-printing character from the Baudot set and most often the LTRS character is used. Baudot encodes a LTRS as five bits of all ones making it particularly useful when the decoder is recovering from a misidentified start bit.

An RTTY diddle is also useful when there is selective fading. Good RTTY demodulators counter selective fading by measuring the amplitudes of the mark and space signals and automatically adjusting the decoding threshold when making the decision of whether a mark or a space is being received. If a station does not transmit diddles and has been idle for a period of time, the receiver will have no idea if selective fading has affected the space frequency. By transmitting a diddle, the RTTY demodulator is ensured of a measurement of the strength of the space carrier during each character period.

### UNSHIFT-ON-SPACE (USOS)

Since the Baudot code aliases characters (for example, Q is encoded to the same 5-bit code as 1) using the LTRS and FIGS Baudot shift to steer the decoder, decoding could turn into gibberish if the Baudot shift characters are altered by noise. For this reason, many amateurs use a protocol called *unshift-on-space* (USOS). Under this protocol, both the sender and the receiver agree that the Baudot character set is always shifted to the LTRS state after a space character is received. In a stream of text that includes space characters, this provides additional, implicit, Baudot shifts.

Not everyone uses USOS. When used with messages that have mostly numbers and spaces, the use of USOS causes extra FIGS characters to be sent. A decoder that complies with USOS will not properly decode an RTTY stream that does not have USOS set. Likewise, a decoder that has USOS turned off will not properly decode an RTTY stream that has USOS turned on.

### OTHER FSK SHIFTS AND RTTY BAUD RATE

The most commonly used FSK shift in amateur RTTY is 170 Hz. However, on rare occasions stations can be found using 425 and 850 Hz shifts. The wider FSK shifts are especially useful in the presence of selective fading since they provide better frequency diversity than 170 Hz.

Because HF packet radio uses 200 Hz shifts, some TNCs use 200 Hz as the FSK shift for RTTY. Although they are mostly compatible with the 170 Hz shift protocol, under poor signal to noise ratio conditions these demodulators will produce more er-

ror hits than a demodulator that is designed for 170 Hz shift. Likewise, a signal that is transmitted using 170 Hz shift will not be optimally copied by a demodulator that is designed for a 200 Hz shift.

To conserve spectrum space, amateurs have experimented with narrower FSK shifts, down to 22.5 Hz. At 22.5 Hz, optimal demodulators are designed as *minimal shift keyed* (MSK) instead of frequency shift keyed (FSK) demodulators.

### SOME PRACTICAL CHARACTERISTICS

When the demodulator is properly implemented, RTTY can be very resilient against certain HF fading conditions, namely when selective fading causes only one of the two FSK carriers to fade while the other carrier remains strong. However, RTTY is still susceptible to “flat fading” (where the mark and space channels both fade at the same instant). There is neither an error correction scheme nor an interleaver (a method of rearranging — interleaving — the distribution of bits to make errors easier to correct) that can make an RTTY decoder print through a flat and deep fade. The lack of a data interleaver, however, also makes RTTY a very interactive mode. There is practically no latency when compared to a mode such as MFSK16, where the interleaver causes a latency of over 120 bit durations before incoming data can even be decoded. This makes RTTY attractive to operating styles that have short exchanges with rapid turnarounds, such as in contests.

Although RTTY is not as “sensitive” as PSK31 (when there is no multipath, PSK31 has a lower error rate than RTTY when the same amount of power is used) it is not affected by phase distortion that can render even a strong PSK31 signal from being copied. When HF propagation conditions deteriorate, RTTY can often function as long as sufficient power is used. Tuning is also moderately uncritical with RTTY. When the signal-to-noise ratio is good, RTTY tuning can be off by 50 Hz and still print well.

### 15.2.2 PSK31 and Variants

PSK31 is a family of modes that uses differentially encoded varicode (see the next section), envelope-shaped phase shift keying. BPSK31, or binary PSK31, operates at 31.25 bit/s (one bit every 32 ms). QPSK31, or quadrature PSK31, operates at 31.25 baud. Each symbol consists of four possible quadrature phase change (or *dibits*) at the signaling rate of one dibit every 32 ms. QPSK31 sends a phase change symbol of 0°, 90°, 180° or 270° every 32 ms.

Characters that are typed from the keyboard are first encoded into variable-length varicode binary digits. With BPSK31, the

varicode bits directly modulate the PSK31 modulator, causing a 180° phase change if the varicode bit is a 0 and keeping a constant phase if the varicode bit is a 1. With QPSK31, the varicode bits first pass through two convolution encoders to create a sequence of bit pairs (dibits). Each dibit is then used to shift the QPSK31 modulator into one of four different phase changes.

PSK63 is a double-clock-rate version of a PSK31 signal, operating at the rate of one symbol every 16 ms (62.5 symbols per second). PSK125 is a PSK31 signal clocked at four times the rate, with one symbol every 8 ms (125 symbols per second). Although PSK63 and PSK125 are both in use, including the binary and quadrature forms, the most popular PSK31 variant remains BPSK31.

Most implementations of PSK31 first generate an audio PSK31 signal. The audio signal is then used to modulate an SSB transmitter. Since BPSK31 is based upon phase reversals, it can be used with either upper sideband (USB) or lower sideband (LSB) systems. With QPSK31 however, the 90° and 270° phase shifts have to be swapped when using LSB transmitters or receivers.

### PSK31 VARICODE

Characters that are sent in PSK31 are encoded as varicode, a variable length prefix code as varicode. As described earlier, characters that occur more frequently in English text, such as spaces and the lower-case e, are encoded into a fewer number of bits than characters that are less frequent in English, such as the character q and the upper case E.

PSK31 varicode characters always end with two bits of zeros. A space character is sent as a one followed by the two zeros (100); a lower case e is sent as two ones, again terminated by the two bits of zero (1100). None of the varicode code words contain two consecutive zero bits. Because of this, the PSK31 decoder can uniquely identify the boundary between characters. A special “character” in PSK31 is the idle code, which consists of nothing but the two prefix bits. A long pause at the keyboard is encoded into a string of even numbers of zeros. The start of a new character is signaled by the first non-zero bit received after at least two consecutive zeros.

### CONVOLUTION CODE

As described earlier, QPSK31 encodes the varicode stream with two convolution encoders to form the dibits that are used to modulate the QPSK31 generator. Both convolution encoders are fourth-order polynomials, shown in **Figure 15.2**.

The varicode data is first inverted before the bits are given to the convolution encoders. The first polynomial generates the most significant bit and the second polynomial generates the least significant bit of the dibit. Since we are

$$G_1(x) = x^4 + x^3 + 1$$

$$G_0(x) = x^4 + x^2 + x^1 + 1$$

HBK0429

Figure 15.2 — QPSK31 convolution encoders.

working with binary numbers, the GF(2) sums shown in the above figure are exclusive-OR functions and the delay elements  $x_1, x_2, x_3$  and  $x_4$  are stages of binary shift registers. As each inverted varicode bit is available, it is clocked into the shift register and the two bits of the dibit are computed from the shift register taps.

## MODULATION

PSK31 uses both differential phase shift modulation and envelope modulation to maintain its narrow-band characteristics. The most common way to generate an envelope-shaped PSK31 signal is to start with baseband in-phase (I) and quadrature (Q) signals. Both I and Q signals settle at either a value of +1 or a value of -1. When no phase transition is needed between symbols, the I and Q signals remain constant (at their original +1 or -1 values). See the **Modulation** chapter for information on creating I and Q signals.

To encode a 180° transition between symbols, both I and Q signals are slewed with a cosinusoidal envelope. If the in-phase signal had a value of +1 during the previous symbol, it is slewed to -1 cosinusoidally. If the in-phase signal had a value of -1 in the previous symbols, it is slewed cosinusoidally to +1. The quadrature signal behaves in a likewise manner. To encode a 90° phase shift in QPSK31, only the in-phase signal is slewed between the two symbols, the quadrature signal remains constant between the two symbols. To encode a 270° phase shift in QPSK31, only the quadrature signal is slewed between the two symbols; the in-phase signal remains constant between the two symbols.

The envelope of the real signal remains constant if there is no phase change. When the signal makes a 180° phase transition, the amplitude of a PSK31 signal will drop to zero in between the two symbols. The actual phase reversal occurs when the signal amplitude is zero, when there is no signal energy. During the 90° and 270° phase shifts between

symbols of QPSK31, the amplitude of the signal does not reach zero. It dips to only half the peak power in between the two symbols.

To provide a changing envelope when the operator is idle at the keyboard, a zero in the varicode (remember that an idle varicode consists of two 0 bits) is encoded as a 180° phase change between two BPSK31 symbols. A 1 in the varicode is encoded as no phase change from one BPSK31 symbol to the next symbol. This changing envelope allows the receiver to extract bit timing information even when the sender is idle. Bit clock recovery is implemented by using a comb filter on the envelope of the PSK31 signal.

The convolution code that is used by QPSK31 converts a constant idle stream of zeros into a stream of repeated 10 dibits. To produce the same constant phase change during idle periods as BPSK31, the QPSK31 10 dibit is chosen to represent the 180° phase shift modulating term. **Table 15.4** shows the QPSK31 modulation.

To produce bit clocks during idle, combined with the particular convolution code that was chosen for QPSK31, results in a slightly sub-optimal (non-Gray code) encoding of the four dibits. At the end of a transmission, PSK31 stops all modulation for a short period and transmits a short unmodulated carrier. The intended function is as a squelch mechanism.

## DEMODULATION AND DECODING

Many techniques are available to decode differential PSK, where a reference phase is not present. Okunev has a good presentation of the methods (reference: Yuri Okunev, *Phase and Phase-difference Modulation in Digital Communications* (1997, Artech House), ISBN 0-89006-937-9).

As mentioned earlier, there is sufficient amplitude information to extract the bit clock from a PSK31 signal. The output of a differential-phase demodulator is an estimate of the phase angle difference between the centers

Table 15.4  
QPSK31 Modulation

Dibit	Phase Change
00	0°
01	90°
10	180°
11	270°

of one symbol and the previous one. With BPSK31, the output can be compared to a threshold to determine if a phase reversal or a non-reversal is more likely. The decoder then looks for two phase reversals in a row, followed by a non-reversal, to determine the beginning of a new character. The bits are gathered until two phase reversals are again seen and the accumulated bits are decoded into one of the characters in the varicode table.

QPSK31 decoding is more involved. As in the BPSK31 case, the phase difference demodulator estimates the phase change from one bit to another. However, one cannot simply invert the convolution function to derive the data dibits. Various techniques exist to decode the measured phase angles into dibits. The *Viterbi algorithm* is a relatively simple algorithm for the convolution polynomials used in QPSK31. The estimated phase angles can first be fixed to one of the four quadrature angles before the angles are submitted to the Viterbi algorithm. This is called a hard-decision *Viterbi decoder*.

A soft-decision Viterbi decoder (that is not that much more complex to construct) usually gives better results. The soft-decision decoder uses arbitrary phase angles and some measure of how “far” an angle is away from one of the four quadrature angles. Error correction occurs within the trellis that implements the Viterbi algorithm. References to convolution code, trellis and the Viterbi algorithm can be found at [en.wikipedia.org/wiki/Convolutional\\_code](http://en.wikipedia.org/wiki/Convolutional_code).

## 15.2.3 MFSK16

MFSK16 uses M-ary FSK modulation with 16 “tones” (also known as 16-FSK modulation), where only a single tone is present at any instant. MFSK16 has a crest factor of 1, with no wave shaping performed on the data bits. The tone centers of MFSK16 are separated by 15.625 Hz. Data switches at a rate of 15.625 baud (one symbol change every 64 ms).

Characters are first encoded into the MFSK16 varicode, creating a constant bit stream whose rate is one bit every 32 ms. This results in a similar, although not identical, character rate as PSK31. The difference is due to the different varicode tables that are used by the two modes.

This bit stream is clocked into a pair of 6th-order convolution encoders. The result

is a pair of bits (dibit) for each varicode bit, at a rate of one dibit every 32 ms. Consecutive pairs of dibits are next combined into sets of four bits (*quadbit* or *nibble*). Each nibble, at the rate of one per 64 ms, is then passed through an interleaver. The interleaver produces one nibble for each nibble that is sent to it. Each nibble from the interleaver is then Gray-coded and the resultant 4-bit Gray code is the ordered index of each 16 tones that are separated by 15.625 Hz. The result is a 16-FSK signal with a rate of one symbol per 64 ms. Since the symbol time is the reciprocal of the tone separation, a 16-point fast Fourier transform (FFT) can be conveniently used as an MFSK16 modulator.

### MFSK16 VARICODE

Although the varicode table that is used by MFSK16 (see the downloadable supplemental content) is not the same as the one used by PSK31, they share similar characteristics. Please refer to the PSK31 section of this chapter for a more detailed description of varicode. Unlike PSK31 varicode, MSK16 varicode

encodings can contain two or more consecutive zero bits, as long as the consecutive zeros are at the tail of a code word. Character boundaries are determined when two or more consecutive zeros are followed by a one.

### CONVOLUTION CODE

As described earlier, MFSK16 encodes the varicode stream with two convolution encoders to form the dibits that are passed on to the interleaver. Both convolution encoders are sixth order polynomial, shown in Figure 15.3.

The first polynomial generates the most significant bit and the second polynomial generates the least significant bit of the dibit. Since we are working with binary numbers, the GF(2) sums shown in the above figure are exclusive OR functions and the delay elements x1, x2, x3, x4, x5 and x6 are stages of binary shift registers. As each varicode bit is available, it is clocked into the shift register and the two bits of the dibit are computed from the shift register taps.

### INTERLEAVER

HF fading channels tend to generate “burst” errors that are clumped together. An interleaver is used to permute the errors temporally so that they appear as uncorrelated errors to the convolution decoder. MFSK16 uses 10 concatenated stages of an IZ8BLY Diagonal Interleaver. More information on the interleaver can be found at [www.qsl.net/z11bpu/MFSK/Interleaver.htm](http://www.qsl.net/z11bpu/MFSK/Interleaver.htm). Figure 15.4 illustrates how a single IZ8BLY interleaver spreads a sequence of bits.

The bits enter the IZ8BLY interleaver in the order 0, 1, 2, 3, 4,... and are passed to the output in the order 0, 5, 10, 15, 8, 13, ... (shown in the diagonal boxes). In MFSK16, the output of one interleaver is sent to the input of a second interleaver, for a total of 10 such stages. Each stage spreads the bits out over a longer time frame.

Figure 15.5 — Bit spreading through interpolation.

This concatenated 10-stage interpolator is equivalent to a single interpolator that is 123 bits long. **Figure 15.5** shows the structure of the single interpolator and demonstrates how four consecutive input bits are spread evenly over 123 time periods.

An error burst can be seen to be spread over a duration of almost two seconds. This gives MFSK16 the capability to correct errors over deep and long fades. While it is good for correcting errors, the delay through the long interleaver also causes a long decoding latency.

## GRAY CODE

The Gray code creates a condition where tones that are next to one another are also different by a smaller *Hamming* distance. This optimizes the error correction process at the receiver. References to Gray code and Hamming distance can be found at [en.wikipedia.org/wiki/Gray\\_code](http://en.wikipedia.org/wiki/Gray_code) and [en.wikipedia.org/wiki/Hamming\\_distance](http://en.wikipedia.org/wiki/Hamming_distance).

## DEMODULATION AND DECODING

A 16-point FFT can be used to implement a set of matched filters for demodulating an MFSK16 signal once the input waveform is properly time aligned so that each transform is performed on an integral symbol and the signal is tuned so that the MFSK16 tones are perfectly centered in the FFT bins. A reference to a matched filter can be found at [en.wikipedia.org/wiki/Matched\\_filter](http://en.wikipedia.org/wiki/Matched_filter).

The 16 output bins from an FFT demodulator can first be converted to the “best” 4-bit index of an FFT frequency bin, or they can be converted to a vector of four numerical values representing four “soft” bits. The four bits are then passed through an MFSK16 de-interleaver. In the case of “soft decoding,” the de-interleaver would contain numerical values rather than a 0 or 1 bit.

The output of the de-interleaver is passed into a convolution decoder. The Gray code makes sure that adjacent FFT bins also have the lowest Hamming distance; i.e., the most likely error is also associated with the closest FFT bin. The hard or the soft Viterbi Algorithm can be used to decode and correct errors.

## 15.2.4 DominoEX

DominoEX is a digital mode with MFSK (multi-frequency shift keying) designed for simplex chats on HF by Murray Greenman, ZL1BPU. It was designed to be easier to use and tune than other similar modes, offer low latency for contesting or other quick exchange situations, offer reliable copy down into the noise floor, and work well as an NVIS (near-vertical incidence skywave, see the **Propagation of Radio Signals** chapter) mode for emergency communications.

Generally MFSK requires a high degree of tuning accuracy and frequency stability and can be susceptible to multipath distortion. DominoEX specifically addresses these issues. To avoid tuning issues, IFK (*incremental frequency keying*) is used. With IFK, the data is represented not by the frequency of each tone, but by the frequency difference between one tone and the next. It also uses off-set incremental keying to reduce inter-symbol interference caused by multipath reception. These techniques provide a tuning tolerance of 200 Hz and a drift of 200 Hz/minute. DominoEX also features an optional FEC mode that increases latency but provides communications over even more difficult channels. More information can be found online at [www.qsl.net/zl1bpu/MFSK/DEX.htm](http://www.qsl.net/zl1bpu/MFSK/DEX.htm).

DominoEX uses M-ary FSK modulation with 18 tones in which only a single tone is present at any instant. Information is sent as a sequence of separate 4-bit (“nibble”) symbols. The value of each nibble is represented during transmission as the position of the single tone.

The position of the tone is computed as the difference of the current nibble value from the nibble value of the previously transmitted symbol. In addition, a constant offset of 2 is applied to this difference. Because there are 18 tones, any possible 4-bit value between 0 and 15 can be represented, including the offset of 2.

The additional offset of 2 tone positions ensures that a transmitted tone is separated from the previously transmitted tone by at least two tone positions. It is thus impossible for two sequential symbols to result in the same tone being transmitted for two sequential tone periods. This means sequential tones will always be different by at least two positions, an important consideration in maintaining sync.

This minimum separation of successive tones of incremental frequency keying (IFK) in DominoEX reduces the inter-symbol distortion that results from a pulse being temporally smeared when passing through an HF channel. The double-tone spacing of DominoEX modes (see **Table 15.5**) further reduces inter-symbol distortion caused by frequency smearing.

Incremental frequency keying allows the DominoEX nibbles to immediately decode without having to wait for the absolute tone

to be identified. With MFSK16, a tone cannot be uniquely identified until the lowest and highest of the 16 tones have passed through the receiver. This contributes to the decoding latency of MFSK15. There is no such latency with IFK.

Since IFK depends upon frequency differences and not absolute tone frequencies, DominoEX tolerates tuning errors and drifting signals without requiring any additional automatic frequency tracking algorithms.

Like MFSK16, the DominoEX signal is not wave-shaped and has constant output power. The baud rates for DominoEX are shown in **Table 15.5**. The tone spacings for DominoEX 11, DominoEX 16 and DominoEX 16 have the same values as their baud rates. The tone spacings for DominoEX 8, DominoEX 5 and DominoEX 4 are twice the value of their baud rates.

Unlike PSK31 and MFSK16, characters in DominoEX are encoded into varicode nibbles instead of encoding into varicode bits. The DominoEX varicode table can be found with the downloadable supplemental content.

## BEACON MESSAGE

Instead of transmitting an idle varicode symbol when there is no keyboard activity, DominoEX transmits a “beacon” message from an alternate set of varicode (SECVAR columns in the DominoEX varicode table). This user-supplied repeating beacon message is displayed at the receiving station when the sending station is not actively sending the primary message. On average, the character rate of the beacon channel is about half of the character rate of the primary channel.

## FORWARD ERROR CORRECTION (FEC)

When FEC is turned off, DominoEX has very low decoding latency, providing an interactive quality that approaches RTTY and PSK31. The first character is decoded virtually instantly by the receiver after it is transmitted. Because of that, FEC is not usually used even though it is available in most software that implements DominoEX.

DominoEX FEC is similar to the FEC that is used in MFSK15. When FEC is on, each 4-bit IFK symbol that is decoded by the receiver is split into two di-bits. The dibits enter

**Table 15.5**  
**Comparison of DominoEX Modes**

Mode	Baud/ (sec)	BW (Hz)	Tones	Speed (WPM)	FEC (WPM)	Tone Spacing
DominoEX 4	3.90625	173	18	~25	~12	Baud rate ×2
DominoEX 5	5.3833	244	18	~31	~16	Baud rate ×2
DominoEX 8	7.8125	346	18	~50	~25	Baud rate ×2
DominoEX 11	10.766	262	18	~70	~35	Baud rate ×1
DominoEX 16	15.625	355	18	~100	~50	Baud rate ×1
DominoEX 22	21.533	524	18	~140	~70	Baud rate ×1

an identical convolution coder to that used by MFSK15. However, instead of a 10-stage IZ8BLY interleaver (see Figure 15.4), only 4 cascaded stages of the basic 4-bit interleaver are present in DominoEX. In the presence of long duration fading, the performance of the shortened interleaver is moderately poor when used with DominoEX 16 and DominoEX 22. However, the interleaver is quite efficient in countering fading when FEC is used with DominoEX 4, DominoEX 5 and DominoEX 8, with their longer symbol periods.

Since DominoEX works in dibit units rather than nibble units when FEC is turned on, it also switches to using the same binary varicode used by MFSK16 instead of using the nibble-based varicode. DominoEX does not implement Gray code as is used by MFSK16 FEC.

Even without FEC, DominoEX works well under many HF propagation conditions, including the ITU NVIS ("Mid-latitude Disturbed") propagation profile. However, there are conditions where DominoEX is not usable unless FEC is switched on, specifically the CCIR Flutter and ITU High Latitude Moderate Conditions profiles. DominoEX modes, especially those with tone spacings that are twice the baud rate, are very robust even under these extreme conditions once FEC is switched on.

DominoEX performance charts (character error rates versus signal-to-noise ratios) are included as the HTML document "DominoEX Performance" with the downloadable supplemental content and online at [www.w7ay.net/site/Technical/DominoEX/Measurements/](http://www.w7ay.net/site/Technical/DominoEX/Measurements/).

## CHIP64/128

Chip64 and Chip128 modes were released in 2004 by Antonino Porcino, IZ8BLY. The modes were tested on the air by IZ8BLY, Murray Greenman, ZL1BPU, (who also contributed in the design of the system), Chris Gerber, HB9BDM, and Manfred Salzwedel, OH/DK4ZC. According to IZ8BLY, "The design of this new digital mode served to introduce the spread spectrum technology among radio amateurs by providing a communication tool to experiment with. Its purpose was to prove that it's possible to take advantage of the spread spectrum techniques even on the HF channels, making the communication possible under conditions where traditional narrowband modes fail.

"Among the different possible implementations of spread spectrum, Chip64 uses the so-called Direct Sequence Spread Spectrum (DSSS). In a DSSS transmission, the low speed signal containing the data bits to be transmitted is mixed (multiplied) with a greatly higher speed signal called code. The result of this mixing operation, called *spreading*, is a high-speed bit stream which is then transmitted as a normal DBPSK. Indeed, a

DSSS signal looks like nothing else than wideband BPSK.

"The system proved to be efficient and we found it comparable to the other modern digital modes. Being totally different in its architecture, it shows better performance during certain circumstances, while in others it shows no actual gain. In particular, it performs better under multipath where normal BPSK can't track arriving symbols, but in quiet environments it doesn't show any improvement over plain BPSK. This is expected because of the losses that occur due to the imperfect autocorrelation of the codes."

Chip64 has a total data rate of 37.5 bit/s and the more robust Chip128 is 21.09 bit/s. Both use the same varicode used by MFSK15. The software can be downloaded from [antoninoporcino.xoom.it/Chip64/index.htm](http://antoninoporcino.xoom.it/Chip64/index.htm) and more information is available at [www.arrl.org/technical-characteristics](http://www.arrl.org/technical-characteristics). Spread spectrum is discussed in the **Modulation** chapter, as well.

## 15.2.5 THROB

Throb is an experimental mode written by Lionel Sear, G3PPT, and gets the name from the "throbbing" sound it makes on the air. It uses either single tones or pairs from a possible nine tones spaced 8 or 16 Hz apart, resulting in a bandwidth of 72 or 144 Hz, respectively. It has three transmission speeds — 1, 2 and 4 throbs/s — resulting in data rates of 10, 20 and 40 WPM, respectively. The 1 and 2 throb/s speeds use a tone spacing of 8 Hz for a 72 Hz bandwidth and the 4-throb/s speed uses a spacing of 16 Hz for a 144 Hz bandwidth. It is implemented as a stand-alone application or included in a multimode package such as *MixW* ([www.mixw.net](http://www.mixw.net)).

## 15.2.6 MT63

MT63 is a mode developed by Pawel Jalocho, SP9VRC. MT63 is very complex with wide bandwidth, low speed and very high noise immunity. By using 64 different modulated tones, MT63 includes a large amount of extra data in the transmission of each character, so that the receiving equipment can work out, with no ambiguity, which character was sent, even if 25% of the character is obliterated. MT63 also features a secondary channel that operates simultaneously with the main channel that can be used for an ID or beacon.

MT63 likely has the most extensive error correction and can be quite processor intensive. It uses a Walsh function that spreads the data bits of each 7-bit ASCII character across all 64 of the tones of the signal spectrum and simultaneously repeats the information over a period of 64 symbols within any one tone. This coding takes several seconds. The combination of time domain (temporal) and frequency domain (spectral) interleaving re-

sults in superb impulse noise rejection. At the same time, in the frequency domain, significant portions of the signal can be masked by unwanted noise or other transmissions without any noticeable effect on successful reception.

On each of the 64 tones, the transmission data rate is fairly slow, which suits the nature of ionospheric disturbances. Despite the low data rate, good text speed is maintained because the text is sent on many tones at once. The system runs at several different speeds, which can be chosen to suit conditions but 100 WPM is typical of the MT63-1K mode. Although the 1 kHz bandwidth mode is typical, MT63 can also run at 500 Hz and 2 kHz bandwidth where the tone spacing and baud rate are halved or doubled and the throughput is halved or doubled, respectively.

Tuning of MT63 modes is not critical. This is because the mode can use FEC techniques to examine different combinations of the 64 tones that calculate the correct location within the spectrum. As an example, MT63-1K will still work if the decoder is off-frequency by as much as 100 Hz. MT63-2K requires even less precision and can tolerate an error of 250 Hz.

The incredible noise immunity comes at a price beyond the large bandwidth required. There is a large latency caused by the error correction and interleaving process. Quick-turnaround QSOs are not possible because there is a several second delay between typing the last character and it being transmitted.

Without confirming each transmission with some type of ARQ mode, there is no more robust digital mode than MT63. The mode was evaluated and recommended for Navy MARS message handling. The evaluation is published on the Navy MARS website ([www.navymars.org](http://www.navymars.org)), along with other information on this mode.

## 15.2.7 Olivia

Olivia is an MFSK-based protocol designed to work in difficult (low signal-to-noise ratio plus multipath propagation) conditions on the HF bands. The signal can still be copied accurately at 10 dB below the noise floor. Olivia was developed in 2003 by Pawel Jalocho, SP9VRC, and performs well for digital data transfer with white noise, fading and multipath, polar path flutter and auroral conditions.

Olivia transmits a stream of 7-bit ASCII characters. The characters are sent in blocks of five with each block requiring two seconds to transmit. This results in an effective data rate of 2.5 characters/second or 150 characters/minute. A transmission bandwidth of 1000 Hz and the baud rate of 31.25 MFSK tones/second, also known as *Olivia 1000/32*, is the most common. To adapt to different propagation conditions, the number of tones

and the bandwidth can be changed and the time and frequency parameters are proportionally scaled. The number of tones can be 2, 4, 8, 16, 32, 64, 128 or 256 and the bandwidth can be 125, 250, 500, 1000 or 2000 Hz.

The Olivia is constructed of two layers: the lower, modulation and FEC code layer is a classical MFSK while the higher layer is an FEC code based on Walsh functions. More detail on Walsh functions is available online at [en.wikipedia.org/wiki/Walsh\\_function](http://en.wikipedia.org/wiki/Walsh_function).

Assuming Olivia 1000/32 is being used,

## 15.3 Fuzzy Modes

There is a group of modes referred to as “fuzzy modes” because although they are machine generated and decoded, they are designed to be human-read. These include facsimile (fax), slow-scan TV (SSTV) and Hellschreiber.

### 15.3.1 Facsimile (fax)

Facsimile was developed as a mechanically transmitted technology where the source material was placed on a spinning drum and scanned line by line into an electrical signal which would be transmitted by wire or over the air. It is important that the receiving station have their drum spinning at the correct speed in order to correctly recreate the image. A value known as the *index of cooperation* (IOC) must also be known to decode a transmission. IOC governs the image resolution and is the product of the total line length and the number of lines per unit length divided by  $\pi$ . Most fax transmissions are sent with LPM (RPM) at 120 and an IOC of 576.

Facsimile is generally transmitted in single sideband with a tone of 1500 Hz representing black and 2300 Hz representing white. The *automatic picture transmission* (APT) format is used by most terrestrial weather facsimile stations and geostationary weather satellites. It features a start tone that triggers

in the first layer the orthogonal functions are cosine functions, with 32 different tones. Since only one of those 32 tones is being sent at a time, the demodulator measures the amplitudes of all the 32 possible tones and identifies the tone with the highest amplitude. In the second layer every ASCII character is encoded as one of 64 possible Walsh functions. The receiver again measures the amplitudes for all 64 vectors and selects the greatest as the true value.

the receiving system, originally used to allow the receiving drum to come up to speed. It also includes a phasing signal with a periodic pulse that synchronizes the receiver so the image appears centered on the page. A stop tone, optionally followed by black, indicates the end of the transmission. The APT format is shown in **Table 15.6**.

Stations with Russian equipment sometimes use RPM 60 or 90 and sometimes an IOC of 288. Photofax transmissions such as those from North Korea use RPM 60 and an IOC 352 with gray tones, and satellite rebroadcast use also RPM 120 IOC 576, with gray tones (4 or more bit depth). For software decoding of weather fax images it is best to decode with Black and White (2-bit depth).

### 15.3.2 Slow-Scan TV (SSTV)

Slow-Scan TV or SSTV is similar to facsimile where a single image is converted to individual scanned lines and those lines sent as variable tones between 1500 and 2300 Hz. Modern systems use computer software and a sound card to generate and receive the required tones. (Some SSTV communication uses purely digital protocols, in which the picture content is sent as digital data and not directly represented in the modulation scheme.)

To avoid simple transmitted patterns (like a constant tone) and to minimize the chance for a false lock at the synchronizer, the characters encoded into the Walsh function pass through a scrambler and interleaver. The receiver synchronizes automatically by searching through time and frequency offsets for a matching pattern.

More information can be found online at [n1su.com/olivia](http://n1su.com/olivia) and Olivia is supported in a number of digital multimode packages such as *MixW*, *MultiPSK* and *Ham Radio Deluxe*.

There are a number of different SSTV “modes” that define image resolution and color scheme. A color image takes about 2 minutes to transmit, depending on mode. Some black and white modes can transmit an image in under 10 seconds. More information about SSTV may be found in the **Image Communications** chapter with the downloadable supplemental content.

### 15.3.3 Hellschreiber, Feld-Hell or Hell

Hellschreiber is a facsimile-based mode developed by Rudolph Hell in the 1920s. The name is German and means “bright writer” or “light writer” and is a pun on the inventor’s name. In Hellschreiber, text is transmitted by dividing each column into seven pixels and transmitting them sequentially starting at the lowest pixel. Black pixels are transmitted as a signal and white as silence at 122.5 bit/s (about a 35 WPM text rate). Originally the text was printed on continuous rolls of paper so the message could be any length.

Even though each pixel is only transmitted once, they are printed twice, one below the other. This compensates for slight timing errors in the equipment that causes the text to slant. If properly in sync, the text will appear as two identical rows, one below the other or a line of text in the middle with chopped lines top and bottom. Regardless of the slant, it is always possible to read one copy of the text. Since the text is read visually, it can be sent in nearly any language and tends to look like an old dot matrix printer. More information can be found online at [www.qsl.net/z11bpu/HELL/Feld.htm](http://www.qsl.net/z11bpu/HELL/Feld.htm) and Randy, K7AGE, has a great introduction to Hellschreiber available on YouTube at [www.youtube.com/watch?v=yR-EmyEBVqA](http://www.youtube.com/watch?v=yR-EmyEBVqA).

**Table 15.6**  
**Facsimile Automatic Picture Format**

Signal	Duration	IOC576	IOC288	Remarks
Start Tone	5 s	300 Hz	675 Hz	200Hz for color fax modes
Phasing Signal	30 s			White line interrupted by black pulse
Image	Variable	1200 lines	600 lines	At 120 LPM
Stop Tone	5 s	450 Hz	450 Hz	
Black	10 s			

# 15.4 Structured Digital Modes

This group of digital modes has more structured data. This provides more robust data connections and better weak signal performance or more sophisticated data. Each of these modes bundles data into packets or blocks that can be transmitted and error checked at the receive end.

## 15.4.1 WSJT-X Modes

All modes described in Sections 15.4.1 through 15.4.4 are available in a multi-author, open-source software package called *WSJT-X*. Some are also available in other programs derived from *WSJT-X*. These modes are designed around structured messages that optimize the exchange of minimal contact information including call signs, signal reports, Maidenhead grid locators, and acknowledgments, even at very low signal-to-noise ratios. These modes were pioneered by Joe Taylor, K1JT, starting in 2001 when home computers were first widely equipped with sound cards and fast enough to do significant signal processing. The first modes were optimized for use over especially difficult paths such as meteor scatter and Earth-Moon-Earth (EME, or “moonbounce”) on VHF and higher bands. More recently, several of the modes have become very popular for HF DXing, as well.

The *WSJT-X* structured modes divide naturally into two groups, *slow* and *fast*. Slow modes send each message frame once per transmission interval, while fast modes send the message frame repeatedly, as many times as will fit into the transmission interval. The modes intended for making two-way QSOs use message formats based on compressed,

fixed-length packets of 72 or 77 information bits. The mode called WSPR allows individual stations to transmit a call sign, location and power level using 50-bit packets. As outlined in this chapter’s section “Error Detection and Correction,” a number of additional bits are added to the message frames to effect error detection and correction. Details of the mathematical encoding schemes and modulation types differ from mode to mode. In all cases the forward error correction (FEC) algorithm is strong enough that false decodes are very rare: a receiving operator nearly always sees exactly the message that was transmitted, or nothing at all. All of the modes implemented in *WSJT-X* use constant-envelope waveforms, making it possible to amplify a single signal with efficient nonlinear amplifiers without generating intermodulation products. Transmissions have a fixed duration, for example one minute or 15 seconds, and their start times are synchronized with Coordinated Universal Time (UTC) as maintained by the computer’s operating system.

## 15.4.2 Message Compression

The information packets normally consist of two 28-bit call signs and a 15-bit field for a grid locator, signal report, acknowledgment, or “73”. Additional bits can flag message formats containing arbitrary text (up to 13 characters), nonstandard call signs, contest exchanges, or the like. The basic aim is to compress the most common message formats used for minimal contacts into fixed-length packets.

A standard amateur call sign consists of a

one- or two-character prefix, at least one of which must be a letter, followed by a decimal digit and a suffix of one to three letters. Within these rules, the number of possible call signs is equal to  $37 \times 36 \times 10 \times 27 \times 27 \times 27$ , or somewhat over 262 million. (The numbers 27 and 37 arise because in the first and last three positions a character may be absent, or a letter, or perhaps a digit.) Since  $2^{28}$  is more than 268 million, 28 bits are enough to encode any standard call sign uniquely. Similarly, the number of 4-digit Maidenhead grid locators on Earth is  $180 \times 180 = 32,400$ , which is less than  $2^{15} = 32,768$ ; thus, a grid locator requires 15 bits. Some otherwise unused values in the 28-bit fields are used for special message components such as CQ, DE, and QRZ, and some values of the 15-bit field not needed for grid locators are used for signal reports, acknowledgments, and the like. Structured messages using these 28-bit and 15-bit fields underlie the efficient, reliable exchange of basic and essential information for minimal station-to-station contacts.

## 15.4.3 Slow Modes

The slow modes in *WSJT-X* are called FT4, FT8, JT4, JT9, JT65, QRA64, and WSPR. Each mode uses continuous-phase frequency-shift keying (FSK), with waveforms normally generated at audio frequency and transmitted as upper sideband by a standard SSB transceiver. Numbers in the mode names indicate the number of distinct tone frequencies used. JT4, JT65, and QRA64 were originally designed for EME on VHF and higher UHF bands; JT9 was intended

**Table 15.7**  
**Parameters of Structured Modes**

### A — Structured Slow Modes

Mode	FEC Type	(n, k)	Q	Modulation Type	Keying Rate	Bandwidth (Hz)	Sync Energy	Transmit Duration (s)	S/N Threshold (dB)
FT4	LDPC	(174,91)	4	4-GFSK	20.833	83.3	0.16	5.04	-17.5
FT8	LDPC	(174,91)	8	8-GFSK	6.25	50.0	0.27	12.6	-20.8
JT4	Convolutional	(206,72)	2	4-FSK	4.375	17.5	0.50	47.1	-23
JT9	Convolutional	(206,72)	8	9-FSK	1.736	15.6	0.19	49.0	-27
JT65	Reed-Solomon	(63,12)	64	65-FSK	2.692	177.6	0.50	46.8	-25
QRA64	Q-ary Repeat Accumulate	(63,12)	64	64-FSK	1.736	111.1	0.25	48.4	-26
WSPR	Convolutional	(162,50)	2	4-FSK	1.465	5.9	0.50	110.6	-31

### B — Structured Fast Modes

Mode	FEC Type	(n, k)	Q	Modulation Type	Keying Rate	Bandwidth (Hz)	Sync Energy	Transmit Duration (s)	S/N Threshold (dB)
JT9E	Convolutional	(206,72)	8	9-FSK	25	225	0.19	3.4	
JT9F	Convolutional	(206,72)	8	9-FSK	50	450	0.19	1.7	
JT9G	Convolutional	(206,72)	8	9-FSK	100	900	0.19	0.85	
JT9H	Convolutional	(206,72)	8	9-FSK	200	1800	0.19	0.425	
MSK144	LDPC	(128,90)	2	OQPSK	2000	2400	0.11	0.072	MSK144 Sh LDPC (32,16) 2

for the LF, MF, and lower HF bands, FT8 for multi-hop sporadic E at 50 MHz, FT4 for fast contest QSOs on HF and 50 MHz, and WSPR for probing potential propagation paths using low-power transmissions. Not surprisingly, amateurs have discovered many other ways in which each mode can be used. On the HF bands, worldwide contacts are possible with any of these modes using power levels of a few watts (or even milliwatts) and compromise antennas. Reliable two-way contacts can be made with signal levels far too weak to be heard, 10 to 15 dB below the levels required for Morse-coded CW when received and decoded by ear.

**Table 15.7A** provides a brief summary of essential parameters for the *WSJT-X* slow modes. Column 1 gives the mode name, column 2 the type of forward error correction used. Each code maps a sequence of  $k$  information symbols into a longer sequence of  $n$  transmitted symbols. The results are called  $(n, k)$  block codes. After encoding, digital message information is modulated onto a carrier so that transfer can take place over a radio channel. The basic unit of transmitted data is called a *channel symbol*. Parameter  $Q$  (column 4 in the table) is the *alphabet size*, the number of different symbols used.  $Q$  is also the number of distinct waveforms used for conveying information. For frequency-shift keying the waveforms are sinusoids at different frequencies. Additional columns in Table 15.7A specify the keying rate, occupied bandwidth, fraction of transmitted energy devoted to synchronization, duration of transmitted waveform, and threshold signal-to-noise ratio for reliable decoding of each mode. Here and elsewhere in this section, signal-to-noise ratios are measured in a standard reference bandwidth of 2500 Hz.

**Figure 15.6** illustrates the appearance of each of the *WSJT-X* slow modes in a typical waterfall-type spectral display. For comparison, this collection of simulated signals also includes an unmodulated carrier and a 25 WPM CW signal. The signals were generated with a key-down signal-to-noise ratio 0 dB, thus simulating typical over-the-air reception of moderately weak, barely audible signals. WSPR has the narrowest occupied bandwidth of the basic *WSJT-X* modes, 5.9 Hz, while JT65 is the widest at 177.6 Hz. As described further below, some of the modes offer several submodes with wider tone spacings, which can be useful under certain propagation conditions. JT4, JT9, JT65, and QRA64 use one-minute timed sequences of transmission and reception, synchronized with UTC. WSPR uses two-minute sequences, FT8, 15 seconds, and FT4, 7.5 seconds. The following paragraphs give further details for each of the slow modes and describe their typical uses.

**Figure 15.6** — Spectrograms of simulated signals for an unmodulated carrier, a 25 WPM CW signal, and the *WSJT-X* slow modes WSPR, JT9, JT4, FT8, FT4, QRA64, and JT65. All signals have S/N = 0 dB in a 2500 Hz reference bandwidth. Horizontal scale is frequency in Hz; vertical axis represents time over the displayed interval of about 50 seconds.

### FT8

The FT8 protocol was developed by Steven Franke, K9AN, and K1JT. The mode became popular soon after its introduction in early summer of 2017, and is now one of the most widely used modes of any type in amateur radio. FT8 was designed for circumstances where signals may be weak and fading, so that quick completion of reliable, confirmable QSOs is especially desirable. The terse message exchanges of call signs, locators, signal reports, and acknowledgments serve well for those engaged in country-counting, award-chasing, and the like. The short, 15 second timed sequences for transmission and reception mean that basic sensitivity for steady signals is several dB worse than the modes with one-minute transmissions. Message packets include 77 information bits and a 14-bit cyclic redundancy check (CRC). Three of the information bits define special message types, some of which include several subtypes. These are used for such purposes as free text and contest exchanges. FT8 uses a (174,91) low-density parity check (LDPC) code for forward error correction, and the 14-bit CRC ensures a very low false decode rate. FT8 modulation uses Gaussian filtered 8-tone FSK (8-GFSK) at 6.25 baud, and accomplishes frame synchronization with three  $7 \times 7$  Costas arrays.

One special message subtype is used for *FT8 DXpedition Mode*, which enables a much-sought-after station to make QSOs at very high rates. In this mode *WSJT-X* allows the rare station to transmit up to five FT8 signals simultaneously, thereby conducting as many as five minimal contacts at once. The special multi-signal transmissions are subject to undesirable spectral broadening caused by intermodulation between the signals. This is true even when care is taken to

avoid overdriving the transmitter audio chain because most modern transmitters produce intermodulation products at levels that can cause significant interference to weak-signal digital modes. Multi-signal transmissions are therefore not suitable for general use or for use in contests — situations where good engineering practice and common courtesy dictate that any individual station use only the minimum bandwidth necessary. Multi-signal transmission is intended only for use by DXpeditions who will operate on frequency segments that do not overlap with those in use for regular QSOs, to avoid causing unnecessary QRM.

### FT4

FT4 was designed for use in contests where, under certain circumstances, it is worthwhile to trade a few dB of sensitivity for higher QSO rates. It uses the same 77-bit messages and (174,91) error-correcting code as FT8, but with transmit/receive sequences of just 7.5 seconds. Although twice as fast as FT8, with only 4 tones the occupied bandwidth of FT4 is only 83 Hz, less than twice that of FT8. The decoding threshold is  $-17.5$  dB, 3.3 dB higher than that of FT8. FT4 uses Gaussian filtered 4-tone FSK (4-GFSK) waveforms at 20.833 baud, and frame synchronization uses four  $4 \times 4$  Costas arrays.

### JT4

In JT4 mode, each channel symbol carries one information bit (the most significant bit) and one synchronizing bit. The sync bits are defined by a pseudo-random binary sequence known to the software at both transmitting and receiving ends. FEC is accomplished using a strong convolutional code designed by NASA for deep space use. After the sync pattern is recognized and removed by the receiving software, the remaining signal

amounts to a 2-tone FSK signal. Submodes JT4A through JT4G have tone spacings at increasing multiples 1, 2, 4, 9, 18, 36, and 72 times the basic keying rate, 4.375 baud. The wider submodes have proven very useful on propagation paths with large Doppler spread. For example, JT4F is frequently used for Earth-Moon-Earth (EME) communication on the 10 GHz band.

## JT9

The JT9 mode uses eight tone frequencies to convey message information, one additional tone for synchronization, and the same convolutional code as JT4. Submodes JT9A-H have tone spacings at multiples 1, 2, 4, 8, 16, 32, and 64 times the 1.736-baud keying rate. JT9A (often called simply JT9) uses less than 10% the bandwidth of JT65, and for steady, undistorted signals is about 2 dB more sensitive. These characteristics have made JT9 very popular on the 630 meter band.

## JT65

The JT65 protocol is the oldest of the weak-signal structured modes; a detailed description was published in *QEX* in 2005 (see References and Bibliography). The protocol uses a (63,12) Reed-Solomon code with alphabet size  $Q = 64$ . Modulation uses one synchronizing tone and 64 data tones, with data and sync information interspersed according to a pseudo-random sync pattern. In *WSJT-X* decoding is accomplished using the Frank-Taylor soft decision algorithm (see References and Bibliography). Special features can be used to convey an EME-style “OOO” signal report and short messages interpreted as RO, RRR, and 73. Submodes JT65B and JT65C, also used only for EME, use tone spacings 2 and 4 times larger than JT65A. JT65 is widely used for EME on VHF and higher bands. It was popular for low-power DXing at MF and HF, as well, but has been largely superseded on those bands by FT8.

## QRA64

QRA64 is intended for EME and other extreme weak-signal paths. Its error-correcting code was designed by Nico Palermo, IV3N-WV (see References and Bibliography). Synchronization is accomplished by using three  $7 \times 7$  Costas arrays. Submodes QRA64A-E use tone spacings 1, 2, 4, 8, and 16 times the 1.736 baud keying rate. QRA64 is very effective for EME on the VHF and UHF bands. The wider submodes QRA64C-E work extremely well for EME on microwave bands up to 24 GHz.

## WSPR

The WSPR mode was designed as a propagation probe rather than for making two-way contacts. It uses the same convolutional code as JT4 but differs from the other structured modes in *WSJT-X* by using message lengths

of 50 information bits and two-minute T/R sequences. Message packets normally include a 28-bit call sign, a 15-bit grid locator, and 7 bits to convey transmitter power in dBm (decibels above one milliwatt). Alternative formats can convey a compound call sign and/or a 6-digit grid locator, using a two-transmission sequence. Typical WSPR usage was described in *QST* in 2010 (see References and Bibliography).

## 15.4.4 Fast Modes

The fast modes in *WSJT-X* aim to take advantage of brief propagation enhancements that bring a signal up to useful levels for a very short time. Keying rates and occupied bandwidths are much larger than for the slow modes so that full messages can be conveyed in these very short intervals. **Table 15.7B** lists essential parameter values for the *WSJT-X* fast modes. The last column gives the time required to transmit a message once at the specified keying rate. In these modes the transmitted information is repeated for the full duration of a T/R sequence.

### JT9 Fast

Fast submodes JT9E-H differ from their slow JT9 counterparts by using much higher keying rates and wider tone spacings. Otherwise the coding, modulation, and synchronization schemes are the same as for the slow JT9 modes. JT9 fast modes have proven useful for such propagation types as ionospheric scatter and weak multi-hop sporadic E on the 6 meter band.

### MSK144

Messages in MSK144 contain 77 information bits and a 13-bit CRC, and use the same types of user message as FT8 and FT4. Forward error correction is accomplished with a (128, 90) LDPC code designed by Steven Franke, K9AN, specifically for this purpose. Two 8-bit synchronizing sequences are added to make a message frame 144 bits long. Modulation uses offset quadrature phase-shift keying (OQPSK) at 2000 baud, so the frame duration is  $144/2000 = 0.72$  second. With the advantages of strong error correction and an effective character transmission rate around 250 characters per second (see References and Bibliography), MSK144 has become the dominant mode for amateur meteor-scatter contacts. (See the Reference entry for Barry Hansen, K7BWH’s introduction to meteor scatter operation.)

## 15.4.5 HF Digital Voice AOR

In 2004, AOR Corporation introduced its HF digital voice and data modem, the AR9800. Digital voice offers a quality simi-

lar to FM with no background noise or fading as long as the signal can be properly decoded. The AR9800 can alternatively transmit binary files and images. AOR later released the AR9000 which is compatible with the AR9800 but less expensive and only supports the HF digital voice mode.

The AR9800 uses a protocol developed by Charles Brain, G4GUO. The protocol uses the AMBE (Advanced Multi-Band Excitation) codec from DVSI Inc. to carry voice. It uses 2400 bit/s for voice data with an additional 1200 bit/s for Forward Error Correction for a total 3600 bit/s data stream. The protocol is detailed below:

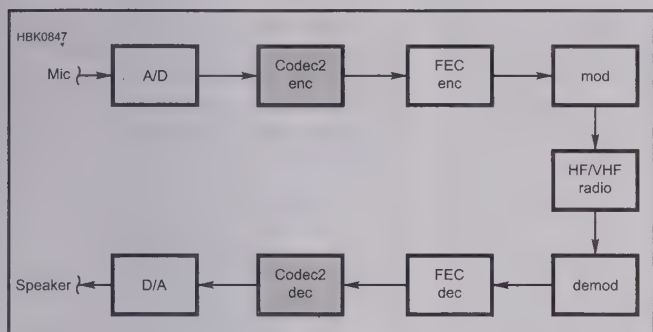

- Bandwidth: 300-2500 Hz, 36 carriers
  - Symbol Rate: 20 ms (50 baud)
  - Guard interval: 4 ms
  - Tone steps: 62.5 Hz
  - Modulation method: 36 carriers: DQPSK (3.6K)
    - AFC:  $\pm 125$  Hz
    - Error correction: Voice: Golay and Hamming
      - Video/Data: Convolution and Reed-Solomon
        - Header: 1 s; 3 tones plus BPSK training pattern for synchronization
        - Digital voice: DVSI AMBE2020 coder, decoder
          - Signal detection: Automatic Digital detect, Automatic switching between analog mode and digital mode
            - Video Compression: AOR original adaptive JPEG
- AOR has more information online at [www.aorusa.com/others/ard9800.html](http://www.aorusa.com/others/ard9800.html).

### FreeDV

*FreeDV* is available for *Windows*, *Linux*, and *MacOS* clients, and allows any SSB radio to be used for low-bit-rate digital voice. Speech and call sign data is compressed down to 1400 bit/s, which then modulates an 1125 Hz-wide QPSK signal, which is then applied to the microphone input of an SSB transceiver. On receive, the signal is received as SSB, demodulated to audio, then further demodulated and decoded by *FreeDV* running on a PC.

*FreeDV* is entirely open source — even the voice codec. This makes it unique among Amateur Radio digital voice systems which typically rely on a proprietary voice codec that is not available to ham experimentation.

*FreeDV* was coded from scratch by David Witten, KDØEAG (GUI, architecture), and David Rowe, VK5DGR (*Codec2*, modem implementation, integration). The *FreeDV* design and user interface is based on *FD-MDV*, which was developed by Francesco Lanza, HB9TLK. The large team of reviewers and beta testers who have supported the development of *FreeDV* are credited on the [freedv.org](http://freedv.org) home page.

(A)

(B)

**Figure 15.7 — Typical FreeDV system architecture (A) and FreeDV 1.1 screen shot during reception (B).**

### Key FreeDV Features

- Waterfall, spectrum, scatter and audio oscilloscope displays
- Adjustable squelch
- Fast/slow SNR estimation
- Microphone and speaker signal audio equalizer
- Control of transmitter PTT via RS-232 levels
- Works with one (receive only) or two (transmit and receive) sound cards (for example, a built-in sound card and USB headphones)

### FreeDV Overview

There are three implementations of FreeDV:

#### FreeDV 1600:

- Codec2 voice codec and FDMDV modem
- 1.25 kHz spectrum bandwidth (half SSB) with 75 Hz carrier spacing
- 1275 bit/s voice coding, 25 bit/s text for call sign ID, 300 bit/s FEC,
- 16×50 baud DQPSK carriers, Differential QPSK demodulation
- 1 center BPSK carrier with 2× power for fast and robust synchronization
- 44.1 or 48 kHz sample rate, sound card compatible

#### FreeDV 700(C):

- 700 bit/s voice coding; no FEC, uses frequency diversity to combat fading, 14×75 baud QPSK carriers, pilot-symbol assisted coherent QPSK demodulation

#### FreeDV 2400A (for VHF/UHF):

- Bit rate: 2400 bit/s
- RF bandwidth: 5 kHz
- Suggested channel spacing: 6.25 kHz
- Modulation: 4FSK with non-coherent demodulation
- Symbol rate: 1200 symbols/s
- Tone spacing: 1200 Hz
- Frame period: 40 ms
- Bits/frame: 96
- Unique word: 16 bits/frame
- Codec2 1300: 52 bits/frame
- Spare bits: 28 bits/frame

FreeDV is composed of two primary software components:

1) The FreeDV GUI (see Figure 15.7A): A FreeDV Windows/Linux/OSX GUI application. The FreeDV GUI software runs on any PC and requires two sound cards, for example a USB rig interface and a USB headset.

2) The FreeDV API: An open source, C-callable software library, that has interfaces for audio and modem samples. The API can be linked into third-party SDR programs that wish to support FreeDV.

A standalone hardware implementation of FreeDV (SM1000) is also available that does not require a PC host. (See [freedv.org](http://freedv.org) for more information about FreeDV software and accessories.)

### FreeDV Architecture

Figure 15.7B shows a typical FreeDV system. Voice signals from a microphone are sampled by the ADC, typically at 8 kHz with 16-bit resolution. A speech encoder (Codec2) then compresses the speech to a low bit rate, for example 1300 bit/s. FEC bits are then added to protect against errors encountered in the channel. This may increase the bit rate to 1600 bit/s. A modulator (labeled “mod”) then converts the bit stream to tones that can be passed via a radio channel. Over the channel the digital speech signal will encounter noise and other impairments such as fading and frequency offsets.

On the receive side, the demodulator (labeled “demod”) then converts the tones back into a bit stream. The FEC decoder attempts to correct channel errors before passing the payload compressed voice information to the voice decoder (labeled “codec 2 dec”). The output of the voice decoder is an 8 kHz, 16-bit/sample sequence that is converted back

**Table 15.8  
ALE Tones**

Frequency	Data
750 Hz	000
1000 Hz	001
1250 Hz	011
1500 Hz	010
1750 Hz	110
2000 Hz	111
2250 Hz	101
2500 Hz	100

into analog speech by the DAC and played through a speaker or headphones.

More details and the software can be found at [freedv.org](http://freedv.org) as well as written and video setup guides. A coordinating website for FreeDV QSOs is available at [qso.k7ve.org](http://qso.k7ve.org).

### 15.4.6 ALE

Automatic link establishment (ALE) was created as a series of protocols for government users to simplify HF communications. The protocol provides a mechanism to analyze signal quality on various channels/bands and choose the best option. The purpose is to provide a reliable rapid method of calling and connecting during constantly changing HF ionospheric propagation, reception interference and shared spectrum use of busy or congested HF channels. It also supports text messages with a very robust protocol that can get through even if no voice-quality channel can be found.

Each radio ALE station uses a call sign or address in the ALE controller. When not actively in communication with another station, each HF SSB transceiver constantly scans through a list of frequencies, listening for its call sign. It decodes calls and soundings sent

by other stations, using the bit error rate to store a quality score for that frequency and sender call sign.

To reach a specific station, the caller simply enters the call sign, just like dialing a phone number. The ALE controller selects the best available frequency and sends out brief digital selective calling signals containing the call signs. When the distant scanning station detects the first few characters of its call sign, it stops scanning and stays on that frequency. The two stations' ALE controllers automatically handshake to confirm that a link of sufficient quality is established and they are ready to communicate.

When successfully linked, the receiving station which was muted will typically emit an audible alarm and visual alert for the receiving operator of the incoming call. It also indicates the call sign of the linked station. The operators then can talk in a regular conversation. At the conclusion of the QSO, one of

the stations sends a disconnect signal to the other station, and they each return their ALE stations to the scanning mode. Some military/commercial HF transceivers are available with ALE available internally. Amateur Radio operators commonly use the PCALÉ soundcard software ALE controller, interfaced to a ham transceiver via rig control cable and multi-frequency antenna.

The ALE waveform is designed to be compatible with the audio passband of a standard SSB radio. It has a robust waveform for reliability during poor path conditions. It consists of 8-ary frequency-shift keying (FSK) modulation with eight orthogonal tones, a single tone for a symbol. These tones represent three bits of data, with least significant bit to the right, as shown in **Table 15.8**.

The tones are transmitted at a rate of 125 tones per second, 8 ms per tone. The resultant transmitted bit rate is 375 bit/s. The basic ALE word consists of 24 bits of information. De-

tails can be found in Federal Standard 1045, Detailed Requirements at [www.its.bldrdoc.gov/fs-1054a/45-detr.htm](http://www.its.bldrdoc.gov/fs-1054a/45-detr.htm).

It would require a lot of time for the radio to go through the sequence of calling a station on every possible frequency to establish a link. Time can be decreased by using a "smarter" way of predictive or synchronized linking. With *Link Quality Analysis* (LQA), an ALE system uses periodic sounding and linking signals between other stations in the network to stay in touch and to predict which channel is likely to support a connection to the desired station at any given time. Various stations may be operating on different channels, and this enables the stations to find and use a common open channel.

The PCALÉ software developed by Charles Brain, G4GUO, is available for download at [hfink.com/software](http://hfink.com/software). Much more ALE information and real-time data is available online at [hfink.com](http://hfink.com).

## 15.5 Networking Modes

The modes described in this section operate using features and functions associated with computer-to-computer networking. Even though communication using these modes may not involve the creation of a network, the modes are referred to as "networking modes" because of their structure. In cases such as Winlink and D-STAR, the most common use is to implement a networked system and those features are described along with the modes and protocols used to implement communications within the network.

is just a conceptual model of the functions required. Real-world protocols rarely implement each layer individually and often span multiple layers.

This description is by no means exhaustive and more information can be found online and in every networking textbook. **Table 15.10** shows the placement of commonly recognized protocols within the OSI layered structure.

### 15.5.2 Connected and Connectionless Protocols

The protocols discussed to this point have been *connectionless* meaning they don't establish a connection with a specific machine for the purpose of transferring data. Even with packetized modes like FSK441 with a destination call sign specified, the packet is transmitted and it's up to the user to identify

### 15.5.1 OSI Networking Model

The Open Systems Interconnection Model or *OSI Model* is an abstract description for computer network protocol design. It defines seven different *layers* or functions performed by a *protocol stack*. In the OSI model, the highest level is closest to the user and the lowest is closest to the hardware required to transport the data (network card and wire or radio). The seven layers are described in **Table 15.9**. The modes examined previously implemented the protocols as a *monolithic stack* where all the functions are performed inside a single piece of code. The modes described in this section implement networking features in a more modular fashion. This allows greater flexibility (and complexity) when mixing features.

As a data packet moves through these layers the header or preamble is removed and any required action performed before the data is passed to the next layer, much like peeling away layers of an onion until just the basic clean data is left. The OSI model does not define any interfaces between layers; it

**Table 15.9**  
**OSI Seven Layer Networking Model**

7 — Application Layer	End-user program or "application" that uses the network
6 — Presentation Layer	The format of data after transfer (code conversion, encryption)
5 — Session Layer	Manages the transfer process
4 — Transport Layer	Provides reliable data transfer to the upper layers
3 — Network Layer	Controls data routing
2 — Data Link Layer	Provides error detection and flow control
1 — Physical Layer	Signal used on the medium—voltage, current, frequency, etc.

**Table 15.10**  
**Networking Protocols in the OSI Model**

Layer	Examples	IP Protocol Suite
7 — Application		NNTP, DNS, FTP, Gopher, HTTP, DHCP, SMTP, SNMP, TELNET
6 — Presentation	ASCII, EBCDIC, MIDI, MPEG	MIME, SSL
5 — Session	Named Pipes, NetBIOS, Half Duplex, Full Duplex, Simplex	Sockets, Session establishment in TCP
4 — Transport		TCP, UDP
3 — Network	AX.25	IP, IPsec, ICMP, IGMP
2 — Data Link	802.3 (Ethernet), 802.11a/b/g/n MAC/LLC, ATM, FDDI, Frame Relay, HDLC, Token Ring, ARP (maps layer 3 to layer 2 address)	PPP, SLIP, PPTP, L2TP
1 — Physical	RS-232, T1, 10BASE-T, 100BASE-TX, POTS, DSL, 802.11a/b/g/n, Soundcard, TNC, Radio	

they are the intended recipient. In a packet-switched network, connectionless mode transmission is a transmission in which each packet is prepended with a header containing a destination address to allow delivery of the packet without the aid of additional instructions. A packet transmitted in a connectionless mode is frequently called a *datagram*.

In *connection-oriented protocols*, the stations about to exchange data need to first declare to each other they want to "establish a connection". A connection is sometimes defined as a logical relationship between the peers exchanging data. Connected protocols can use a method called *automatic repeat request (ARQ)* to insure accurate delivery of packets using *acknowledgements* and *timeouts*. This allows the detection and correction of corrupted packets, misdelivery, duplication, or out-of-sequence delivery of the packets.

Connectionless modes can have error correction and detection included by a higher layer of the protocol but they have no mechanism to request a correction. An advantage of connectionless mode over connection-oriented mode is that it has a low data overhead. It also allows for *multicast* and *broadcast* (net-type) operations, which may save even more network resources when the same data needs to be transmitted to several recipients. In contrast, a connected mode is always *unicast* (point-to-point).

Another drawback of the connectionless mode is that no optimizations are possible when sending several frames between the same two peers. By establishing a connection at the beginning of such a data exchange the components (routers, bridges) along the network path would be able to pre-compute (and hence cache) routing-related information, avoiding re-computation for every packet.

Many network modes incorporate both types of protocol for different purposes. In the Internet TCP/IP protocol, TCP is a connection-oriented transport protocol where UDP is connectionless.

### 15.5.3 The Terminal Node Controller (TNC)

While a *terminal node controller (TNC)* is nominally an OSI Physical layer device, the internal firmware often implements a protocol such as PACTOR that handles all the routing, and error correction through the transport layer. This greatly simplifies the coding of any protocol or application that uses these devices.

A TNC is actually a computer that contains the protocols implemented in firmware and a *modem* (modulator/demodulator). The TNC generally connects to a PC as a serial or USB device on one side and to the radio with appropriate audio and PTT cables on the

other. Most of the newer rigs have dedicated data connections available that feature audio lines with fixed levels that are unaffected by settings in the radio. These jacks make swapping mike cables unnecessary when switching between voice and digital modes. Bypassing internal audio processing circuitry eliminates a number of issues that can cause problems with digital modes and makes the use of digital modes more reproducible/reliable by eliminating a number of variables when configuring equipment. These same data jacks are recommended when using a computer sound card.

Although many of the modes discussed can use a computer sound card to generate the required modulation and a separate mechanism to support push-to-talk (PTT), a TNC offers some advantages:

- TNC hardware can be used with any computer platform.
- A computer of nearly any vintage/performance level can be used.
- Data transmission/reception is unaffected by computer interruptions from virus checkers or other "inits."
- Initialization settings are held internal to the TNC and can easily be reset as needed — once working, they stay working.
- Virtually eliminates the computer as a problem/failure point.
- Offers features independent of the computer (digipeat, BBS, APRS beacon, telemetry, weather beacon, and so forth).

The majority of TNCs are designed for 300 or 1200-bit/s packet and implement the Bell 103 or Bell 202 modulation respectively. A *multimode communications processor (MCP)* or *multi-protocol controller (MPC)* may offer the capability to operate RTTY, CW, AMTOR, PACTOR, G-TOR, Clover, fax, SSTV and other modes in addition to packet. Some of these modes are only available in TNC hardware because the real-time operating system in the TNC provides a more reliable platform to implement the mode and it also helps protect proprietary intellectual property.

KISS-Mode TNCs have become popular. These devices simply provide the modem and filters to implement the baseband signals for a type of digital modulation. They rely on the computer software to generate the

appropriate packet protocol and complete the mode. This means the software must be written specifically to support these TNCs by creating the entire AX.25 packet with the data embedded, rather than simply sending the data to the TNC expecting the TNC to frame the packet. By leaving the TNC to handle only the baseband signal generation and data recovery, much simpler, smaller and less expensive designs are possible while still retaining the platform independence and robustness of a separate TNC. The TNC-X from Coastal Chipworks at [tnc-x.com](http://tnc-x.com) is a good example of a KISS-mode TNC.

### 15.5.4 FACTOR-I

FACTOR, now often referred to as PACTOR-I, is an HF radio transmission system developed by German amateurs Hans-Peter Helfert, DL6MAA, and Ulrich Strate, DF4KV. It was designed to overcome the shortcomings of AMTOR and packet radio. It performs well under both weak-signal and high-noise conditions. PACTOR-I has been overtaken by PACTOR-II and PACTOR-III but remains in use.

#### TRANSMISSION FORMATS

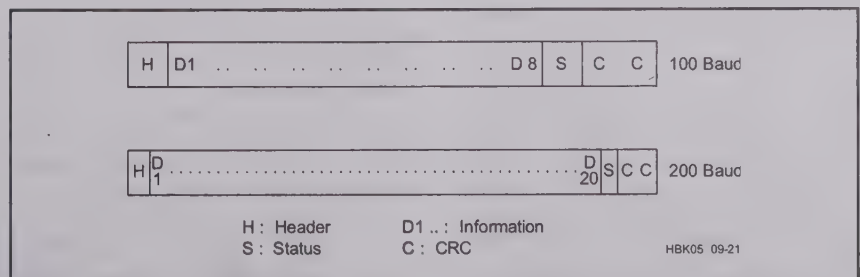

All packets have the basic structure shown in **Figure 15.8**, and their timing is as shown in **Table 15.11**.

- Header: Contains a fixed bit pattern to simplify repeat requests, synchronization and monitoring. The header is also important for the Memory ARQ function. In each packet that carries new information, the bit pattern is inverted.

- Data: Any binary information. The

**Table 15.11**  
**PACTOR Timing**

Object	Length (seconds)
Packet	0.96 (200 baud: 192 bits; 100 baud: 96 bits)
CS receive time	0.29
Control signals	0.12 (12 bits at 10 ms each)
Propagation delay	0.17
Cycle	1.25

**Figure 15.8 — PACTOR packet structure.**

**Table 15.12**  
**PACTOR Control Signals**

Code	Chars (hex)	Function
CS1	4D5	Normal acknowledge
CS2	AB2	Normal acknowledge
CS3	34B	Break-in (forms header of first packet from RX to TX)
CS4	D2C	Speed change request

All control signals are sent only from RX to TX

**Table 15.13**  
**PACTOR Initial Contact**

Master Initiating Contact			
Size (bytes)	1	8	6
Content	/Header	/SLAVECAL	/SLAVECAL/
Speed (baud)	100	100	200

*Slave Response*

The receiving station detects a call, determines mark/space polarity, and decodes 100 baud and 200-bd call signs. It uses the two call signs to determine if it is being called and the quality of the communication path. The possible responses are:

First call sign does not match slave's call sign (Master not calling this slave)	none
Only first call sign matches slave's call sign (Master calling this slave, poor communications)	CS1
First and second call signs both match the slaves (good circuit, request speed change to 200 baud)	CS4

format is specified in the status word. Current choices are 8-bit ASCII or 7-bit ASCII (with Huffman encoding). Characters are not broken across packets. ASCII RS (hex 1E) is used as an IDLE character in both formats.

- Status word: See Table 15.11
- CRC: The CRC is calculated according to the CCITT standard, for the data, status and CRC.

The PACTOR acknowledgment signals are shown in **Table 15.12**. Each of the signals is 12-bits long. The characters differ in pairs in eight bits (Hamming offset) so that the chance of confusion is reduced. If the CS is not correctly received, the TX reacts by repeating the last packet. The request status can be uniquely recognized by the 2-bit packet number so that wasteful transmissions of pure RQ blocks are unnecessary.

The receiver pause between two blocks is 0.29 s. After deducting the CS lengths, 0.17 s remains for switching and propagation delays so that there is adequate reserve for DX operation.

**CONTACT FLOW**

In the listen mode, the receiver scans any received packets for a CRC match. This method uses a lot of computer processing resources, but it's flexible.

A station seeking contacts transmits CQ packets in an FEC mode, without pauses for acknowledgment between packets. The transmit time length, number of repetitions

and speed are the transmit operator's choice. (This mode is also suitable for bulletins and other group traffic.) Once a listening station has copied the call, the listener assumes the TX station role and initiates a contact. Thus, the station sending CQ initially takes the RX station role. The contact begins as shown in **Table 15.13**.

With good conditions, PACTOR's normal signaling rate is 200 baud, but the system automatically changes from 200 to 100 baud and back, as conditions demand. In addition, Huffman coding can further increase the throughput by a factor of 1.7. There is no loss of synchronization speed changes; only one packet is repeated.

When the RX receives a bad 200-baud packet, it can acknowledge with CS4. TX immediately assembles the previous packet in 100-baud format and sends it. Thus, one packet is repeated in a change from 200 to 100 baud.

The RX can acknowledge a good 100-baud packet with CS4. TX immediately switches to 200 baud and sends the next packet. There is no packet repeat in an upward speed change.

The RX station can become the TX station by sending a special change-over packet in response to a valid packet. RX sends CS3 as the first section of the changeover packet. This immediately changes the TX station to RX mode to read the data in that packet and responds with CS1 and CS3 (acknowledge) or CS2 (reject).

PACTOR provides a sure end-of-contact

procedure. TX initiates the end of contact by sending a special packet with the QRT bit set in the status word and the call of the RX station in byte-reverse order at 100 baud. The RX station responds with a final CS.

**15.5.5 PACTOR-II**

This is a significant improvement over PACTOR-I, yet it is fully compatible with the older mode. PACTOR-II uses 16PSK to transfer up to 800 bit/s at a 100 baud rate. This keeps the bandwidth less than 500 Hz.

PACTOR-II uses digital signal processing (DSP) with Nyquist waveforms, Huffman and Markov compression and powerful Viterbi decoding to increase transfer rate and sensitivity into the noise level. The effective transfer rate of text is over 1200 bit/s. Features of PACTOR II include:

- Frequency agility — it can automatically adjust or lock two signals together over a ±100 Hz window.
  - Powerful data reconstruction based upon computer power — with over 2 Mbyte of available memory.
  - Cross correlation — applies analog Memory ARQ to acknowledgment frames and headers.
  - Soft decision making — Uses artificial intelligence (AI), as well as digital information received to determine frame validity.
  - Extended data block length — when transferring large files under good conditions, the data length is doubled to increase the transfer rate.
  - Automatic recognition of PACTOR-I, PACTOR-II and so on, with automatic mode switching.
  - Intermodulation products are canceled by the coding system.
  - Two long-path modes extend frame timing for long-path terrestrial and satellite propagation paths.
- This is a fast, robust mode that has excellent coding gain as well. PACTOR-II stations acknowledge each received transmission block. PACTOR-II employs computer logic as well as received data to reassemble defective data blocks into good frames. This reduces the number of transmissions and increases the throughput of the data.

**15.5.6 PACTOR-III**

PACTOR-III is a software upgrade for existing PACTOR-II modems that provides a data transmission mode for improved speed and robustness. Both the transmitting and receiving stations must support PACTOR-III for end-to-end communications using this mode.

PACTOR-III's maximum uncompressed speed is 2722 bit/s. Using online compression,

up to 5.2 kbit/s is achievable. This requires an audio passband from 400 Hz to 2600 Hz (for PACTOR-III speed level 6). On an average channel, PACTOR-III is more than three times faster than PACTOR-II. On good channels, the effective throughput ratio between PACTOR-III and PACTOR-II can exceed five. PACTOR-III is also slightly more robust than PACTOR-II at their lower SNR edges.

The ITU emission designator for PACTOR-III is 2K20J2D. Because PACTOR-III builds on PACTOR-II, most specifications like frame length and frame structure are adopted from PACTOR-II. The only significant difference is PACTOR III's multi-tone waveform that uses up to 18 carriers while PACTOR-II uses only two carriers. PACTOR-III's carriers are located in a 120 Hz grid and modulated with 100 symbols per second DBPSK or DQPSK. Channel coding is also adopted from PACTOR-II's Punctured Convolutional Coding.

### PACTOR-III Link Establishment

The calling modem uses the PACTOR-I FSK connect frame for compatibility. When the called modem answers, the modems negotiate to the highest level of which both modems are capable. If one modem is only capable of PACTOR-II, then the 500 Hz PACTOR-II mode is used for the session. With the MYLevel (MYL) command a user may limit a modem's highest mode. For example, a user may set MYL to 1 and only a PACTOR-I connection will be made, set to 2 and PACTOR-I and II connections are available, set to 3 and PACTOR-I through III connections are enabled. The default MYL is set to 2 with the current firmware and with PACTOR-III firmware it will be set to 3. If a user is only allowed to occupy a 500 Hz channel, MYL can be set to 2 and the modem will stay in its PACTOR-II mode.

The PACTOR-III Protocol Specification is available online at [www.scs-ptc.com/pactor.html](http://www.scs-ptc.com/pactor.html). More information can also be found online at [www.arrl.org/technical-characteristics](http://www.arrl.org/technical-characteristics).

The protocol specifications and equipment for PACTOR-IV have been released, but the mode is not yet legal for US amateurs. The symbol rate for PACTOR-IV is 1800 baud, but FCC rules limit US amateurs to 300 baud below the upper end of 10 meters. PACTOR-IV is being used outside the US by individual amateurs and by Winlink stations that are not subject to FCC rules. It is not known if or when this restriction will be lifted.

### 15.5.7 G-TOR

This brief description has been adapted from "A Hybrid ARQ Protocol for Narrow Bandwidth HF Data Communication" by

Glenn Prescott, WBØSKX, Phil Anderson, WØXI, Mike Huslig, KBØNYK, and Karl Medcalf, WK5M (May 1994 *QEX*).

G-TOR is short for Golay-TOR, an innovation of Kantronics. It was inspired by HF automatic link establishment (ALE) concepts and is structured to be compatible with ALE. The purpose of the G-TOR protocol is to provide an improved digital radio communication capability for the HF bands. The key features of G-TOR are:

- Standard FSK tone pairs (mark and space)
- Link-quality-based signaling rate: 300, 200 or 100 baud
- 2.4-s transmission cycle
- Low overhead within data frames
- Huffman data compression — two types, on demand
- Embedded run-length data compression
- Golay forward-error-correction coding
- Full-frame data interleaving
- CRC error detection with hybrid ARQ
- Error-tolerant "Fuzzy" acknowledgments.

Since one of the objectives of this protocol is ease of implementation in existing TNCs, the modulation format consists of standard tone pairs (FSK), operating at 300, 200 or 100 baud, depending upon channel conditions. G-TOR initiates contacts and sends ACKs only at 100 baud. The G-TOR waveform consists of two phase-continuous tones (BFSK), spaced 200 Hz apart (mark = 1600 Hz, space = 1800 Hz); however, the system can still operate at the familiar 170 Hz shift (mark = 2125 Hz, space = 2295 Hz), or with any other convenient tone pairs. The optimum spacing for 300-baud transmission is 300 Hz, but you trade some performance for a narrower bandwidth.

Each transmission consists of a synchronous ARQ 1.92-s frame and a 0.48-s interval for propagation and ACK transmissions (2.4 s cycles). All advanced protocol features are implemented in the signal-processing software.

Data compression is used to remove redundancy from source data. Therefore, fewer bits are needed to convey any given message. This increases data throughput and decreases transmission time — valuable features for HF. G-TOR uses run-length encoding and two types of Huffman coding during normal text transmissions. Run-length encoding is used when more than two repetitions of an 8-bit character are sent. It provides an especially large savings in total transmission time when repeated characters are being transferred.

The Huffman code works best when the statistics of the data are known. G-TOR applies Huffman A coding with the upper- and lower-case character set, and Huffman B coding with

upper-case-only text. Either type of Huffman code reduces the average number of bits sent per character. In some situations, however, there is no benefit from Huffman coding. The encoding process is then disabled. This decision is made on a frame-by-frame basis by the information sending station.

The real power of G-TOR resides in the properties of the (24, 12) extended Golay error-correcting code, which permits correction of up to three random errors in three received bytes. The (24, 12) extended Golay code is a half-rate error-correcting code: Each 12 data bits are translated into an additional 12 parity bits (24 bits total). Further, the code can be implemented to produce separate input-data and parity-bit frames.

The extended Golay code is used for G-TOR because the encoder and decoder are simple to implement in software. Also, Golay code has mathematical properties that make it an ideal choice for short-cycle synchronous communication. More information can also be found online at [www.arrl.org/technical-characteristics](http://www.arrl.org/technical-characteristics).

### 15.5.8 CLOVER-II

The desire to send data via HF radio at high data rates and the problem encountered when using AX.25 packet radio on HF radio led Ray Petit, W7GHM, to develop a unique modulation waveform and data transfer protocol that is now called CLOVER-II. Bill Henry, K9GWT, supplied this description of the CLOVER-II system.

CLOVER modulation is characterized by the following key parameters:

- Very low base symbol rate: 31.25 symbols/second (all modes).
- Time-sequence of amplitude-shaped pulses in a very narrow frequency spectrum.
- Occupied bandwidth = 500 Hz at 50 dB below peak output level.
- Differential modulation between pulses.
- Multilevel modulation.

The low base symbol rate is very resistant to multipath distortion because the time between modulation transitions is much longer than even the worst-case time-smearing caused by summing of multipath signals. By using a time-sequence of tone pulses, Dolph-Chebychev "windowing" of the modulating signal and differential modulation, the total occupied bandwidth of a CLOVER-II signal is held to 500 Hz.

Multilevel tone, phase and amplitude modulation gives CLOVER a large selection of data modes that may be used (see **Table 15.14**). The adaptive ARQ mode of CLOVER senses current ionospheric conditions and automatically adjusts the modulation mode to produce maximum data throughput. When using the

Fast bias setting, ARQ throughput automatically varies from 11.6 byte/s to 70 byte/s.

The CLOVER-II waveform uses four tone pulses that are spaced in frequency by 125 Hz. The time and frequency domain characteristics of CLOVER modulation are shown in Figures 15.9, 15.10 and 15.11. The time-domain shape of each tone pulse is intentionally shaped to produce a very compact frequency spectrum. The four tone pulses are spaced in time and then combined to produce the composite output shown. Unlike other modulation schemes, the CLOVER modulation spectrum is the same for all modulation modes.

Data is modulated on a CLOVER-II signal by varying the phase and/or amplitude of the tone pulses. Further, all data modulation is differential on the same tone pulse — data is represented by the phase (or amplitude) differ-

ence from one pulse to the next. For example, when binary phase modulation is used, a data change from 0 to 1 may be represented by a change in the phase of tone pulse one by 180° between the first and second occurrence of that pulse. Further, the phase state is changed only while the pulse amplitude is zero. Therefore, the wide frequency spectra normally associated with PSK of a continuous carrier is avoided. This is true for all CLOVER-II modulation formats. The term *phase-shift modulation* (PSM) is used when describing CLOVER modes to emphasize this distinction.

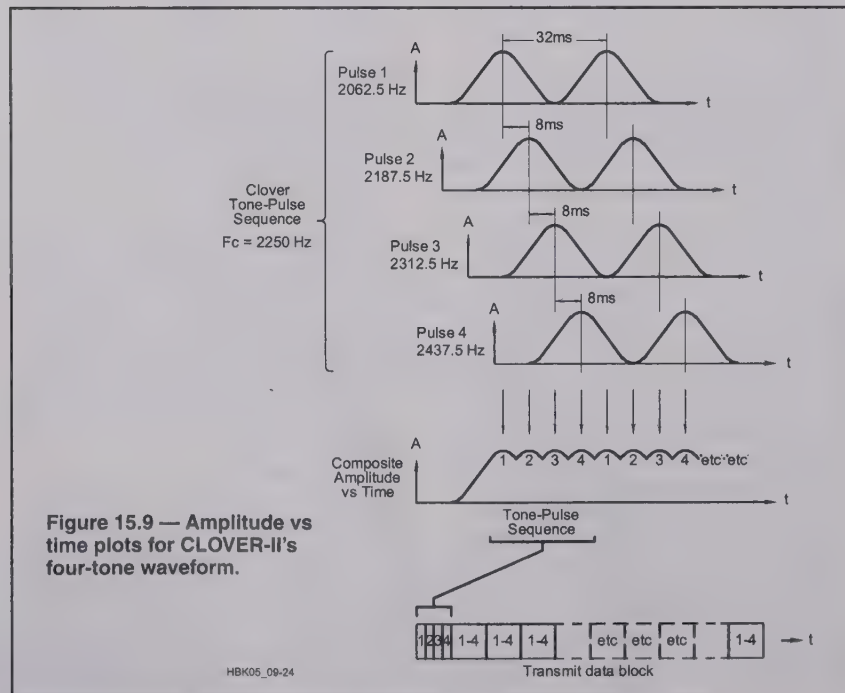

CLOVER-II has four “coder efficiency” options: 60%, 75%, 90% and 100% (“efficiency” being the approximate ratio of real data bytes to total bytes sent). 60% efficiency corrects the most errors but has the lowest net data throughput. 100% efficiency turns the encoder off and has the highest throughput but fixes no errors. There is therefore a tradeoff between raw data throughput versus the number of errors that can be corrected without resorting to retransmission of the entire data block.

Note that while the In Block Data Rate numbers listed in the table go as high as 750 bit/s, overhead reduces the net throughput or overall efficiency of a CLOVER transmission. The FEC coder efficiency setting and protocol requirements of FEC and ARQ modes add overhead and reduce the net efficiency. Tables 15.15

**Table 15.14**  
**CLOVER-II Modulation Modes**

As presently implemented, CLOVER-II supports a total of seven different modulation formats: five using PSM and two using a combination of PSM and ASM (Amplitude Shift Modulation).

Name	Description	In-Block Data Rate
16P4A	16 PSM, 4-ASM	750 bps
16PSM	16 PSM	500 bps
8P2A	8 PSM, 2-ASM	500 bps
8PSM	8 PSM	375 bps
QPSM	4 PSM	250 bps
BPSM	Binary PSM	125 bps
2DPSM	2-Channel Diversity BPSM	62.5 bps

**Figure 15.9 — Amplitude vs time plots for CLOVER-II's four-tone waveform.**

and 15.16 detail the relationships between block size, coder efficiency, data bytes per block and correctable byte errors per block.

With seven different modulation formats, four data-block lengths (17, 51, 85 or 255 bytes) and four Reed-Solomon coder efficiencies (60%, 75%, 90% and 100%), there are 112 (7 × 4 × 4) different waveform modes that could be used to send data via CLOVER. Once all of the determining factors are considered, however, there are eight different waveform combinations that are actually used for FEC and/or ARQ modes.

### 15.5.9 CLOVER-2000

CLOVER-2000 is a faster version of CLOVER (about four times faster) that uses eight tone pulses, each of which is 250 Hz wide, spaced at 250 Hz centers, contained within the 2 kHz bandwidth between 500 and 2500 Hz. The eight tone pulses are sequential, with only one tone being present at any instant and each tone lasting 2 ms. Each frame consists of eight tone pulses lasting a total of 16 ms, so the base modulation rate of a CLOVER-2000 signal is always 62.5 symbols per second (regardless of the type of modulation being used). CLOVER-2000's maximum raw data rate is 3000 bit/s.

Allowing for overhead, CLOVER-2000 can deliver error-corrected data over a standard HF SSB radio channel at up to 1994 bit/s, or 249 characters (8-bit bytes) per second. These are the uncompressed data rates; the maximum throughput is typically doubled for plain text if compression is used. The effective data throughput rate of CLOVER-2000 can be even higher when binary file transfer mode is used with data compression.

**Figure 15.10 — A frequency-domain plot of a CLOVER-II waveform.**

**Table 15.15**  
**Data Bytes Transmitted Per Block**

Block Size	Reed-Solomon Encoder Efficiency			
	60%	75%	90%	100%
17	8	10	12	14
51	28	36	42	48
85	48	60	74	82
255	150	188	226	252

**Table 15.16**  
**Correctable Byte Errors Per Block**

Block Size	Reed-Solomon Encoder Efficiency			
	60%	75%	90%	100%
17	1	1	0	0
51	9	5	2	0
85	16	10	3	0
255	50	31	12	0

The binary file transfer protocol used by HAL Communications operates with a terminal program explained in the HAL E2004 engineering document. Data compression algorithms tend to be context sensitive — compression that works well for one mode (say, text), may not work well for other data forms (graphics, for example). The HAL terminal program uses the PK-WARE compression algorithm, which has proved to be a good general-purpose compressor for most computer files and programs. Other algorithms may be more efficient for some data formats, particularly for compression of graphic image files and digitized voice data. The HAL Communications CLOVER-2000 modems can be operated with other data compression

algorithms in the users' computers.

CLOVER-2000 is similar to the previous version of CLOVER, including the transmission protocols and Reed-Solomon error detection and correction algorithm. The original descriptions of the CLOVER Control Block (CCB) and Error Correction Block (ECB) still apply for CLOVER-2000, except for the higher data rates inherent to CLOVER-2000. Just like CLOVER, all data sent via CLOVER-2000 is encoded as 8-bit data bytes and the error-correction coding and modulation formatting processes are transparent to the data stream — every bit of source data is delivered to the receiving terminal without modification.

Control characters and special "escape sequences" are not required or used by CLOVER-2000. Compressed or encrypted data may therefore be sent without the need to insert (and filter) additional control characters and without concern for data integrity. Five different types of modulation may be used in the ARQ mode — BPSM (Binary Phase Shift Modulation), QPSM (Quadrature PSM), 8PSM (8-level PSM), 8P2A (8PSM + 2-level Amplitude-Shift Modulation) and 16P4A (16 PSM plus 4 ASM).

The same five types of modulation used in ARQ mode are also available in Broadcast (FEC) mode, with the addition of 2-Channel Diversity BPSM (2DPSPM). Each CCB is sent using 2DPSPM modulation, 17-byte block size and 60% bias. The maximum ARQ data throughput varies from 336 bit/s for BPSM to 1992 bit/s for 16P4A modulation. BPSM is most useful for weak and badly distorted data signals, while the highest format (16P4A) needs extremely good channels, with high SNRs and almost no multipath.

Most ARQ protocols designed for use with HF radio systems can send data in only one direction at a time. CLOVER-2000 does not need an OVER command; data may flow in either direction at any time. The CLOVER ARQ time frame automatically adjusts to match the data volume sent in either or both directions. When first linked, both sides of the ARQ link exchange information using six bytes of the CCB. When one station has a large volume of data buffered and ready to send, ARQ mode automatically shifts to an expanded time frame during which one or more 255 byte data blocks are sent.

If the second station also has a large volume of data buffered and ready to send, its half of the ARQ frame is also expanded. Either or both stations will shift back to CCB level when all buffered data has been sent. This feature provides the benefit of full-duplex data transfer but requires use of only simplex frequencies and half-duplex radio equipment. This two-way feature of CLOVER can also provide a back-channel "order-wire" capability. Communications may be maintained in this chat mode at 55 WPM, which is more than adequate for real-time keyboard-to-keyboard communications.

More information can also be found at [www.arrrl.org/technical-characteristics](http://www.arrrl.org/technical-characteristics).

### 15.5.10 WINMOR

While the various PACTOR modes currently dominate and generally represent the best available performance HF ARQ protocols suitable for digital messaging, PC sound cards with appropriate DSP software can now begin to approach PACTOR performance. The WINMOR (Winlink Message Over Radio) protocol is an outgrowth of the work SCAMP (Sound Card Amateur Message Protocol) by Rick Muething, KN6KB. SCAMP put an ARQ "wrapper" around Barry Sanderson's RDFT (Redundant Digital File Transfer) then integrated SCAMP into a Client and Server for access to the Winlink message system. (More on Winlink in a later section.) SCAMP worked well on good channels but suffered from the following issues:

- The RDFT batch-oriented DLLs were slow and required frame pipelining, increasing complexity and overhead.
- RDFT only changed the RS encoding on its 8PSK multi carrier waveform to achieve a 3:1 range in speed/robustness which is not enough.
- RDFT was inefficient in Partial Frame recovery (no memory ARQ).
- RDFT was a 2.4 kHz mode and limited to narrow HF sub bands.
- SCAMP's simple multi-tone ACK/NAK did not carry session ID info, increas-

**Figure 15.11** — Spectra plots of AMTOR, HF packet-radio and CLOVER-II signals.

**Table 15.17**  
**WINMOR Development Guidelines**

*Absolute Requirements*

Work with standard HF (SSB) radios  
 Accommodate Automatic Connections  
 Error-free transmission and confirmation  
 Fast Lock for practical length ARQ cycles  
 Auto adapt to a wide range of changing channel conditions  
 Must support true transparent binary to allow attachments and compression  
 Must use loosely synchronous ARQ timing to accommodate OS and DSP demands

*Desirable Requirements*

Modest CPU & OS demands  
 Bandwidth options (200, 500, 3000 Hz)  
 Work with most sound cards/interfaces  
 Good bit/s/Hz performance ~ P2 goal  
 Efficient modulation and demodulation for acceptable ARQ latency  
 Selective ARQ & memory ARQ to maximize throughput and robustness.

Near Factor ARQ efficiency (~70% of raw theoretical throughput)

ing chances of fatal cross session contamination.

WINMOR is an ARQ mode generated from the ground up to address the limitations of SCAMP/RDFT and leverage what was learned. Today, a viable message system (with the need for compression and binary attachments) requires true “error-free” delivery of binary data. To achieve this there must be some “back channel” or ARQ so the receiving station can notify the sender of lost or damaged data and request retransmission or repair. **Table 15.17** outlines the guidelines used in the development of WINMOR.

Perhaps the most challenging of these requirements are:

- The ability to quickly tune, lock and acquire the signal which is necessary for practical length ARQ cycles in the 2-6 s range.
- The ability to automatically adapt the modulation scheme to changing channel conditions. An excellent example of this is Pactor III’s extremely wide range of speed/robustness (18:1) and is one reason it is such an effective mode in both good and poor channel conditions.

The most recent development effort has focused on 62.5 baud BPSK, QPSK and 16QAM and 31.25-baud 4FSK using 1 (200 Hz), 3 (500 Hz) and 15 (2000 Hz). With carriers spaced at twice the symbol rate. These appear to offer high throughput and robustness especially when combined with

multi-level FEC coding.

WINMOR uses several mechanisms for error recovery and redundancy.

- 1) FEC data encoding currently using:
  - 4,8 Extended Hamming Dmin = 4 (used in ACK and Frame ID)
  - 16-bit CRC for data verification
- Two-level Reed-Solomon (RS) FEC for data:
  - First level Weak FEC, for example RS 140,116 (corrects 12 errors)
  - Second level Strong FEC, for example RS 254,116 (corrects 69 errors)
- 2) Selective ARQ. Each carrier’s data contains a Packet Sequence Number (PSN). The ACK independently acknowledges each PSN so only carriers with failed PSNs get repeated. The software manages all the PSN accounting and re-sequencing.
- 3) Memory ARQ. The analog phase and amplitude of each demodulated symbol is saved for summation (phasor averaging) over multiple frames. Summation is cleared and re-started if max count reached. Reed-Solomon FEC error decoding done after summation.
- 4) Multiple Carrier Assignment (MCA). The same PSN can be assigned to multiple carriers (allows tradeoff of throughput for robustness). Provides an automatic mechanism for frequency redundancy and protection from interference on some carriers.
- 5) Dynamic threshold adjustment (used on QAM modes) helps compensate for fading which would render QAM modes poor in

fading channels.

In trying to anticipate how WINMOR might be integrated into applications they came up with a “Virtual TNC” concept. This essentially allows an application to integrate the WINMOR protocol by simply treating the WINMOR code as just another TNC and writing a driver for that TNC. Like all TNCs there are some (<10) parameters to set up: call sign, timing info, sound card, keying mechanism, etc. A sample image of the virtual TNC appears in **Figure 15.12**.

The WINMOR software DLL can even be made to appear as a physical TNC by “wrapping” the DLL with code that accesses it through a virtual serial port or a TCP/IP port. Like a physical TNC WINMOR has a “front panel” with flashing lights. But since operation is automatic with no front panel user interaction required the WINMOR TNC can be visible or hidden.

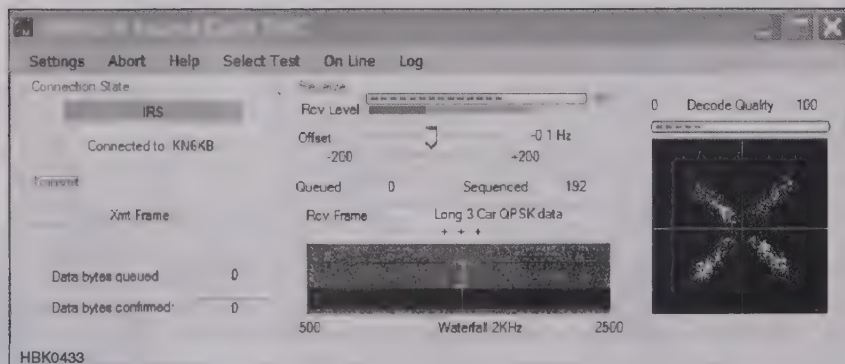

WINMOR looks promising and the testing to date confirms:

- Sound card ARQ is possible with a modern CPU and OS while making acceptable CPU processing demands. (CPU Loading of < 20% on a 1.5 GHz Celeron/Win XP)
- Throughput and robustness can be adjusted automatically to cover a wide range of bandwidth needs and channel conditions. (10:1 bandwidth range, 57:1 throughput range)
- ARQ throughput in excess of 0.5 bit/s/Hz is possible in fair to good channels (0.68 - 0.82 bit/s/Hz measured)
- Good ARQ efficiency — 70-75%
- Throughput is currently competitive with P2 and P3 and significantly better than P1

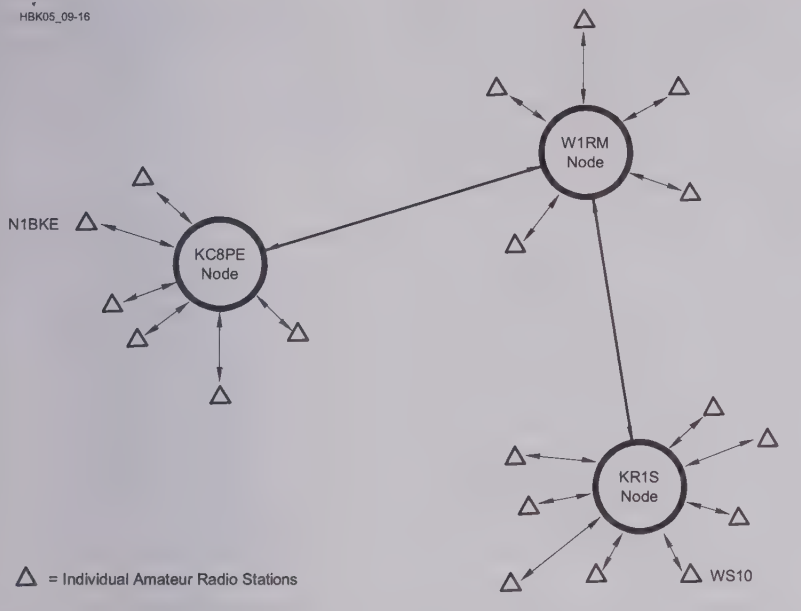

More information about WINMOR is available at [www.winlink.org/WinlinkExpress](http://www.winlink.org/WinlinkExpress).

**15.5.11 Packet Radio**

Amateur packet radio began in Canada after the Canadian Department of Communications permitted amateurs to use the mode in 1978. The FCC permitted amateur packet radio in the US in 1980. In the first half of the 1980s, packet radio was the habitat of a

**Figure 15.12** — WINMOR sound card TNC screen.

**Figure 15.13** — DX spotting clusters (based on *PacketCluster* software) are networks comprised of individual nodes and stations with an interest in DXing and contesting. In this example, N1BKE is connected to the KC8PE node. If he finds a DX station on the air, he'll post a notice — otherwise known as a spot — which the KC8PE node distributes to all its local stations. In addition, KC8PE passes the information along to the W1RM node. W1RM distributes the information and then passes it to the KR1S node, which does the same. Eventually, WS10 — who is connected to the KR1S node — sees the spot on his screen. Depending on the size of the network, WS10 will receive the information within minutes after it was posted by N1BKE. Many such networks can also be found on the web or are accessible by the use of *TELNET* software.

small group of experimenters who did not mind communicating with a limited number of potential fellow packet communicators. In the second half of the decade, packet radio took off as the experimenters built a network that increased the potential number of packet stations that could intercommunicate and thus attracted tens of thousands of communicators who wanted to take advantage of this potential.

Packet radio provides error-free data transfer via the AX.25 protocol. The receiving station receives information exactly as the transmitting station sends it, so you do not waste time deciphering communication errors caused by interference or changes in propagation. This simplifies the effort required to build other protocols or applications on top of packet technology since much of the data transfer work is handled seamlessly by the TNC in the lower layers. There are a number of other advantages to the packet radio design:

- Packet uses time efficiently, since packet bulletin-board systems (PBBs) permit packet operators to store information for later retrieval by other amateurs.

- Packet uses the radio spectrum efficiently, since one radio channel may be used for

multiple communications simultaneously, or one radio channel may be used to interconnect a number of packet stations to form a "cluster" that provides for the distribution of information to all of the clustered stations. The DX PacketCluster nodes are typical examples (see **Figure 15.13**). Each local channel may be connected to other local channels to form a network that affords interstate and international data communications. This network can be used by interlinked packet bulletin-board systems to transfer information, messages and third party traffic via HF, VHF, UHF, satellite and the Internet.

- Packet uses other stations efficiently, since any packet-radio station can use one or more other packet-radio stations to relay data to its intended destination.

- Packet uses current station transmitting and receiving equipment efficiently, since the same equipment used for voice communications may be used for packet communications. The outlay for the additional equipment necessary to add packet capability to a voice station may be less than \$100.

## DIGIPEATERS

A *digipeater* is a packet-radio station capable of recognizing and selectively repeat-

ing packet frames. An equivalent term used in the network industry is *bridge*. Virtually any TNC can be used as a single-port digipeater, because the digipeater function is included in the AX.25 Level 2 protocol firmware. The digipeater function is handy when you need a relay and no node is available, or for on-the-air testing. Digipeaters are used extensively with APRS (Automatic Packet Reporting System) covered below.

## TCP/IP

Despite its name, TCP/IP (Transmission Control Protocol/Internet Protocol) is more than two protocols; it's actually a set of several protocols. TCP/IP provides a standardized set of protocols familiar to many and compatible with existing network technologies and applications. TCP/IP has a unique solution for busy networks. Rather than transmitting packets at randomly determined intervals, TCP/IP stations automatically adapt to network delays as they occur. As network throughput slows down, active TCP/IP stations sense the change and lengthen their transmission delays accordingly. As the network speeds up, the TCP/IP stations shorten their delays to match the pace. This kind of intelligent network sharing virtually guarantees that all packets will reach their destinations with the greatest efficiency the network can provide.

With TCP/IP's adaptive networking scheme, you can chat using the TELNET protocol with a ham in a distant city and rest assured that you're not overburdening the system. Your packets simply join the constantly moving "freeway" of data. They might slow down in heavy traffic, but they will reach their destination eventually. This adaptive system is used for all TCP/IP packets, no matter what they contain.

TCP/IP excels when it comes to transferring files from one station to another. By using the TCP/IP File Transfer Protocol (FTP), you can connect to another station and transfer computer files — including software. As might be imagined, transferring large files can take time. With TCP/IP, however, you can still send and receive mail (using the SMTP protocol) or talk to another ham while the transfer is taking place.

When you attempt to contact another station using TCP/IP, all network routing is performed automatically according to the TCP/IP address of the station you're trying to reach. In fact, TCP/IP networks are transparent to the average user. To operate TCP/IP, all you need is a computer, a 2 meter FM transceiver and a TNC with KISS (keep it simple, stupid) capability. As you might guess, the heart of your TCP/IP setup is software. The TCP/IP software set was written by Phil Karn, KA9Q, and is called NOSNET or just NOS for short. There are dozens of NOS derivatives available

today. All are based on the original NOSNET. NOS takes care of all TCP/IP functions, using your “KISSable” TNC to communicate with the outside world. The only other item necessary is your own IP address in Network 44, termed AMPRNet (AMateur Packet Radio Network). Individual IP Address Coordinators assign addresses to new TCP/IP users in the 44.x.x.x subnet based on physical location worldwide. Your local coordinator can be found on AMPR.org on the list at [portal.ampr.org/networks.php](http://portal.ampr.org/networks.php).

More packet information can be found in the annual ARRL/TAPR Digital Communications Conference proceedings and on the TAPR (Tucson Amateur Packet Radio) website at [www.tapr.org](http://www.tapr.org). TAPR also maintains the AX.25 protocol specification at [www.tapr.org/pub\\_ax25.html](http://www.tapr.org/pub_ax25.html).

### 15.5.12 APRS

APRS ([aprs.org](http://aprs.org)) was developed by Bob Bruninga, WB4APR, for tracking and digital communications with mobile GPS equipped stations with two-way radio. APRS is different from regular packet in four ways:

- Integration of maps and other data displays to organize and display data
- By using a one-to-many protocol to update everyone in real time
- By using generic digipeating so that prior knowledge of the network is not required
- Provides worldwide transparent Internet backbone, linking everyone worldwide

APRS turns packet radio into a real-time tactical communications and display system for emergencies, public service applications and global communications. Normal packet radio has shown usefulness in passing bulk message traffic (e-mail) from point to point. It has been difficult to apply conventional packet to real time events where information has a very short life time and needs to get to everyone.

The APRS network consists of five types of APRS stations:

- Basic — Full transmit and receive capability
- Tracker — Transmit-only device (portable or weather station)
- RELAY — Provides basic digipeating
- WIDE — Dedicated digipeaters with special coverage areas
- IGate — Internet gateways to repeat APRS packets to servers on the Internet

APRS stations are generally set to beacon their position and other information at frequent intervals. Fixed stations don't require a GPS and should beacon infrequently to avoid crowding the channel with needless reports. Moving mobile stations can receive their coordinates from a GPS and should report more frequently. More sophisticated APRS devices support “smart beaconing” and “corner pin-

ning” where a station will beacon more frequently when it moves faster or automatically beacon when changing direction more than a predefined angle. An APRS beacon will generally contain a call sign with *Secondary Station ID (SSID)*, position report (lat/long), heading, speed, altitude, display icon type, status text and routing information. It may also contain antenna/power information, weather data or short message data.

Call signs generally include an SSID that historically provided information about the type of station. For example, a call sign of N7SS-9 would generally indicate a mobile station. Since there are several systems in use, the SSID information is not definitive. Recently a number of dedicated APRS radios have appeared that feature an internal TNC and APRS software. These radios include a method of displaying and entering messages without requiring the use of a computer meaning their user can directly respond to a message sent. There is value in knowing someone can respond and it is recommended they use an SSID of -7. Tactical call signs can also be used if the assigned call sign is included as part of the status text.

The APRS packet includes PATH information that determines how many times it should be digipeated. A local group should be able to offer guidance on how the PATH should be set to not overload the local network. Listening to squawking signals on the national APRS frequency of 144.390 MHz will provide some idea how busy the channel is. In much of the country the APRS network is well developed and a beacon doesn't need more than a couple hops to cover a wide area and find an IGate.

### APRS SOFTWARE

There is APRS software available for most any platform with varying levels of support. Some of the most common are DOSAPRS (DOS), WinAPRS / APRS+SA / APRSPoint / UI-View (*Windows*), MacAPRS (Macintosh), PocketAPRS (Palm devices), APRScE (*Windows CE devices*) and Xastir / X-APRS (*Linux*). Because APRS beacons find their way to the Internet via IGates, it is also possible to track station or view the network online. There is a good network view available at [aprs.fi](http://aprs.fi) and individual station information can be found at [map.findu.com/](http://map.findu.com/)[call sign to be tracked]. The [Findu.com](http://Findu.com) site also offers historical weather data, a message display and a large list of other queries.

### APRS INTEGRATION WITH OTHER TECHNOLOGIES

APRS is very similar to the AIS (*Automatic Identification System*) used to track ships in coastal waters. The AIS transponder equipment is becoming more common in commercial ships and private vessels. The

AIS information can be displayed simultaneously with APRS data on the [aprs.fi](http://aprs.fi) website. More information about AIS can be found at [en.wikipedia.org/wiki/Automatic\\_Identification\\_System](http://en.wikipedia.org/wiki/Automatic_Identification_System).

APRS RF networks worldwide are interconnected via APRS-IS. APRS-IS is an ad hoc network of Amateur Radio servers, gateways (IGates), and clients (display software). APRS-IS facilitates world-wide messaging without having to define special paths. Because all clients have access to all gated packets, databases such as [aprs.fi](http://aprs.fi) and [findu.com](http://findu.com) can store and parse the packets for later retrieval from browsers and other clients. APRS-IS messaging support allows many interfaces for the RF ham running an APRS client such as call sign lookups, e-mail, and calling CQ world-wide. More information on many of these features can be found at [www.aprs-is.net](http://www.aprs-is.net).

APRS position reports are also available from GPS-equipped D-STAR radios via DPRS gateways (more on D-STAR in a later section). The DPRS specification defines how to translate the continuous stream of GPS position reports in the D-STAR DV stream to individual APRS packets. This definition restricts the number of APRS packets generated to prevent overrunning a local RF network because the D-STAR radios continuously stream new position reports while the user is talking. Most D-STAR repeaters have DPRS IGates running on the gateway providing the D-STAR radio positions to APRS-IS. Those positions can be gated to local RF by APRS IGates if the APRS IGate sysop enables this feature.

Keith Sproul, WU2Z, operates an e-mail gateway that allows APRS messages to be converted to short e-mail or text messages. When entering a message, E-MAIL is used for the destination address. The message body must then contain the actual e-mail address followed by a space and very short message. If the message is picked up by an IGate it will be sent to the WU2Z mail server and out to the recipient, with a confirmation APRS message. For dozens of other messaging options, check online at [aprs.org/aprs-messaging.html](http://aprs.org/aprs-messaging.html).

There is connectivity between APRS and the Winlink system via APRSLink. APRSLink monitors all APRS traffic gated to the Internet, worldwide, and watches for special commands that allow APRS users to:

- Read short e-mail messages sent to their call sign@winlink.org
- Send short e-mail messages to any valid e-mail address or Winlink user
- Perform e-mail related maintenance (see commands below)
- Be notified of pending Winlink e-mail via APRS message

• Query APRSLink for information on the closest Winlink RMS packet station

Attention must be paid to the APRS traffic generated when using these features but they can be very handy. Details on the APRSLink system are available at [www.winlink.org/aprslink](http://www.winlink.org/aprslink).

### 15.5.13 Winlink

Winlink is a worldwide radio messaging system that takes advantage of the Internet where possible. It does this in order to allow the end-user more radio spectrum on the crowded spectrum. The system provides radio interconnection services including: e-mail with attachments, position reporting, graphic and text weather bulletins, emergency / disaster relief communications, and message relay. The PACTOR-I, II, and III protocols are used on HF, and AX.25 Packet, D-STAR and 802.11 are used on VHF/UHF.

Winlink has been assisting the maritime and RV community around the clock for many years. More recently there has been an increasing interest in emergency communications (emcomm), and the Winlink development team has responded by adding features and functions that make the system more reliable, flexible and redundant. The role of Winlink in emergency communications is to supplement existing methodologies to add another tool in the toolkit of the volunteer services deploying emergency communications in their communities.

The Winlink system is a “star” based network containing five mirror-image, redundant Common Message Servers (CMS) located in San Diego (USA), Washington DC (USA), Vienna (Austria), Halifax (Canada) and Perth (Australia). These ensure that the system will remain in operation should any piece of the Internet become inoperative. Each Radio Message Server node (RMS) is tied together as would be the ends of a spoke on a wheel with the hub function performed by the Common Message Servers. Traffic goes in and out between the CMS and the Internet e-mail recipient, and between the end users and the Radio Message Server (RMS) gateways. Multiple radio-to-radio addresses may be mixed with radio-to-Internet e-mail addresses, allowing complete flexibility.

Because each Radio Message Server gateway is a mirror image of the next, it does not matter which station is used. Each can provide over 700 text-based or graphic weather products, and each can relay the user’s position to a web-based view of reporting users and interoperates with the APRS system.

One of the most important objectives in the eyes of the Winlink development team was to reduce the use of the HF spectrum to only that

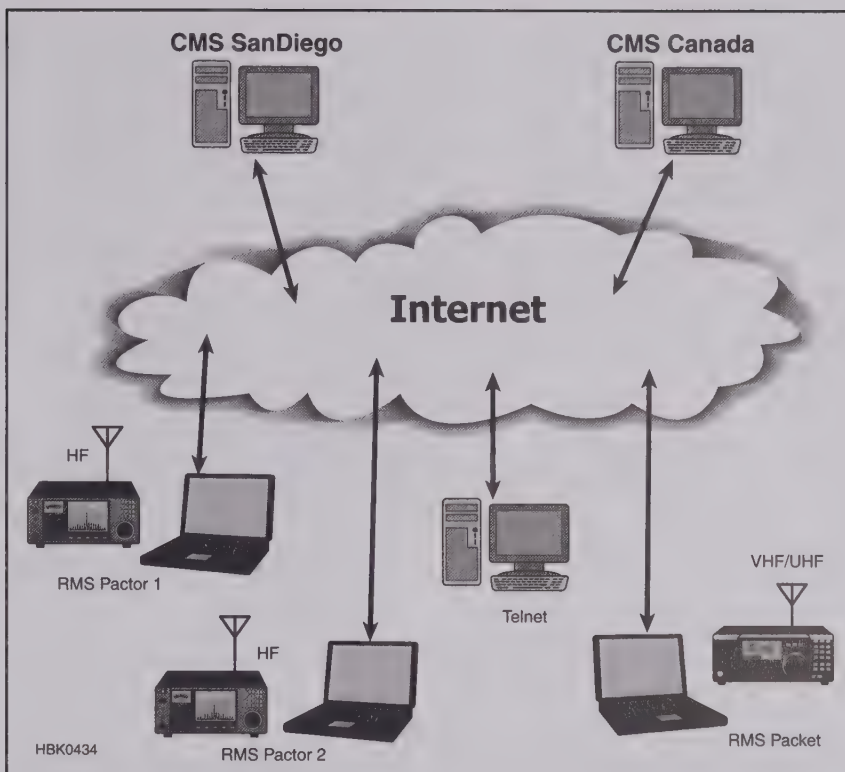

Figure 15.14 — Winlink system.

required to exchange messages with a user, and to do that at full “machine” speeds. The HF spectrum is very crowded, and limiting the forwarding of messages between Winlink RMS stations to the Internet, a great deal of radio air time is eliminated, making the time and spectrum available to individual users either for message handling or for other operations. A number of the RMS PACTOR servers found on HF restrict their protocols to PACTOR II (400 to 800 bit/s) and PACTOR III (1400 to 3600 bit/s.) In doing so, these RMS stations typically have a much higher ratio of traffic minutes and message counts to connect times than do the RMS stations that also receive the slower PACTOR I (100 to 200 bps) protocol. In other words, the amount of traffic that is passed with an Express station is much greater for an equivalent amount of connect time with approximately the same number of connections. On average, this translates to a PACTOR I station downloading an 80,000 byte file in approximately 80 minutes while on PACTOR III, the same download takes approximately six minutes. Note that PACTOR IV is not yet legal for US amateurs as discussed earlier in the PACTOR section.

The RMS servers provide endpoint connectivity to users via HF or VHF and can be found worldwide. When connecting via the Internet, users can connect directly to the CMS server operational closest to them via

TELNET. Formerly, the full-featured message servers on HF were known as PMBOs (Participating Mail Box Offices) and there was a packet radio to TELNET bridge component for VHF/UHF called Telpac. These have been replaced with the newer RMS PACTOR (HF) and RMS Packet (VHF/UHF) software although the older terms are still in use. Over the air, PACTOR is used on HF, AX.25 packet on VHF/UHF and both employ the B2F compressed binary format to maximize transmission efficiency. A diagram of the Winlink architecture is shown in Figure 15.14.

#### CLIENT ACCESS TO WINLINK

The primary purpose of the Winlink network system is to assist the mobile or remotely located user and to provide emergency e-mail capabilities to community agencies. Because of this, Winlink supports a clean, simple interface to the Internet SMTP e-mail system. Any message sent or received may include multiple recipients and multiple binary attachments. The radio user’s e-mail address, however, must be known to the system as a radio user or the message will be rejected. This simple Internet interface protocol has an added benefit in case of an emergency where local services are interrupted and the system must be used by non-Amateur groups as an alternative to normal SMTP e-mail.

Connecting to any one of the Winlink publicly-used RMS Packet stations via HF

or the specialized non-public emcomm RMS stations, can immediately and automatically connect a local amateur station to the Internet for emergency traffic. Using a standard SMTP e-mail client, the *Paclink* mini-e-mail server can replace a network of computers (behind a router) as a transparent substitute for normal SMTP mail. Winlink uses no external source for sending or receiving Internet e-mail. It is a stand-alone function which interacts directly with the Internet rather than through any external Internet service provider.

*Airmail* is independently developed, distributed and supported by Jim Corenman, KE6RK. It is the oldest and most widely used program for sending and receiving messages using the Winlink system. Airmail may be used for HF Pactor, VHF/UHF Packet, and for TELNET connections over any TCP/IP medium including the Internet and high-speed radio media, such as D-STAR and HSM. Once connected to a Winlink station, message transfer is completely automatic. On the ham bands, Airmail can transfer messages automatically with any station supporting the BBS or F6FBB protocols, such as Winlink, F6FBB, MSYS and other Airmail stations. When used with Winlink, Airmail also contains position reporting capabilities, and a propagation prediction program to determine which of the participating Winlink stations will work from anywhere on Earth. Airmail also contains a limited mail server that allows it to host e-mail independently from the Winlink network.

To obtain a copy of Airmail, including the installation and operating instructions, download the program from the Airmail web page at [www.siriuscyber.net/ham](http://www.siriuscyber.net/ham).

When an RF connection is not available (or necessary) but web access is available, Winlink messages can be retrieved or sent via a web interface. The web browser access is limited to text-based messages without the use of bulletins or file attachments. Password-protected access to the Winlink mailbox is available through the Winlink page at [www.winlink.org/webmail](http://www.winlink.org/webmail). There is also a terminal mode for interactive keyboard commands, allowing a terminal rather than computer-based software to connect to an RMS via RF. Because of the inefficient use of airtime, this method is discouraged but may be used for the listing and deletion of messages only.

Airmail provides a super-fast replica of Winlink radio operations while directly connected through the Internet to one of the CMS servers. This method of obtaining messages over the Internet allows multiple attachments, catalog bulletins, and all other Winlink services normally available over radio channels, but at Internet speeds. In order to use this service, a user must currently be listed as a radio user, and obtain the connection information for the closest CMS server. Both

Paclink and Airmail support the TELNET client service. This operation allows regular use of the system with the same software configuration at high speed, without using RF bandwidth and provides a full-featured mechanism to access the system where no RF connection is available. An Emergency Operations Center with Internet access can use the TELNET path with RF as a fallback with just a minor change in the software. Similarly, an RV or marine user can use the software from an Internet café or home via TELNET and switch the software back to the TNC when mobile, with no change in functionality.

## WINLINK FEATURES

To address the needs of mobile users for near real-time data, Winlink uses an “on-demand” bulletin distribution mechanism. (Note that such bulletins are not the same as traditional AX.25 Packet Bulletins.) Users must first select requested bulletins from an available “catalog” list managed in Airmail. When bulletin requests are received by an RMS station, a fresh locally cached copy of the requested bulletin is delivered. If no fresh locally-cached version is available, the RMS accesses the Internet and finds the bulletin which is then downloaded to the RMS and then sent to the user. The global catalog currently includes over 700 available weather, propagation, and information bulletins, including, instructions for using the system, World news, and piracy reports. All Winlink RMS stations support a single global catalog which ensures users can access any bulletin from any RMS. Bulletins can contain basic text, graphic fax or satellite images, binary or encoded files like GRIB or WMO weather reports. Local processing is used to re-process images to sizes suitable for HF Pactor transmission. The system prevents bulletin duplication and automatically purges obsolete time-sensitive weather bulletins and replaces them with the current version.

The system also has the ability to contain bulletins with attachment information which is local to each RMS. This is especially useful for the non-public emcomm RMS which may house valuable procedural information pertinent to complex information or instruction needed by specific agencies in any community emergency.

Multiple binary or text-based file attachments of any type or number may be attached to a message by simply selecting the file to be sent from a *Windows* selection dialog in the user’s HF AirMail or the Winlink VHF/UHF Paclink server with a standard SMTP e-mail client. E-mail message attachments sent through the Winlink system must be limited in size. Users are provided an option to allow this limit to be determined. When using the default B2F format, the protocol chosen by

the user usually determines the file size of an attachment. A user may also turn off the ability to receive file attachments. Certain file attachment types are blocked from the system for the protection of the user from virus attacks.

The Winlink network administrator may post notices that are delivered to all individual Winlink users as a private message. This is a valuable tool for notifying users of system changes, outages, software upgrades, emergencies, etc.

The integrated nature of the system makes possible other services beyond just simple messaging. The bulletin services mentioned above is beyond normal messaging, but Winlink also provides rapid position reporting from anywhere in the world. This facility is interconnected with the APRS, ShipTrak, and YotReps networks. It supports weather reporting from cruising yachts at sea and an interconnection with the YotReps network which is used by government forecasters for weather observations in parts of the world where no others are available. It also allows the maritime user to participate in the National Weather Service’s NOAA MAROB a voluntary marine observation reporting program.

To ensure equitable access to the system individual users are assigned daily time limits on HF frequencies by RMS sysops. The default time per any 24-hour period is 30 minutes, however, the user may request more time from the RMS sysop should it be needed. The time limit is individual to each RMS station. Utilization of the PACTOR-II and PACTOR-III protocols are a great timesaver, allowing the user up to 18 times the volume of messages over that of PACTOR-I for the same period of time.

The system has a number of other secondary features to help keep it healthy. Extensive traffic reports are collected, the state of individual RMS stations are monitored and reported if it becomes inactive and daily backups are performed automatically at all RMS stations as well as the Common Message Servers to ensure the system integrity. Security is ensured through the vigorous updating of virus definitions and automatic virus screening for all Internet mail and files. The system has the ability to block any user by both radio (by frequency band) and Internet (by e-mail address) to prevent abuse of the system. Spam is controlled through the use of a secure “acceptance list” or “white list” methodology. More information about the Winlink system is available on the Winlink website at [www.winlink.org](http://www.winlink.org).

## 15.5.14 D-STAR

D-STAR (Digital Smart Technologies for Amateur Radio) is a digital voice and data protocol specification developed as the result

of research by the Japan Amateur Radio League (JARL) to investigate digital technologies for Amateur Radio in 2001. While there are other digital on-air technologies being used by amateurs that were developed for other services, D-STAR is one of the first on-air protocols to be widely deployed and sold by a major radio manufacturer that is designed specifically for amateur service use. D-STAR transfers both voice and data via a data stream over the 2 meter (VHF), 70 cm (UHF) and 23 cm (1.2 GHz) Amateur Radio bands either simplex or via repeater.

One of the interesting features about the D-STAR protocol is the fact the system uses Amateur Radio call signs not only as an identifier, but also for signal routing. In the most common configuration, the most vital part of a D-STAR system is the gateway server, which networks a single system into a D-STAR network via a *trust server*. The trust server provides a central, master database to look up users and their associated system. This allows Amateur Radio operators to respond to calls made to them, regardless of their location on the D-STAR network. While almost all documentation references the Internet as the connection point for a network, any IP network connectivity will work, depending on signal latency. Currently, the global D-STAR trust server is maintained by a group of dedicated D-STAR enthusiasts from Dallas, Texas — the Texas Interconnect Team.

The D-STAR protocol specifies two modes; Digital Voice (DV) and Digital Data (DD). In the protocol, the DV mode provides both voice and low speed data channel on 2 meters, 70 cm and 23 cm over a 4800-bit/s data stream. In the protocol, the DV mode uses a data rate of 4800 bit/s. This data stream is broken down to three main packages: voice, forward error correction (FEC) and data. The largest portion of the data stream is the voice package, which is a total of 3600 bits/s with 1200 bit/s dedicated to forward error correction, leaving 1200 bit/s for data. This additional data contains various data flags as well as the data header, leaving about 950 bit/s available for either GPS or serial data. This portion of the data stream does not provide any type of error correction, which has been overcome by implementing error correction in the application software.

While there are various techniques of encoding and transporting a DV signal, the focus of D-STAR's design was the most efficient way to conserve RF spectrum. While D-STAR's "advertised" occupied bandwidth is 6.25 kHz, tests reveal a band plan of 10 kHz spacing is adequate to incorporate the D-STAR signal as well as provide space for channel guards.

In addition to DV mode, the D-STAR protocol outlines the high speed Digital

Figure 15.15 — Full D-STAR system.

Data (DD) mode. This higher speed data, 128 kbit/s, is available only on the 23 cm band because it requires an advertised 130 kHz bandwidth, only available at 23 cm in world-wide band plans. Unlike the DV mode repeaters, the DD mode module operates as an "access point" operating in half duplex, switching quickly on a single channel.

As with the DV mode, there is a portion of the data stream used for signal identification with the data header as well as various system flags and other D-STAR related items. Once this portion of the data stream is taken into consideration, the 128 kbit/s is reduced to approximately 100 kbit/s — still more than double a dial-up connection speed with significant range. Another consideration is the data rate specified at 128 kbit/s is the gross data rate. Therefore, the system developers are challenged by the area coverage/potential user issue. This means the higher the elevation of the system, the more potential users and the slower the system will become as all the users split the data bandwidth. Finally, there is an issue from the days of packet radio. While technically, the opportunity for "hidden transmitter" issues does exist and collisions do occur, the TR switching is very fast and this effect is handled by TCP/IP as it is for WiFi access points.

The simplex channel eliminates the need for duplexers at a repeater site if only the DD mode system is installed. It is still recommended to have filtering, such as a band-pass filter, in place to reduce possible interference from other digital sources close to the 23 cm band as well as to reduce RF overload from nearby RF sources. While some DD mode system owners would like more sensitivity or more output power (10 W), at the time of print, no manufacturer has developed pre-amps or

RF power amplifiers with an adequate TR switching time to boost the signals.

Radios currently providing DV mode data service use a serial port for low-speed data (1200 bit/s), while the DD mode radio offers a standard Ethernet connection for high-speed (128 kbit/s) connections, to allow easy interfacing with computer equipment. The DD mode Ethernet jack allows two radios to act as an Ethernet bridge without any special software support required. This allows standard file sharing, FTP, TELNET, HTTP/web browsing, IRC chat or even remote desktop connections to function as if connected by wire.

In a Gateway configuration, *all* users must be registered in the network. This provides the DD mode sysop a layer of authorization, meaning that if someone wants to use a DD mode system, and they have not received authorization to use the gateway, their DD mode access will be denied. Any gateway registered user, on the common network, can use any DD mode system, even if the registration was not made on that system. While we are not able to use encryption in the Amateur Radio service, security can be implemented in standard software or consumer routers and firewalls.

A D-STAR repeater system consists of at least one RF module and a controller. While any combination of RF modules can be installed, typically a full system includes the three voice modules (2 meters, 70 cm and 23 cm) and the 23 cm DD mode module shown in Figure 15.15. A computer with dual Ethernet ports, running the Gateway software, is required for Internet access to the global network. An additional server, as shown in the diagram, can be incorporated for local hosting of e-mail, chat, FTP, web and other

services. In a D-STAR system installation, the standard repeater components (cavities, isolators, antennas and so forth) are not shown but are required as with any analog system. Some groups have removed analog gear and replaced it with D-STAR components on the same frequency with no additional work beyond connecting the power and feed lines. More information about D-STAR systems may be found in the **Repeaters** chapter and in the **Digital Communications** chapter with the downloadable supplemental content.

## USER-CREATED FEATURES AND TOOLS

D-STAR has already benefitted from a strong user community that has been developing applications, products and upgrades at a rapid pace. The *DPlus* gateway add-on provides a number of new features, such as an echo test, voicemail, simulcast to all modules, a linking feature, playback of voice or text messages and more. There are also a number of “D-STAR Reflectors” around the world that act like conference bridges for connecting multiple repeater systems.

One of the other projects that came from the Open D-STAR project is the DV Dongle by Robin Cutshaw, AA4RC. The DV Dongle contains the DSVI AMBE codec chip and a USB interface to allow a computer user to talk with other D-STAR voice users much the way EchoLink users can connect to the system with a PC. The DV Tool software is written in Java to provide cross-platform support. The DV Dongle is available at ham radio dealers and the latest software and manual can be downloaded from [www.opendstar.org/tools](http://www.opendstar.org/tools).

Pete Loveall, AE5PL, created a DPRS-to-APRS gateway that moves D-STAR GPS data to the APRS-IS network. Although it doesn’t natively appear on the APRS RF network (unless IGated specifically), it does appear in all the online APRS tools. DPRS has been implemented in software with *DStarMonitor* running on many D-STAR gateways and *DPRS Interface* available for most computers at [www.aprs-is.net/dprs](http://www.aprs-is.net/dprs). DPRS has been implemented in hardware with the  $\mu$ SmartDigi manufactured by Rich Painter, AB0VO. The  $\mu$ SmartDigi offers a compact, portable TNC designed to act as a gateway for position packets between a D-STAR digital network and a conventional analog APRS RF network via a D-STAR radio and a conventional FM radio. More DPRS and  $\mu$ SmartDigi information is available at [www.aprs-is.net/dprs](http://www.aprs-is.net/dprs) and [www.usmartdigi.com](http://www.usmartdigi.com) respectively.

Satoshi Yasuda, 7M3TJZ/AD6GZ, created a D-STAR node adapter or “hot spot” that connects to a standard simplex FM radio and allows a D-STAR radio user to access

the D-STAR network. The system requires the FM rig be accurately configured for a clean signal and loses the D-STAR benefit of only consuming 6.25 kHz of bandwidth. It does allow D-STAR users access to the network via RF where there is Internet access and no repeater infrastructure available. More information can be found online at [d-star.dyndns.org/rig.html.en](http://d-star.dyndns.org/rig.html.en).

Dan Smith, KK7DS developed D-RATS with public service users in mind. In addition to chat, D-RATS supports file/photo downloads bulletins, forms, email and a sophisticated mapping capability. It also has a “repeater” functionality that allows sharing a D-STAR radio data stream over a LAN. The repeater feature is interesting in an environment where the radio would be physically separated from the software user, like in an emergency operations center. Dan has current developments and downloads available at [www.d-rats.com/wiki](http://www.d-rats.com/wiki).

This is just a sample of the development taking place and there will undoubtedly be more applications coming as the user base increases. The two websites with the most current D-STAR information are [www.dstarinfo.com](http://www.dstarinfo.com) and [www.dstarusers.org](http://www.dstarusers.org).

## 15.5.15 APCO Project 25 (P25)

Project 25 (P25) or APCO-25 is a suite of standards for digital radio communications for use by public safety agencies in North America. P25 was established by Association of Public-Safety Communications Officials (APCO) to address the need for common digital public safety radio communications standards for first responders and Homeland Security/Emergency Response professionals. In this regard, P25 fills the same role as the European Tetra protocol, although not interoperable with it.

P25 has been developed in phases with Phase 1 completed in 1995. P25 Phase 1 radio systems operate in 12.5 kHz analog, digital or mixed mode. Phase 1 radios use Continuous 4-level FM (C4FM) modulation for digital transmissions at 4800 baud and two bits per symbol, yielding 9600 bit/s total channel throughput. In the case of data transmission, data packets basically consist of a header, containing overhead information, followed by data. In the case of digitized voice transmission, after the transmission of a header containing error protected overhead information, 2400 bit/s is devoted to periodically repeating the overhead information needed to allow for late entry (or the missed reception of the header).

After evaluating several candidates, Project 25 selected the IMBE (Improved MultiBand Excitation) vocoder from DSVI for phase 1, operating at 4400 bit/s. An additional 2800

bit/s of forward error correction is added for error correction of the digitized voice. An 88.9-bit/s low-speed data channel is provided in the digitized voice frame structure and several forms of encryption are supported.

P25 Phase 2 requires a further effective bandwidth reduction to 6.25 kHz by operating as two-slot TDMA (Time Division Multiple Access) with support for trunking systems. This provides two channels from the same 12.5 kHz spectrum when working through a repeater to provide time synchronization. The TDMA timing requirements does limit range to a published 35 km but this is plenty for public safety users. It uses the newer AMBE (Advanced MultiBand Excitation) codec from DSVI to accommodate the bit rate reduction to 4800 bit/s. Phase 2 radios will still offer backward compatibility with Phase 1. Phase 3 work has started and will support access to the new 700 MHz band in the US.

P25 radios offer a number of features of interest to public service agencies such as an emergency mode, optional text messaging, over the air programming/deactivation. More P25 information can be found at [www.apointl.org/spectrum-management/resources/interoperability/p25.html](http://www.apointl.org/spectrum-management/resources/interoperability/p25.html).

## 15.5.16 Yaesu System Fusion

Yaesu released a specification for System Fusion in 2013, becoming the most recent DV methodology. System Fusion supports digital voice and data in a 12.5 kHz narrow-band channel at 9600 bps, using C4FM modulation over VHF (144-148 MHz) and UHF (440-450 MHz). System Fusion supports three modes of operation: voice full rate (Voice FR) mode, data full rate (Data FR) mode, or voice/data (V/D) mode. Voice FR mode is typically displayed on System Fusion transceivers as “VW” with voice/data mode appearing as “DN.” The two full rate modes use the entire 9600 bps channel for their respective voice or data payloads, whereas the V/D mode splits the channel into two 4800 bps payloads, with voice information on one and data on the other.

The voice modes also include robust forward error correction (FEC) and utilize the AMBE+2 (Advanced MultiBand Excitation) CODEC from DSVI. In V/D mode, the voice and FEC data use the AMBE+2 “Enhanced Half-Rate” mode where voice and FEC payloads consume individual 3600 bps totals, with header, synchronization, and routing data consuming much of the remainder of the 4800 bps available. The data component of the V/D mode can be used for features like GPS information, in order to provide APRS-like functionality. The Voice FR mode encodes using the AMBE+2 “Enhanced Full-

Rate” mode, where voice information and FEC consume 7200 bps. The Voice FR mode provides the highest quality voice exchange.

Each transmission comprises 960 byte (100 ms) packets. Each transmission begins with a header packet (HC), followed by communication channel packets (CC), and ends with a terminator packet (TC). The HC and TC packets synchronization information, source, and destination call signs, plus uplink and downlink call signs, as used for routing. In the V/D mode, each of the CC packets contain 40 bytes of frame sync, then 200 bytes of frame information, followed by 72 bytes of interleaved voice and data frames, for a total of 960 bytes. In the Voice FR mode, the first CC packet contains some overflow call sign information, but is generally segmented into 144 byte frames with voice information.

Yaesu repeaters offer the System Fusion environment with an “Automatic Mode Select” (AMS), operating in both FM analog and System Fusion digital modes. The repeaters can be configured in a combination of modes. While the repeaters are capable of operation in a purely analog mode, this prevents digitally equipped users from taking advantage of the enhancements that digital operation offers. With a similar discouragement toward digital enhancements, the repeaters can be configured in such a way as to allow analog or digital reception, but forcing the output to analog only. While this configuration allows both analog and digital users to coexist, it does so in a constrained fashion, negating the digital advantages of a white noise and hiss free experience, plus strips away GPS and call sign information. Operating in purely digital mode is also possible, offering enhancements for digital users, but effectively “locking out” analog FM operations, as with other DV methodologies. This is typically implemented when there is more than one System Fusion repeater operating in a given area.

More interesting (and common) is the hybrid AMS configuration, allowing analog FM in to analog FM out and digital in to digital out. In this configuration, analog users are not suddenly “disconnected” from a repeater and other analog-only capable operators. Also, digital users are free to take full advantage of the enhancements available with their transceivers. With the users’ System Fusion transceivers configured in AMS, digital users can hear an analog call placed on the repeater, in between transmission exchanges. The transceivers will switch to analog, automatically allowing them to communicate with the analog station. This furthers an environment of inclusion for both “camps” to enjoy and allows analog users to upgrade to System Fusion digital at a time of their choosing, rather than forcing a transition, all at once.

In order for analog FM transceivers to remain quiet during digital transmissions on the selected receive frequency, enabling the tone squelch feature to match the repeater’s transmitted continuous tone coded subaudible squelch (CTCSS) or digital coded squelch (DCS) signal, is required. Watching for a visual “channel busy” indicator on the analog users’ transceivers or enabling a Busy Channel Lockout feature will prevent accidental interference, when digital communications are taking place.

### 15.5.17 Digital Mobile Radio — DMR

Digital Mobile Radio (DMR) is a worldwide standard defined by the European Telecommunications Standards Institute (ETSI) based on Motorola MOTOTRBO and is used in commercial products from a number of manufacturers. Although the transmission fits in a standard 12.5 kHz-wide narrowband channel, it is structured as a two-time-slot Time Division Multiple Access (TDMA) so two channels fit in same the narrowband spectrum. This makes DMR ultra-narrowband compliant by providing the equivalent of two 6.25 kHz channels.

DMR uses C4FM modulation and the DVSI AMBE+2 codec to encode and decode the voice audio. Each TDMA time slot is 30 ms long with a 108-bit payload and 2.5 ms of guard time between the time slots. Since a user radio would only be transmitting using a single time slot, it has to be good quality for the transmitter to turn on and insure that its frequency settles during the guard time. It also means that the transmitter is only operating at 50% duty cycle, unlike an FM or FDMA-based digital mode transmitter. This translates to longer battery life on handheld units.

The timing is also critical and requires a time source. During simplex communications, the first transmitter becomes the time source and the repeater acts as a time source when the signal is retransmitted. The critical nature of this timing also limits the practical range of the system to about 50 miles. This is entirely acceptable for commercial communications where there is significant infrastructure but

may be an issue for long-range amateur use.

The original specification for DMR covered conventional simplex or repeater operation. In 2013 the specification for trunked operation was approved. It also features the ability to link repeater sites over the Internet using IP (Internet Protocol), IP-addressable radios, and a beaconing capability to allow radios to scan and acquire new sites.

Like many digital modes, the DMR specification only covers the air interface to allow radios to interoperate over the air. It does not cover the network linking protocols so these are manufacturer-specific. Motorola’s IP SiteConnect system has been expanded by the use of a product called a c-Bridge by Rayfield Communications to allow many more linked systems and many more users. The ultimate limit may be more a practical one than physical. This has allowed the creation of two major Amateur Radio networks; DCI ([www.trbo.org](http://www.trbo.org)) and MARC ([www.dmr-marc.net](http://www.dmr-marc.net)) which are bridged.

The DMR networks generally reserve one time slot for local communications and the other is used for linked operations within a region, nationally or international. The trunked talk groups programmed into the radios determine which connections are used. This requires locating local programming information for the radio or a pre-existing programming template and each radio must be registered and authorized by the system. Details and the latest information are available online at the DCI and MARC websites. (See also the **Repeaters** chapter for information about DMR.)

### 15.5.18 High-Speed Multimedia (HSMM)

*The following material is excerpted from High-Speed Multimedia for Amateur Radio by Glen Popiel, KW5GP, and from the 2014 ARRL-TAPR Digital Communications Conference presentation “High-Speed Wireless Networking in the UHF and Microwave Bands” by David Bern, W2LNX, and Keith Elkin, KB3TCB. This section identifies certain key elements of the rapidly expanding Broadband-Hamnet family of network technologies. For detailed information, see the book by KW5GP.*

Currently, three primary technologies are used to implement Amateur Radio HSMM networks. HSMM is *high-speed multimedia* and covers a wide range of software and hardware components. Broadband-Hamnet (BBHN — [www.broadband-hamnet.org](http://www.broadband-hamnet.org)) and Amateur Radio Emergency Data Network (AREDN) technologies are used to create a peer-to-peer mesh topology, while HamWAN is used to implement a star topology. The GGHN and AREDN technologies use the 802.11g modulation method, while HamWAN uses the 802.11n-based MikroTik Nv2 modulation method. Both are TCP/IP-based, and you can provide the same applications and services regardless of which networking technology you choose to implement. Both also provide a means of connecting your HSMM network to the public Internet. The systems use commercial systems operating in the amateur allocations of microwave frequency bands as shown in **Table 15.18**.

Originally known as HSMM-Mesh, BBHN uses inexpensive, commercial off-the-shelf (COTS) Linksys and Ubiquiti wireless routers. The firmware in the routers is replaced to become a fully functional node in a peer-to-peer mesh topology network. The router is configured to only connect to other BBHN devices using the same firmware. Non-amateur devices such as smartphones, tablets, and laptops can detect and display the BBHN network, they cannot connect to it. The system uses the Domain Name Server (DNS) system and also includes the station call sign in beacon packets to satisfy the FCC Part 97 requirements.

The AREDN development group is focused on developing software for the Ubiquiti series of wireless routes in HSMM networks. The current firmware includes Virtual Private Network (VPN) tunneling capability. AREDN is implemented based on the BBHN firmware and is self-discovering, self-configuring, and self-advertising with the same peer-to-peer mesh technology as BBHN. Both BBHN and AREDN are based on carrier-sense, multiple-access (CSMA) technology.

HamWAN is based on a star network topology, in which all of the user nodes (also known as client nodes) connect directly to

a central node, also known as a cell site or distribution node. The cell sites typically have a point-to-point link between other cell sites. The cell sites are linked together, forming the HamWAN network's backbone. HamWAN cell sites communicate over a dedicated link at 3.4 or 5 GHz. HamWAN client nodes use

MicroTik Nv2 command protocols, which allows time division multiple access (TDMA) technology. HamWAN also uses digital certificates to authenticate users.

Additional information on amateur high-speed multimedia networking is available in the referenced book and article (see the

book's online supplemental information) and at the following websites:

[www.aredn.org](http://www.aredn.org)  
[www.broadband-hamnet.org](http://www.broadband-hamnet.org)

[www.memHamWAN](http://www.memHamWAN)

## 15.6 Digital Mode Table

**Table 15.19** is a summary of common digital modes used by amateurs as of early 2013 and their primary characteristics. The following text is intended to make high-level comparisons. For more information on these modes see the earlier sections of this chapter. This table and a detailed listing showing the lowest permitted frequency for a number of digital mode variants are also available as a PDF file with the downloadable supplemental content.

Many modes have a number of variants, with the most common shown in the table. High reliability, low data rate modes are more common on HF. Higher data rates are available on VHF/UHF, where the bands have less noise and require less effort to

make them reliable. Some modes have very specific intended uses like the meteor scatter, moonbounce and beaconing modes created by Joe Taylor, K1JT as *WSJT* (see the section Structured Digital Modes).

There can be a significant difference between data rate and bit rate in high reliability modes. The data rate is the amount of user data transmitted where the bit rate includes the packet and error correction overhead. Some of these rates are approximate and can vary based on conditions and the variant of the mode used. The symbol rate is a function of the modulation scheme and how many simultaneous carriers are used to transmit the data.

The error handling mechanism is critical to

note when sending data. Some modes include no error handling which means errors are not detected and must be addressed in a higher protocol layer (as in AX.25 packet). Forward error correction (FEC) makes a best effort to address errors in real time as part of the data sent in each packet. FEC can add substantial overhead to each packet and does not guarantee error-free delivery but does make the mode robust in high noise environments. Automatic Retry Request (ARQ) can guarantee error-free delivery of data but has no ability to actually correct received data. The combination of FEC and ARQ allows minor errors to be corrected in real time with major errors generating a retry request.

## 15.7 Glossary

**ACK** — Acknowledgment, the control signal sent to indicate the correct receipt of a transmission block.

**Address** — A character or group of characters that identifies a source or destination.

**AFSK** — Audio frequency-shift keying.

**ALE** — Automatic link establishment.

**Algorithm** — Numerical method or process.

**APCO** — Association of Public Safety Communications Officials.

**ARQ** — Automatic Repeat reQuest, an error-sending station, after transmitting a data block, awaits a reply (ACK or NAK) to determine whether to repeat the last block or proceed to the next.

**ASCII** — American National Standard Code for Information Interchange, a code consisting of seven information bits.

**AX.25** — Amateur packet-radio link-layer protocol.

**Baud** — A unit of signaling speed equal to the number of discrete conditions or events per second. (If the duration of a pulse is 20 ms, the signaling rate

is 50 baud or the reciprocal of 0.02, abbreviated Bd).

**Baudot code** — A coded character set in which five bits represent one character. Used in the US to refer to ITA2.

**Bell 103** — A 300-baud full-duplex modem using 200-Hz-shift FSK of tones centered at 1170 and 2125 Hz.

**Bell 202** — A 1200-baud modem standard with 1200-Hz mark, 2200-Hz space, used for VHF FM packet radio.

**BER** — Bit error rate.

**BERT** — Bit-error-rate test.

**Bit stuffing** — Insertion and deletion of 0s in a frame to preclude accidental occurrences of flags other than at the beginning and end of frames.

**Bit** — Binary digit, a single symbol, in binary terms either a one or zero.

**Bit/s** or **bps** — Bits per second.

**Bitmap** — See **raster**.

**Bit rate** — Rate at which bits are transmitted in bit/s or bps. **Gross** (or **raw**) **bit rate** includes all bits

transmitted, regardless of purpose. **Net bit rate** (also called **throughput**) only includes bits that represent data.

**BLER** — Block error rate.

**BLERT** — Block-error-rate test.

**BPSK** — Binary phase-shift keying in which there are two combinations of phase used to represent data symbols.

**Byte** — A group of bits, usually eight.

**Cache** — To store data or packets in anticipation of future use, thus improving routing or delivery performance.

**Channel** — Medium through which data is transmitted.

**Checksum** — Data representing the sum of all character values in a packet or message.

**CLOVER** — Trade name of digital communications system developed by Hal Communications.

**COFDM** — Coded Orthogonal Frequency Division Multiplex, OFDM plus coding to provide error correction and noise immunity.

**ode** — Method of representing data.  
**odoc** — Algorithm for compressing and decompressing data.  
**ollision** — A condition that occurs when two or more transmissions occur at the same time and cause interference to the intended receivers.  
**ompression** — Method of reducing the amount of data required to represent a signal or data set. **Decompression** is the method of reversing the compression process.  
**onstellation** — A set of points that represent the various combinations of phase and amplitude in a QAM or other complex modulation scheme.  
**ontention** — A condition on a communications channel that occurs when two or more stations try to transmit at the same time.  
**ontrol characters** — Data values with special meanings in a protocol, used to cause specific functions to be performed.  
**ontrol field** — An 8-bit pattern in an HDLC frame containing commands or responses, and sequence numbers.  
**onvolution** — The process of combining or comparing signals based on their behavior over time.  
**yclic Redundancy Check (CRC)** — The result of a calculation representing all character values in a packet or message. The result of the CRC is sent with a transmission block. The receiving station uses the received CRC to check transmitted data integrity.  
**atagram** — A data packet in a connectionless protocol.  
**ata stream** — Flow of information, either over the air or in a network.  
**BPSK** — Differential binary phase-shift keying.  
**ibit** — A two-bit combination.  
**QPSK** — Differential quadrature phase-shift keying.  
**omino** — A conversational HF digital mode similar in some respects to MFSK15.  
**RM** — Digital Radio Mondiale. A consortium of broadcasters, manufacturers, research and governmental organizations which developed a system for digital sound broadcasting in bands between 100 kHz and 30 MHz.  
**V** — Digital voice.  
**mission** — A signal transmitted over the air.  
**ncoding** — Changing data into a form represented by a particular code.  
**ncryption** — Process of using codes and encoding in an effort to obscure the meaning of a transmitted message. **Decryption** reverses the encryption process to recover the original data.

**Error Correcting Code (ECC)** — Code used to repair transmission errors.  
**Eye pattern** — An oscilloscope display in the shape of one or more eyes for observing the shape of a serial digital stream and any impairments.  
**Fast Fourier Transform (FFT)** — An algorithm that produces the spectrum of a signal from the set of sampled value of the waveform.  
**FEC** — Forward error correction.  
**Frame** — Data set transmitted as one package or set.  
**Facsimile** (fax) — A form of telegraphy for the transmission of fixed images, with or without half-tones, with a view to their reproduction in a permanent form.  
**FCS** — Frame check sequence. (see also **CRC**)  
**FDM** — Frequency division multiplexing.  
**FDMA** — Frequency division multiple access.  
**FEC** — Forward error correction, an error-control technique in which the transmitted data is sufficiently redundant to permit the receiving station to correct some errors.  
**FSK** — Frequency-shift keying.  
**Gray code** — A code that minimizes the number of bits that change between sequential numeric values.  
**G-TOR** — A digital communications system developed by Kantronics.  
**HDLC** — High-level data link control procedures as specified in ISO 3309.  
**Hellschreiber** — A facsimile system for transmitting text.  
**Host** — As used in packet radio, a computer with applications programs accessible by remote stations.  
**IAS** — International Alphabet, designating a specific set of characters as an ITU standard.  
**Information field** — Any sequence of bits containing the intelligence to be conveyed.  
**Interleave** — Combine more than one data stream into a single stream or alter the data stream in such a way as to optimize it for the modulation and channel characteristics being used.  
**IP** — Internet Protocol, a network protocol used to route information between addresses on the Internet.  
**ISO** — International Organization for Standardization.  
**ITU** — International Telecommunication Union, a specialized agency of the United Nations. (See [www.itu.int](http://www.itu.int).)  
**ITU-T** — Telecommunication Standardization Sector of the ITU, formerly CCIIT.  
**Jitter** — Unwanted variations in timing or phase in a digital signal.  
**Layer** — In communications protocols, one

of the strata or levels in a reference model.  
**Least significant bit (LSB)** — The bit in a byte or word that represents the smallest value.  
**Level 1** — Physical layer of the OSI reference model.  
**Level 2** — Link layer of the OSI reference model.  
**Level 3** — Network layer of the OSI reference model.  
**Level 4** — Transport layer of the OSI reference model.  
**Level 5** — Session layer of the OSI reference model.  
**Level 6** — Presentation layer of the OSI reference model.  
**Level 7** — Application layer of the OSI reference model.  
**Lossless** (compression) — Method of compression that results in an exact copy of the original data  
**Lossy** (compression) — Method of compression in which some of the original data is lost  
**MFSK16** — A multi-frequency shift communications system  
**Modem** — Modulator-demodulator, a device that connects between a data terminal and communication line (or radio). Also called **data set**.  
**Most significant bit (MSB)** — The bit in a byte or word that represents the greatest value.  
**Multicast** — A protocol designed to distribute packets of data to many users without communications between the user and data source.  
**MSK** — Frequency-shift keying where the shift in Hz is equal to half the signaling rate in bit/s.  
**MT63** — A keyboard-to-keyboard mode similar to PSK31 and RTTY.  
**Nibble** — A four-bit quantity. Half a byte.  
**Node** — A point within a network, usually where two or more links come together, performing switching, routine and concentrating functions.  
**OFDM** — Orthogonal Frequency Division Multiplex. A method of using spaced subcarriers that are phased in such a way as to reduce the interference between them.  
**OSI-RM** — Open Systems Interconnection Reference Model specified in ISO 7498 and ITU-T Recommendation X.200.  
**FACTOR** — Trade name of digital communications protocols offered by Special Communications Systems GmbH & Co KG (SCS).  
**Packet** — 1) Radio: communication using the AX.25 protocol. 2) Data: transmitted data structure for a particular protocol (see also **frame**.)

**Parity** (parity check) — Number of bits with a particular value in a specific data element, such as a byte or word or packet. Parity can be odd or even. A **parity bit** contains the information about the element parity.

**Pixel** — Abbreviation for “picture element.”

**Primitive** — An instruction for creating a signal or data set, such as in a drawing or for speech.

**Project 25** — Digital voice system developed for APCO, also known as P25.

**Protocol** — A formal set of rules and procedures for the exchange of information.

**PSK** — Phase-shift keying.

**PSK31** — A narrow-band digital communications system developed by Peter Martinez, G3PLX.

**QAM** — Quadrature Amplitude Modulation. A method of simultaneous phase and amplitude modulation. The number that precedes it, for example, 64QAM, indicates the number of discrete stages in each symbol.

**QPSK** — Quadrature phase-shift keying in which there are four different combinations of signal phase that represent symbols.

**Raster** (image) — Images represented as individual data elements, called pixels.

**Router** — A network packet switch. In packet radio, a network level relay station capable of routing packets.

**RTTY** — Radioteletype.

**Sample** — Convert an analog signal to a set of digital values.

**Shift** — 1) The difference between mark and space frequencies in an FSK or AFSK signal. 2) To change between character sets, such as between LTRS and FIGS in RTTY.

**SSID** — Secondary station identifier. In AX.25 link-layer protocol, a multipurpose octet to identify several packet radio stations operating under the same call sign.

**State** — Particular combination of signal attributes used to represent data, such as amplitude or phase.

**Start (stop) bit** — Symbol used to synchronize receiving equipment at the beginning (end) of a data byte.

**Symbol** — Specific state or change in state of a transmission representing a particular signaling event. **Symbol rate** is the number of symbols transmitted per unit of time (see also **baud**).

**TAPR** — Tucson Amateur Packet Radio Corporation, a nonprofit organization involved in digital mode development.

**TDM** — Time division multiplexing.

**TDMA** — Time division multiple access.

**Throb** — A multi-frequency shift mode like MFSK15.

**TNC** — Terminal node controller, a device that assembles and disassembles packets (frames).

**Trellis** — The set of allowed combination of signal states that represent data. (see also **Viterbi coding** and **constellation**.)

**Turnaround time** — The time required to reverse the direction of a half-duplex circuit, required by propagation, modem reversal and transmit-receive switching time of transceiver.

**Uncast** — A protocol in which information is exchanged between a single pair of points on a network.

**Varicode** — A code in which the different data values are represented by codes with different lengths.

**Vector** — Image represented as a collection of drawing instructions.

**Word** — Set of bits larger than a byte.

# Amateur Radio Data Platforms

This chapter addresses the increasing use of amateur communication as a key element of scientific experimentation. The use of amateur means to collect and track data focuses on high-altitude balloons which are the most popular platform used for this purpose today. Other types of platforms, such as drones and rockets, are also used for experimenting and enjoying operating them. Amateur Radio plays an important role in supporting their use.

The chapter begins with a discussion of what types of sensors and transducers are used to collect data on these platforms. Navigation and telemetry streams are also fundamental to collecting data and operating the platform. Several types of telemetry and location data are covered here along with a review of how the information is transmitted from the platform. (See the **Digital Protocols and Modes** for descriptions of the modes themselves.)

Future editions will continue to expand coverage to additional technologies, platforms and applications. Material in this edition was updated by Paul Verhage, KD4STH and Bill Brown, WB8ELK.

Amateurs conducting science experiments and operating mobile craft frequently use Amateur Radio for their data links and control signals, even as they cross continents and entire oceans! Such *platforms* include balloons and multi-rotor copters. Others are land-based (such as weather stations, animal tracking, or robots) or marine (ocean or river buoys or rovers). CubeSats ([www.cubesat.org](http://www.cubesat.org)) also use Amateur Radio control and data links.

Building these platforms combines several technical fields: using sensors and data acquisition systems to measure events and phenomena, mechanical and electrical engineering to construct the platform, 3-dimensional navigation, and the data link and associated radio technologies. These hybrids are attracting the experimentalists and scientists to Amateur Radio, just as they were attracted at the dawn of the wireless age.

Support of scientific experimentation is hardly a new aspect of Amateur Radio — amateurs have supported science almost since the beginning when Tom Mix, 1TS, accompanied the explorer MacMillan to the Arctic aboard the *Bowdoin* in 1923. Amateurs assisted the Naval Laboratory in listening tests that helped establish the existence of the ionosphere. The story continued with Grote Reber, W9GFZ, and radio astronomy in the 1930s, broad participation by hams during the International Geophysical Year of 1957-1958, wildlife tracking, propagation reporting, satellite construction, and numerous other instances. Recently, hundreds of amateurs participated in the Solar Eclipse QSO Party ([hamsci.org](http://hamsci.org)) to observe the effect of a total solar eclipse on HF propagation. There is no doubt that fulfillment of FCC Part 97.1 is thriving as hams continue to “improve the radio art” by adapting technology to new uses.

This chapter is organized in four parts: platform overview, sensors, telemetry and navigation, and platform design. The goal is to cover the engineering necessary to assemble an effective platform. In recognition of the rapid innovation in these activities, this chapter will change in future editions. Expect to see new digital protocols and miniature telemetry and audio-image transmitters. Improvements will be forthcoming in portable-mobile power sources and antennas.

Although the *ARRL Handbook* strives to be complete, covering all aspects of these efforts is beyond the scope of this book. The referenced magazines and websites in the References and Bibliography section at the end of this chapter provide additional material and the latest updates on platforms and technology.

---

## 16.1 Platform Overview

Automated platforms are found in many locations carrying out a multitude of functions. They are often the solution to data collection in locations where it's not practical for humans to operate data collection devices for reasons such as safety or extensive time commitment requirements. Aside from data collection, automated platforms are also pressed into service as transponders, repeaters, and beacons. In instances such as these, automated platforms are well served by Amateur Radio because of the wireless communication requirements these platforms need to telemeter the data they generate, report their location and status, or forward analog and digital radio communications.

Although the primary platforms used today involve high-altitude balloon-borne exper-

iments, similar considerations apply to other fixed and mobile terrestrial and marine experiment platforms.

### 16.1.1 Platform Structure

The generic structure of a remote sensing platform is shown in **Figure 16.1**. Along with the power source, there are five separate functions:

- 1) Sensor data or image acquisition — conversion of analog data into digital format and acquisition of still images or video
- 2) GPS or navigation data — acquisition of location data in digital form
- 3) Integration of sensor and location data — collection of all data to be stored and/or transmitted to the ground station
- 4) Protocol engine — packaging and encoding of data for transmission
- 5) Amateur transmitter — generates the digitally modulated RF signal

These functions can be implemented by separate modules, or everything can be performed by a single microcontroller-based module such as one of the APRS trackers.

The choice is completely up to the platform designer and varies with the requirements for the particular mission. For example, **Figure 16.2** shows a two-module solution in which everything except GPS location is provided by the single MMT module. The ATV payload described later uses a separate controller to integrate the video and GPS data for transmission as part of the overall audio-video signal. The combinations are endless! The websites listed in the following section on High-Altitude Platforms (balloons) are good places to begin looking for the right subsystems for your mission.

### DATALOGGERS

Dataloggers are standalone microprocessor-based devices that acquire or “log” digital and analog data on a pre-determined schedule or when prompted by a pre-determined event. They can also acquire digital data from avionics and navigation equipment. The data is stored or transmitted for later analysis. Dataloggers are available as commercial products or they can be home-built. Commercial dataloggers have the advantage

of being durable and standardized. On the other hand, they may not be customizable to the extent desired for a science flight into the stratosphere. Popular microcontrollers such as the BASIC Stamp (Parallax), PICAXE, Arduino, and Raspberry Pi have made it much easier to create custom dataloggers that are also capable of operating experiments as well as just recording data.

### TEMPERATURE RANGES AND HUMIDITY

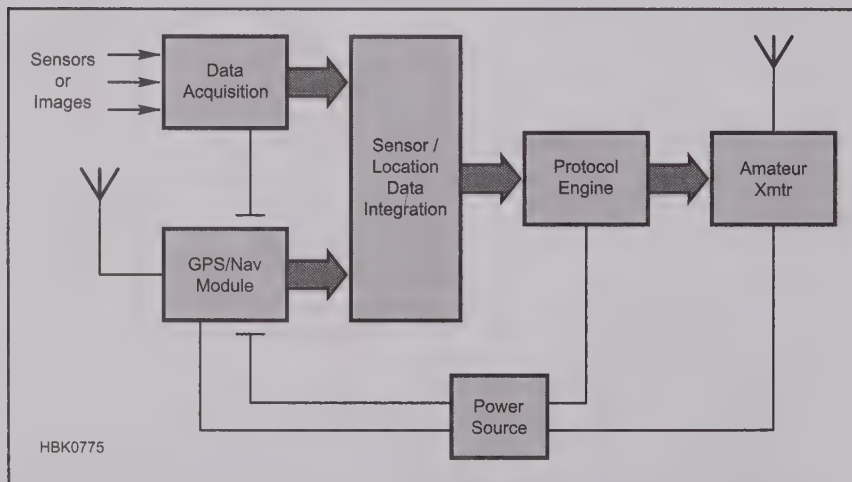

The platforms discussed in this chapter are often used outdoors or in unprotected environments. As a result, the electronics and other sub-systems can be subjected to extreme temperatures for long periods of time. When selecting components, modules, or other equipment, make sure they are properly rated for the intended use.

The four most common temperature specifications for electronics and electro-mechanical systems are as follows:

- Commercial: 0 °C to 85 °C
- Industrial: -40 °C to 100 °C
- Automotive: -40 °C to 125 °C
- MIL-SPEC (or MIL-STD): -55 °C to 125 °C

Components meeting Commercial Specifications will work well for fixed stations residing indoors. However, when designing outdoor fixed stations, the amateur must consider using components that at least meet Industrial Specifications.

A closely related specification is for relative humidity (RH) which is specified in percent and condensing or non-condensing. RH can range from 0% in the desert or upper atmosphere to 100% from rain or fog or in water-borne environments. “Condensing” means that liquid water forms on surfaces of the device or component directly from the air. If your platform will be subjected to condensing humidity or direct water spray or splash, consult the equipment manufacturer for the best methods of protecting the platform components.

**Figure 16.1** — The basic structure of a remote sensing platform using Amateur Radio for the telemetry link.

**Figure 16.2** — A two-module payload consisting of a GPS receiver module (right) and WB8ELK's MMT (Multi-Mode Transmitter) on the left.

## 16.1.2 Types of Platforms

### HIGH ALTITUDE BALLOONS

High altitude balloons are most frequently latex (mixed with neoprene) weather balloons designed to carry automated platforms weighing up to 12 pounds (heavier weights are possible) into near space. Altitudes above 60,000 feet (flight level 600) and below 328,000 feet are often referred to as *near space*. This region of the atmosphere has conditions that are closer to those found in Earth orbit than to Earth's surface.

Altitudes in excess of 100,000 feet are accessible using large weather balloons and lightweight platforms. Heavier platforms rely on polyethylene skinned balloons called *zero pressure balloons*. These balloons are vented to the atmosphere and do not develop an internal pressure above that of the surrounding atmosphere at any height. ([www.eoss.org/faq/zero\\_pressure](http://www.eoss.org/faq/zero_pressure))

The need for long duration flights across continents, oceans, and even circumnavigating the planet has necessitated the development of *super-pressure balloons*. These balloons have skins of high-tech plastics and are sealed airtight. This prevents their lifting gas from escaping and shortening their flight times. While zero pressure and super pressure balloons are traditionally in the realm of professionals, amateurs have been making use of sealed Mylar foil party balloons as well as larger custom-built super-pressure envelopes using a special plastic film.

To be successful, the total weight of the payload should be a half-ounce or less. A handful of amateurs have developed incredibly lightweight payloads and most are totally solar-powered. In one instance, a UK-launched Mylar party balloon remained aloft for months and circled the globe nine times. More recently, a balloon launched from Atlanta, Georgia has stayed aloft over a year and has circled the globe more than 20 times.

A number of conditions are commonly measured or monitored, with a microprocessor-based datalogging system to acquire the data and convert it to digital form. The data is stored in onboard memory for recovery or transmitted to ground stations as a telemetry stream. The sensor data can also be integrated with the GPS data for transmission via APRS.

Some APRS trackers can acquire analog and digital sensor data and integrate it into the APRS data messages.

Standalone experiments can also be attached to the balloon then located and recovered after landing. Data collected by sensors carried by the weather balloon can then be analyzed and correlated to the balloon's altitude. Thus, it is extremely important that the payload be able to transmit or store position and altitude data during the flight while collecting data.

You can find a considerable amount of information about balloons and experimental platforms suitable for balloons at [arhab.org](http://arhab.org), [wb8elk.com](http://wb8elk.com), [eoss.org](http://eoss.org), [ansr.org](http://ansr.org), and [near-sys.com](http://near-sys.com). See also the References and Bibliography section at the end of this chapter.

### BalloonSats

*BalloonSats* are packages with standalone high-altitude experiments. They do not include a tracker since it is assumed they will be carried by operational platforms that include trackers. BalloonSats are an excellent way to introduce school students to near space exploration. They are simple systems that permit students to perform experiments in the space-like environment of near space.

### UNMANNED AERIAL VEHICLES (UAV)

UAV development goes back centuries. However, it was the development of lightweight electronic autopilots that turned the UAV into the practical and affordable platform of today. With the commercial marketing of the four-bladed quadcopter and the six-bladed hexacopter with rechargeable lithium-polymer batteries, amateurs gained access to practical UAVs. The UAV has severe altitude and weight limits that balloons do not. However, the UAV provides a platform for imaging and datalogging at higher resolutions, over more restricted regions, with higher data immediacy, and quicker turnaround time. The popularity of this platform and the potential risks posed to conventional aviation have resulted in registration requirements and flight restrictions.

### AMATEUR ROCKETRY

Experiments with amateur rocketry began

in the late 1920s in Germany. By the 1950s, amateur rocketry had become a growing hobby for post-war America, especially after the launch of Sputnik 1 in 1957.

With the introduction of modern composite propellants and lightweight digital electronics, serious data collection is now possible. Unlike balloons and UAVs, rocket-based platforms must account for the rapid accelerations and tight dimensions inherent in rocketry. Because of their high accelerations, the rocket makes data collection possible at high altitudes but only over very short time frames.

### ROBOTICS

Robots can be described as either *autonomous* or *semiautonomous*, depending on the amount of human input they require. Among the most famous robots are the series of rovers NASA has sent to explore the surface of Mars. Inexpensive microcontrollers, which are a form of programmable logic, have brought robotics to the amateur level. Robots often have fewer weight limits than balloons, rockets, or UAVs. They are also capable carrying platforms to desired locations and remaining on site while their platform performs its mission. Finally, robots usually place fewer power limits to their platforms than balloons, rockets, and UAVs. However, robots tend to cover the ground at slow speeds and limit their platforms to recording data from the ground level.

### FIXED AND FLOATING PLATFORMS

Fixed platforms are any data collection stations that remain in one location. This can be due to their being mounted to a pole like a weather station or anchored to the seabed like a buoy. Typically, fixed platforms remain in place for long duration data collecting or imaging. As such, they require protection from the elements. They also require occasional maintenance from a human who goes onsite to service the fixed platform.

Some are floating buoys that may or may not be anchored. Anchored buoys can be treated as a fixed station. Free-floating buoys or marine rover-style platforms travel on the body of water either under self-contained power or by following the winds and currents.

## 16.2 Sensors

Inexpensive sensors and microcontrollers combined with Amateur Radio create opportunities for the amateur to perform experiments in environments that are otherwise inaccessible for one reason or another. Many interesting regions of the Earth, including extremely high altitudes in the atmosphere or the distant ocean, fall into this category. Hams can be instrumental in helping both amateurs and professionals explore these environments.

These platforms enable *remote sensing* — observing or measuring an object or event without a human being actually being in contact with the condition being measured. Data from the measurement is then stored on the platform for eventual collection after recovery or transmitted to a ground station for recording and analysis (telemetry). Examples of parameters that are measured by amateur remote sensing platforms include temperature, pressure (air and water/fluid), humidity, ozone and other gasses, acceleration, and light.

A sensor is a device that reacts to a specific condition of interest, such as temperature or pressure, and produces a predictable output in response. The first step is to select the appropriate sensor or sensors for the parameter of interest and a means of converting sensor outputs to digital data, usually by connecting the outputs to a microcontroller or analog to digital converter IC. Sensors and their associated *signal conditioning* circuits are the “front end” of remote sensing. Analogous to the speech and video circuits of traditional amateur transmitters, the same care in their design is required if quality results are to be obtained.

This section divides sensors into the following four types of outputs: *resistance-based*, *current-based*, *voltage-based*, and *digital*. In addition, four common types of sensor outputs are discussed here. Not all of these outputs are directly readable by a microcontroller. However, methods exist to convert the output of these sensors into a form that can be interfaced to a microcontroller. (See the Analog/Digital Conversion section of the **DSP and SDR Fundamentals** chapter.)

### 16.2.1 Resistance-Based Sensors

Resistance-based sensors change an internal resistance in response to the environmental variable they measure. An example includes the photocell, which is constructed of the chemical cadmium sulfide (CdS), a semiconductor that produces electrons and holes when irradiated by light. The production of free electrons and holes reduces the

resistance of CdS when it is exposed to light.

In many cases, the change in resistance in response to changes in the measured condition is small. Therefore, sensor manufacturers often incorporate additional circuitry with the sensing element to convert this changing resistance into a more easily measured change in voltage. However, resistive-type sensors (without signal conditioning) are still available and quite useable.

Resistance-based sensors do not create a signal that a microcontroller can measure directly. Instead, the resistance of the sensor is used to vary the voltage from a regulated voltage source. A simple and popular circuit capable of converting a changing resistance into a changing voltage is the voltage divider as described in the **Electrical Fundamentals** chapter.

The voltage divider circuit of two resistors as shown in **Figure 16.3**. One resistor is fixed

in resistance ( $R_F$ ) and the other is the sensor and therefore variable in resistance ( $R_V$ ). The current through the voltage divider circuit is variable. It increases as the resistance of the variable sensing element decreases and vice-versa. However, the sum of the two voltage drops is always equal to the supply voltage. The preferred arrangement of the two resistors depends on the response of the sensing resistor to the condition to which it responds — temperature, humidity, illumination, and so on.

A microcontroller connected to the voltage divider circuit digitizes the voltage across the resistor connected to ground. This permits the design of resistance-based sensors into circuits that produce changing voltages which follow the change in the condition. For example, the resistance of photocells decreases as the light intensity increases. A microcontroller digitizing the voltage across a photocell connected as  $R_V$  in Figure 16.3A will observe  $V_{OUT}$  increasing as light intensity decreases. If however, the photocell is connected as  $R_V$  in Figure 16.3B,  $V_{OUT}$  increases as the light intensity increases. The latter case is easier to understand and work with than having output voltage and the sensed condition varying in opposite directions (or inversely proportional).

There are two equations that describe the output of the voltage divider circuit. The first describes the voltage drop across the variable resistor and the second describes the voltage drop across the fixed resistor.

For Figure 16.3A:

$$V_{OUT} = +V (R_V / (R_F + R_V))$$

For Figure 16.3B:

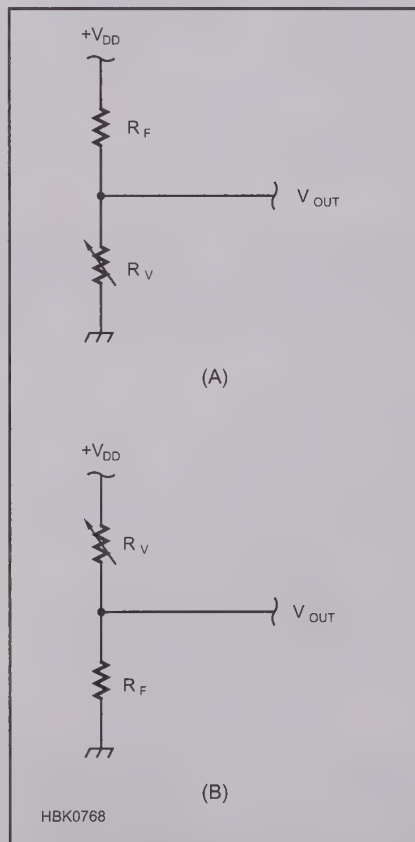

$$V_{OUT} = +V (R_F / (R_F + R_V))$$

#### OPTIMIZING $R_F$

The equations above show that the value selected for  $R_F$  has a large impact on the range of output voltages created by the voltage divider circuit. The precision of the sensor output is greatest when the voltage range of  $V_{OUT}$  is maximized. The value of  $R_F$  that generates the maximum range is the geometric mean of the sensor's highest expected resistance ( $R_H$ ) and lowest expected resistance ( $R_L$ ). The equation for calculating the best fixed resistor value ( $R_F$ ) in a voltage divider circuit is:

$$R_f = \sqrt{R_H R_L}$$

The maximum range for  $V_{OUT}$  of the voltage divider circuit is thus equal to 1/3 of the supply voltage,  $V_{DD}$ . Furthermore, the voltage range is centered at the midpoint of the

**Figure 16.3** — The voltage divider circuit, a series circuit of two resistors. The orientation of resistors in A is preferable when the sensing resistor increases resistance in response to an increasing condition. Use B when the sensing resistor decreases resistance in response to an increasing condition. This results in the output voltage increasing with the increasing condition.

supply voltage. The following three equations calculate the minimum voltage, maximum voltage, and voltage range of an optimized voltage divider.

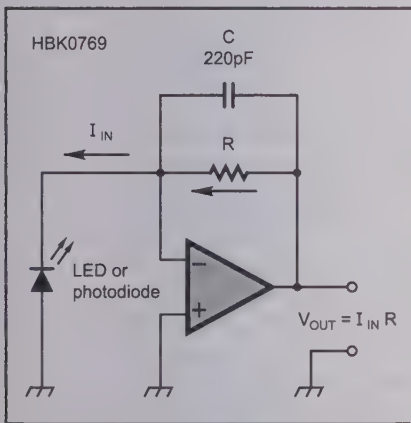

$$V_{\text{MIN}} = V_{\text{DD}}/3$$

$$V_{\text{MAX}} = 2V_{\text{DD}}/3$$

$$\text{Range} = V_{\text{MIN}} - V_{\text{MAX}} = V_{\text{DD}}/3$$

## 16.2.2 Current-Based Sensors

Some types of sensors generate or change output current in response to the environmental condition they are measuring. Examples include the photodiode, solar cell and light-emitting diode (LED). All three of these devices are similar, although not used in similar ways. When a photon of light is absorbed, its energy gives an electron in the device enough energy to jump across the PN junction. The electron creates a measurable current from the sensor.

The LED is one of the most surprising current-based sensors. While the photodiode is sensitive to a wide range of frequencies, the LED is most sensitive to light at the wavelength it emits when forward biased. This makes the LED a very inexpensive spectrally sensitive photometer. (See the References and Bibliography section entry for Mims for a description of the LED responses.)

A current-based sensor can provide useful data when connected to a digital multimeter (DMM) set to measure milliamps of current. However, this is not a suitable configuration for a microcontroller with the capability to digitize voltage. Therefore, it is necessary to find a way to convert changing current into a changing voltage. Two popular ways to accomplish this are to use a transimpedance amplifier or by measuring the charging time of a capacitor.

### THE TRANSIMPEDANCE AMPLIFIER

The transimpedance amplifier in Figure 16.4 is a popular op amp circuit that converts input current into an output voltage. The feedback resistor, R, sets the gain of the transimpedance amplifier. The output voltage is given by the following equation:

$$V_{\text{OUT}} = I_{\text{IN}} \times R$$

The capacitor, C, reduces gain at high frequencies above  $1/RC$ , acting as a low-pass filter to reduce noise. A generally useful value is 220 pF with the usual values of R for LED light-sensing. You will have to take the bandwidth of your measurement into account when choosing the value of C.

It is important that the value selected for the feedback resistor does not result in amplifier saturation for high sensor output levels. In those circumstances, data is lost when the sensor output is too high and the amplifier saturates.

### USING CAPACITOR CHARGE TIME

A second method to digitize the current from a sensor is to measure the length of time required for a current to charge or discharge a capacitor to a certain voltage. One example can be found in the book *Earth Measurements* by Parallax ([www.parallax.com](http://www.parallax.com), manufacturer of the BASIC Stamp microcontrollers). Here, the BASIC Stamp initially charges a capacitor. The Stamp then measures the length of time required for the capacitor to discharge due to the current entering it from the current-based sensor. The capacitor and resistor values are selected according to the expected current output of the sensor. The book uses the circuit in Figure 16.5 to measure the current output of a photodiode or LED.

The program shown in Table 16.1 (*Earth Measurements*, Program 4.2) was written to use the schematic in Figure 16.5. It assumes the circuit connects to the BASIC Stamp via I/O pin 6. Change the I/O reference to another pin as needed by your circuit.

The program reports the light intensity once per second. It begins by charging the supply voltage through the use of the HIGH 6 command. Afterward, the reverse current emitted by the LED, due to its exposure to light, discharges the capacitor. The changing potential of the capacitor makes the voltage drop across the LED appear to decrease from its start at +5 V. Any voltage above 1.4 V is treated as a logic high by the BASIC Stamp. Therefore, as reverse current from the LED brings the capacitor voltage lower, the voltage across the LED eventually becomes lower than 1.4 V and a logic low.

The RCTime command counts the time (in units of 2  $\mu\text{s}$ ) required for I/O pin 6 to change from a logic high (above 1.4 V) to a logic low (below 1.4 V). The result in units of 2  $\mu\text{s}$  is stored in the variable RCT. The greater the

**Table 16.1**

intensity of the light shining on the LED, the faster the capacitor discharges and the smaller the value stored in the variable RCT. The value in RCT is then divided into 65535 to invert the relationship and then stored in the variable Light which then contains a value directly proportional to light intensity.

### 16.2.3 Voltage-Based Sensors

Some types of sensors change their voltage output in response to the condition they are measuring. Examples include the LM355 temperature sensor, Honeywell's HIH-4000 relative humidity sensor, and Microdyne's MPS-3138 pressure sensor. These devices are typically current or resistance-based sensors along with circuitry to amplify and condition the output into a useable voltage change.

The voltage-based sensors easiest to interface are those that include signal amplification and correction on the chip. The result can be a ratiometric output that is linear and proportional to the supply voltage. The conversion factor for the sensor needed to convert its voltage into the environmental condition being measured is documented in the device's datasheet.

Pressure sensors can be used as altitude sensors for an airborne platform if a digital solution, such as GPS, is not available. Absolute pressure is preferred although it must be calibrated against ground barometric pressure before launch and, if the flight covers long distance, requires additional corrections based on local pressure data.

### 16.2.4 Capacitance-Based Sensors

Capacitance-based sensors use changes in capacitance as their primary means of measurement. Capacitance between two electrodes of known area depends on the distance between the electrodes and the dielectric constant of the insulating material separating them. Any process that changes either separation or dielectric constant can be then be sensed as a change in the capacitance. Parameters that are sensed in this manner include motion, moisture, fluid and material level, chemical composition, and acceleration.

Sensors based on capacitance are rarely supplied without signal conditioning and linearization. Many have digital outputs that supply the measurement as a digital value. Another option is to have the sensor's capacitance control the frequency of an oscillator, which can then be read by a digital circuit. For more information on capacitive sensing, the excellent overview at [www.capsense.com/capsense-wp.pdf](http://www.capsense.com/capsense-wp.pdf) is recommended.

## 16.2.5 Sensor Calibration

Sensors come in two basic configurations: *sensing elements* and *conditioned sensors*. The voltage divider discussed earlier is an example of a sensing element. There are no electronics associated with the divider—the package contains only the two resistors and the necessary connecting wires or terminals. Conditioned sensors contain electronic circuitry that operates on the signal from the sensing element before it is made available externally. The circuits usually regulate power applied to the sensor and also *linearize* the data so that a linear range of measurements are represented by a linear change in output voltage.

All sensing elements and some conditioned sensors require a calibration equation to convert the output signal into the parameter value the sensor is measuring. In some cases, the equation is simple and linear as in the LM335 temperature sensor. In other cases, the equation may be complicated, such as for the thermistor and photocell when used in a voltage divider circuit.

It is important to understand the range over which a sensor will be measuring a condition before attempting to calibrate it. The calibration equation is usually more accurate when based on the interpolation of measurements than when based on the extrapolation of measurements. There are exceptions to this rule. For example, the calibration equations of linear sensors can be just as accurate when extrapolated, as long as the maximum operating conditions of the sensor are not exceeded. Otherwise, is it best to expose the sensor to the entire range of expected environmental conditions while collecting measurements of its output to create the calibration equation.

The ham can easily create some of these conditions, such as temperature, on the bench top. High temperatures can be created with the use of heat lamps and low temperatures created with the use of dry ice packed in Styrofoam coolers. Other conditions might need to be simulated. For example, light intensity is easily changed by changing the distance between the sensor and a fixed light source. Recall however that light intensity decreases by a factor of  $1/r^2$  when using this method to create the calibration curve of a sensor.

The spreadsheet is a powerful tool for creating calibration equations. To create the calibration equation, carefully measure the output of the sensor as the environmental condition is varied. Enter the readings and distance into a spreadsheet. In the next column, calculate the intensity of the source, based solely on its distance from the sensor. Graph the results so that the independent variable (X axis) is the distance and the dependent

variable (Y axis) is the intensity. Then select the function to create a regression line from the data in the chart.

### 16.2.6 Digital Sensor Protocols

Some types of sensor outputs are in digital form. These sensors communicate their data as a serial protocol in which data is exchanged as a series of bits over one or more circuits. Data can be transmitted synchronized to an external timing signal (*synchronous protocol*) or synchronized to special signals embedded within the data being transmitted (*asynchronous protocol*).

Examples of synchronous serial data protocols include 1-Wire, Inter-Integrated Circuit (I2C), and Serial Peripheral Interface (SPI). Examples of asynchronous serial data transmission include USB and the RS-232 (COM) ports on PCs. These serial protocols can transfer measured data to a microprocessor without additional conditioning.

Another type of digital sensor is one in which an event's detection is signaled as a voltage pulse or as a switch closure. For example, the detection of ionizing radiation by Geiger counters is signaled by voltage pulses created when ionizing radiation passes through a Geiger-Muller tube. These signals require additional processing, such as a counter or register circuit that is often implemented by a microprocessor.

## SYNCHRONOUS SENSOR DATA PROTOCOLS

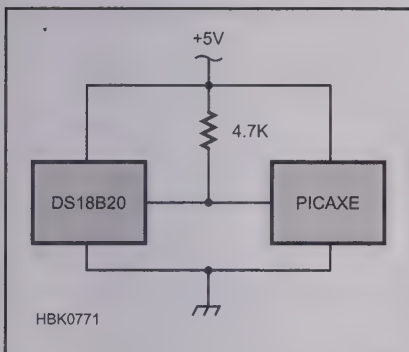

The following protocols are by no means the only ones used by sensors, but they are the ones amateurs are most likely to use on an encounter. The manufacturer websites mentioned below have numerous resources to support design and development with devices that support these protocols.

### 1-Wire

1-Wire is a communication system developed by Dallas Semiconductor (now part of Maxim Electronics — [www.maximintegrated.com](http://www.maximintegrated.com)) to enable communication between two or more integrated circuits. Devices on a 1-Wire network are daisy-chained together on a single-wire bus, called a *microlan*. (See **Figure 16.6**.) One device acts as the master device, and it controls communication between itself and the slave devices connected to the microlan. Some available 1-Wire devices include:

- Temperature sensor: (MAX51826)
- EEPROM memory (DS24B33)
- Low voltage sensor (DS25LV02)

Since a microlan may not include a separate power wire, many devices attached to the microlan include a small capacitor in their

**Figure 16.6** — The DS18B20 is a 1-Wire temperature sensor. In this circuit, the device does not use parasitic power and is connected to a 5 V source. A PICAXE microcontroller communicates with this device using the READTEMP or READTEMP12 command.

**Figure 16.7** — A comparison between an iButton and a nickel.

design. The capacitor provides *parasitic power* to the device while communications are taking place. The capacitor is necessary because communication requires the voltage on the single wire to alternate between power and ground. Without some temporary power source, devices would lose power during communications.

The master device communicates with each slave device by transmitting the slave address over the microlan prior to other commands. Because multiple devices can be connected to a microlan, each device must have a unique address to avoid confusion. Slave addresses are laser etched into 1-Wire devices. Alternatively, if a single 1-Wire device is attached to a microlan, communication on the network can ignore addressing altogether.

1-Wire is a two-way communication protocol. The master device begins communication by sending the slave device's address and then commands over the network. Only the device with the address in the message will respond to the commands.

### iButtons

An iButton is a sealed 1-Wire device resembling a thick watch battery (see **Figure 16.7**). iButtons include memory and a lithium battery. The memory contains the ID

**Figure 16.8** — An example of a master and two slave ICs connected via an I2C network.

of the device and can often be used to store data. The battery permits an iButton to operate independently of a microlan.

iButton devices download their stored data when connected to a microlan. The microlan connection is made by pressing the iButton device against a 1-Wire receptor. 1-Wire receptors are available for integration into microcontroller projects. Some available iButton devices include the following:

- Time and temperature loggers (DS1920 Thermochron)
- Time, temperature and humidity data loggers (DS1923 Hygrochron)

The amateur may be interested in the ongoing development of a 1-Wire weather station. Consult Maxim Integrated ([www.maximintegrated.com](http://www.maximintegrated.com)) for the latest information concerning 1-Wire devices, including iButtons.

### I2C

Inter-Integrated Circuit or I2C is a communication method developed by Phillips to enable communication between two or more ICs. Devices on an I2C network are daisy-chained together on a two-wire bus as in **Figure 16.8**. One device acts as the master device and it controls communications between itself and the slave devices connected to the network. The I2C network is described in detail at [www.i2c-bus.org](http://www.i2c-bus.org) and in the application notes supplied by manufacturers of devices that use it.

The first connection in the I2C network is the serial data (SDA) line. This line carries slave device addresses, data, and instructions between devices. The second line is the serial clock (SCL) line. This connection provides timing pulses to synchronize the data sent from the sending IC (master) to the receiving IC (slave). In an I2C network, the SDA and SCL lines are pulled up to +5 V by pull-up resistors. A value of 4.7 k $\Omega$  works well.

The master device communicates with each slave device by transmitting an address over the I2C bus prior to other commands. Because multiple devices can be connected to an I2C network, each device must have a unique address to avoid confusion. Slave addresses may be designed into the IC or may be externally configured for an IC by connecting a combination of address pins to +5 V and ground.

I2C is a two-way communication protocol. The master device begins communication by sending the slave device's address and then commands over the network. Only the device receiving its address in the message will respond to the commands. Serial data can be sent in either in fast (400 kHz) or slow (100 kHz) mode. The master device sends commands and memory addresses in either one byte or one word (two bytes) long commands. Some available I2C devices include the following:

- Memory: the 24LCxxx series of I2C memory.
- Real-time clocks: DS1307
- Analog to digital converters: LTC2903 (12 bit), AD7991 (12 bit), and MCP3421 (18 bit)

### SPI and Microwire

Serial Peripheral Interface or SPI is a communication method developed by Motorola (now Freescale) to enable communication between two or more ICs. Devices on a SPI network are daisy-chained together on a two- or three-wire bus. (See **Figure 16.9**.) Like I2C, one device is the master that controls communications between it and the slave devices connected to the network. The Microwire network originally developed by National Semiconductor (now Texas Instruments) is essentially a subset of SPI. Microchip (manufacturer of the PIC processor family) has published an overview and

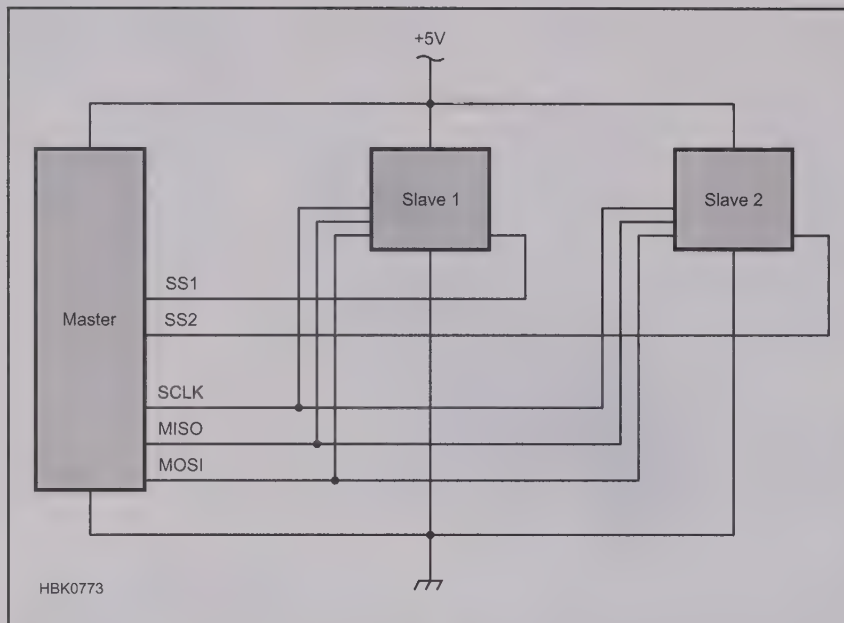

Figure 16.9 — An example of a master and two slave ICs connected via an SPI network.

tutorial about SPI at [ww1.microchip.com/downloads/en/DeviceDoc/spi.pdf](http://ww1.microchip.com/downloads/en/DeviceDoc/spi.pdf).

Two lines of the SPI bus are used to transmit data and instructions: MOSI (master out/slave in) and MISO (master in/slave out). In some cases, the MISO and MOSI lines can be combined into a single shared line. The third line of the bus is the timing clock line (SCLK) that provides timing pulses to synchronize the data sent between the master device and the slave device. None of these lines requires being pulled high by a resistor.

The master device communicates with the slave devices by activating each slave device's Slave Select (SS) line. To avoid confusion, each slave device must have a unique connection to the master device. This is a major difference between I2C and SPI. An I2C network requires only two communication lines between devices, while an SPI network requires two or three communication lines in addition to an SS line between the master and each slave. A large number of slave devices require a large number of dedicated SS lines between the master and the slave devices.

SPI is also a two-way communication protocol. The master device begins communications by activating the slave device's SS line. Only the device with the activated SS line will respond to the commands. Serial data is sent as fast as the master device pulses the SCLK line. The number of bytes in each transmission between master device and slave device is limited by the design of the slave device rather than to eight or 16 bits. Some available SPI devices include the following:

- Analog to digital converters: MAX186 (12 bit resolution)

- Temperature sensor: LM74
- Hall effect sensor: MLX90363
- Pressure sensor: MPL115A1
- Memory: AT25010B

Note that the popular Dallas Semiconductor DS1620 Temperature Sensor uses a three-wire interface similar to SPI.

## ASYNCHRONOUS SENSOR DATA PROTOCOLS

Asynchronous communication is any form of communication that does not use a clock signal to maintain timing between the sender and the receiver. A message begins with a start signal that allows the receiver to synchronize with the transmitter's message. The rest of the communication follows at a predefined rate in bits of data per second or baud. (See the **Digital Protocols and Modes** chapter for a discussion of data rate.) As long as the sender and receiver use equally accurate clocks, they will transmit and receive the same bits of data.

Some sensors supply their output data using RS-232 and USB ports. The data is transmitted as a stream of characters controlled by a protocol developed by the manufacturer. USB devices often conform to certain classes of data objects so that generic device drivers can be used to acquire data from the sensor. Control and configuration protocols that allow the user to interact with the sensor are usually proprietary.

Time-independent serial devices produce a change in output voltage only at the detection of an event. The primary example is the *event counter*. The simplest event counters detect the closure of a switch, which can be

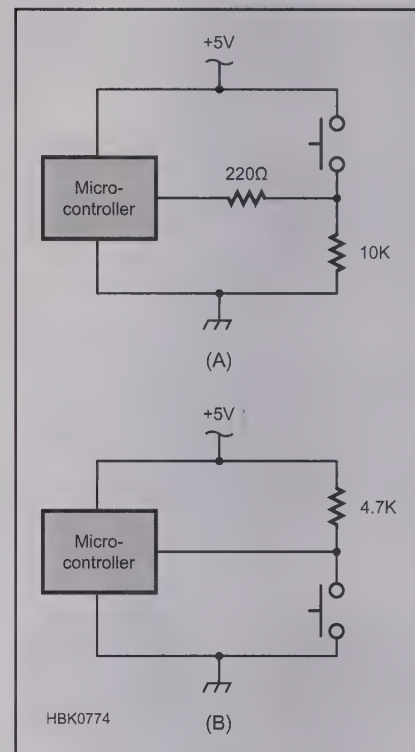

Figure 16.10 — (A) This circuit produces a logic high signal, typically 5 V, when an event is detected, represented as a switch closure. (B) This circuit produces a logic low signal, typically ground or 0 V, when an event is detected.

useful for detecting the presence of wildlife. Game cameras use switches in this way to trigger a camera to record an image of wildlife. Thermostats and thermal switches are another example.

Switches can be used to signal a microcontroller by two different methods. In the first, called *active low*, the switch connects a microcontroller I/O pin to ground at the detection of an event. When the event is not present, the I/O pin is connected to positive voltage or pulled up to a positive voltage by a pull-up resistor. In the second method, called *active high*, the switch connects a microcontroller I/O pin to positive voltage at the detection of an event. When the event is not present, the I/O pin is connected to ground. Schematics for both of these switch circuits are shown in **Figure 16.10**.

An example of a sensor that produces asynchronous output is the Geiger counter. The output of the RM-60 Geiger counter from Aware Electronics' RM-60 ([www.aw-el.com](http://www.aw-el.com)) maintains a 5 V level until ionizing radiation is detected. Then the output voltage drops to 0 V for 20  $\mu$ s. The amount of radiation detected by a RM-60 Geiger counter is measured by counting the number of pulses emitted by the sensor over a fixed period.

Other event counters can be modified for microcontroller use if they use an LED indicator or piezoelectric annunciator. When an LED is illuminated, greater than 1.4 V appears across its terminals. Wires soldered to the LED can be connected to ground and one of a microcontroller's I/O pins to permit the microcontroller to count the number of LED flashes. Care in counting the number of flashes is necessary since some inexpensive sensors may output several pulses each time the event is detected or in the case of contact bounce for a switch closure.

### 16.2.7 Powering Sensors

The output of sensing element sensors is typically very sensitive to power supply voltage and noise. Any changes in power supply voltage on the voltage divider also appear, proportionally reduced, at the output of the

voltage divider. This includes noise, transients, slowly dropping battery voltage—any change in the sensing element's supply voltage. The sensing element user must provide clean, filtered, regulated power to the sensor to avoid contaminating the sensor output voltage.

Loading of the sensing element is also an issue for the designer to deal with. A high-impedance sensing element will output erroneous voltages if connected to a load impedance that is too low. Be sure you know what the sensing element's ratings are!

Conditioned sensors are far less sensitive to noise and power supply variations. Some kind of voltage regulator circuit is included to make sure the electronics operate with a "clean" supply. The conditioning electronics, which often include laser-trimmed calibration circuitry, assume clean, well-regulated

dc voltage from a power supply. They are much less sensitive to the effects of output loading although there are usually limits as to the amount of capacitance they can tolerate at the output, such as from a long run of wire.

In portable or mobile platforms, power is usually supplied by a battery pack. Make sure you have fresh, fully charged batteries before heading out to launch the platform for the experiment. Take into account the gradual reduction in voltage from the battery pack as its charge is consumed — it's awfully hard to swap out batteries with a balloon that is in flight! In the quest to save weight in these platforms, make sure you still have enough capacity in the battery pack voltage (see the **Power Sources** chapter) so that the experiment won't run out of power during its mission.

## 16.3 Navigation Data and Telemetry

Navigation data allows the sensor measurements to be combined with geographical data, which is important for correlating data to location (including altitude). A final step involves using Amateur Radio to either transmit the collected data to a ground station as telemetry or to track and recover a remote sensing payload for later data extraction. Since the most common use of this data is for weather balloons and other near-space missions, that context will be used.

It is important to note that transmitting data as ASCII characters (7- or 8-bit) is preferred to more compact binary formats. ASCII characters have the advantage of being human-readable so that even raw data can be inspected and used. At the low data rates of most amateur remote sensing, little overall throughput is lost by using ASCII characters. The ability to read the raw data stream directly is often invaluable during troubleshooting, as well.

### 16.3.1 Dead Reckoning

If a digital navigation data source such as GPS is not available, it is also possible to estimate platform position, including altitude by the process of dead reckoning. In dead reckoning, navigation (or tracking) depends on determining a known position — called a *fix* — and then calculating subsequent positions from the platform speed and direction.

Direction data can be obtained from compass sensors that output direction as an analog voltage or digitally encoded signal. Altitude can be calculated based on ground barometric pressure and absolute pressure readings from the platform.

Obtaining accurate ground speed data is difficult for mobile platforms such as balloons or water-borne instruments which move with the wind or current. If some other form of position tracking is available, it is possible to infer ground speed although rarely accurately.

### 16.3.2 GPS Data

As currently practiced, a GPS (Global Positioning System) module is the usual means of acquiring navigation data which is then transmitted as a telemetry stream using the Automatic Packet Reporting System (APRS). Thus, the two are combined in this section.

Depending on the model, GPS receivers produce a number of *navigation sentences*, such as the GPGGA and GPRMC sentences described below. GPS sentences are human-readable text with information in fields separated by commas. Below is a brief description of the two more important GPS sentences (when it comes to high altitude ballooning) and their fields.

#### THE GPGGA SENTENCE

The GPGGA sentence is the Global Positioning System Fixed Data sentence and a typical GPGGA sentence from a balloon-based GPS looks like this.

```
$GPGGA,153919.00,4332.2076,N,  
11608.6666,W,1,08,1.1,13497.1  
,M,18.3,M,,*78
```

There are 13 fields in the GPGGA sentence

following the sentence identifier, "\$GPGGA". The fields from left to right are as follows.

- 1) Time in UTC (hours, minutes, seconds)
- 2) Latitude North (degrees and decimal minutes — note that there is no separator between degrees and minutes)
- 3) N (north)
- 4) Longitude West (degrees and decimal minutes — note that there is no separator between degrees and minutes)
- 5) W (west)
- 6) GPS Quality Indicator (0 = no GPS fix, 1 = GPS fix, and 2 = differential GPS fix)
- 7) Number of Satellites (number of satellites detected — not all of them may be used in determining the position)
- 8) Dilution of Horizontal Position (or DOHP, which is an indication of how precise the fix is and the closer to 1.0 the better)
- 9) Altitude (in meters)
- 10) M (meters)
- 11) Geoidal Separation (the difference in the actual height and a mathematic description of the height of an idealized Earth's surface in meters)
- 12) M (meters)
- 13) Checksum (result of exclusive ORing the sentence and used to verify that the text is not corrupted)

#### THE GPRMC SENTENCE

The GPRMC sentence is the Recommended Minimum Specific GPS/Transit Data sentence and a typical GPRMC sentence from a balloon-based GPS looks like this.

```
$GPRMC,153924.00,A,4332.2317,  
N,11608.6330,W,24.4,46.3,2310  
99,16.1,E,*7E
```

There are 12 fields in the GPRMC sentence following the sentence identifier, "\$GPRMC". The fields from left to right are as follows:

- 1) Time in UTC (hours, minutes, seconds)
- 2) Navigation warning (A = okay and V = warning)
- 3) Latitude North (degrees and decimal minutes — note that there is no separator between degrees and minutes)
- 4) N (north)
- 5) Longitude West (degrees and decimal minutes — note that there is no separator between degrees and minutes)
- 6) W (west)
- 7) Speed (in knots)
- 8) Heading (in degrees true north)
- 9) Date (day, month, and year — note that there is no separation between them)
- 10) Magnetic Variation (number of degrees)
- 11) Direction of magnetic variation (E = east and W = west)
- 12) Checksum (result of exclusive ORing the sentence and used to verify that the text is not corrupted)

### 16.3.3 Automatic Packet Reporting System (APRS)

Most mobile platforms include an APRS station in order to follow the platform's position and altitude throughout a mission to the edge of space. The APRS position reports, usually containing GPS data as described above, can be used directly to locate the position of the platform for recovery or tracking. (For more details about APRS, see the **Digital Protocols and Modes** chapter.)

There is a large network of dedicated ground stations, digipeater and Internet gateway stations operating on the US national APRS frequency of 144.390 MHz (144.800 and other frequencies are used elsewhere in the world). Thanks to this network, the platform's position will be plotted onto a map in near real-time. Two popular websites to view the maps are at [aprs.fi](http://aprs.fi) and [findu.com](http://findu.com). These sites are databases of APRS packets received and routed through APRS Internet gateways.

Chase crews collect a platform's APRS data directly over Amateur Radio or over the Internet using the APRS maps. The platform or payload can then be recovered based on this position data. Later the data is correlated with other sensor data and images that are stored in on-board memory.

There are a number of APRS "trackers" that combine a low-power GPS module with a VHF transmitter and microprocessor that creates the APRS message packets. For example, Byonics ([www.byonics.com](http://www.byonics.com)) makes a number of APRS tracking and telemetry products, including the Micro-Trak RTG FA High Altitude Combo that contains an altitude-certified GPS for balloon payloads.

The RPC-Electronics ([www.rpc-electronics.com](http://www.rpc-electronics.com)) RTrak-HAB - High Altitude APRS Tracker Payload is specially made for high-altitude ballooning, as well.

The tracker combination built by WB8ELK is shown in Figure 16.2. On the right is a GPS module that creates the GPS sentences discussed previously. On the left is the MMT (Multi-Mode Transmitter) that creates and transmits the APRS packets.

### APRS POSITION DATA

A simple APRS tracker can generate a stream of useful navigation data for a mission. The data begins at the GPS receiver where two navigation sentences are generated. The sentences are then combined to create a position report in the required APRS format. Like GPS sentences, the raw APRS packets are also readable text that is easily interpreted.

An APRS position report uses a combination of commas and slashes as field delimiters. An example of an APRS report from a balloon mission looks like this:

```
13:37:23 UTC: KD4STH-  
8>APT311,WIDE1-2,qAS,KC0QBU,1  
33721h3836.39N/09500.  
51W>160/031/A=049114
```

There are 12 fields in the APRS report. The fields from left to right are as follows:

- 1) Time in UTC (hours, minutes, seconds)
- 2) Call sign and SSID
- 3) Routing Information
- 4) GPS Time (time in UTC — note there is no separator between hours, minutes, and seconds)
- 5) h (hours)
- 6) Latitude North (degrees and decimal minutes — note that there is no separator between degrees and minutes)
- 7) N/ (north)
- 8) Longitude West (degrees and decimal minutes — note that there is no separator between degrees and minutes)
- 9) W> (west)
- 10) Heading (in degrees from true north)
- 11) Speed (in knots)
- 12) A= (altitude equals)
- 13) Altitude (feet)

There are other formats and fields that may be present. Additional telemetry fields can be added in a variety of formats following the altitude data. For more information about the APRS reports, see "APRS Formats Used in Edge of Space Sciences," at [www.eoss.org/aprs/aprs\\_formats\\_eoss](http://www.eoss.org/aprs/aprs_formats_eoss).

### APRS CONFIGURATION

High altitude APRS trackers should be programmed to provide altitude data and not to use Smart Beaconing. Altitude data is a fascinating datum and useful for determining

when a platform has landed. Smart Beaconing prevents APRS trackers from transmitting their position while the tracker is not changing its speed or direction. At landing, it's important that the tracker continue to announce its position on a regular schedule. This is particularly important if the tracker was out of range of the chase crew at the time of landing.

The horizon for high altitude balloons and larger rockets can be hundreds of miles away. Therefore, their transmission footprint can cover tens of thousands of square miles. To prevent high altitude APRS trackers from interfering with orderly use of APRS, the high-altitude ballooning community recommends programming an APRS tracker with the following settings if a frequency of 144.390 MHz is used. (Thanks, Jerry Gable, KF7MVY)

1. Path Recommendations: Use no Path or set Path to WIDE2-1. Never use a two-part path such as the common WIDE2-1, WIDE-1 nor use WIDE2-2 or WIDE3-3.

2. Transmit Rate: Limit the transmit rate to once per 60 seconds during ascent and no less than 30 seconds during descent.

If possible or practical, you may want to use a frequency other than 144.390 MHz.

### 16.3.4 Satellite Telemetry

Amateur satellites use a variety of modulation methods and data encoding to construct and transmit the stream of data coming from the satellite. Bit rates vary from 1200 to 9600 bps and modulation types of CW, PSK, BPSK, FSK, and AFSK are common. Each satellite also uses a custom scheme to encode the data, often using the AX.25 packet radio protocol.

Decoding satellite data would be very challenging except that the team building the satellite usually publishes a description of the telemetry stream and provides software for receiving and decoding the data. In this way, individual amateurs can collect telemetry data for the satellite's operational team.

Information on particular satellites is often available at one of the AMSAT websites such as [www.amsat.org](http://www.amsat.org) (AMSAT North America) or [amsat-uk.org/satellites/telemetry/](http://amsat-uk.org/satellites/telemetry/) (AMSAT UK). Satellite status, including whether telemetry decoder software is available, can be found at DK3WN's website ([www.dk3wn.info/p/?page\\_id=29535](http://www.dk3wn.info/p/?page_id=29535)). Additional information for CubeSats launched by universities or other private groups is usually available on a web page provided by the satellite's sponsor.

To decode satellite telemetry reliably at the higher bit rates, particularly 9600 bps, you will need to provide the full bandwidth audio from the receiver or use packet radio TNCs that are rated for 9600 baud operation.

The Fox-1 satellite (AO-85, see [www.amsat.org/status](http://www.amsat.org/status) for the satellite's current status) has both a low-speed 200 bps DUV (data under voice) and a high-performance 9600 bps FSK telemetry stream. *FoxTelem* software is available for decoding the information. As an example of current best practices for satellite data, a two-part article from *AMSAT Journal* on the Fox-1 telemetry system is available as a PDF on the downloadable supplemental information. (See the reference listings for Burns Fisher, W2BFJ and Chris Thompson, AC2CZ.) Numerous other satellites use the same or similar telemetry formats and modulations.

### 16.3.5 Non-Licensed Telemetry Transmissions

There are many low-power data links operating in the unlicensed 915 MHz and 2.4 GHz bands. Typically, these are intended to be used for short-range applications but with the balloon payload at great altitude, the range of these devices is much longer, particularly if a high-gain Yagi antenna is used to track the payload. (See the **Antennas** chapter for information on VHF and UHF beams.)

Many of the data link modules use a standard two-way protocol such as Zigbee and have direct analog and digital inputs and outputs. Some modules support Ethernet and Bluetooth interfaces, offering even more options for modules that can be assembled into the payload.

It is also important to note that unlicensed transmitters operating under FCC Part 15 rules are also subject to certain restrictions such as field strength. In addition, the type of antenna may be fixed and even required to be attached to the transmitter permanently. These and other restrictions are required in order to limit the range of these devices. Amateurs are used to modifying and adjusting their equipment, and this may not be allowed for some of these devices! Be sure to obtain the full documentation for any unlicensed device you plan on using and be sure you can use it in the way you expect.

### 16.3.6 Other Telemetry Digital Modes

The usual method of communication from airborne and other remotely located platforms is via the APRS network. APRS messages are packaged in X.25 packets and usually transmitted as FSK or PSK modulation on FM transmissions. This works well and takes advantage of the extensive ground network of APRS digipeaters and servers.

Along with APRS, other subsystems are popular in the amateur balloon community. These include Weak Signal Propagation

Reporter (WSPR), Hellschreiber, DominoEX, Contestia, JT9, PSK31, RTTY, CW (especially for fox hunting a lost near space balloon), FM for voice repeaters, and imagery through ATV and SSTV. (All of these digital modes are described in detail in the **Digital Protocols and Modes** chapter.)

#### WSPR

WSPR, part of the *WSJT-X* software suite (see the **Digital Protocols and Modes** chapter), is a simple location reporting method using HF and therefore, a practical tracking data system for long duration balloon flights. WSPR takes a bit less than two minutes for one transmission.

The format of a WSPR report specified in the protocol definition is limited to: call sign, transmitter location (using the Maidenhead grid locator system), and transmitter power (in dBm). To send telemetry, amateurs have developed a way to encode altitude, voltage, temperature and a six-digit grid locator by sending a second WSPR transmission that uses a call sign beginning with a "0" or a "Q" which are prefixes not used in Amateur Radio. The telemetry is embedded in the call sign field and power levels and one method also uses the grid square. There are several protocols in use and undergoing development as of early 2018. You can find information on them by doing an Internet search for "wspwr telemetry".

**Figure 16.11** shows the track of WB8ELK's balloon that took six trips around the world in 75 days. The track is based on WSPR.net reports and displayed on the UK High Altitude Society's (UKHAS) [tracker.habhub.org](http://tracker.habhub.org) website which features tracking of many balloons that are flying at any given time.

WSPR has a similar advantage to APRS in that there is a distributed network of ground stations around the world that relay reports to a centralized web server which can be

viewed on the [wspwrnet.org](http://wspwrnet.org) website. The data from a long duration balloon can be picked up from many thousands of miles away using a very low power HF transmitter in the 10 to 25-mW range.

#### JT9

JT9, part of the *WSJT-X* software suite (see the **Digital Protocols and Modes** chapter), is also very effective for low-power HF telemetry and has been used for long duration, high altitude balloon platforms. It takes less than a minute to send a transmission. It does allow a free-form transmission in which telemetry can be embedded, however the amount of information is very limited. There is no distributed world-wide ground station network that exists, as there is for the APRS and WSPR modes.

#### HELLSCHREIBER

Hellschreiber ("light writer" in German) is an HF transmission method that can send balloon location and other data as a fax image. The characters are formed with an accurately timed sequence of on/off keying that forms an image of the data in a received waterfall-style display. This makes it an ideal mode for poor reception conditions, since human eyes are very good at retrieving information from a noisy image.

#### ASCII RTTY

ASCII RTTY is very easy to implement with a small microcontroller. It uses two tones and speeds similar to Baudot RTTY but uses the full ASCII character set to send telemetry. Speeds ranging from 45 baud for HF systems. 100 to 300 baud RTTY can be sent via VHF and UHF FM transmitters.

#### CONTESTIA AND OLIVIA

Contestia and Olivia are MFSK modes with excellent FEC correction. They can be

**The track of a balloon launched by WB8ELK that managed 6 trips around the world in 75 days. The image was generated from WSPR reports collected by the UKHAS website ([tracker.habhub.org](http://tracker.habhub.org)).**

used for HF, VHF and UHF payloads. Information about these modes and how to encode them in a microcontroller can be found here: [ukhas.org.uk/guides:olivia\\_and\\_contestia](http://ukhas.org.uk/guides:olivia_and_contestia)

### DOMINOEX

DominoEX is designed for very weak signals using an 18-tone sequence that can send balloon data using a low power signal on either HF, VHF or UHF. It uses Offset Incremental Frequency Keying (IFK+) which uses the frequency difference between tones rather than the absolute frequency of each tone. As a result, it is very tolerant of frequency drift.

### PSK31

PSK31 is a phased shift keyed mode primarily for HF payloads that requires a stable transmitter and can provide a 31.25 baud data rate.

### CW (MORSE CODE)

CW is likely the easiest mode to implement with a small microcontroller performing On/Off Keying or OOK. It is primarily used as a backup transmitter for direction-finding a lost balloon payload. With the addition of a small GPS, some balloon groups actually

send the position and altitude via Morse code so that the chase crew can decode the position without using a decoding program on a laptop computer.

### SATELLITE COMMUNICATION

Some missions use satellite communications as a backup and telemetry-message system. These are unlicensed communication methods that charge a subscription fee. The two satellite communications services used today are Spot (for position tracking below 20,000 feet altitude — [www.findmespot.com](http://www.findmespot.com)) and Iridium modems (for sending messages — such as the RockBlock Mk2 modem ([www.sparkfun.com/products/13745](http://www.sparkfun.com/products/13745))). There are no format standards for data transmitted using satellite or mobile phone systems.

#### 16.3.7 Receiving and Relaying Telemetry

Most digital modes can be readily received by a modified version of the free software package *FLdigi* called *dl-FLdigi* which can be downloaded from [ukhas.org.uk/projects:dl-fldigi](http://ukhas.org.uk/projects:dl-fldigi). This software receives

and decodes the telemetry, uses a checksum to ensure the accuracy of the received data and sends that data to a server. The position report can then be viewed at: [tracker.habhub.org](http://tracker.habhub.org) which is maintained by the UK High Altitude Society (UKHAS). The site can display telemetry from any platform but has a number of features specifically designed for high altitude balloon platforms, both Amateur Radio and license-free transmitters.

The format for generating telemetry for use with [tracker.habhub.org](http://tracker.habhub.org) is comma-separated values (CSV) of ASCII characters as follows:

```

$$CALLSIGN,
sentence_id,
time,latitude,
longitude,
altitude,
speed (optional),
bearing (optional),
internal temperature (optional),
*CHECKSUMn

```

Although these parameters can be changed with the exception of \$\$ to start and a checksum at the end. More information on the telemetry formats can be found at [ukhas.org.uk/communication:protocol](http://ukhas.org.uk/communication:protocol).

## 16.4 Payloads

### 16.4.1 VHF/UHF/Microwave Payloads

#### NEAR SPACE TRACKER

A very popular configuration for high-altitude payloads is the Near Space Tracker, consisting of avionics to acquire and record or transmit data, an APRS tracker module coupled with a GPS receiver for position data, and a simple dipole or omnidirectional antenna. **Figure 16.12** shows a typical physical layout for such a package. The APRS tracker module consists of a *terminal node controller* (TNC) and a transceiver module. It is advisable to use a complete APRS tracker for balloons than to use a separate TNC and radio. Using a combined system reduces the complexity, weight, and battery needs of the tracker.

A complete construction article is included in this book's downloadable supplemental content, titled "Touching Near Space on a Budget," by Paul Verhage, KD4STH. The assembled tracker is shown in **Figure 16.13**. It uses an inexpensive insulated lunch cooler to hold the electronics, battery, and antenna.

Tracker packages such as this are excellent experiments not only for hams but for students and other groups when assisted by a licensed amateur to allow the use of the APRS module. Such experiments are a good way to

introduce students to Amateur Radio and can often be supported by a local radio club.

Key considerations for trackers are their weight (less is better) and time of operation (or how long will they operate on a fully charged battery). The lighter the tracking system, the more available weight for science

payloads. It also means a given balloon will reach a higher altitude before bursting (on account of the reduced initial volume of lifting gas). Since it can take an hour to fill a launch a balloon, ninety minutes to reach peak altitude, forty-five minutes to descend, and a few hours to recover, a tracker should

**Figure 16.12** — A cut-away graphic showing an idealized Near Space Tracker including an APRS tracker, GPS receiver, an avionics package, batteries, and a dipole antenna.

Figure 16.13 — The complete Near Space Tracker assembled in an insulated fabric lunch cooler.

be capable of running for at least six hours on a set of batteries.

APRS trackers such as the Bionic TinyTrak 3, Argent Data Systems Tracker3, Tracksoar, and others are software configurable. This means the tracker's behavior can be pre-programmed using configuration software provided for the tracker. An APRS tracker is configured for settings such as Callsign, SSID, Symbol, Smart Tracking, Transmit Times, Time Slotting, and Status Messages. (See the previous section on APRS.)

A tracker producing a 300 mW signal is adequate for a balloon flight. Even an APRS transmitter producing only 25 mW such as the Skytracker ([wb8elk.com](http://wb8elk.com)) can be used as a backup tracker. Even at this low power it is comparable to higher power transmitters down to about 1500 feet AGL (above ground level). This means a battery with a capacity of several hundred mAh's will be sufficient for most balloon flights (a 2200 mAh is even better since it permits an overnight recovery).

Since a 5-V LM2940T-5 voltage regulator has a drop-out of 0.5 V, a two-cell (2S) rechargeable LiPo battery can provide more than enough power for most avionics on a balloon flight. In addition, these batteries are commonly available from hobby stores where they are sold for RC racing cars.

A vertical dipole is the recommended antenna for near space tracking modules using APRS. They are simple to construct, light weight, and are not direction sensitive with respect to chase vehicle antennas (which

tend to be mag-mounted vertical whips).

### GPS RECEIVERS

GPS receivers are a vital component for APRS trackers. To prevent their use in guided missiles, the Coordinating Committee for Multilateral Export Controls requires GPS receivers to stop creating position data when they are moving faster than 1,000 knots at an altitude above 59,000 feet. Some companies have taken this as an OR condition and not an AND condition as it was meant. Therefore, amateurs must verify their selected GPS receiver will operate above 59,000 feet. Amateurs can find a list of appropriate receivers through an Internet search.

GPS signals are weak signals. This means it can be easy to block the radio signals that GPS receivers depend upon. Experiments have shown that several inches of Styrofoam will not block a GPS signal, but that a layer of aluminized Mylar will. It's important that amateurs test their APRS tracker prior to launch after they have finished constructing their airframe.

### SIMPLEX REPEATER

Readers should be aware that a high-altitude balloon at 100,000 feet has a radio line-of-sight horizon of more than 400 miles. The formula for radio signal line-of-sight in miles can be calculated as follows:

$$\text{Distance (in miles)} = 1.41 \times \sqrt{\text{height (in feet)}}$$

where H is the height in feet.

Since antenna height is so important for operating on VHF and UHF, imagine having an antenna that is 19 miles high. If you could fly a repeater to that altitude, two ground stations 800 miles apart could communicate with each other through the repeater. One simple way to do this is to fly a single handheld radio operating on 2 meters or the 70 cm band. Connecting a voice recorder and playback device to the handheld radio creates a *simplex repeater*. One such device is the Argent Data ADS-SR1. A discontinued Radio Shack simplex repeater module can be sometimes found online.

It takes some practice and patience to get the hang of a simplex repeater conversation, but this provides a very simple way to make some very exciting contacts over a multi-state region using minimal equipment on the ground.

### CROSSBAND REPEATER

If you use two handheld radios, one on 2 meters and one on 70 cm, you can build a crossband repeater payload. (Some handheld radios can also operate as crossband repeaters by themselves.) You'll need to build an audio level control to adjust the audio between the two radios and also provide a PTT control.

Although more complicated, heavier and more expensive than the simplex repeater, this does provide a real-time repeater without having to worry about flying large filters to prevent desense. The input is usually on the 2 meter band with the output on the 70 cm band. Although you can set it up the other way around, the 3rd harmonic of the 2 meter transmit can cause desense issues with the 70 cm receiver.

### STILL IMAGES

A great addition to any balloon flight is the ability to actually receive live images during the flight. From 100,000 feet you can clearly see a spectacular view of the blackness of space and the curve of the Earth since the balloon is above 99 percent of the atmosphere. **Figure 16.14** shows a photo taken from by a balloon-launched camera. Suitable lightweight cameras are available in thumb drive (USB) formats and helmet- or bike-cams designed to be used while being worn.

SSTV has been flown since at least 1998 and is still used with 2 meter FM transmitters by using a SSTV module such as SSTVcam by ArgentData ([www.argentdata.com](http://www.argentdata.com)). The SSTV images are decoded using sound cards and software on a PC. The ability to use software means amateurs are free to use virtually any SSTV mode they prefer. The Argent system is configurable to produce images in the following four modes, Robot 36, Robot 72, Scottie 1, and Scottie 2. Scottie 2 will transmit one image in 71 seconds and Robot

Figure 16.14 — A balloon carrying a camera payload was launched from the Dayton Hamvention in 2010 by Bill Brown, WB8ELK. This picture was obtained a few minutes later from an altitude of about 1000 feet.

Figure 16.15 — This payload consists of a GPS receiver (right), payload controller (center), and an ATV transmitter (left). Batteries and cables are in the far-right compartment and the entire platform is contained in a Styrofoam enclosure.

36 is somewhat quicker although with some loss of resolution. The Scottie modes are most commonly used for balloon flights. (See the downloadable **Image Communications** chapter)

There are several programs to decode the SSTV audio signal and display the images on a computer screen. *MMSSTV*, *MixW*, *MultiPSK* and *Ham Radio Deluxe* (DM780) are a few programs that can be used to capture and view SSTV images.

## VIDEO

There is nothing like watching a live video camera view from a flight to the edge of space. Typically, a 1 W to 3 W AM-modulated ATV transmitter on either 434 or 439.25 MHz is used for best results. You can also use FM ATV transmitters on higher frequencies, such as the 23 cm and 13 cm bands, but the path loss will be much higher on those frequencies and that will limit your maximum downrange reception distance. There are many lightweight video cameras that can be used. (See

the **Image Communications** chapter with the downloadable supplemental material for more information about analog and digital ATV.)

Analog and digital methods are used to transmit video. In digital mode, Raspberry Pi computers can produce the video and 5.8 GHz modems are used to transmit the video. UHF can also be used to transmit digital video. By using video overlays, GPS data can be superimposed on images as a backup tracking method.

A variety of transmitters can be found at these websites: [www.hamtv.com](http://www.hamtv.com), [www.hamtv.com/vidcolynx.html#VM70X](http://www.hamtv.com/vidcolynx.html#VM70X), [kh6htv.com](http://kh6htv.com) and [www.hides.com.tw/product\\_eng.html](http://www.hides.com.tw/product_eng.html).

Figure 16.15 shows a typical ATV payload in the insulating Styrofoam box enclosure. On the left is the low-power 70 cm transmitter. In the middle is the microprocessor-based controller. The GPS receiver module is on the right. The batteries and cables are placed in the separate compartment at the far right. Note that the three electronics boards are mounted over a common PCB ground-plane to provide mechanical stability and to minimize RFI from the transmitter. The antenna for the ATV link hangs below the package.

On UHF, Little Wheel or Big Wheel omnidirectional antennas have been a staple of high altitude weather balloons. The balloon group Project Traveler has a webpage on making a Little Wheel antenna for high altitude balloon flights at [www.projecttraveler.org/index.php/how-to-s/6-little-wheel-antenna-for-70cm-atv](http://www.projecttraveler.org/index.php/how-to-s/6-little-wheel-antenna-for-70cm-atv). PC Electronics ([www.hamtv.com/wheel.html](http://www.hamtv.com/wheel.html)) carries the Olde Antenna Labs line of “wheel” antennas for various bands as well as video camera modules, ATV transmitters and receivers.

Analog video will produce P5 (high-quality) signals early in the flight while the balloon’s altitude is relative low. At high altitudes, it’s not uncommon to receive P1 (low-quality) signals on the ground, even from below the balloon.

Remember that the power requirements for a continually operating 1 W TV transmitter will be much higher than an APRS or audio repeater payload. You’ll typically need at least 12 V with an Ah rating sufficient to allow for at least three hours of operating time. High capacity, four-cell, RC racing car batteries are a good option for powering ATV transmitters.

You will need a good antenna on the ground, an ATV downconverter, and an analog TV receiver. If you are flying in an area where horizontal polarization is used for local ATV activity, the Big Wheel antenna is a good option for the payload’s ATV antenna. It provides good coverage at the horizon as well as underneath the payload. You can also use a vertical antenna, but there will be a null directly underneath a vertical radiator.

## 16.4.2 HF Payloads

The RF range of a high-altitude balloon at peak altitude is limited to about 450 miles when using VHF and UHF. Some balloon groups have flown transmitters on the HF bands with reception reports many thousands of miles away. It's a great way to include Amateur Radio operators far outside your local region.

There are several digital modes that can be programmed into a small microcontroller without having to invoke floating point math (see [www.elktronics.com](http://www.elktronics.com) for an example of a multi-mode HF balloon transmitter). Morse code, RTTY, PSK31, DominoEX, and Hellschreiber have all been successfully flown, as well.

Transmit power levels under 1 W will work well due to the weak signal advantage of some of these digital modes. DominoEX, Hellschreiber, and PSK31 are particularly good for very weak signal reception. WSPR will also provide tracking information.

## 16.5 High Altitude Balloon Platforms

The reader will find plenty of near space information downloadable by using search terms such as “near space,” “ARHAB,” or “BalloonSats”. Persons and organizations planning a near space event will find a series of papers and presentations on the [nearsys.com](http://nearsys.com) website in its “Other People’s Helium” section ([www.nearsys.com/arhab/ophe/ophe.htm](http://www.nearsys.com/arhab/ophe/ophe.htm)). The free e-book *BASIC Stamp Near Space* (see the References section) covers every aspect of high altitude ballooning. It is written for the amateur who wants to begin a near space program from scratch or who is looking for new ideas. Finally, the “Near Space” column in *Nuts and Volts* magazine contains articles on designing and using microcontrollers for high altitude balloon projects.

Here are a few websites with a great deal of information about Amateur Radio high altitude ballooning (ARHAB):

- Amateur Radio High Altitude Ballooning (ARHAB) — [www.arhab.org](http://www.arhab.org)
- Near Space — [nearsys.com](http://nearsys.com)
- Edge of Space Sciences — [www.eoss.org](http://www.eoss.org)
- WB8ELK Balloons — [www.wb8elk.com](http://www.wb8elk.com)
- UK High Altitude Society — [www.habhub.org](http://www.habhub.org)
- Great Plains Super Launch — [www.superlaunch.org](http://www.superlaunch.org)

### RESTRICTIONS ON UNATTENDED OPERATION

Note that unattended “beacon” operation and stations making transmission on their own are restricted to the automatic control band segments when located in areas under FCC jurisdiction. There should be a way to turn the HF transmitter on or off under remote control. (Being able to turn the transmitter on and off does not constitute full control via the remote link so the transmitter is still considered to be operating under automatic control.) There are a number of inexpensive and lightweight UHF handheld radios that can be used as a control receiver along with a DTMF decoder board.

Be sure to comply with the requirements of FCC Part 97.221 – Restricted Operation, which reads as follows:

§97.221 *Automatically controlled digital station.*

(a) *This rule section does not apply to an auxiliary station, a beacon station, a repeater*

*station, an earth station, a space station, or a space telecommand station.*

(b) *A station may be automatically controlled while transmitting a RTTY or data emission on the 6 m or shorter wavelength bands, and on the 28.120-28.189 MHz, 24.925-24.930 MHz, 21.090-21.100 MHz, 18.105-18.110 MHz, 14.0950-14.0995 MHz, 14.1005-14.112 MHz, 10.140-10.150 MHz, 7.100-7.105 MHz, or 3.585-3.600 MHz segments.*

(c) *Except for channels specified in §97.303(h), a station may be automatically controlled while transmitting a RTTY or data emission on any other frequency authorized for such emission types provided that:*

(1) *The station is responding to interrogation by a station under local or remote control; and*

(2) *No transmission from the automatically controlled station occupies a bandwidth of more than 500 Hz.*

### 16.5.1 FAA Requirements

The regulating agency for unmanned free balloons is the Federal Aviation Administration (FAA). The applicable regulation for unmanned free balloons is the Federal Aviation Regulation Part 101 (FAR 101) or Title 14: Aeronautics and Space, 14 CFR 101.

FAR 101 Section 101.1 applies to any unmanned free balloon if it falls under one of these four conditions:

1. The unmanned free balloon carries a payload weighing more than 4 pounds and has a weight/size ratio greater than 3 ounces per square inch (This “surface density” is measured on the side of a payload with the smallest area).

2. The unmanned free balloon carries a single payload weighing more than 6 pounds

3. The unmanned free balloon carries a payload of two or more packages weighing a combined 12 pounds

4. The unmanned free balloon uses a rope or line to connect the payload to the balloon, which requires more than 50 pounds of force to separate the payload from the balloon.

Amateurs are strongly encouraged not to exceed the four limitations outlined above. When any of these limitations are exceeded, the balloon flight must meet additional requirements. These requirements are explained in Subpart D and include the following.

A) Limitations on launch site selection

B) Limitations regarding cloud cover at the time of launch

C) Requirement to add payload cutdown devices

D) Requirement to add balloon termination devices

E) Requirement to add a radar reflector to the balloon train

F) Requirement to increase the visibility of the balloon train

G) Additional pre-launch notification requirements

H) The requirement to regularly report the balloon’s position

Section 101.3 states that one can request a waiver for a balloon flight that cannot meet the requirements of FAR 101. Anyone requiring a waiver must complete an FAA Form 7711-2, Application for Certificate of Waiver or Authorization.

Section 101.5 states that an unmanned free balloon cannot be launched from a restricted or prohibited area without permission from the controlling agency, or agency that uses that restricted or prohibited area.

Section 101.7 states that you cannot operate a balloon in a manner that creates a hazard to people or their property. For example, a balloon cannot be launched if during its flight objects will be dropped objects in such a way that can harm or injure people or their property.

The maximum weight per payload is six

pounds for a total of twelve pounds for the platform. Launching additional weight requires getting special permission from the FAA. This doesn't mean that you can fly 6-pound lead weights. You have to make sure that the density of your payload will not inflict damage to others, and it also needs to protect all those expensive electronics that you have packed inside.

### 16.5.2 Balloon Platform Environment

The near space environment has environmental conditions that are in many ways closer to those found in outer space than Earth's surface as Table 16.2 illustrates (LEO stands for Low Earth Orbit).

#### HORIZONTAL DEPRESSION

For an observer at the Earth's surface, the visual horizon forms a horizontal line, 90 degrees from the zenith (the point overhead) for all azimuths (directions). As height increases, the horizon is determined by the point at which a line from the observer's eye is tangent to the Earth's surface. (The radio

horizon is a bit more distant as explained in the chapter on **Propagation of Radio Signals**.) As an observer's altitude increases, as shown in Figure 16.16, that tangent point becomes more distant due to the curvature of the Earth. The angle from the zenith to the tangent line also increases, therefore the horizon appears lower to the observer. This lowering of the horizon is called *horizontal depression*.

#### ATMOSPHERIC DENSITY AND PRESSURE

Air pressure, and therefore density, decreases as altitude increases because the weight of air still above that level decreases. The scientific way of specifying changes in atmospheric density is *scale height*. Similar to a capacitor discharging, scale height is the change in height by which the density of the atmosphere decreases by a factor of *e* (which equals 2.718). Scale height depends on factors such as acceleration of gravity, the average atomic mass of atmospheric gases, and temperature. Scale height is a characteristic of every planet's atmosphere and a useful measurement for astrodynamics and astron-

omy. The scale height of Earth's atmosphere is 4.9 miles. Therefore, for every 4.9-mile increase in height, Earth's atmosphere is 1/*e* or 37% as dense. A simple rule of thumb is that air pressure drops by 50% per 18,000-foot increase in altitude.

Air pressure (see Figure 16.17) is a concern in near space experiments for keeping organisms alive, high voltage electrical circuits that might arc over without the insulation provided by the air, and where contact with the air is a factor in keeping devices cool.

#### TEMPERATURE

The atmosphere consists of four layers, two of which are observable in the Figure 16.18 chart. The lowest layer is the *troposphere* and it includes all our weather. It's heated by its contact with the ground (which is heated by sunlight) and not directly by sunlight. The higher in the troposphere, the farther from the warm ground and therefore the colder the air.

The second atmospheric layer is the *stratosphere* and it grows warmer from energy absorbed by ozone molecules in the layer. As ozone blocks solar ultraviolet from reaching the ground, the energy of the ultraviolet photons warms the ozone molecules. The higher one climbs into the stratosphere, the more ultraviolet there is to block and therefore the warmer the air.

The *tropopause* is the boundary between the troposphere and stratosphere. Sensors often show the air temperature remaining constant within this transition layer. Figure 16.18 shows a typical temperature profile measured during a balloon experiment.

Temperature is a factor in how fast chemical processes operate. Low temperatures are a concern for the voltage and current output of batteries. Low temperature can also increase viscosity to the point that lubricated mechanical systems will seize. Another issue is that some items (such as plastic zip ties) become brittle in the cold and may not perform as expected in near space.

#### ALTITUDE AND TEMPERATURE RATING

Many GPS receiver modules will not work above 60,000 feet. When choosing a GPS receiver, make sure the datasheet specifies a maximum altitude above the expected maximum altitude of the balloon. Some popular modules known to work at stratospheric altitudes are those made by Trimble, Garmin, u-Blox and Inventek as well as high-altitude modules offered by Byonics and Argent Data.

Instrument modules designed for high altitude experiments should have a sufficient rating for conditions found at high altitude. Modules and other items made for general purpose use may not have an adequate altitude

Table 16.2  
Balloon Environment Summary

	Sea Level	Near Space	LEO
Pressure	1013 mb	60 mb to 5 mb	0 mb
Temperature	59 °F	-60 °F to 20 °F	undefined
Gravity	32.2 ft/sec <sup>2</sup>	31.09 ft/s <sup>2</sup>	28.9 ft/s <sup>2</sup>
Distance to Horizon*	3 miles for 6' tall adult	300 miles to 400 miles	1260 miles
Horizontal Depression**	0 degrees	5 degrees	18 deg
Cosmic Rays	8 counts/min	800 counts/min	?
UV Radiation	UV-A, small amount UV-B	UV-A and UV-B	UV-A, B, & C

\* Distance to horizon can be calculated by the formula distance (miles) = sqrt(height(feet) \* 1.5)

\*\* See text

Figure 16.16 — In this highly exaggerated view, the higher balloon has a more distant horizon than at lower altitudes. This depresses the higher altitude balloon's horizon as altitude increases.

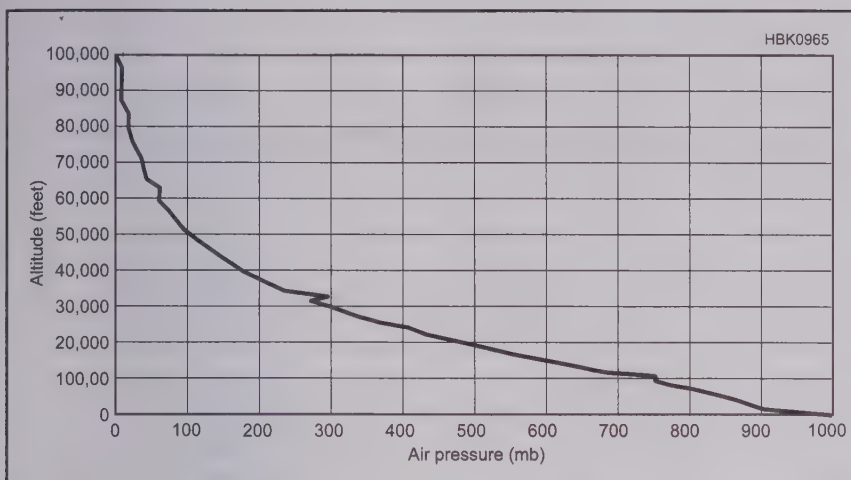

Figure 16.17 — A typical change of air pressure versus altitude.

Figure 16.18 — Typical air temperature profile versus altitude, showing the troposphere (up to 50,000 feet) and the stratosphere (above 50,000 feet).

Figure 16.19 — Cosmic rays are encountered more frequently with increasing altitude in this typical balloon experiment.

and temperature rating. That does not mean that will not work when those ratings are exceeded but they may become unreliable or fail to meet their performance specifications.

Since most consumer electronics and integrated circuits are rated for 0 to 70 °C you may want to find devices that are rated for the industrial temperature range (-40 to 100 °C) or the automotive temperature range (-40 to 125 °C) for near space payloads. Forums and user communities involved with high altitude ballooning will often have recommendations for specific models of equipment that perform well in these extreme conditions. (See the preceding section on Temperature and Relative Humidity.)

Cosmic rays are energetic subatomic particles. Most of this population of particles are protons, or the nuclei of hydrogen atoms. A smaller population of heavier nuclei can also be found in cosmic rays. When atomic particles enter the upper atmosphere, they are called *primary cosmic rays*.

When primary cosmic rays collide with molecules of oxygen and nitrogen, they break apart the atoms and create a shower of *secondary cosmic rays*. These secondary cosmic rays contain energetic X-rays and other subatomic particles such as neutrons, pions, and muons. Many of the secondary cosmic rays decay and lose energy through further collisions. The result of the multiple collisions is a peak in cosmic ray flux at around 62,000 feet (called the Pflotz Line). Depending on the type of radiation sensor used, at the Pflotz line, the cosmic ray flux can be one hundred times greater than at sea level. (See Figure 16.19.)

Cosmic ray strikes can affect sensitive electronics. However, this should only be a concern in electronic devices with Very Large Scale Integration (VLSI) integrated circuits. This includes memories, processors, and advanced processing units. Smaller scale ICs have larger logic and circuit structures, making it more difficult for a cosmic ray to “flip a bit.”

High-speed avionics may be at a slightly greater risk from cosmic-ray induced *single-event upsets* (SEU) during a near space flight. In fact, NASA research has found that avionics at 100,000 feet may experience an SEU once per 2.3 hours on average. Chances are the amateur will not have access to radiation-hardened electronics; in fact, it may raise suspicions if an amateur were to purchase such electronics! Advanced avionics uses software to detect and correct SEUs, but this may not be practical for amateurs either. The amateur’s simplest solution is to design their avionics using electronics with large memory cells, and therefore not to use VLSI integrated circuits.

### 16.5.3 Balloon Platform Physical Design

Figure 16.20 shows a pair of typical balloon platforms. A weather balloon, once filled, is around seven feet tall. It is attached to the parachute and payloads with a *load line*. The load line is cut between 15 and 20 feet long so that the burst balloon's remains don't collapse on top of the parachute. Doing so may prevent the parachute from opening properly and slowing down the payload. Just after burst, the balloon's remains will fall slower than the parachute which places the balloon above the parachute during the early descent.

There is however a risk of entanglement between the burst balloon and the parachute shroud lines or tracking antenna during late descent. This risk rarely is a problem as long as the load line is long enough to suspend the burst balloon below the tracking modules.

The parachute's diameter is chosen based on the payload's total weight. The goal is to provide a low-speed landing no greater than 5 meters/second, 1,000 feet/minute, or 10 miles per hour. A parachute six feet in diameter is usually large enough for a 12-pound payload.

Figure 16.20 — (A) An idealized balloon platform showing the various components. (B) A simplified balloon platform with only the minimum necessary components.

Below the parachute and part of its shroud lines is a plastic ring called the *spreader ring*. The spreader ring is usually a plastic ring one foot in diameter loosely suspended between the parachute's shroud lines. It keeps the shroud lines from touching and wrapping around each other during the ascent. As long as the parachute shroud lines do not twist, the parachute will open properly soon after the balloon bursts (video records indicate this can take as little as one second). If the shroud lines are allowed to twist, the payload's descent is not properly braked. A descent from 70,000 feet can take as little as seven minutes in such cases. Furthermore, an improperly operating parachute can tangle up in payload antennas or even the payload itself.

A *cutdown device* is optional on a balloon flight meeting the strictest limits of FAR 101. The cutdown separates the parachute and payload from the balloon and load line on command or when conditions such as balloon burst or time of flight requirements are met. Most, if not all cutdown systems in use today use a series of DTMF tones sent over VHF or UHF FM channels. Typically, a DTMF decoder chip is connected to a VHF or UHF receiver on the payload and the commands are sent as audio tones from a transmitter on the ground on the command frequency.

DTMF tone control permits the user to transmit a cutdown command followed by its password. Password protection for balloon cutdown ensures no false activation from DTMF tones intended for another purpose or payload. The cutdown is designed to either melt the load line with a coil of nichrome wire or slice the load line with a sharp blade.

Initiating cutdown starts the descent of the payload and allows the balloon to continue rising until it reaches its burst altitude. A cutdown that operates after the balloon bursts separates the balloon remains from the parachute. Separating the balloon fragments and load line from the parachute makes the descent less chaotic and protects the payload from the shock and acceleration of initial descent.

Following cutdown, the release of a near space balloon generates shaking and twisting for the attached platforms; however, the descent after balloon burst is significantly more traumatic. In fact, it's very evident when the balloon bursts in the accelerometer chart shown in Figure 16.21.

Any object that places mass away from its center (has a lever arm) is subject to damage during balloon burst. Any object that is significantly denser than the rest of the platform can break free during balloon burst and become an impact hazard inside the platform or even escape the platform completely. Mounting methods that become brittle in the

cold cannot be used to restrain dense or heavy objects on the platform.

### ENCLOSURE AND INSTALLATION

The platform design must take into account the low temperature and low pressure of near space, the shock and vibration of the balloon burst, and to a much lesser extent, increased cosmic radiation.

A Styrofoam box is one of the most common enclosures. The foam is very light, provides insulation against the extreme temperatures encountered during flight for the payload electronics, and helps reduce the impact of landing. Even on the hottest summer day on the ground, it can be approximately  $-60^{\circ}\text{F}$  at 50,000 feet above the Earth. Most battery types do not work well at these temperature extremes which are also outside the specification range of most electronic components. Fortunately, a Styrofoam box will help keep the internal temperatures well above those brutal outside conditions.

Covering the exterior of the Styrofoam housing with black tape (such as black packing tape) creates a passive heating system for the enclosed components. A second heat source is a chemical hand warmer. Hand warmers produce heat from the oxidation of iron and can produce heat for a two-hour flight. Start hand warmers an hour before launch to ensure the items they are heating get thoroughly warm. The ability of hand warmers to produce heat will degrade during the ascent (less oxygen availability) but the initial warmth and gradually decreasing heat output of the hand warmers will keep items about 10 degrees warmer throughout the flight.

Another technique is to mount the electronics and batteries on a foam-core board and wrap everything with three layers of small-cell bubble wrap. The insulation and trapped sunlight will keep the electronics warm.

Components inside the balloon platform can be protected from shock using foam rubber (foamed urethane). In all cases, every component must be mounted to the platform using fasteners that are strong enough to hold several times the weight of the component being immobilized. In addition, the fasteners cannot be constructed of materials that become brittle due to cold. Therefore, do not use plastic zip ties to restrain heavy or dense objects for high altitude balloon flights.

Any instrument requiring high voltage should receive additional electrical insulation, such as a coating of silicone glue. Items that may expand in volume when exposed to low air pressure should be evaluated on the ground (a vacuum chamber is ideal for this purpose) before being sent into near space. Devices requiring air cooling should be replaced with items not requiring air cooling, or perhaps given larger heat sinks.

Figure 16.21 — The acceleration profile of a typical balloon experiment clearly shows the balloon bursting very clearly at about 95 minutes.

## BATTERIES

Lithium-based batteries are strongly recommended as a high-altitude power source as they tend to handle the cold temperatures without excessive voltage drop. Batteries may be incorporated into the main enclosure or they can be included in a separate container. The weight of a separate battery box below the main enclosure helps to stabilize the entire platform.

A practical source of lithium batteries is an RC hobby shop. Racing car batteries come in several voltages and capacities. Since many APRS trackers are designed to operate on 5 V, select a two- or three-cell battery pack (7.2 V or 11.1 V). If your tracker electronics has a low dropout voltage regulator, then your tracker can operate with a two-cell battery pack. The Eveready L91 AA lithium battery is popular for use with Amateur Radio high-altitude balloon platforms.

Not only do you have a choice of battery voltages with RC racing car batteries, you also have a choice of capacities. Measure the current draw of your APRS tracker and avionics and multiply that value by 24 hours. That will give a rough idea of the minimum battery capacity for your tracker.

Batteries must have sufficient capacity to operate the tracking system for its typical three-hour near-space flight plus additional time spent on the ground prior to launch and awaiting recovery. For example, it's nice to have extra reserve to make sure the tracker produces position reports overnight should it get lost during descent.

## PREDICTING FLIGHT PATHS AND TRACKING

When flying a high-altitude balloon, it is a good idea to run a flight prediction a few days before launch. Repeat the prediction the night before a flight. The goal is to be sure the balloon doesn't land in a densely populated area or where making a successful recovery will be difficult. There are two popular downloadable prediction programs that can be accessed at the [www.arhab.org](http://www.arhab.org) website.

Amateur Radio is a popular way to monitor the progress of a balloon's flight. The minimum system required to track a weather balloon flight consists of a GPS receiver that is certified to operate above 60,000 feet, an APRS TNC (terminal node controller), and a 2 meter FM transmitter. (A radar reflector is often included to increase the platform's visibility to air traffic control systems.)

The usual APRS configuration is to transmit a position report once a minute with the recommended path set to WIDE2-1. A power level below 1 W is quite sufficient and many systems work quite well with just 200 mW.

Note that time and altitude data can be used to calculate the ascent rate of the weather balloon as a function of altitude. In addition, the same information can be used to calculate the descent rate of the parachute. Since a parachute's descent rate is a function of air drag which is controlled by air density, the parachute's descent speed during descent can be used to estimate air density as a function of altitude. Note also that since a weather balloon is captive to the wind, measurements

of altitude, speed, and heading are measurements of wind speed and direction at specific altitudes.

Including a second tracker may be an attractive form of insurance for mobile automated platforms such as weather balloons. If an APRS tracker were to fail at an altitude of 100,000 feet, the weather balloon can still be tracked and recovered using the second tracker. Redundant APRS trackers will need to use different SSIDs. In addition, they need to be time slotted so that their transmissions do not occur at the same time and jam each other. Preferably, redundant trackers will transmit on the same frequency as the primary tracker, which simplifies tracking for the people in search of the automated platform.

Finally, a *recovery aid* is a backup recovery method that's most useful after the parachute and its payload have landed. A recovery aid can include systems such as a loud audio beeper, strobe lights, or a fox-hunting (direction finding) transmitter. These help a chase crew recover a balloon platform after it has landed in trees or brush or tall crops where a GPS position is not enough to locate the platform.

## APRS TELEMETRY

APRS is most popular and often used on short duration balloon flights (lasting for only a few hours) and where line of sight communication is possible between the chase crew and digipeaters. The use of IGates permits unlicensed individuals to participate in balloon chases by using a smartphone or tablet.

The simplest APRS telemetry string useful for balloon flights includes an identification, time of message, the balloon's three-dimensional position, the balloon's course and the

balloon's speed. Such a string looks like the following as described in the APRS message format specification at [www.eoss.org/aprs/aprs\\_formats\\_eoss](http://www.eoss.org/aprs/aprs_formats_eoss) and in the APRS-IS.net

specification at [www.aprs-is.net/q.aspx](http://www.aprs-is.net/q.aspx). (See the preceding section on APRS for a sample string.)

## 16.6 Unmanned Aerial Vehicles (UAVs)

### 16.6.1 General UAV Platform Requirements

Drones or UAVs and their control systems are grouped in the category of *Unmanned Aerial Systems* (UAS). The regulating agency for UAS is the Federal Aviation Administration (FAA). For the purposes of Part 107, the FAA does not consider UAVs to be the same as model airplanes. One reason is that model airplanes are considered to be simple systems incapable of flying autonomously. Therefore, a model airplane must remain within sight of the pilot to be controlled. The applicable regulation for UAS is Federal Aviation Regulation Part 107 (FAR 107) or Title 14: Small Unmanned Aircraft Systems (14 CFR 107). Part 107 applies to pilots flying UAVs for a business; hobbyists have different requirements. By becoming a licensed remote pilot however, additional privileges become available to the pilot.

This chapter will only focus on the requirement for people flying UAVs as a hobby or for education. For these people, the following stipulations apply:

- 1) You do not need to be certified as a remote pilot to fly your UAV if you are flying for a hobby or pleasure.
- 2) You must register your UAV if it weighs between 0.55 and 55 pounds (this requirement has changed several times since it was first implemented).
- 3) You cannot fly your UAV within five miles of an airport without first contacting the airport and/or *air traffic control* (ATC). Note that some small airports do not have an ATC. In those cases, you'll need to contact the airport manager.
- 4) Your UAV must always yield right of way to manned aircraft.
- 5) You must keep your UAV within sight, or in visual line-of-sight.
- 6) Your UAV must weigh less than 55 pounds.
- 7) You must follow any community-based safety guidelines.
- 8) You cannot fly a UAV higher than 400 feet above the ground.
- 9) You cannot fly a UAV over people or stadiums.
- 10) You cannot fly a UAV over people who are not a part of the drone operation.
- 11) You cannot fly a UAV over moving vehicles.

12) You cannot fly a UAV while under the influence of drugs or alcohol.

13) You cannot fly a UAV over or around sensitive property or infrastructure.

14) You cannot use a UAV to spy on or monitor people when they have a reasonable expectation of privacy.

UAV pilots can find additional information at [www.faa.gov/uas](http://www.faa.gov/uas) and from the Academy of Model Aeronautics (AMA) at [www.modelaircraft.org](http://www.modelaircraft.org).

UAV pilots are strongly encouraged to download the app *B4Ufly* to their mobile phones prior to flying a UAV. The app shows airports and other restricted sites close to your location, or in other words, locations near which you are not allowed to fly a UAV.

### 16.6.2 UAV Data and Navigation Subsystems

Commercial UAVs require the same digital radio controllers used for traditional radio-controlled airplanes. These controllers can come with the UAV or may be purchased separately. A separate purchase is more common for advanced UAV pilots who are assembling their UAV from parts. Since the radio controller is operating a multirotor aircraft rather than a fixed wing aircraft, the aircraft pilot must configure the radio controller for UAV operation. Otherwise, the operation of the radio controller for a UAV is nearly identical to that of a fixed-wing aircraft.

An outdoor multirotor UAV is so complex that a human pilot cannot directly operate one by controlling each of the UAV's rotors. Instead, many UAVs carry an onboard flight controller that incorporates a GPS receiver and inertial navigation components such as accelerometers, gyroscopes, and a compass (magnetometer). The flight controller makes adjustments to the UAV's rotors based on joystick input and internal conditions. Combining all these elements into a single flight controller makes it so much easier to fly a UAV — the pilot only needs to push joysticks to control the thrust, pitch, roll, and yaw of the UAV.

Many onboard UAV flight controllers permit the pilot to set the UAV's flight characteristics and behaviors by changing the flight computer's settings through RC switch settings or even software. For example, a UAV can be configured to hold altitude (remain at

the same altitude when the thrust joystick is left centered), fly in the direction the joysticks are pushed (regardless of the UAV's heading), and even programmed to fly predefined course without further joystick input.

The most popular data transmitted from a UAV is video imagery (called *first person view* or FPV). Some UAVs transmit helpful navigational data such as altitude, heading, and speed. In addition, battery condition is transmitted in some UAVs to help the pilot manage the UAV's flight. Battery condition is frequently indicated by onboard LED colors.

To be a successful platform, UAVs are not usually required to transmit other types of data as a telemetry stream, because of the immediacy of the data collected. In other words, a drone can rapidly reach operational altitude, record data, then return to the launch site in a few minutes or less. Therefore, unlike weather balloons, data from UAVs is rapidly accessible and remains timely when it's downloaded.

However, if a UAV is going to transmit data, the pilot must test for the compatibility between the data transmitter and the radio controller and the onboard GPS. A pilot cannot safely operate a UAV if an onboard data transmitter interferes with the reception of RC commands or if it interferes with the UAV's GPS receiver.

Testing for interference between the data transmitter and the UAV must be performed outdoors and with the UAV propeller removed. The pilot can then safely monitor the UAV's status LEDs or other status transmissions while the data transmitter operates onboard the UAV.

One additional safety test the pilot should perform is a measure of the UAV's center of gravity. UAV flight controllers have expectations about the UAV's center of gravity. Adding a payload to a UAV that changes that center of gravity substantially will make the UAV difficult or even impossible to control. If a payload will be added to a UAV, the pilot must determine the center of gravity before and after the modification.

### 16.6.3 UAV Platform Configuration

Most pilots purchase their UAV *ready to fly* (RTF) or *almost ready to fly* (ATF). There-

fore, in the vast majority of the cases, there is no need to worry about mounting or protecting the UAV's flight subsystems.

If a pilot is purchasing a UAV in parts and assembling it, then follow the assembly directions to construct the UAV. Directions will show the proper way to mount the UAV's flight subsystems. The proper placement is important in order to maintain the UAV's proper *center of gravity* (CG). When the CG is not located as the UAV's flight controller expects, unpredictable flights and even crashes can result.

## 16.6.4 UAV Electronic Subsystems

Prior to installing a new electronic system on a UAV, the pilot must ensure RFI from the payload cannot interfere with the UAV's GPS receiver. This can be an issue with some digital cameras for example, where the crystal-controlled clock inside the camera can emit enough RF to prevent a GPS from gaining a proper lock or even worse, losing satellite lock during flight. Therefore, the UAV should be left on the ground while its new electronics payload is tested in place on the UAV and then tested around the UAV. Since many commercial UAVs are capable of reporting their GPS status through LEDs and the radio controller, the remote pilot should monitor them for a while to ensure GPS lock remains steady as the new payload electronics is tested.

# 16.7 Rockets

## 16.7.1 General Rocket Platform Requirements

Like Amateur Radio, amateur rocketry is a self-regulated activity. Since model rockets use the national air space, the ultimate regulating agency for model rockets is the Federal Aviation Administration (FAA). The applicable FAA regulation for model rockets is the Federal Aviation Regulation Part 101 (FAR 101) or Title 14: Aeronautics and Space, 14 CFR 101. In addition, the National Fire Protection Association (NFPA) creates safety codes that keep rocket motors safe to transport and use. NFPA 1127 - Code for High Power Rocketry Scope covers the construction, propellant mass, and reliability of rocket motors for amateur use. Rocket motor manufacturers follow these codes and as long as amateurs purchase their motors from reputable dealers, this will not be a concern when flying model rockets. The National Association of Rocketry (NAR) and Tripoli Rocketry Association (TRA) are the self-regulating organizations for model rocketry. Therefore,

One useful electronic subsystem for a UAV is a voice or digital repeater. (See the preceding section on VHF/UHF Payloads.) The UAV's ability to climb to an altitude of several hundred feet with a payload makes it a rapid-deploy antenna tower. The limitations of a UAV-based antenna tower include some of the following:

- Limited weight — usually no more than one pound
- Limited time aloft — upwards of 30 minutes with new batteries and less as the payload becomes heavier
- Limited authority — poor authority means a UAV cannot prevent it from drifting with the wind, if the wind blows too strongly
- Limited to flying during daylight hours
- Limited antenna orientations — antennas must be placed where they do not interfere with the UAV's propellers
- Limited to only flying above people who are not involved with operation of the UAV

A second useful electronic subsystem is FPV or first person view video. (See the preceding section on Image and Video payloads.) A UAV flown with FPV adds a synergy to search and rescue (SAR). Hams can use the UAV to rapidly scan long distances, fly over steep terrain, and even peer over fences and into steep canyons. These abilities can reduce search times and the risk hams experience climbing into and out of potentially hazardous terrain. A thermal imaging camera is another powerful tool to add to a UAV-enhanced SAR.

it's strongly encouraged that you join either one of these organizations prior to launching model or amateur rockets.

## 16.7.2 Suitable Rocket Data and Navigation Subsystems

Amateur Radio is seldom used with low-power model rocket flights. This is mostly because of the extreme weight limits placed on payloads by small model rockets and their limited range. Amateur Radio does however appear in some high power amateur rockets as an aid to recovering rockets after flight. There are several commercial products available for this purpose.

Radio tracking products for rockets are available in licensed and unlicensed frequencies. They also appear as either APRS (onboard rocket GPS receivers) or radio direction finding (fox hunting) products. The only other tracking system is an audio beacon and therefore does not rely on Amateur Radio.

Complete FPV systems, containing the video camera and the transmitter are readily available at minimal cost. They use the unlicensed 5.8 GHz radio frequencies and transmit with a power of hundreds of milliwatts. In addition, the systems are designed to be lightweight and not to interfere with the operation of the UAV. However, the remote pilot will need an observer to provide assistance to the pilot who is flying the UAV.

A non-electronic application of UAVs is carrying one end of a lightweight string over a tree or structure so that an antenna can be pulled up afterward. This permits an operator to place an antenna with more precision than is usually possible with a sling shot or "antenna launcher."

## 16.6.5 Powering the UAV

The motors of a UAV have a very high current demand. Twenty or more amps per motor isn't uncommon. The heavy current demands of motors (four of them on a quadcopter and six on a hexacopter) and requirement for a lightweight quadcopter means a high capacity, high current draw, and lightweight battery is required. These requirements and the ability to recharge the flight battery is best met with lithium polymer (LiPo) batteries. Read the recommendations for your UAV before purchasing new batteries.

Amateur Radio is also making an appearance in model rocketry for purposes of telemetry. Data typically includes acceleration, velocity, and altitude. UHF frequencies are preferable for rocket telemetry in order to keep the antenna short and lightweight. The antenna's orientation is necessarily vertical due to the construction of the rocket.

## 16.7.3 Rocket Platform Configuration

All electronics mounted inside an amateur rocket will experience very high accelerations at lift off, over 10 g of acceleration in some cases. (1 g is equivalent to the force of gravity at the Earth's surface.) Therefore, all electronics must be securely mounted to the rocket's airframe in a way that will prevent them from coming loose. This is especially true for batteries, which can be denser than electronics. In addition to acceleration, rocket payloads can experience mechanical shock and rapid shaking in multiple directions.

Most model rockets can't climb high enough to experience significant changes in temperature and pressure. Therefore, their electronics payloads do not have to be protected from these conditions. However, there are some high power amateur rockets that do climb to over 10,000 feet and can therefore experience rapid changes in air pressure and air temperature. Unlike high altitude weather balloons, the electronics reach high altitudes so fast (compared to a balloon) that the payload does not cold soak long enough to become completely chilled.

Sensors onboard rockets experience rapid changes in the physical conditions they are measuring. This can result in noisy reading

from the sensors that must be accounted for. Sensors used to control the operation of the rocket, such as for determining peak altitude for parachute deployment, must have their outputs filtered in real-time to be useful. Other data can be filtered after the rocket is recovered and its data downloaded.

Antennas on rockets must be small and lightweight and they must not interfere with rocket staging or parachute deployment (which involves ejecting the rocket nose cone). These requirements make a UHF dipole a useful antenna. The ends of the antenna must be secured to the rocket body so they don't vibrate in the air flowing over the rocket body. Or the antenna must be

secured inside the rocket body. Some radio trackers use flexible antennas and whips. Bird trackers make popular radio trackers for rockets since they have similar requirements.

As with UAVs, any electronic devices included in a rocket's payload should be tested for interference — especially when a GPS receiver is used for the rocket's maximum altitude determination.

Since rocket flights tend to be short, a high capacity battery is not typically required. Form factor (shape and dimensions) and weight are often the important considerations. This means alkaline batteries are often acceptable for rocket electronics.

## 16.8 Robotics

### 16.8.1 General Robotics Platform Requirements

Robots are defined as systems capable of acquiring sensory input, making decisions based on that input and the robot's current state, then acting based on the results of that decision. A robot's need to combine sensory data and current status means most robots include some type of programmable microcontroller.

Being able to act doesn't mean a robot must be very mobile. Industrial robots for example, are typically stationary and only able to operate within defined boundaries. A robot's method of acting can be electrical (such as motors and servos), pneumatic (air pressure), or hydraulic (liquid pressure). Each has its own abilities, requirements, and interfacing requirements to a robot controller.

Robots span a range of autonomies. A robot can be completely autonomous and capable of operating without any human intervention for long periods of time or a robot can require regular, predictable human intervention (such as a planetary rover). When a robot requires human input, that communication can be wireless or via a tether containing wire or fiber optics.

The many types of sensors, the many internal states, the many types of control systems, the many levels of limitation of mobility, many mechanical systems, and many ways to communicate between humans and robots makes it impossible to define a general platform for robotics. Each robot is typically as unique as the person or people creating it.

Unless robots interact with the public, there is no regulation controlling the amateur use of robots. This is changing with the advent of self-driving cars and trucks.

### 16.8.2 Suitable Robotics Data and Navigation Subsystems

Robots confined to traveling in small areas typically use inertia navigation methods or position measurement systems to navigate. Typical sensors include:

- Accelerometers
- Magnetometers
- Encoders
- Range Finders
- Light Detectors
- Line Detectors
- Laser Range Finders
- Limit Switches

Robots traveling over large distances or regions can combine GPS-based navigation systems into onboard inertia and local position measurement systems.

Robots that send navigation or sensory data to a human operator/monitor (such as the Mars Rover) will find APRS a good method for relaying this information wirelessly. In addition, a human operator can send instructions back to the robot via APRS messages.

Robots that transmit imagery can rely on either slow scan (SSTV) or amateur television (ATV). SSTV is a suitable method when conditions are slow to change or when where only low power levels are available to send imagery. ATV is important where the robot is traveling at speeds high enough that human intervention is needed constantly. (See the preceding sections on Image and Video payloads.)

Although robotics projects using Amateur Radio are currently few, one of the more successful as of early 2018 is the HF Voyager project. ([www.jrfarc.org/hf-voyager](http://www.jrfarc.org/hf-voyager)) An autonomous "wave glider", HF Voyager operates under automatic control, making contacts with the call sign KH6JF/mm on 20 meters using FT8 and PSK-31 as the pri-

mary operating modes. It can also use WSPR in times of poor propagation.

A possible solution to long-range communication between humans and a robot might be through satellites. An Iridium modem would permit the onboard robot controller to send and receive data from virtually anywhere in the world.

Finally, there are unlicensed radio bands, such as ISM, that amateur robotics engineers are using for their short-range robotics projects. These bands permit human-robot communications in both imagery and data.

### 16.8.3 Robotics Platform Configuration

Small, indoor robots typically have few limitations (other than those imposed for competitions). The roboticist can replace their batteries frequently, the robots don't experience extreme high or low temperatures, no rain falls on them, and small and lightweight motors suffice for making them mobile.

A roboticist designing a large, outdoor robot will need to balance the robot design with the many of the limitations mentioned above. This starts with a strong, but lightweight robot body (often made from aluminum). Weatherproof enclosures are required to protect the onboard electronics. Motors need to be sealed where dust and rain are issues. The motors must be powerful enough to make the robot mobile at reasonable speeds. The robot's battery design must have the capacity to operate the robot's electronics and motors without excessively weighing down the robot. Finally, depending on the speed of the robot, the design might call for physical shock protection.

Most robots use flexible antennas to com-

communicate with human operators. The antennas are typically mounted at a high location on the robot where it can't interfere with cameras and robotic arms.

Robots that operate without direct human contact for long periods of time will need to

## 16.9 Fixed Stations

### 16.9.1 General Fixed Station Platform Requirements

Fixed stations such as weather stations are found in locations where environmental conditions are hostile to humans or where it's not practical or safe to record data. Moored or drifting buoys are included in this classification. Therefore, fixed stations must be constructed to handle extreme weather conditions. And their data subsystems are critically important if they can't be tended on a regular basis.

The FCC is the agency responsible for the telemetry requirements of fixed stations that use radios to communicate. The data transmission requirements for fixed site data collectors and dataloggers (such as moored buoys) are simpler than they are for drifting buoys. This is because a drifting buoy can be carried by ocean currents into international waters or the coastal waters of other countries. Since each country has its own rules governing the use of Amateur Radio, a drifting buoy designer and builder must become acquainted with the communication rules of other countries to insure their drifting buoy doesn't violate Amateur Radio laws.

When the need is to monitor weather conditions continuously on land, a weather station is the preferred solution. An amateur must mount a weather station above the level of obstacles (such as buildings and trees) that will interfere with the flow of wind. This means many weather stations can be found mounted above roofs and on tall masts or radio towers.

When it comes to monitoring conditions in bodies of water, a buoy is used. Buoys can be of two types — those remaining stationary by mooring them to the seabed or those free to drift with the ocean and wind currents. Moored buoys have been used by the National Oceanographic and Atmospheric Administration (NOAA) since 1951 and drifting buoys have been in use since 1979 (Wikipedia). At this time, the editors are unaware of any communication requirements from NOAA.

Anchored or fixed datalogging stations should not be anchored or fixed in locations where people have a reasonable expectation of privacy or their presence will interfere with navigation or right of way.

use solar charging in order to keep their batteries topped off. Solar charging systems need to monitor the battery level and then act to recharge batteries at the appropriate voltage and current. The high power demands of robots means they can never operate solely on solar power and without batteries. This

### 16.9.2 Suitable Fixed Station Data and Navigation Subsystems

The needs of data and navigation systems for weather stations and buoys are similar to those mentioned in previous sections. The data needs are addressed based on the distance between the station and the amateur recording the data.

For short distances, such as from the roof to the interior of a house, a wire connection between the station and a PC or display often suffices. Where it's not practical to route a communication cable into the house, then an unlicensed radio system will often work and is usually available with the fixed station. Otherwise, where long distance, line-of-sight communication is needed, APRS is one of the best methods available. In fact, there are many weather stations with integrated APRS capability available for purchase.

For fixed stations located long distances from the data user, HF modes are often the best solution. This includes the WSPR, Hellschreiber, RTTY, CW, and JT9 modes.

Satellite communication methods such as Spot ([findmespot.com](http://findmespot.com)) and Iridium modems are a possible solution for long distance fixed and mobile stations. A Spot tracker only reports its position; therefore it is best used for reporting the position of mobile stations such as buoys. An Iridium satellite modem will telemeter data, unlike the Spot. Both of these satellite systems require a subscription. Therefore the amateur must determine whether or not the value of the data justifies the cost of a subscription prior to placing the fixed station into operation.

### 16.9.3 Fixed Station Platform Configuration

#### WEATHER STATIONS

Commercial weather stations use components capable of handling hot and cold temperatures and house most of them inside of an enclosure. Weather sensors, on the other hand, must be exposed to the elements in order to collect their data.

Pressure sensors can be left inside the house (if it's close to the weather station) or inside the enclosure since the enclosure is not

also means robots will need down time at some point in order to recharge their batteries.

Lithium polymer (LiPo) batteries are good batteries for robots since they are light weight, can operate across a large range of temperatures, and are capable of meeting high current demands. This

air tight. Relative humidity sensors must be exposed to the air, while at the same time, protected from rain and condensation. One solution is to house the relative humidity (RH) sensor inside of a housing with vents cut in its sides. Temperature sensors (such as the LM335) must be exposed to the air, but not to sunlight because solar absorption will warm the sensor above ambient air temperature. A sun shield placed over the temperature sensor usually suffices. Alternatively, a temperature sensor can be mounted to the underside of the weather station enclosure.

Two of the more difficult weather sensors are the anemometer and wind vane. They are often made from position sensors that can rotate 360 degrees without needing to unwind (for the wind vane) or with generators (for the anemometer). These are mechanical systems that need protection from moisture while still remaining free to rotate continuously without impediment. Other solutions that are less difficult to protect include the hot wire anemometer and the ultrasonic anemometer and wind vane.

#### BUOYS

Drifting buoys are used to track ocean currents, water, and weather conditions (temperature, pressure, RH, water temperature, salinity). A moored buoy can report on wind speed and direction while a drifting buoy can't report with the same level of accuracy due to its movement.

Buoys must have an overall density less than the density of water (1.0 grams/cc) if they are to float. A lower density will raise the top of the buoy higher above the water than for a higher density buoy. Be careful — density that is too low can result in an unstable buoy that tips over. Therefore, buoys need ballast so they can maintain an upright configuration in rolling waters and waves. The ballast placed in a buoy must be located below the buoy's desired center of gravity. Any ballast must be securely attached to the buoy so that it can't shift its position when the buoy is tilted by waves. Finally, the ballast attachment cannot compromise the watertightness of the buoy.

All buoy components must be protected from fresh or salt water. Therefore, buoys must be constructed with water-tight seals.

This can be a challenge for buoy antennas which are often located on top of the buoy. These antennas will be exposed to fresh or salt water on a regular basis. Therefore, buoy antennas require insulation to keep salt water off of their metal components, including connectors. Be careful in the selection of insulating materials, cold water can make some materials stiff or brittle. Select insulating materials that maintain their strength and flexibility when they get cold.

Insulation slows changes in temperature but can't stop those changes. Since buoys can operate for days or weeks in cold conditions,

insulation such as Styrofoam is less effective in protecting electronics. Two options are to add heaters to the buoy or to use electronics that are designed to operate in cold conditions.

### 16.9.4 Powering the Fixed Station Platform

Indoor and some outdoor fixed stations may have access to household or commercial electrical power. If so, there will be no power concerns for these stations. Other outdoor fixed stations require batteries that must func-

tion in extreme conditions unless heating and cooling is provided for the batteries. In addition, batteries may be exposed to damp conditions if they can't be hermetically sealed in protective containers. The requirement to seal batteries is critical for buoys since they are exposed to salt water.

If a fixed station must operate for a good part of a year without maintenance, then the amateur should give consideration to using solar power to recharge the station's batteries. The solar cells must be encapsulated to protect them from moisture.

## Chapter 17 Downloadable Software

The following software is available with this book’s downloadable supplemental content.

- *TubeCalculator* by Bentley Chan and John Stanley, K4ERO, for analysis of operation of popular high power transmitting tubes.
- *PI-EL* by Jim Tonne, W4ENE, for design and analysis of PI and PI-L networks for transmitter output.
- *MeterBasic* by Jim Tonne, W4ENE, for design and printing of custom analog meter scales.
- *MATCH.EXE* software (for use with Tuned

# RF Power Amplifiers

Amateur Radio operators typically use a very wide range of transmitted power — from milliwatts to the full legal power limit of 1.5 kW. This chapter covers RF power amplifiers beyond the 100 – 150 W level of the typical transceiver. The sections on tube-type amplifiers, including a new sidebar on a design method to avoid interactive tuning, were prepared by John Stanley, K4ERO. The sections on solid-state amplifiers were contributed by Richard Frey, K4XU, along with an overview of the new “pallet” amplifier modules. Roger Halstead, K8RI, contributed material on amplifier tuning and the use of surplus components in amplifier construction. Amplifier projects using tubes, transistors, and integrated circuits that appeared in previous editions of *The ARRL Handbook* are included with the downloadable supplemental content.

## 17.1 High Power, Who Needs It?

There are certain activities where higher power levels are almost always required for the greatest success — contesting and DXing, for example. While there are some outstanding operators who enjoy being competitive in spite of that disadvantage, the high-power stations usually have the biggest scores and get through the pileups first. On the VHF and higher bands, sometimes high power is the only way to overcome path loss and poor propagation.

Another useful and important area where higher power may be needed is in net operations. The net control station needs to be heard by all potential net participants, some of whom may be hindered by a noisy location or limited antenna options or operating mobile. This can be crucial to effective emergency communications. General operation also benefits from the availability of high power when conditions demand it to maintain contact.

How do you decide that you need amplification? As a rule of thumb, if you have a good antenna and hear a lot of stations that don't seem to hear you, you probably need to run more power. If you operate on bands where noise levels are high (160 and 75/80 meters) or at times when signals are weak then you may find that running the legal limit makes operations more enjoyable. On the other hand, many stations will find that they can be heard fine with the standard 100 W transmitter or even with lower power.

Power requirements also depend on the mode being used. Some digital modes, such as PSK31, work very well with surprisingly low power. CW is more power efficient than SSB voice. Least effective is full carrier AM, which is used by vintage equipment lovers. Once you have determined that higher power will enhance your operations, you should study the material in this chapter no matter whether you plan to build or buy your amplifier.

Note that many power amplifiers are capable of exceeding the legal limit, just as most

### Safety First!

**YOU CAN BE KILLED** by coming in contact with the high voltages inside a commercial or homebrew RF amplifier. Please don't take foolish chances. Remember that you cannot go wrong by treating each amplifier as potentially lethal! For a more thorough treatment of this all-important subject, please review the applicable sections of the **Power Sources** and the **Safety** chapters in this *Handbook*.

High-power amplifiers generate strong RF fields, especially near a tube or transistor and around the output circuits. High levels of RF at frequencies of 50 MHz through microwaves are particularly hazardous. Avoid exposing yourself to intense RF fields when adjusting or measuring energized equipment and follow the RF exposure guidelines for yourself and others. See the **Safety** chapter for more information.

automobiles are capable of exceeding posted speed limits. That does not mean that every operator with an amplifier capable of more than 1.5 kW output is a scowflaw. Longer life for the amplifying devices and other amplifier

components as well as a cleaner signal result from running an amplifier below its maximum rating. However, just as with automobiles, that extra capability also presents

certain temptations. Remember that FCC rules require you to employ an accurate way to determine output power, especially when you are running close to the limit.

## 17.2 Types of Power Amplifiers

Power amplifiers are categorized by their power level, intended frequencies of operation, device type, class of operation and circuit configuration. Within each of these categories there are almost always two or more options available. Choosing the most appropriate set of options from all those available is the fundamental concept of design.

### 17.2.1 Why a “Linear” Amplifier?

The amplifiers commonly used by amateurs for increasing their transmitted power are often referred to as “linears” rather than amplifiers or linear amplifiers. What does this mean and why is it important?

The active device in amplifiers, either tube or transistor, is like a switch. In addition to the “on” and “off” states of a true switch, the active device has intermediate conditions where it presents a finite value of resistance, neither zero nor infinity. As discussed in more detail in the **RF Techniques** chapter, active devices may be operated in various *classes of operation*. Class A operation never turns the device fully on or off; it is always somewhere in between. Class B turns the device fully off for about half the time, but never fully on. Class C turns the device off for about 66% of the time, and almost achieves the fully on condition. Class D switches as quickly as possible between the on and off conditions. Other letters have been assigned to various rapid switching methods that try to do what Class D does, only better. Class E and beyond use special techniques to ensure that high voltage and current do not occur during switching.

During the operating cycle, the highest efficiency is achieved when the active device spends most of its time in the on or off condition and the least in the resistive condition. For this reason, efficiency increases as we go from Class A to B to C to D.

A *linear amplifier* is one that produces an output signal that is identical to the input signal, except that it is stronger. Not all amplifiers do this. Linear amplifiers use Class A, AB or B operation. They are used for modes such as SSB where it is critical that the output be a close reproduction of the input.

The Class C amplifiers used for FM trans-

mitters are *not* linear. A Class C amplifier, properly filtered to remove harmonics, reproduces the frequencies present in the input signal, but the *envelope* of the signal is distorted or even flattened completely. (See the **Modulation** chapter for more information on waveforms, envelopes and other signal characteristics.)

An FM signal has a constant amplitude, so it carries no information in the envelope. A CW signal does carry information in the amplitude variations. Only the on and off states must be preserved, so a Class C amplifier retains the information content of a CW signal. However, modern CW transmitters carefully shape the pulses so that key clicks are reduced to the minimum practical value. A Class C amplifier will distort the pulse shape and make the key clicks worse. Therefore, except for FM, a linear amplifier is recommended for all amateur transmission modes.

Some digital modes, such as RTTY using FSK, are a form of FM and can also use a nonlinear Class C, D or E amplifier. If these signals are not clean, however, a Class C amplifier may make them worse. Also, Class C or even D and E can be used for very slow CW, for very simple low-power CW transmitters or on uncrowded bands where slightly worse key clicks are not so serious. After all, Class C was used for many years with CW operation.

Class of operation as it relates to tube-type

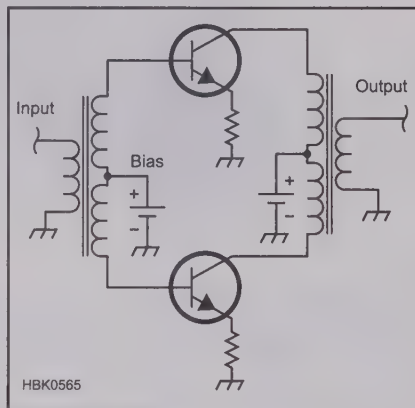

Figure 17.1 — This simple circuit can operate in a linear manner if properly

Figure 17.2 — Input versus output signals from an amplifier, as observed with the X-Y display on an oscilloscope. At A, an amplifier with proper bias and input voltage. At B, the same amplifier with improper bias and high input voltage.

amplifier design is discussed in more detail in a later section of this chapter.

### ACHIEVING LINEAR AMPLIFICATION

How is linear amplification achieved? Transistors and tubes are capable of being operated in a linear mode by restricting the input signal to values that fall on the linear portion of the curve that relates the input and output power of the device. Improper bias and excessive drive power are the two most common causes of distortion in linear amplifiers. All linear amplifiers can be improperly

**Figure 17.3 — Improper operation of a linear using a two-tone test will show peak clipping on an oscilloscope (A) and the presence of additional frequencies on a spectrum analyzer (B). When these patterns appear, your “linear” has become a “nonlinear” amplifier. Users of adjacent channels will not be happy. More information on transmitter testing may be found in the Test Equipment and Measurements chapter.**

biased or overdriven, regardless of the power level or whether transistors or tubes are used.

Figure 17.1 shows a simple circuit capable of operating in a linear manner. For linear operation, the bias on the base of the transistors must be such that the circuit begins to produce an output signal even with very small input signal values. As shown in Figure 17.2, when properly adjusted for linear operation, the amplifier’s output signal faithfully tracks

the input signal. Without proper bias on the transistors, there will be no output signal until the input voltage goes above a threshold. As shown in Figure 17.2B, the improperly adjusted amplifier suddenly switches on and produces output when the input signal reaches 0.5 V.

Some tubes are designed for *zero bias* operation. This means that an optimum bias current is inherent in the design of the tube when it is operated with the correct plate voltage. Other types of tubes and all transistors must have bias applied with circuits made for that purpose.

All amplifiers have a limit to the amount of power they can produce, even if the input power is very large. When the output power runs up against this upper limit (that is, when additional drive power results in no more output power), *flat topping* occurs and the output is distorted, as shown in Figure 17.3. Many amplifiers use *automatic level control* (ALC) circuits to provide feedback between the amplifier and the companion transceiver or transmitter. When adjusted properly, ALC will control the transmitter output power, preventing the worst effects of overdriving the amplifier. Even with ALC, however, overdriving can occur.

## 17.2.2 Solid State vs Vacuum Tubes

With the exception of high-power amplifiers, nearly all items of amateur equipment manufactured commercially today use solid state (semiconductor) devices exclusively. Semiconductor diodes, transistors and integrated circuits (ICs) offer several advantages in designing and fabricating equipment. Solid state equipment is smaller, offers broadband (no-tune-up) operation, and is easily manufactured using PC boards and automated (lower cost) processes.

Based on all these facts, it might seem that there would be no place for vacuum tubes in a solid state world. Transistors and ICs do have significant limitations, however, especially in a practical sense. Individual present-day transistors cannot generally handle the combination of current and voltage needed nor can they safely dispose of the amount of

heat dissipated for RF amplification to high power levels. Pairs of transistors, or even pairs of pairs, are usually employed in practical power amplifier designs at the 100 W level and beyond. Sometimes various techniques of power combination from multiple amplifiers must be used.

Tube amplifiers can be more economical to build for a given output power. Vacuum tubes operate satisfactorily at surface temperatures as high as 150-200 °C, so they may be cooled by simply blowing sufficient ambient air past or through their relative large cooling surfaces. The very small cooling surfaces of power transistors should be held to 75-100 °C to avoid drastically shortening their life expectancy. Thus, assuming worst-case 50 °C ambient air temperature, the large cooling surface of a vacuum tube can be allowed to rise 100-150 °C above ambient, while the small surface of a transistor must not be allowed to rise more than about 50 °C.

Furthermore, RF power transistors are much less tolerant of electrical abuse than are most vacuum tubes. An overvoltage spike lasting only microseconds can—and is likely to—destroy RF power transistors. A comparable spike is unlikely to have any effect on a tube. So the important message is this: designing with RF power transistors demands caution to ensure that adequate thermal and electrical protection is provided.

Even if one ignores the challenge of the RF portions of a high-power solid state amplifier, there is the dc power supply to consider. A solid state amplifier capable of delivering 1 kW of RF output might require regulated (and transient-free) 50 V at more than 40 A. Developing that much current can be challenging. A vacuum tube amplifier at the same power level might require 2000 to 3000 V, unregulated, at less than 1 A.

At the kilowatt level, the vacuum tube is still a viable option for amateur constructors because of its cost-effectiveness and ease of equipment design. Because tube amplifiers and solid state amplifiers are quite different in many ways, we shall treat them in different sections of this chapter. Also, the author of the solid state section presents a slightly different perspective on the tube-vs-solid state discussion.

## Care and Feeding of Power Grid Tubes Available

The classic handbook of power tube design and maintenance from the Eimac Corporation, *Care and Feeding of Power Grid Tubes*, is once again available, courtesy of Communications and Power Industries ([cpil.com](http://cpil.com) — Eimac is a division of CPI). The book consists of six PDF sections covering all phases of tube operation and design. It can be downloaded from [www.arrl.org/engineering-references](http://www.arrl.org/engineering-references) or [www.arrl.org/arrl-handbook-reference](http://www.arrl.org/arrl-handbook-reference). (A hard copy of the book is available on request from CPI.) Additional references are downloadable from [cpil.com/library.cfm/9](http://cpil.com/library.cfm/9). The ARRL thanks CPI for making this important reference available to radio amateurs!

## 17.3 Vacuum Tube Basics

The term *vacuum tube* describes the physical construction of the devices, which are usually tubular and have a vacuum inside. The British call them electron valves which describes the operation of the devices, since they control the flow of electrons, like a water valve controls the flow of water.

### 17.3.1 Thermionic Emission

Metals are electrical conductors because the electrons in them readily move from one atom to the next under the influence of an electrical field. It is also possible to cause the electrons to be emitted into space if enough energy is added to them. Heat is one way of adding energy to metal atoms, and the resulting flow of electrons into space is called *thermionic emission*. As each electron leaves the metal surface, it is replaced by another provided there is an electrical connection from outside the tube to the heated metal.

In a vacuum tube, the emitted electrons hover around the surface of the metal unless acted upon by an electric field. If a positively charged conductor is placed nearby, the electrons are drawn through the vacuum and arrive at that conductor, thus providing a continuous flow of current through the vacuum tube.

### 17.3.2 Components of a Vacuum Tube

A basic vacuum tube contains at least two parts: a *cathode* and a *plate*. The electrons are emitted from the *cathode*. The cathode can be *directly heated* by passing a large dc current through it, or it can be located adjacent to a heating element (*indirectly heated*). Although ac currents can also be used to directly heat cathodes, if any of the ac voltage mixes with the signal, ac hum will be introduced into the output. If the ac heater supply voltage can be obtained from a center tapped transformer, and the center tap is connected to the signal ground, hum can be minimized.

The difficulty of producing thermionic emission varies with the metal used for the cathode, and is called the “work function” of that metal. An ideal cathode would be made of a metal with a low work function that can sustain high temperatures without melting. Pure tungsten was used in early tubes as it could be heated to a very high temperature. Later it was learned that a very thin layer of thorium greatly increased the emission. Oxides of metals with low work functions were also developed. In modern tubes, thoriated-tungsten is used for the higher power tubes and oxide-coated metals are commonly used at lower power levels.

Filament voltage is important to the proper

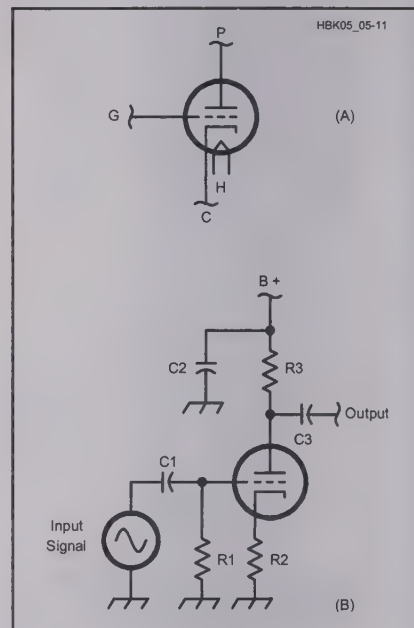

operation of a tube. If too low, the emission will not be sufficient. If too high, the useful life of the tube will be greatly shortened. It is important to know which type of cathode is being used. Oxide-coated cathodes can be run at 5 to 10%. Tube manufacturers specify an allowable range of filament voltages for proper operation and maximum tube life — follow those recommendations. Tubes should never be operated with filament voltages above the allowable value. Reducing filament voltage below the specified range in hopes of extending tube life is definitely not recommended for tubes with oxide-coated cathodes. In addition, low filament voltage can cause distortion and spurious emissions for any type of tube. Tube failures from low filament emission in amateur service are rare. For more information, see the Reference section entry for T. Rauch, W8JI, on filament voltage management.

Every vacuum tube needs a receptor for the emitted electrons. After moving through the vacuum, the electrons are absorbed by the *plate*, also called the *anode*. This two-element tube — anode and cathode — is called a *diode*. The diode tube is similar to a semiconductor diode: it allows current to pass in only one direction. If the plate goes negative relative to the cathode, current cannot flow because electrons are not emitted from the plate. Years ago, in the days before semiconductors, tube diodes were used as rectifiers.

### TRIODES

To amplify signals, a vacuum tube must also contain a control *grid*. This name comes from its physical construction. The grid is a mesh of wires located between the cathode and the plate. Electrons from the cathode pass between the grid wires on their way to the plate. The electrical field that is set up by the voltage on these wires affects the electron flow from cathode to plate. A negative grid voltage repels electrons, blocking their flow to the plate. A positive grid voltage enhances the flow of electrons to the plate. Vacuum tubes containing a cathode, a grid and a plate are called *triode* tubes (*tri* for three components). See **Figure 17.4**.

The input impedance of a vacuum tube amplifier is directly related to the grid current. Grid current varies with grid voltage, increasing as the voltage becomes more positive. When the grid voltage is negative, no grid current flows and the input impedance of a tube is nearly infinite. When the grid is driven positive, it draws current and thus presents a lower input impedance, and requires significant drive power. The load placed across the plate of the tube strongly affects its output power and efficiency. An important part of tube design involves determining the opti-

**Figure 17.4 — Vacuum tube triode.** (A) Schematic symbol detailing heater (H), cathode (C), grid (G) and plate (P). (B) Audio amplifier circuit using a triode. C1 and C3 are dc blocking capacitors for the input and output signals to isolate the grid and plate bias voltages. C2 is a bypass filter capacitor to decrease noise in the plate bias voltage, B+. R1 is the grid bias resistor, R2 is the cathode bias resistor and R3 is the plate bias resistor. Note that although the cathode and grid bias voltages are positive with respect to ground, they are still negative with respect to the plate.

imum load resistance. These parameters are plotted as *characteristic curves* and are used to aid the design process. **Figure 17.5** shows an example.

Since the elements within the vacuum tube are conductors that are separated by an insulating vacuum, the tube is very similar to a capacitor. The capacitance between the cathode and grid, between the grid and plate, and between the cathode and plate can be large enough to affect the operation of the amplifier at high frequencies. These capacitances, which are usually on the order of a few picofarads, can limit the frequency response of an amplifier and can also provide signal feedback paths that may lead to unwanted oscillation. Neutralizing circuits are sometimes used to prevent such oscillations. Techniques for neutralization are presented later in this chapter.

### TETRODES

The grid-to-plate capacitance is the chief source of unwanted signal feedback. Therefore tubes were developed with a

HBK0568

Figure 17.5 — Characteristic curves for a 3CX800A7 triode tube. Grid voltage is plotted on the left, plate voltage along the bottom. The solid lines are plate current, the dashed lines are grid current. This graph is typical of characteristic curves shown in this chapter and used with the *TubeCalculator* program described in the text and available with this book's downloadable supplemental content.

second grid, called a *screen grid*, inserted between the original grid (now called a *control grid*) and the plate. Such tubes are called tetrodes (having four elements). See **Figure 17.6**. This second grid is usually tied to RF ground and acts as a screen between the grid and the plate, thus preventing energy from feeding back, which could cause instability. Like the control grid, the screen grid is made of a wire mesh and electrons pass through the spaces between the wires to get to the plate.

The screen grid carries a high positive voltage with respect to the cathode, and its proximity to the control grid produces a strong electric field that enhances the attraction of electrons from the cathode. The gain of a tetrode increases sharply as the screen voltage is increased. The electrons accelerate toward the screen grid and most of them pass through the spaces and continue to accelerate until they reach the plate. In large tubes this is aided by careful alignment of the screen wires with the grid wires.

Figure 17.6 — Vacuum tube tetrode. Schematic symbol detailing heater (H), cathode (C), the two grids: control and screen, and the plate (P).

The effect of the screen can also be seen in the flattening of the tube curves. Since the screen shields the grid from the plate, the plate current vs plate voltages becomes almost flat, for a given screen and grid voltage. **Figure 17.7** shows characteristic curves for a typical tetrode, and curves for many

more tube types are available with this book's downloadable supplemental content.

A special form of tetrode concentrates the electrons flowing between the cathode and the plate into a tight beam. The decreased electron-beam area increases the efficiency of the tube. *Beam tetrodes* permit higher plate currents with lower plate voltages and large power outputs with smaller grid driving power. The 6146 is an example of a beam power tube.

## PENTODES

Another unwanted effect in vacuum tubes is the so-called *secondary emission*. The electrons flowing within the tube can have so much energy that they are capable of dislodging electrons from the metal atoms in the grids and plate. Secondary emission can cause a grid, especially the screen grid, to lose more electrons than it absorbs. Thus while a screen usually draws current from its supply, it occasionally pushes current into the supply. Screen supplies must be able to absorb as well as supply current.

Figure 17.7 — Characteristic curves for a 4-125 tetrode tube.

A third grid, called the *suppressor grid*, can be added between the screen grid and the plate. This overcomes the effects of secondary emission in tetrodes. A vacuum tube with three grids is called a *pentode* (penta- for five elements). The suppressor grid is connected to a low voltage, often to the cathode.

### 17.3.3 Tube Nomenclature

Vacuum tubes are constructed with their elements (cathode, grid, plate) encased in an envelope to maintain the vacuum. Tubes with glass envelopes, such as the classic transmitting tube shown in **Figure 17.8**, are most familiar. Over time, manufacturers started exploring other, more rugged, methods for making high power transmitting tubes. Modern power tubes tend to be made of metal parts separated by ceramic insulating sections (**Figure 17.9**).

Because of their long history, vacuum tube types do not all follow a single logical system of identification. Many smaller tubes types begin with an indication of the filament voltage, such as the 6AU6 or 12AT7. Other tubes such as the 811 (**Figure 17.8**) and 6146 were assigned numbers in a more or less chronological order, much as transistors are today. Some glass envelope power tubes follow a numbering system that indicates number of tube elements and plate dissipation — 3-500Z and 4-1000A are two common examples in amateur circles.

Some power tubes follow the 3CX and 4CX numbering system. The first number indicates a triode (3) or tetrode (4) and the C indicates ceramic/metal construction. The X

indicates cooling type: X for air, W for water and V for vapor cooling. The cooling type is followed by the plate dissipation. (The tubes that amateurs use typically have three or four numbers indicating plate dissipation; those used in commercial and broadcast service can have much higher numbers.) Thus a 4CX250 is a ceramic, air cooled 250 W tetrode. A 3CX1200 is a ceramic, air cooled, 1200 W triode. Often these tubes have additional characters following the plate dissipation to indicate special features or an upgraded design. For example, a 4CX250R is a special version of the 4CX250 designed for AB1 linear operation. A 4CX1500B is an updated version of the 4CX1500A.

During the heyday of tube technology, some tube types were developed with several tubes in the same glass envelope, such as the 12AX7 (a dual triode). Except for a very few devices used in the specialty audio market, tubes of this type are no longer made.

### 17.3.4 Tube Mounting and Cooling Methods

Most tubes mount in some kind of socket so that they can be easily replaced when they reach the end of their useful life. Connections to the tube elements are typically made through pins on the base. The pins are arranged or keyed so that the tube can be inserted into the socket only one way and are sized and spaced to handle the operating voltages and currents involved. Tubes generally use a standard base or socket, although a great many different bases developed over the years. Tube data sheets show pinouts for

Figure 17.8 — The RCA 811A is an example of a transmitting triode with a glass envelope. [Photo courtesy the Virtual Valve Museum, [www.tubecollector.org](http://www.tubecollector.org)]

Figure 17.9 — Modern power tubes, such as this 4CX1000A tetrode, tend to use metal and ceramic construction.

the various tube elements, just like data sheets for ICs and transistors. See the **Component Data and References** chapter for base diagrams of some popular transmitting tubes.

For transmitting tubes, a common arrangement is for filament and grid connections to be made through pins in the main base, which

plate connection is made through a large or post at the top of the tube for easier connection to the high voltage supply and circuit. This construction is evident in examples shown in Figures 17.8 and 17.9. To reduce stray reactances, in some older glass tubes the grid used a separate connection.

Heat dissipation from the plate is one of the major limiting factors for vacuum tube power amplifiers. Most early vacuum tubes were encased in glass, and heat passed through it as infrared radiation. If more cooling was needed, air was simply blown over the outside of the glass. Modern ceramic tubes suitable for powers up to 5 kW are usually cooled by forcing air directly through an external anode. These tubes require a special socket that allows free flow of air. The external anode and cooling fins may be seen in the example in Figure 17.9. Conduction through an insulating block and water cooling are other options, though they are not often used in amateur equipment. Practical amplification and cooling methods are discussed in detail in this chapter.

### 17.3.5 Vacuum Tube Configurations

Just as the case with solid state devices described in the **Circuits and Components** chapter, any of the elements of the vacuum tube can be common to both input and output. The common plate connection — called a cathode follower and similar to the emitter follower — was once used to reduce output impedance (current gain) with little loss of stage. This application is virtually obsolete. Most modern tube applications use either common cathode or the common grid

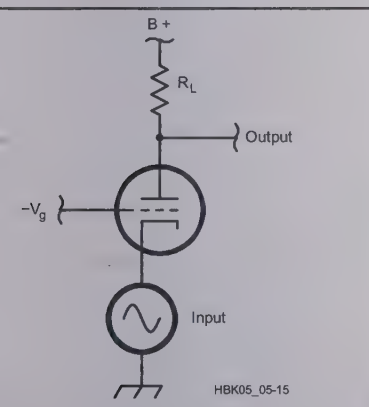

Figure 17.10 — Grounded grid amplifier schematic. The input signal is connected to the cathode, the grid is biased to the appropriate operating point by a dc bias voltage,  $-V_G$ , and the output voltage is obtained by the voltage drop through  $R_L$  that developed by the plate current,  $I_P$ .

connection. Figure 17.4B shows the common cathode connection, which gives both current and voltage gain. The common grid (often called *grounded grid*) connection shown in **Figure 17.10** gives only voltage gain. Thus the common cathode connection is capable of 20 to 30 dB of gain in a single stage, whereas the grounded grid connection typically gives 10 to 15 dB of gain.

The input impedance of a grounded grid stage is low, typically less than a few hundred ohms. The input impedance of a grounded cathode stage is much higher.

### 17.3.6 Classes of Operation in Tube Amplifiers

Class of operation was discussed briefly in the previous section describing the need for linear operation of RF power amplifiers for most Amateur Radio modes except FM. The class of operation of an amplifier stage is defined by its conduction angle, the angular portion of each RF drive cycle, in degrees, during which plate current flows. The conduction angle is determined by the bias on the device, and to a lesser extent on the drive level. These, in turn, determine the amplifier's efficiency, linearity and operating impedances. Refer to **Figure 17.11** for the following discussion.

Class A is defined as operation where plate current is always flowing. For a sine wave this means during  $360^\circ$  of the wave. Class A has the best linearity, but poor efficiency.

Class B is when the bias is set so that the tube is cut off for negative input signals, but current flows when the input signal is positive. Thus for a sine wave, conduction occurs during  $1/2$  of the cycle, or  $180^\circ$ . Class B is linear only when two devices operate in push-pull, so as to provide the missing half of the wave, or when a tuned circuit is present to restore the missing half by "flywheel" action (discussed later in this chapter).

Class AB is defined as operation that falls between Class A and Class B. For a sine wave, the conduction angle will be more than  $180^\circ$ , but less than  $360^\circ$ . In practice Class AB amplifiers usually fall within the gray area shown in the center area of the graph. Like Class B, a push pull connection or a tuned circuit are needed for linear operation. Class AB is less efficient than class B, but better than Class A. The linearity is better than class B but worse than class A.

Class AB vacuum tube amplifiers are further defined as class AB1 or AB2. In class AB1, the grid is not driven positive, so no grid current flows. Virtually no drive power is required. In Class AB2, the grid is driven positive at times with respect to the cathode and some grid current flows. Drive power and output both increase as compared to AB1. Most linear amplifiers used in the Amateur service operate Class AB2, although for greater linearity some operate Class AB1 or even Class A.

Class C is when conduction angle is less than  $180^\circ$  — typically  $120^\circ$  to  $160^\circ$  for vacuum

Figure 17.11 — Efficiency and K for various classes of operation. Read the solid line to determine efficiency. Read the dashed line for K, which is a constant used to calculate the plate load required, as explained in the text.

## The Flywheel Effect

The operation of a resonant tank circuit (see the **Oscillators and Synthesizers** chapter for a discussion of resonant LC circuits) is sometimes referred to as the “flywheel” effect. A flywheel does illustrate certain functions of a resonant tank, but a flywheel alone is non-resonant; that is, it has no preferred frequency of operation.

A better analogy for a resonant tank — although not exact — is found in the balance wheel used in mechanical watches and clocks in which a weighted wheel rotates back and forth, being returned to its center position by a spiral spring, sometimes called a hairspring. The balance wheel stores energy as inertia and is analogous to an inductor. The hairspring also stores energy and is similar in operation to a capacitor. The spring has an adjustment for the frequency of operation or resonance (1 Hz). An escapement mechanism gives the wheel a small kick with each tick of the watch to keep it going.

A plot of the rotational (or radial) velocity of the balance wheel will give a sine function. It thus converts the pulses from the escapement into smooth sinusoidal motion. In a similar way, pulses of current in the plate of a tube are smoothed into a sine wave in the tank circuit.

The plate (or collector or drain) voltage is a sine wave, even though the plate current is made up of pulses. Just as the escapement mechanism must apply its kicks at just the right time, the frequency at which current pulses are added to the tank must match the natural resonant frequency of the tank, which is adjusted with the “plate tune” capacitor.

Efficient operation of the tank itself occurs when the losses are small compared to the energy transferred to the output. In a similar manner, lowering the losses in a balance wheel by using jeweled bearings makes the watch more efficient. The amount of energy stored in the balance wheel should also be kept as low as practical since excess “oscillation” of the wheel wastes energy to the air and bearings. Likewise, the “circulating currents” in the tank must be limited to reduce heating from the inevitable losses in the components.

Figure 17.A1 — A balance wheel and hairspring in a mechanical clock illustrate the flywheel effect in tank circuits.

tube amplifiers or within the gray area to the left in Figure 17.11. The tube is biased well beyond cutoff when no drive signal is applied. Output current flows only during positive crests in the drive cycle, so it consists of relatively narrow pulses at the drive frequency. Efficiency is high, but nonlinear operation results. Class C amplifiers always use tuned circuits at the input and output. Attempts to achieve extreme efficiency with very narrow pulses (small conduction angles) require very high drive power, so a point of diminishing returns is eventually reached.

Classes D through H use various switch-mode techniques. These are used almost exclusively with solid state circuits.

### 17.3.7 Understanding Tube Operation

Vacuum tubes have complex current transfer characteristics, and each class of operation

produces different RMS values of RF current through the load impedance. As described earlier, tube manufacturers provide characteristic curves that show how the tube behaves as operating parameters (such as plate and grid voltage and current) vary. See Figures 17.5 and 17.7 for examples of characteristic curves for two different transmitting tubes. The use of tube curves provides the best way to gain insight into the characteristics of a given tube. Before designing with a tube, get a set of these curves and study them thoroughly.

Because of the complexity and interaction among the various parameters, computer-aided design (CAD) software is useful in analyzing tube operation. One such program, *TubeCalculator*, is available with this book’s downloadable supplemental content, along with curves for many popular transmitting tubes. This software makes it easier to do analysis of a given operation with the tube

you have chosen. Figure 17.12 shows a *TubeCalculator* screen with an example of “constant current” curves for a typical tube used in high power amplifiers and tables showing values for the various operating parameters. The curves shown have grid voltage on the vertical axis and plate voltage on the horizontal axis. Older tubes and some newer ones use a slightly different format in which plate voltage is plotted on the horizontal axis and plate current on the vertical axis. *TubeCalculator* allows analysis using either type.

The tube is the heart of any amplifier. Using the software to arrive at the desired operating parameters is a major step toward understanding and designing an amplifier. The second most important part of the design is the tuning components. Before they can be designed the required plate load resistance must be determined and *TubeCalculator* will do that. In addition it will give insight into what happens when a tube is under driven or over driven, when the bias is wrong, or when the load resistance is incorrect.

If a tube is to be used other than with nominal voltages and currents, analysis using the tube curves is the only solution short of trial and error. Trial and error is not a good idea because of the high voltages and currents found in high power amplifiers. It’s best to conduct your analysis using curves and software, or else stick to operating the tube very close to the voltages, currents, drive level and load values specified by the manufacturer.

### ANALYZING OPERATING PARAMETERS

Characteristic curves allow a detailed look at tube operation as voltages and currents vary. For example, you can quickly see how much negative grid voltage is required to set the plate current to any desired value, depending also on the plate voltage and screen voltages. You can also see how much grid voltage is needed to drive the plate current to the maximum desired value.

With RF power amplifiers, both the grid voltage and the plate voltage will be sinusoidal and will be 180° out of phase. With constant current curves, an operating line can be drawn that will trace out every point of the operating cycle. This will be a straight line connecting two points. One point will be at the intersection of the peak plate voltage and the peak negative grid voltage. The other point will be at the intersection of the peak positive grid voltage and the minimum plate voltage.

If we plot the plate current along this line as a function of time, it will be seen that it changes in a nonlinear fashion; the exact shape of which depends on the class of operation. For class AB2 operation, which is the most commonly used in linear RF power amplifiers, it will look something like the

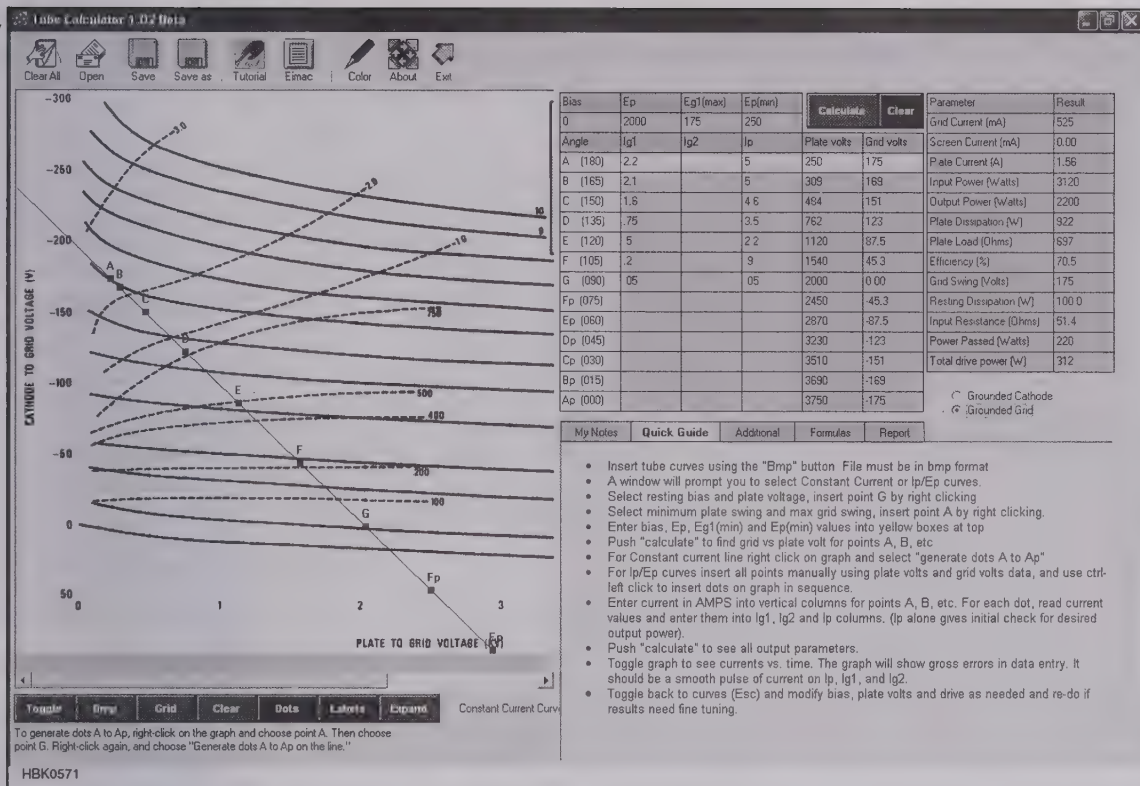

Figure 17.12 — Main screen of *TubeCalculator* program (available with this book's downloadable supplemental content). A characteristic curve plot is loaded in the window on the left side of the screen.

not shown in Figure 17.13. This rather complicated waveform is not easily evaluated using simple formulas, but it can be analyzed by taking the current values vs time and applying averaging techniques. This method was developed by Chaffee in 1936 and popularized by Eimac, the company that developed many of the power tubes used today. With *TubeCalculator*, data can be extracted from the curves and can be converted to many useful operating parameters such as input power, output power, grid power required, grid and plate dissipation and required load resistance.

### MANUAL METHODS FOR TUBE PARAMETER SELECTION

For those not wishing to use a computer design, most tube manufacturers will supply a table of typical operating values. A summary of some of this information is available in the **Component Data and References** chapter. These values have already been determined both from the tube characteristics and actual operational tests. As long as your proposed operation is close to the typical values in terms of voltages and currents, the typical values can provide you the desired load resistance and expected output power

Figure 17.13 — Class AB2 plate and grid current over one cycle as plotted by the *TubeCalculator* program. This plot is for a triode, so there is no curve for screen (G2) current.

and efficiency. The typical operating parameters may also include a suggested optimum load resistance. If not, we can use well established "rules of thumb."

The optimum load resistance for vacuum-tube amplifiers can be approximated by the ratio of the dc plate voltage to the dc plate

current at maximum signal, divided by a constant appropriate to each class of operation. The load resistance, in turn, determines the maximum power output and efficiency the amplifier can provide. The approximate value for tube load resistance is

$$R_L = \frac{V_p}{K \times I_p} \quad (1)$$

where

$R_L$  = the appropriate load resistance, in ohms

$V_p$  = the dc plate potential, in V

$I_p$  = the dc plate current, in A

$K$  = a constant that approximates the

RMS current to dc current ratio appropriate for each class. For the different classes of operation: Class A,

$K \approx 1.3$ ; Class AB,  $K \approx 1.5-1.7$ ;

Class B,  $K \approx 1.57-1.8$ ; Class C,  $K \approx$

2. The way in which  $K$  varies for different conduction angles is shown in

Figure 17.11 (right scale).

Once we determine the optimum load resistance value for the tube(s) to be used we are ready to design the output networks for the amplifier. After tube selection, this is the most important part of the total design.

# 17.4 Tank Circuits

Usually we want to drive a transmission line, typically 50 Ω, with the output of our amplifier. An output network is used to transform that 50 Ω impedance to the optimum load resistance for the tube. This transformation is accomplished by resonant output networks which also serve to reduce harmonics to a suitable level. The **Radio Fundamentals** chapter of this *Handbook* gives a detailed analysis of the operation of resonant circuits. We summarize here only the most important points.

Resonant circuits have the ability to store energy. Capacitors store electrical energy in the electric field between their plates; inductors store energy in the magnetic field induced by the coil winding. These circuits are referred to as *tank circuits* since they act as storage “tanks” for RF energy. This energy is continuously passed back and forth between the inductive storage and the capacitive storage. It can be shown mathematically that the “alternating” current and voltage produced by this process are sinusoidal in waveform with a frequency of

$$f = \frac{1}{2\pi\sqrt{LC}} \tag{2}$$

which, of course, is the resonant frequency of the tank circuit.

## 17.4.1 Tank Circuit Q

In order to quantify the ability of a tank circuit to store energy, a quality factor, Q, is defined. Q is the ratio of energy stored in a system during one complete RF cycle to energy lost.

$$Q = 2\pi \frac{W_S}{W_L} \tag{3}$$

where

$W_S$  = is the energy stored

$W_L$  = the energy lost to heat and the load

A load connected to a tank circuit has exactly the same effect on tank operation as circuit losses. Both consume energy. It just happens that energy consumed by circuit losses becomes heat rather than useful output. When energy is coupled out of the tank circuit into a load, the loaded Q ( $Q_L$ ) is:

$$Q_L = \frac{X}{R_{Loss} + R_{Load}} \tag{4}$$

where  $R_{Load}$  is the load resistance. Energy dissipated in  $R_{Loss}$  is wasted as heat. And X represents the reactance of the inductor or the capacitor, assumed to be equal at resonance. Ideally, all the tank circuit energy should be

delivered to  $R_{Load}$ . This implies that  $R_{Loss}$  should be as small as possible.

## 17.4.2 Tank Circuit Efficiency

The efficiency of a tank circuit is the ratio of power delivered to the load resistance ( $R_{Load}$ ) to the total power dissipated by losses ( $R_{Load}$  and  $R_{Loss}$ ) in the tank circuit. Within the tank circuit,  $R_{Load}$  and  $R_{Loss}$  are effectively in series and the circulating current flows through both. The power dissipated by each is proportional to its resistance. The loaded tank efficiency can, therefore, be defined as

$$\text{Tank Efficiency} = \frac{R_{Load}}{R_{Load} + R_{Loss}} \times 100 \tag{5}$$

where efficiency is stated as a percentage. The loaded tank efficiency can also be expressed as

$$\text{Tank Efficiency} = \left(1 - \frac{Q_L}{Q_U}\right) \times 100 \tag{6}$$

where

$Q_L$  = the tank circuit loaded Q, and

$Q_U$  = the unloaded Q of the tank circuit.

For practical circuits,  $Q_U$  is very nearly the Q of the coil with switches, capacitors and parasitic suppressors making a smaller contribution. It follows, then, that tank efficiency can be maximized by keeping  $Q_L$  low which keeps the circulating current low and the  $I^2R$  losses down.  $Q_U$  should be maximized for best efficiency; this means keeping the circuit losses low. With a typical  $Q_L$  of 10, about 10% of the stored energy is transferred to the load in each cycle. This energy is replaced by energy supplied by the tube. It is interesting to contemplate that in a typical amplifier which uses a  $Q_L$  of 10 and passes 1.5 kW from the tube to the output, the plate tank is storing about 15 kW of RF energy. This is

why component selection is very important, not only for low loss, but to resist the high voltages and currents.

Resonant circuits are always used in the plate circuit. When the grid is used as the input (common cathode), both matching and a tuned circuit may be used or else a low impedance load is connected from grid to ground with a broad matching transformer or network. The “loaded grid” reduces gain, but improves stability. In grounded grid operation, a tuned circuit may not be needed in the cathode circuit, as the input Z may be close to 50 Ω, but a tuned network may improve the match and usually improves the linearity. These resonant circuits help to ensure that the voltages on grid and plate are sine waves. This wave-shaping effect is the same thing as harmonic rejection. The reinforcing of the fundamental frequency and rejection of the harmonics is a form of filtering or selectivity.

The amount of harmonic suppression is dependent upon circuit loaded  $Q_L$ , so a dilemma exists for the amplifier designer. A low  $Q_L$  is desirable for best tank efficiency, but yields poorer harmonic suppression. High  $Q_L$  keeps amplifier harmonic levels lower at the expense of some tank efficiency. At HF, a compromise value of  $Q_L$  can usually be chosen such that tank efficiency remains high and harmonic suppression is also reasonable. At higher frequencies, tank  $Q_L$  is not always readily controllable, due to unavoidable stray reactances in the circuit. Unloaded  $Q_U$  can always be maximized, however, regardless of frequency, by keeping circuit losses low.

## 17.4.3 Tank Output Circuits

### THE PI NETWORK

The pi network with the capacitors to ground and the inductor in series is commonly used for tube type amplifier matching. This acts like a low pass filter, which is helpful for

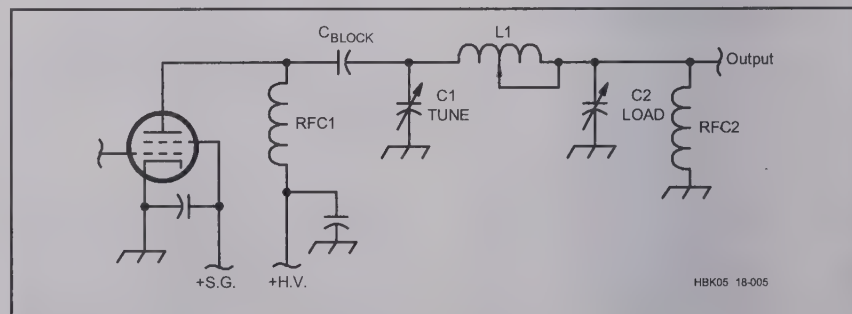

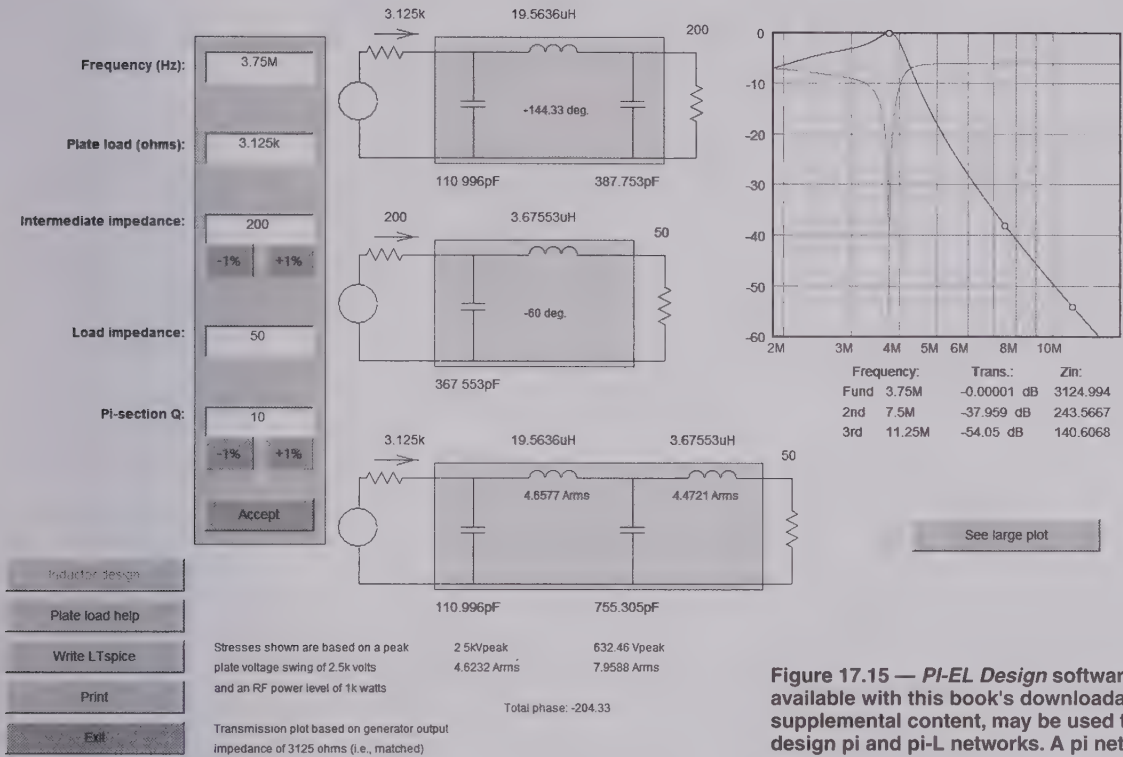

Figure 17.14 — A pi matching network used at the output of a tetrode power amplifier. RFC2 is used for protective purposes in the event  $C_{BLOCK}$  fails.

# PI-EL Design

**Figure 17.15 — PI-EL Design software, available with this book's downloadable supplemental content, may be used to design pi and pi-L networks. A pi network is shown at top right and a pi-L network at**

getting rid of harmonics. Harmonic suppression of a pi network is a function of the impedance transformation ratio and the  $Q_L$  of the circuit. Second-harmonic attenuation is approximately 35 dB for a load impedance of 2000  $\Omega$  in a pi network with a  $Q_L$  of 10. In addition to the low pass effect of the pi network, at the tube plate the third harmonic is already typically 10 dB lower and the fourth approximately 7 dB below that. A typical pi network as used in the output circuit of a tube amplifier is shown in **Figure 17.14**. The **Analog and Digital Filtering** chapter describes harmonic filters that can also greatly reduce harmonics. These are typically not switched but left in the circuit at all times. With such a filter, the requirements for reducing the harmonics on the higher bands with the amplifier pi network is greatly reduced.

The formulas for calculating the component values for a pi network, for those who wish to use them, are included with this book's downloadable supplemental content, along with tabular data for finished designs. The input variables are desired plate load resistance, output impedance to be matched

(usually 50  $\Omega$ ), the desired loaded Q (typically 10 or 12) and the frequency. With these inputs one can calculate the values of the components C1, L1 and C2. These components are usually referred to as the plate tune capacitor, the tank inductor and the loading capacitor. In a multi-frequency amplifier, the coil inductance is changed with a band switch

and the capacitors are adjusted to the correct value for the band in question.

Tank circuit component values are most easily found using computer software. The program *PI-EL Design* by Jim Tonne, W4ENE, is available with this book's downloadable supplemental content and is illustrated here. With this software, all of the components for a pi or pi-L network (described in the next section) can be quickly calculated. Since there are so many possible variables, especially with a pi-L network, it is impractical to publish graphical or tabular data to cover all cases. Therefore, the use of this software is highly recommended for those designing output networks. The software allows many "what-if" possibilities to be quickly checked and an optimum design found.

## THE PI-L NETWORK

There are some advantages in using an additional inductor in the output network, effectively changing it from a pi network to a pi-L network as shown in the bottom right corner of **Figure 17.15**. The harmonic rejection is increased, as shown in **Figure 17.16**,

**Figure 17.16 — Relative harmonic rejection of pi and pi-L circuits**

**Figure 17.17** — Plate tuning capacitor values for various bands and values of load resistance. Figures 17.17 through 17.19 may be used for manual design of a tank circuit, as explained in the text.

**Figure 17.18** — Plate loading capacitor values for various bands and values of load resistance.

**Figure 17.19** — Tank inductor values for various bands and values of load resistance.

and the component values may become more convenient. Alternatively, the Q can be reduced to lower losses while retaining the same harmonic rejection as the simple pi. This can reduce maximum required tuning capacitance to more easily achievable values.

With a pi-L design, there are many more options than with the simple pi network. This is because the intermediate impedance can take on any value we wish to assign between the output impedance (usually 50 Ω) and the desired plate resistance. This intermediate impedance need not be the same for each frequency, providing the possibility of further optimizing the design. For that reason, it is especially desirable that the software be used instead of using the chart values when a pi-L is contemplated. Using this software, one can quickly determine component values for the required load resistance and Q values for any frequency as well as plotting the harmonic rejection values. Even the voltage and current ratings of the components are calculated.

Further analysis can be done using various versions of SPICE. A popular SPICE version is LTspice available from Linear Technologies and downloadable for free on their website,

[www.linear.com](http://www.linear.com). The PI-EL Design software mentioned above generates files for LTspice automatically. PI-EL Design assumes that the blocking capacitor has negligible reactance and the RF choke has infinite reactance. There are times when these assumptions may not be valid. The effect of these components and changes to compensate for them can easily be evaluated using LTspice. It can also evaluate the effects of parasitic and stray effects, which all components have. The deep nulls in the response curves in Figure 17.16 are caused by the stray capacitance in the inductors. These can be used to advantage but, if not understood, can also lead to unexpected results. See the RF Techniques chapter for more information.

### MANUAL METHODS FOR TANK DESIGN

For those who wish to try designing a pi network without a computer, pi designs in chart form are provided. These charts (Figure 17.17 to Figure 17.19) give typical values for the pi network components for various bands and desired plate load resistance. For each value of load resistance the

component values can be read for each band. For bands not shown, an approximate value can be reached by interpolation between the bands shown. It's not necessary to be able to read these values to high precision. In practice, unaccounted-for stray capacitance and inductance will likely make the calculated values only an approximate starting point. For those desiring greater precision, this data is available in tabular form with this book's downloadable supplemental content along with the formulas for calculating them.

Several things become obvious from these charts. The required capacitance is reduced and the required inductance increased when a higher load resistance is used. This means that an amplifier with higher plate voltage and lower plate current will require smaller capacitor values and larger inductors. The capacitors will, of course, also have to withstand higher voltages, so their physical size may or may not be any smaller. The inductors will have less current in them so a smaller size wire may be used. It will be obvious that for an amplifier covering many bands, the most challenging parts of the design are at the frequency extremes. The 1.8 MHz band

**Table 17.1**  
**Pi-L Values for 1.8 MHz**

Plate Load Resistance (Ω)	Plate Tune Capacitor (pF)	Plate Inductor (μH)	Plate Load Capacitor (pF)	Output Inductor (μH)	Intermediate Resistance (Ω)	Loaded Q (Q <sub>L</sub> )	Harmonic Attenuation (3rd/5th, dB)
1000	883	10.5	3550	None (pi)	None (pi)	12	30/42
1000	740	15	2370	7.7	200	12	38/54

5000	114	83	928	11.7	400	8	39/55

## Designing to Avoid Interactive Tune and Load Adjustments

It can be annoying when tuning a tube amplifier if adjusting the loading control requires that we also re-dip the plate current. This happens when the loading capacitor changes the reactance seen by the final tube, rather than just the resistive part of its load. Setting the output power to a chosen value may require numerous readjustments of both controls.

The plate tuning capacitor is directly across the load seen by the tube, hence it only tunes for resonance. The loading capacitor is seen by the tube through the pi network and the network's phase shift will determine how the plate load impedance changes when the loading control is adjusted. For the loading capacitor to change only the resistive part of the tube load, choose a phase shift value for the pi network that is an odd multiple of  $45^\circ$ . Since a pi network with  $45^\circ$  phase shift will have very low Q, the best choice is a network with  $135^\circ$  phase shift.

The Smith chart in **Figure 17.A2** illustrates this effect. The solid line with dots shows the effect of adjusting the plate tuning capacitor. When close to resonance, it does not change the resistive part of the load seen by the tube, but does tune out the reactive part as shown by the fact that it crosses the horizontal resistance axis at a right angle. When the load is purely resistive at resonance, we get a dip in the plate current.

The thick dashed curve shows what happens when we adjust the loading capacitor with a  $135^\circ$  pi network. The resistive part of the tube load changes as shown by the curve moving along the horizontal axis, but the resonance is largely unaffected. The thin dashed line shows an example of what happens when we change the load capacitor with a network with a phase shift that is not  $135^\circ$ . Both the resistive part and the reactive part of the tube load change, making it necessary to retune the plate capacitor to resonance.

The phase shift of a pi network is determined by the Q of the network and the impedance transformation ratio. The value of Q that will give us the "magic"  $135^\circ$  phase shift will thus depend on the plate load to output impedance ratio. For a  $50\ \Omega$  load at the output of the pi network, the desired Q value can be determined from the upper curve of **Figure 17.A3**. Putting this value of Q into the pi-L design program will generate the pi network component values desired. For example, for  $2500\ \Omega$  plate load we see that the desired Q of the tank will be 12.4, a reasonable Q to choose that is close to the commonly used value of 10. Thus, with a slight adjustment of the design Q we can get to a "non interactive loading control" design.

As we can see on the upper curve of **Figure 17.A3**, with very high or low plate load values, the excursion from the normally used Q value of 10 may be excessive and a fully non-interactive tuning solution not practical with the simple pi network. For a plate load of  $4000\ \Omega$  we see that a Q of 16.4 would be required. This is somewhat high and would lead to excessive losses in the tank. An alternate approach would be to use the pi-L network, and allow the intermediate value to be  $100\ \Omega$ . The lower curve shows this allows the pi-L network to be designed using a Q value of 11.2, which is more acceptable.

A further discussion of this method, with formulas, a spreadsheet calculator, and more Smith chart graphics illustrating how it works is available with this book's downloadable supplemental content.

**Figure 17.A2** — Effect of plate and load capacitors for various phase shift values through the pi network.

**Figure 17.A3** — Pi network Q versus plate load resistance for non-interactive tuning. Use the upper curve for a  $50\ \Omega$  simple pi network and the lower curve for a pi-L network with a  $100\ \Omega$  intermediate resistance value

requires the most inductance and capacitance and the 28 MHz band requires the least. Often, the output capacitance of the tube plus the minimum value of the plate capacitor along with assorted stray capacitance will put a lower limit on the effective plate capacitance that can be achieved. These charts assume that value to be  $25\ \text{pF}$  and the other components are adjusted to account for that minimum value. An inevitable trade-off here is that the Q of the tank will be higher than optimum on the highest bands.

When tuning to the lower frequency bands, the maximum value of the capacitor, especially the loading capacitor, will be a limiting factor. Sometimes, fixed mica or ceramic transmitting rated capacitors will be switched in parallel with the variable capacitor to reach the total value required.

### COMPONENT SELECTION FOR THE PI-L NETWORK

For those wishing to use manual methods to design a pi-L network, there are lookup tables with this book's downloadable supplemental content along with the mathematical formulas from which they are derived. **Table 17.1** is an abbreviated version that shows the general trends. Values shown are for 1.8 MHz. Other bands can be approximated by dividing all component values by the frequency ratio. For example, for 18 MHz, divide all component values by 10. For 3.6 MHz, divide values by two, and so on.

For a given  $Q_L$ , the pi-L circuit has better harmonic rejection than the pi circuit. This allows the designer to use a lower  $Q_L$ , resulting in lower losses and lower capacitor values, which is an advantage on the lower frequen-

cies. However, the inductor values will be higher, and the lower capacitor values may be unachievable at higher frequencies. With the pi-L circuit there are many more variables to work with and, thus, one can try many different possibilities to make the circuit work within the limits of the components that are available.

### PROBLEMS AT VHF AND HIGHER FREQUENCIES

As the size of a circuit approaches about 5% of a wavelength, components begin to seriously depart from the pure inductance or capacitance we assume them to be. Inductors begin to act like transmission lines. Capacitors often exhibit values far different from their marked values because of stray internal reactances and lead inductance. Therefore,

tuned circuits are frequently fabricated in the form of striplines or other transmission lines in order to circumvent the problem of building “pure” inductances and capacitances. The choice of components is often more significant than the type of network used.

The high impedances encountered in VHF tube-amplifier plate circuits are not easily matched with typical networks. Tube output capacitance is usually so large that most matching networks are unsuitable. The usual

practice is to resonate the tube output capacitance with a low-loss inductance connected in series or parallel. The result can be a very high-Q tank circuit. Component losses must be kept to an absolute minimum in order to achieve reasonable tank efficiency. Output impedance transformation is usually performed by a link inductively coupled to the tank circuit or by a parallel transformation of the output resistance using a series capacitor.

Since high values of plate load impedance

call for low values of plate tuning capacitance, one might be tempted to add additional tubes in parallel to reduce the required load impedance. This only adds to the stray plate capacitance, and the potential for parasitic oscillations is increased. For these reasons, tubes in parallel are seldom used at VHF. Push-pull circuits offer some advantages, but with modern compact ceramic tube types, most VHF amplifiers use a single tube along with distributed type tuned networks. Other approaches are discussed later in this chapter.

## “COLD TUNING” AN AMPLIFIER

Because of the high voltage and current involved, as well as the danger of damaging an expensive tube or other component, it is prudent to “cold tune” an amplifier before applying power to it. This can actually be done early in the construction as soon as tank components and the tube are in place. Cold tuning requires some test equipment, but is not difficult or time consuming. Only if you have a problem in getting the tuning right will it take much time, but that is exactly the case in which you would not want to turn on the power without having discovered that there is a problem. With cold tuning, you can also add and remove additional components, such as the RF choke, and see how much it affects the tuning.

There are always stray capacitances and inductances in larger sized equipment, so there is a good chance that your carefully designed circuits may not be quite right. Even with commercial equipment, you may want to become aware of the limitations of the tuning ranges and the approximate settings for the dials for each band. The equipment manual may provide this information, but what if the amplifier you have is a bit out of calibration? In all of these cases, cold tests provide cheap insurance against damage caused by bad tuning and, at the same time, give you practice in setting up.

The first step is to ensure that the equipment is truly cold by removing the power plug from the wall. Since you will be working around the high voltage circuits, you may want to remove fuses or otherwise ensure that power cannot come on. In a well-designed amplifier there will be interlocks that prevent turn on and, perhaps, also short out the plate voltage. If these are in a place that affects the RF circuits, they may have to be temporarily removed. Just be sure to put them back when done.

The adjustment of the plate circuit components is the most important. The easiest way to check those is to attach a resistor across the tube from plate to ground. The resistor should be the same value as the design load resistance and must be non-inductive. Several

## Tuning Your Vacuum-Tube Amplifier

Today most hams are used to a wide variety of amplifiers using triodes that are tuned for maximum power output. Unfortunately, not all amplifiers or tubes are rugged enough for this approach. For example, amplifiers that use tetrodes employ a different tuning procedure in which tuning for maximum power may result in a destroyed control grid or screen grid! Procedures vary depending not only on the ratings of the tetrode, but the voltages as well. When tuning any amplifier, monitor grid currents closely and do not exceed the specified maximum current as those are the easiest elements of the tube to damage.

For commercial amplifiers, “Read the Manual” as the following procedures may not be exactly the same as the manufacturer’s directions and can be quite different in some cases. In all cases, the last tuning adjustments should be made at full power output, not at reduced power, because the characteristics of the tube change with different power levels. Operating the amplifier at high power after tuning at low power can result in spurious emissions or over-stressing the output network components.

Begin by making sure you have all band-switching controls set properly. If the amplifier TUNE and LOAD controls (sometimes referred to as PLATE TUNE and OUTPUT, respectively) have recommended settings on a particular band, start at those settings. If your amplifier can be set to a TUNE mode, do so. Set the initial amount of drive (input power) from the exciter — read the amplifier manual or check the tube’s specifications if a manual is not available. The exciter output should be one-half or more of full power so that the exciter’s ALC systems function properly.

Tuning a triode-based, grounded-grid amplifier is the simplest: Tune for maximum output power without exceeding the tube ratings, particularly grid current, or the legal output power limit. The typical procedure is, while monitoring grid current, to increase drive until the plate current equals about one-quarter to one-half of the target current (depending on

the tube and grid bias) while monitoring the output on a wattmeter or the internal power meter. Adjust the TUNE control then advance the LOAD control for maximum output. Repeat the sequence of peaking TUNE then increasing LOAD until no more output power can be obtained without exceeding the ratings for the tube or the legal power limit. If necessary, increase drive and re-peak both the TUNE and LOAD controls.

Operating somewhat differently, a grid-driven tetrode (or pentode) amplifier operating near its designed output power uses the TUNE control for peaking output power and the LOAD control for increasing, but not exceeding, the maximum allowable screen current. Generally, the first part of tetrode amplifier tuning is the same as for a triode amplifier with both the TUNE and LOAD controls adjusted for maximum power output while monitoring screen and control grid current. After the initial tuning step, the LOAD control is used to peak the screen current. Maximum power should coincide with maximum screen current. The screen current is just a better indicator. As with the triode amplifier, if drive needs to be increased, readjust the TUNE and LOAD controls.

For both triode and tetrode amplifiers, once the procedures above have been completed, try moving the TUNE control a small amount higher or lower and re-peaking the LOAD control. Also known as “rocking” the TUNE control, this small variation can find settings with a few percent more output power or better efficiency.

Once tuning has been completed, it is a good idea to mark the settings of the TUNE and LOAD controls for each band. This reduces the amount of time for on-the-air or dummy-load tuning, reducing stress to the tube and interference to other stations. Usually, a quick “fine-tune” adjustment is all that is required for maximum output. The set of markings also serves as a diagnostic tool, should the settings for maximum power suddenly shift. This indicates a change in the antenna system, such as a failing connector or antenna. — *Roger Halstead, K8RI*

series resistors in the 500  $\Omega$  range, either carbon film or the older carbon composition type will work, but *not* wire wound. The tube must remain in its socket and all the normal connections to it should be in place. Covers should be installed, at least for the final tests, since they may affect tuning.

Connect a test instrument to the 50  $\Omega$  output. This can be an antenna bridge or other 50  $\Omega$  measuring device. Examples of suitable test equipment would be a vector network analyzer, preferably with an impedance step up transformer, a vector impedance meter or an RX meter, such as the Boonton 250A. If the wattage of the resistor across the plate can stand it, it can even be a low power transmitter.

Select the correct band and tune the plate and load capacitors so that the instrument at the output connector shows 50  $\Omega$  or a low SWR at the 50  $\Omega$  point. Since this type of circuit is bilateral, you now have settings that will be the same ones you need to transform the 50  $\Omega$  load to look like the resistive load you used at the tube plate for the test. If you

have an instrument capable of measuring relatively high impedances at RF frequencies, you can terminate the output with 50  $\Omega$  and measure the impedance on the plate. It will look something like **Figure 17.20**.

A similar test will work for the input, although it is sometimes more difficult to know what the input impedance at the tube will be. In fact, it will change somewhat with drive level so a low power cold test may not give a full picture. However, just like the case of the plate circuit, you can put your best estimate of the input impedance at the grid using a non-inductive resistor. Then, tune the input circuits for a match.

An old timer's method for tuning these circuits, especially the plate circuit, is to use a dip meter. These are getting pretty hard to find these days and, in any case, only show resonance. You won't know if the transformation ratio between plate and output is correct, but it is better than nothing. At least, if you can't get a dip at the proper frequency, you will know that something is definitely wrong.

**Figure 17.20** — Impedance as would be measured at the plate of an amplifier tube with the output network tuned to 1.9 MHz and the output terminated in its proper load.

## 17.5 Transmitting Tube Ratings

### 17.5.1 Plate, Screen and Grid Dissipation

The ultimate factor limiting the power-handling capability of a tube is often (but not always) its maximum plate dissipation rating. This is the measure of how many watts of heat the tube can safely dissipate, if it is cooled properly, without exceeding critical temperatures. Excessive temperature can damage or destroy internal tube components or vacuum seals — resulting in tube failure. The same tube may have different voltage, current and power ratings depending on the conditions under which it is operated, but its safe temperature ratings must not be exceeded in any case! Important cooling considerations are discussed in more detail later in this chapter.

The efficiency of a power amplifier may range from approximately 25% to 85%, depending on its operating class, adjustment and circuit losses. The efficiency indicates how much of the dc power supplied to the stage is converted to useful RF output power; the rest is dissipated as heat, mostly by the plate. The *Tube Calculator* program will calculate the dissipation of the plate as one of its outputs. Otherwise, it can be determined by multiplying the plate voltage (V) times the plate current (A) and subtracting the output power (W).

For a class AB amplifier, the resting dissipation should also be noted, since with no RF input, *all* of the dc power is dissipated in the plate. Multiply plate voltage times the resting plate current to find this resting dissipation value. Screen dissipation is simply screen voltage times screen current. Grid dissipation is a bit more complicated since some of the power into the grid goes into the bias supply, some is passed through to the output (when grounded grid is used) and some is dissipated in the grid. Some tubes have very fragile grids and cannot be run with any grid current at all.

Almost all vacuum-tube power amplifiers in amateur service today operate as linear amplifiers (Class AB or B) with efficiencies of approximately 50% to 65%. That means that a useful power output of approximately 1 to 2 times the plate dissipation generally can be achieved. This requires, of course, that the tube is cooled enough to realize its maximum plate dissipation rating and that no other tube rating, such as maximum plate current or grid dissipation, is exceeded.

Type of modulation and duty cycle also influence how much output power can be achieved for a given tube dissipation. Some types of operation are less efficient than others, meaning that the tube must dissipate more heat. Some forms of modulation, such as CW

or SSB, are intermittent in nature, causing less average heating than modulation formats in which there is continuous transmission (RTTY or FM, for example).

Power-tube manufacturers use two different rating systems to allow for the variations in service. CCS (Continuous Commercial Service) is the more conservative rating and is used for specifying tubes that are in constant use at full power. The second rating system is based on intermittent, low-duty-cycle operation, and is known as ICAS (Intermittent Commercial and Amateur Service). ICAS ratings are normally used by commercial manufacturers and individual amateurs who wish to obtain maximum power output consistent with reasonable tube life in CW and SSB service. CCS ratings should be used for FM, RTTY and SSTV applications. (Plate power transformers for amateur service are also rated in CCS and ICAS terms.)

### MAXIMUM RATINGS

Tube manufacturers publish sets of maximum values for the tubes they produce. No maximum rated value should ever be exceeded. As an example, a tube might have a maximum plate-voltage rating of 2500 V, a maximum plate-current rating of 500 mA, and a maximum plate dissipation rating of

350 W. Although the plate voltage and current ratings might seem to imply a safe power input of  $2500 \text{ V} \times 500 \text{ mA} = 1250 \text{ W}$ , this is true only if the dissipation rating will not be exceeded. If the tube is used in class AB2 with an expected efficiency of 60%, the maximum safe dc power input is

$$P_{IN} = \frac{100P_D}{100 - N_D} = \frac{100 \times 350}{100 - 60} = 875 \text{ W}$$

## 17.5.2 Tank Circuit Components

### CAPACITOR RATINGS

The tank capacitor in a high-power amplifier should be chosen with sufficient spacing between plates to preclude high-voltage breakdown. The peak RF voltage present across a properly loaded tank circuit, without modulation, may be taken conservatively as being equal to the dc plate voltage. If the dc supply voltage also appears across the tank capacitor, this must be added to the peak RF voltage, making the total peak voltage twice the dc supply voltage. At the higher voltages, it is usually desirable to design the tank circuit so that the dc supply voltages do not appear across the tank capacitor, thereby allowing the use of a smaller capacitor with less plate spacing. Capacitor manufacturers usually rate their products in terms of the peak voltage between plates. Typical plate spacings are given in **Table 17.2**.

Output tank capacitors should be mounted as close to the tube as possible to allow short low inductance leads to the plate. Especially at the higher frequencies, where minimum circuit capacitance becomes important, the capacitor should be mounted with its stator plates well spaced from the chassis or other shielding. In circuits in which the rotor must be insulated from ground, the capacitor should be mounted on ceramic insulators of a size commensurate with the plate voltage involved and — most important of all, from the viewpoint of safety to the operator — a well-insulated coupling should be used between the capacitor shaft and the knob. The section of the shaft attached to the control knob should be well grounded. This can be done conveniently by means of a metal shaft bushing at the panel.

### COIL RATINGS

Tank coils should be mounted at least half their diameter away from shielding or other large metal surfaces, such as blower housings, to prevent a marked loss in Q. Except perhaps at 24 and 28 MHz, it is not essential that the coil be mounted extremely close to the tank capacitor. Leads up to 6 or 8 inches are permissible. It is more important to keep the tank

**Table 17.2**

### Typical Tank-Capacitor Plate Spacings

Spacing Inches	Peak Voltage	Spacing Inches	Peak Voltage	Spacing Inches	Peak Voltage
0.015	1000	0.07	3000	0.175	7000
0.02	1200	0.08	3500	0.25	9000
0.03	1500	0.125	4500	0.35	11000
0.05	2000	0.15	6000	0.5	13000

capacitor, as well as other components, out of the immediate field of the coil.

The principal practical considerations in designing a tank coil usually are to select a conductor size and coil shape that will fit into available space and handle the required power without excessive heating. Excessive power loss as such is not necessarily the worst hazard in using too-small a conductor. It is not uncommon for the heat generated to actually unsolder joints in the tank circuit and lead to physical damage or failure. For this reason it's extremely important, especially at power levels above a few hundred watts, to ensure that all electrical joints in the tank circuit are secured mechanically as well as soldered.

**Table 17.3** shows recommended conductor sizes for amplifier tank coils, assuming loaded tank circuit Q of 15 or less on the 24 and 30 MHz bands and 8 to 12 on the lower frequency bands. In the case of input circuits for screen-grid tubes where driving power is quite small, loss is relatively unimportant and almost any physically convenient wire size and coil shape is adequate.

The conductor sizes in **Table 17.3** are based on experience in continuous-duty amateur CW, SSB and RTTY service and assume that the coils are located in a reasonably well ventilated enclosure. If the tank area is not well ventilated and/or if significant tube heat is transferred to the coils, it is good practice to increase AWG wire sizes by two (for example, change from #12 to #10) and tubing sizes by  $\frac{1}{16}$  inch.

Larger conductors than required for current handling are often used to maximize unloaded Q, particularly at higher frequencies. Where skin depth effects increase losses, the greater surface area of large diameter conductors can be beneficial. Small-diameter copper tubing, up to  $\frac{3}{8}$  inch outer diameter, can be used successfully for tank coils up through the lower VHF range. Copper tubing in sizes suitable for constructing high-power coils is generally available in 50 foot rolls from plumbing and refrigeration equipment suppliers. Silver-plating the tubing may further reduce losses. This is especially true as the tubing ages and oxidizes. Silver oxide is a much better conductor than copper oxide, so silver-plated tank coils maintain their low-loss characteristics even after years of use.

**Table 17.3**

### Copper Conductor Sizes for Transmitting Coils for Tube Transmitters

Power Output (W)	Band (MHz)	Minimum Conductor Size
1500	1.8-3.5	10
	7-14	8 or $\frac{1}{8}$ "
	18-28	6 or $\frac{1}{16}$ "
500	1.8-3.5	12
	7-14	10
	18-28	8 or $\frac{1}{16}$ "
150	1.8-3.5	16
	7-14	12
	18-28	10

\*Whole numbers are AWG; fractions of inches are tubing ODs.

(There is some debate in amateur circles about the benefits of silver plating.)

At VHF and above, tank circuit inductances do not necessarily resemble the familiar coil. The inductances required to resonate tank circuits of reasonable Q at these high frequencies are small enough that only striplines or sections of transmission line are practical. Since these are constructed from sheet metal or large diameter tubing, current-handling capabilities normally are not a relevant factor.

## 17.5.3 Other Components

### RF CHOKES

The characteristics of any RF choke vary with frequency. At low frequencies the choke presents a nearly pure inductance. At some higher frequency it takes on high impedance characteristics resembling those of a parallel resonant circuit. At a still higher frequency it goes through a series-resonant condition where the impedance is lowest — generally much too low to perform satisfactorily as a shunt-feed plate choke. As frequency increases further, the pattern of alternating parallel and series resonances repeats. Between resonances, the choke will show widely varying amounts of inductive or capacitive reactance.

In most high-power amplifiers, the choke

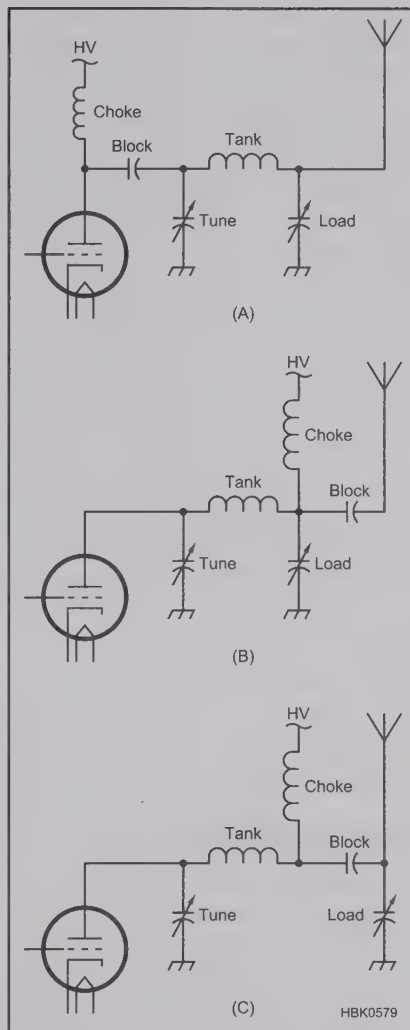

directly in parallel with the tank circuit, and is subject to the full tank RF voltage. See **Figure 17.21A**. If the choke does not present sufficiently high impedance, enough power will be absorbed by the choke to burn it out. To avoid this, the choke must have a sufficiently high reactance to be effective at the lowest frequency (at least equal to the plate load resistance) and yet have no series resonances near any of the higher frequency bands. A resonant-choke failure in a high-power amplifier can be very dramatic and damaging!

An RF choke performs best well below its self-resonant frequency (SRF) but it can be used throughout the range for which it has an acceptably high impedance. The choke's impedance will be inductive below the SRF and capacitive above the SRF. (See the discussion of RF Chokes in the **RF Techniques** chapter.) In the plate circuit, resonances may produce very high voltages at one or more points along the coil. This can cause arcing and damage to the choke. These chokes are often specially wound to minimize the effect of resonances but this must be done to suit the exact application since distributed capacitance to the enclosure and other components affects the SRF.

W8JI has written an informative paper about SRF and plate chokes which can be viewed at [www.w8ji.com/rf\\_plate\\_choke](http://www.w8ji.com/rf_plate_choke). His companion web page on inductors used in high-power RF circuits ([www.w8ji.com/loading\\_inductors.htm](http://www.w8ji.com/loading_inductors.htm)) is also very informative.

Thus, any choke intended for shunt-feed should be carefully investigated. The best way would be to measure its reactance to ground with an impedance measuring instrument. If the dip meter is used, the choke must be shorted end-to-end with a direct, heavy lead or strap. Because nearby metallic objects affect the resonances, it should be mounted in its intended position, but disconnected from the rest of the circuit. A dip meter coupled an inch or two away from one end of the choke nearly always will show a deep, sharp dip at the lowest series-resonant frequency and shallower dips at higher series resonances.

Any choke to be used in an amplifier for the 1.8 to 28 MHz bands requires careful (or at least lucky!) design to perform well on all amateur bands within that range. Most simply put, the challenge is to achieve sufficient inductance that the choke doesn't "cancel" a large part of tuning capacitance at 1.8 MHz. At the same time, try to position all its series resonances where they can do no harm. In general, close wind enough #20 to #24 magnet wire to provide about 135  $\mu$ H inductance on a 3/4 to 1-inch diameter cylindrical form of ceramic, Teflon or fiberglass. This gives a

**Figure 17.21 — Three ways of feeding dc to a tube via an RF choke. See text for a discussion of the tradeoffs.**

reactance of 1500  $\Omega$  at 1.8 MHz and yet yields a first series resonance in the vicinity of 25 MHz. Before the advent of the 24 MHz band this worked fine. But trying to "squeeze" the resonance into the narrow gaps between the 21, 24 and/or 28 MHz bands is quite risky unless sophisticated instrumentation is available. If the number of turns on the choke is selected to place its first series resonance at 23.2 MHz, midway between 21.45 and 24.89 MHz, the choke impedance will typically be high enough for satisfactory operation on the 21, 24 and 28 MHz bands. The choke's first series resonance should be measured very carefully as described above using a dip meter and calibrated receiver or RF impedance bridge, with the choke mounted in place on the chassis.

Investigations with a vector impedance

meter have shown that "trick" designs, such as using several shorter windings spaced along the form, show little if any improvement in choke resonance characteristics. Some commercial amplifiers circumvent the problem by band switching the RF choke. Using a larger diameter (1 to 1.5 inches) form does move the first series resonance somewhat higher for a given value of basic inductance. Beyond that, it is probably easiest for an all-band amplifier to add or subtract enough turns to move the first resonance to about 35 MHz and settle for a little less than optimum reactance on 1.8 MHz.

However, there are other alternatives. If one is willing to switch the choke when changing bands, it is possible to have enough inductance for 1.8 to 10 MHz, with series resonances well above 15 MHz. Then for 14 MHz and above, a smaller choke is used which has its resonances well above 30 MHz. Providing an extra pole on the band switch is, of course, the trade-off. This switch must withstand the full plate voltage. Switches suitable for changing bands for the pi network would handle this fine.

Another approach is to feed the high-voltage dc through the main tank inductor, putting the RF choke at the loading capacitor, instead of at the tube. (See **Figure 17.21B**) This puts a much lower RF voltage on the choke and, thus, not as much reactance is required for satisfactory rejection of the RF voltage. However, this puts both dc and RF voltages on the plate and loading capacitors which may be beyond their ratings. The blocking capacitor can be put before the loading capacitor, as in **Figure 17.21C**. This removes the dc from the loading capacitor, which typically has a lower voltage rating than the plate capacitor, but puts high current in the blocker.

Yet another method involves using hollow tubing for the plate tank and passing the dc lead through it. This lowers the RF voltage on the choke without putting dc voltage on the tuning components. This method works best for higher power transmitters where the tuning inductor can be made of 1/4 inch or larger copper tubing.

## BLOCKING CAPACITORS

A series capacitor is usually used at the input of the amplifier output circuit. Its purpose is to block dc from appearing on matching circuit components of the antenna. As mentioned in the section on tank capacitors, output-circuit voltage requirements are considerably reduced when only RF voltage is present.

To provide a margin of safety, the voltage rating for a blocking capacitor should be at least 25% to 50% greater than the dc voltage applied. A large safety margin is desirable,

since blocking capacitor failure can bring catastrophic results. The worse case is when dc is applied to the output of the transmitter and even to the antenna, with potentially fatal results. Often an RF choke is placed from the RF output jack to ground as a safety backup. A shorted blocker will blow the power supply fuse.

To avoid affecting the amplifier's tuning and matching characteristics, the blocking capacitor should have a low impedance at all operating frequencies. If it presents more than 5% of the plate load resistance, the pi components should be adjusted to compensate. Use of a *SPICE* analysis provides a useful way to see what adjustments might be required to maintain the desired match.

The capacitor also must be capable of handling, without overheating or significantly changing value, the substantial RF current that flows through it. This current usually is greatest at the highest frequency of operation where tube output capacitance constitutes a significant part of the total tank capacitance. A significant portion of circulating tank current, therefore, flows through the blocking

capacitor. When using the connection of the RF choke shown in Figure 17.21C, the entire circulating current must be accommodated.

Transmitting capacitors are rated by their manufacturers in terms of their RF current-carrying capacity at various frequencies. Below a couple hundred watts at the high frequencies, ordinary disc ceramic capacitors of suitable voltage rating work well in high-impedance tube amplifier output circuits. Some larger disk capacitors rated at 5 to 8 kV also work well for higher power levels at HF. For example, two inexpensive Centralab type DD-602 discs (0.002  $\mu$ F, 6 kV) in parallel have proved to be a reliable blocking capacitor for 1.5-kW amplifiers operating at plate voltages to about 2.5 kV. At very high power and voltage levels and at VHF, ceramic "doorknob" transmitting capacitors are needed for their low losses and high current handling capabilities. When in doubt, adding additional capacitors in parallel is cheap insurance against blocking capacitor failure and also reduces the impedance. So-called "TV doorknobs" may break down at high RF current levels and should be avoided.

The very high values of  $Q_L$  found in many VHF and UHF tube-type amplifier tank circuits often require custom fabrication of the blocking capacitor. This can usually be accommodated through the use of a Teflon "sandwich" capacitor. Here, the blocking capacitor is formed from two parallel plates separated by a thin layer of Teflon. This capacitor often is part of the tank circuit itself, forming a very low-loss blocking capacitor. Teflon is rated for a minimum breakdown voltage of 2000 V per mil of thickness, so voltage breakdown should not be a factor in any practically realized circuit. The capacitance formed from such a Teflon sandwich can be calculated from the information presented elsewhere in this *Handbook* (use dielectric constant of 2.1 for Teflon). In order to prevent any potential irregularities caused by dielectric thickness variations (including air gaps), Dow-Corning DC-4 silicone grease should be evenly applied to both sides of the Teflon dielectric. This grease has properties similar to Teflon, and will fill in any surface irregularities that might cause problems.

## 17.6 Sources of Operating Voltages

### 17.6.1 Tube Filament or Heater Voltage

A power vacuum tube can use either a directly heated filament or an indirectly heated cathode. The filament voltage for either type should be held within 5% of rated voltage. Because of internal tube heating at UHF and higher, the manufacturers' filament voltage rating often is reduced at these higher frequencies. The de-rated filament voltages should be followed carefully to maximize tube life.

Series dropping resistors may be required in the filament circuit to attain the correct voltage. Adding resistance in series will also reduce the inrush current when the tube is turned on. Cold tungsten has much lower resistance than when hot. Circuits are available that both limit the inrush current at turn on and also regulate the voltage against changes in line voltage.

The voltage should be measured with a true RMS meter at the filament pins of the tube socket while the amplifier is running. The filament choke and interconnecting wiring all have voltage drops associated with them. The high current drawn by a power-tube heater circuit causes substantial voltage drops to occur across even small resistances. Also, make sure that the plate power drawn from the power line does not cause the fila-

ment voltage to drop below the proper value when plate power is applied.

Thoriated filaments lose emission when the tube is overloaded appreciably. If the overload has not been too prolonged, emission, sometimes, may be restored by operating the filament at rated voltage, with all other voltages removed, for a period of 30 to 60 minutes. Alternatively, you might try operating the tube at 20% above rated filament voltage for five to ten minutes.

### 17.6.2 Vacuum-Tube Plate Voltage

DC plate voltage for the operation of RF amplifiers is most often obtained from a transformer-rectifier-filter system (see the **Power Sources** chapter) designed to deliver the required plate voltage at the required current. It is not unusual for a power tube to arc over internally (generally from the plate to the screen or control grid) once or twice, especially soon after it is first placed into service. The flashover by itself is not normally dangerous to the tube, provided that instantaneous maximum plate current to the tube is held to a safe value and the high-voltage plate supply is shut off very quickly.

A good protective measure against this is the inclusion of a high-wattage power resistor in series with the plate high-voltage cir-

cuit. The value of the resistor, in ohms, should be approximately 10 to 15 times the no-load plate voltage in KV. This will limit peak fault current to 67 to 100 A. The series resistor should be rated for 25 or 50 W power dissipation; vitreous enamel coated wire-wound resistors have been found to be capable of handling repeated momentary fault-current surges without damage. Aluminum-case resistors (Dale) are not recommended for this application. Each resistor also must be large enough to safely handle the maximum value of normal plate current; the wattage rating required may be calculated from  $P = I^2R$ . If the total filter capacitance exceeds 25  $\mu$ F, it is a good idea to use 50 W resistors in any case. Even at high plate-current levels, the addition of the resistors does little to affect the dynamic regulation of the plate supply.

Since tube (or other high-voltage circuit) arcs are not necessarily self-extinguishing, a fast-acting plate overcurrent relay or primary circuit breaker is also recommended. It quickly shut off ac power to the HV supply when an arc begins. Using this protective system, a mild HV flashover may go undetected, while a more severe one will remove ac power from the HV supply. (The cooling blower should remain energized, however, since the tube may be hot when the HV is removed due to an arc.) If effective protection is not provided, however, a "normal" flash-

ver, even in a new tube, is likely to damage or destroy the tube, and also frequently destroys the rectifiers in the power supply as well as the plate RF choke. A power tube that flashes over more than about 3 to 5 times in a period of several months likely is defective and will have to be replaced before long.

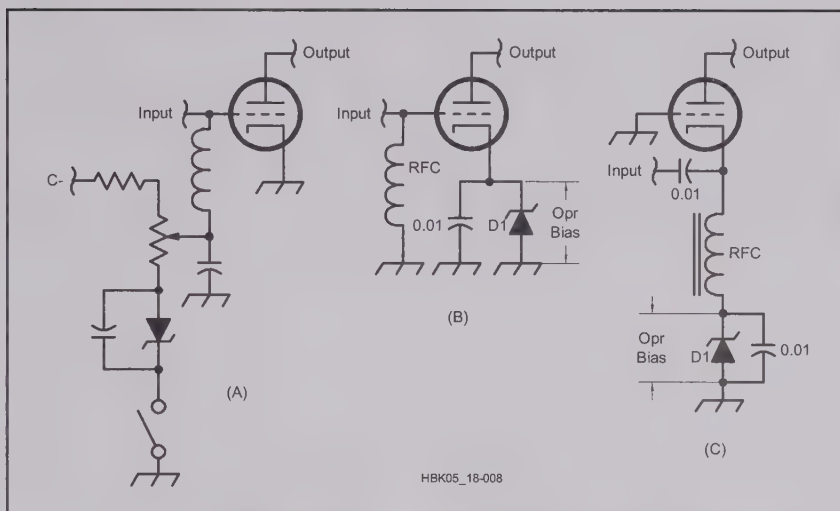

### 7.6.3 Grid Bias

The grid bias for a linear amplifier should be highly filtered and well regulated. Any ripple or other voltage change in the bias circuit modulates the amplifier. This causes hum and/or distortion to appear on the signal. Since most linear amplifiers draw only small amounts of grid current, these bias-supply requirements are not difficult to achieve.

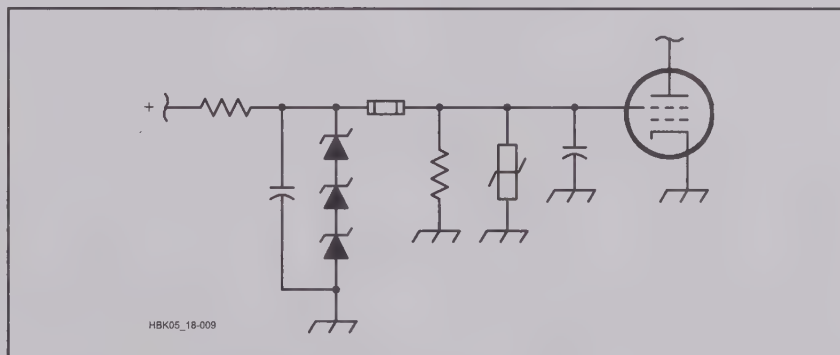

Fixed bias for class AB1 tetrode and pentode amplifiers is usually obtained from a variable-voltage regulated supply. Voltage adjustment allows setting bias level to give the desired resting plate current. **Figure 17.22A** shows a simple Zener-diode-regulated bias supply. The dropping resistor is chosen to allow approximately 10 mA of Zener current. Bias is then reasonably well regulated for all drive conditions up to 2 or 3 mA of grid current. The potentiometer allows bias to be adjusted between Zener and approximately 10 V higher. This range is usually adequate to allow for variations in the characteristics of different tubes. Under standby conditions, when it is desirable to cut off the tube entirely, the Zener ground return is interrupted so the full bias supply voltage is applied to the grid.

In **Figure 17.22B** and **C**, bias is obtained from the voltage drop across a Zener diode in the cathode (or filament center-tap) lead. Operating bias is obtained by the voltage drop across **D1** as a result of plate (and screen) current flow. The diode voltage drop effectively raises the cathode potential relative to the grid. The grid is, therefore, negative with respect to the cathode by the Zener voltage of the diode. The Zener-diode wattage rating should be twice the product of the maximum cathode current times the rated Zener voltage. Therefore, a tube requiring 15 V of bias with a maximum cathode current of 100 mA would dissipate 1.5 W in the Zener diode. To allow suitable safety factor, the diode rating should be 3 W or more. The circuit of **Figure 17.22C** illustrates how **D1** would be used with a cathode-driven (grounded grid) amplifier as opposed to the grid-driven example at **B**.

In all cases, the Zener diode should be bypassed by a 0.01- $\mu$ F capacitor of suitable voltage. Current flow through any type of diode generates shot noise. If not bypassed, this noise would modulate the amplified signal, causing distortion in the amplifier output.

**Figure 17.22** — Various techniques for providing operating bias with tube amplifiers.

**Figure 17.23** — A Zener-regulated screen supply for use with a tetrode. Protection is provided by a fuse and a varistor.

### 17.6.4 Screen Voltage For Tubes

Power tetrode screen current varies widely with both excitation and loading. The current may be either positive or negative, depending on tube characteristics and amplifier operating conditions. In a linear amplifier, the screen voltage should be well regulated for all values of screen current. The power output from a tetrode is very sensitive to screen voltage, and any dynamic change in the screen potential can cause distorted output. Zener diodes are commonly used for screen regulation.

**Figure 17.23** shows a typical example of a regulated screen supply for a power tetrode amplifier. The voltage from a fixed dc supply is dropped to the Zener stack voltage by the current-limiting resistor. A screen bleeder

resistor is connected in parallel with the Zener stack to allow for the negative screen current developed under certain tube operating conditions. Bleeder current is chosen to be roughly 10 to 20 mA greater than the expected maximum negative screen current, so that screen voltage is regulated for all values of current between maximum negative screen current and maximum positive screen current. For external-anode tubes in the 4CX250 family, a typical screen bleeder current value would be 20 mA. For the 4CX1000 family, a screen-bleeder current of 70 mA is required.

Screen voltage should never be applied to a tetrode unless plate voltage and load also are applied; otherwise, the screen will act like an anode and will draw excessive current. Perhaps the best way to insure this is to include logic circuits that will not allow the

screen supply to turn on until it senses plate voltage. Supplying the screen through a series-dropping resistor from the plate supply affords a measure of protection, since the screen voltage only appears when there is plate voltage. Alternatively, a fuse can be placed between the regulator and the bleeder resistor. The fuse should not be installed between the bleeder resistor and the tube be-

cause the tube should never be operated without a load on the screen. Without a load, the screen potential tends to rise to the anode voltage. Any screen bypass capacitors or other associated circuits are likely to be damaged by this high voltage.

In Figure 17.23, a varistor is connected from screen to ground. If, because of some circuit failure, the screen voltage should rise

substantially above its nominal level, the varistor will conduct and clamp the screen voltage to a low level. If necessary to protect the varistor or screen dropping resistors, a fuse or overcurrent relay may be used to shut off the screen supply so that power is interrupted before any damage occurs. The varistor voltage should be approximately 30% to 50% higher than normal screen voltage.

## 17.7 Tube Amplifier Cooling

Vacuum tubes must be operated within the temperature range specified by the manufacturer if long tube life is to be achieved. Tubes having glass envelopes and rated at up to 25 W plate dissipation may be used without forced-air cooling if the design allows a reasonable amount of convection cooling. If a perforated metal enclosure is used, and a ring of ¼ to ⅜-inch-diameter holes is placed around the tube socket, normal convective airflow can be relied on to remove excess heat at room temperatures.

For tubes with greater plate dissipation ratings, and even for very small tubes operated close to maximum rated dissipation, forced-air cooling with a fan or blower is needed. Most manufacturers rate tube-cooling requirements for continuous-duty operation. Their literature will indicate the required volume of airflow, in cubic feet per minute (CFM), at some particular back pressure. Often, this data is given for several different values of plate dissipation, ambient air temperature and even altitude above sea level.

One extremely important consideration is often overlooked by power-amplifier designers and users alike: a tube's plate dissipation rating is only its maximum potential capability. The power that it can actually dissipate safely depends directly on the cooling provided. The actual power capability of virtually all tubes used in high-power amplifiers for amateur service depends on the volume of air forced through the tube's cooling structure.

### 17.7.1 Blower Specifications

This requirement usually is given in terms of cubic feet of air per minute (CFM), delivered into a back pressure, representing the resistance of the tube cooler to air flow, stated in inches of water. Both the CFM of airflow required and the pressure needed to force it through the cooling system are determined

by ambient air temperature and altitude (air density), as well as by the amount of heat to be dissipated. The cooling fan or blower must be capable of delivering the specified airflow into the corresponding back pressure. As a result of basic air flow and heat transfer principles, the volume of airflow required through the tube cooler increases considerably faster than the plate dissipation, and back pressure increases even faster than airflow. In addition, blower air output decreases with increasing back pressure until, at the blower's so-called "cutoff pressure," actual air delivery is zero. Larger and/or faster-rotating blowers are required to deliver larger volumes of air at higher back pressure.

Values of CFM and back pressure required to realize maximum rated plate dissipation for some of the more popular tubes, sockets and chimneys (with 25 °C ambient air and at

sea level) are given in **Table 17.4**. Back pressure is specified in inches of water and can be measured easily in an operational air system as indicated in **Figures 17.24** and **17.25**. The pressure differential between the air passage and atmospheric pressure is measured with a device called a *manometer*. A manometer is nothing more than a piece of clear tubing, open at both ends and fashioned in the shape of a "U." The manometer is temporarily connected to the chassis and is removed after the measurements are completed. As shown in the diagrams, a small amount of water is placed in the tube. At Figure 17.25A, the blower is "off" and the water seeks its own level, because the air pressure (ordinary atmospheric pressure) is the same at both ends of the manometer tube. At B, the blower is "on" (socket, tube and chimney in place) and the pressure difference, in terms

**Table 17.4**  
Specifications of Some Popular Tubes, Sockets and Chimneys

Tube	CFM	Back Pressure (inches)	Socket	Chimney

of inches of water, is measured. For most applications, a standard ruler used for measurement will yield sufficiently accurate results.

Table 17.5 gives the performance specifications for a few of the many Dayton blowers, which are available through Grainger Industrial Supply ([www.grainger.com](http://www.grainger.com)). Other blowers having wheel diameters, widths and rotational speeds similar to any in Table 17.5 likely will have similar flow and back pressure characteristics. If in doubt about specifications, consult the manufacturer. Tube temperature under actual operating conditions is the ultimate criterion for cooling adequacy and may be determined using special crayons or lacquers that melt and change appearance at specific temperatures. The setup of Figure 17.25, however, nearly always gives sufficiently accurate information.

## 17.7.2 Cooling Design Example

As an example, consider the cooling design of a linear amplifier to use one 3CX800A7 tube to operate near sea level with the air temperature not above 25 °C. The tube, running 1150 W dc input, easily delivers 750 W continuous output, resulting in 400 W plate dissipation ( $P_{DIS} = P_{IN} - P_{OUT}$ ). According to the manufacturer's data, adequate tube cooling at 400 W  $P_D$  requires at least 6 CFM of air at 0.09 inches of water back pressure. In Table 17.5, a Dayton no. 1TDN2 will do the job with a good margin of safety.

If the same single tube were to be operated at 2.3 kW dc input to deliver 1.5 kW output (substantially exceeding its maximum electrical ratings!),  $P_{IN}$  would be about 2300 W and  $P_D \approx 800$  W. The minimum cooling air required would be about 19 CFM at 0.5 inches of water pressure—doubling  $P_{DIS}$ , more than

tripling the CFM of air flow required and increasing back pressure requirements on the blower by a factor of 5.5!

However, two 3CX800A7 tubes are needed to deliver 1.5 kW of continuous maximum legal output power in any case. Each tube will operate under the same conditions as in the single-tube example above, dissipating 400 W. The total cooling air requirement for the two tubes is, therefore, 12 CFM at about 0.09 inches of water, only two-thirds as much air volume and one-fifth the back pressure required by a single tube. While this may seem surprising, the reason lies in the previously mentioned fact that both the airflow required by a tube and the resultant back pressure increase much more rapidly than  $P_D$  of the tube. Blower air delivery capability, conversely, decreases as back pressure is increased. Thus, a Dayton 1TDN2 blower can cool two 3CX800A7 tubes dissipating

800 W total, but a much larger (and probably noisier) no. 1TDN7 would be required to handle the same power with a single tube.

In summary, three very important considerations to remember are these:

- A tube's actual safe plate dissipation capability is totally dependent on the amount of cooling air forced through its cooling system. Any air-cooled power tube's maximum plate dissipation rating is meaningless unless the specified amount of cooling air is supplied.

- Two tubes will always safely dissipate a given power with a significantly smaller (and quieter) blower than is required to dissipate the same power with a single tube of the same type. A corollary is that a given blower can virtually always dissipate more power when cooling two tubes than when cooling a single tube of the same type.

- Blowers vary greatly in their ability to deliver air against back pressure so blower selection should not be taken lightly.

### 17.7.3 Other Considerations

A common method for directing the flow of air around a tube involves the use of a pressurized chassis. This system is shown in Figure 17.24. A blower attached to the chassis forces air around the tube base, often through holes in its socket. A chimney is used to guide air leaving the base area around the tube envelope or anode cooler, preventing it from dispersing and concentrating the flow for maximum cooling.

A less conventional approach that offers a significant advantage in certain situations is shown in Figure 17.26. Here the anode compartment is pressurized by the blower. A special chimney is installed between the anode heat exchanger and an exhaust hole in the compartment cover. When the blower pressurizes the anode compartment, there are two parallel paths for airflow: through the anode and its chimney, and through the air

**Figure 17.26 — Anode compartment pressurization may be more efficient than grid compartment pressurization. Hot air exits upwards through the tube anode and through the chimney. Cool air also goes down through the tube socket to cool tube's pins and the socket itself.**

system socket. Dissipation, and hence cooling air required, generally is much greater for the anode than for the tube base. Because high-volume anode airflow need not be forced through restrictive air channels in the base area, back pressure may be very significantly reduced with certain tubes and sockets. Only airflow actually needed is bled through the base area. Blower back pressure requirements may sometimes be reduced by nearly half through this approach.

Table 17.4 also contains the part numbers for air-system sockets and chimneys available for use with the tubes that are listed. The builder should investigate which of the sockets listed for the 4CX250R, 4CX300A, 4CX1000A and 4CX1600A best fit the circuit needs. Some of the sockets have certain tube elements grounded internally through the socket. Others have elements bypassed to ground through capacitors that are integral parts of the sockets.

Depending on your design philosophy and

tube sources, some compromises in the cooling system may be appropriate. For example, if glass tubes are available inexpensively and broadcast pulls, a shorter life span may be acceptable. In such a case, an increase of convenience and a reduction in cost, noise, and complexity can be had by using a pair of “muffin” fans. One fan may be used for the filament seals and one for the anode seal, dispensing with a blower and air-system socket and chimney. The airflow with this scheme is not as uniform as with the use of a chimney. The tube envelope mounted in a cross flow has flow stagnation points and low heat transfer in certain regions of the envelope. These points become hotter than the rest of the envelope. The use of multiple fans to disturb the cross airflow can significantly reduce this problem. Many amateurs have used this cooling method successfully in low-duty-cycle CW and SSB operation but it is not recommended for AM, SSTV or RTTY service.

The true test of the effectiveness of a forced air cooling system is the amount of heat carried away from the tube by the air stream. The power dissipated can be calculated from the airflow temperatures. The dissipated power is

$$P_D = 0.543 Q_A (T_2 - T_1) \quad (7)$$

where

$P_D$  = the dissipated power, in W

$Q_A$  = the air flow, in CFM (cubic feet per minute).

$T_1$  = the inlet air temperature, °C (normally quite close to room temperature).

$T_2$  = the amplifier exhaust temperature, °C.

The exhaust temperature can be measured with a cooking thermometer at the air outlet. The thermometer should not be placed inside the anode compartment because of the high voltage present.

## 17.8 Vacuum Tube Amplifier Stabilization

Purity of emissions and the useful life (or even survival) of a tube depend heavily on stability during operation. Oscillations can occur at the operating frequency, or far from it, because of undesired positive feedback in the amplifier. Unchecked, these oscillations pollute the RF spectrum and can lead to over-dissipation and subsequent failure. Each type of oscillation has its own cause and its own cure.

### 17.8.1 Amplifier Neutralization

An RF amplifier, especially a linear amplifier, can easily become an oscillator at various frequencies. When the amplifier is operating, the power at the output side is large. If a fraction of that power finds its way back to the input and is in the proper phase, it can be re-amplified, repeatedly, leading to oscillation. An understanding of this process can be

had by studying the sections on feedback and oscillation in the **Radio Fundamentals** chapter. Feedback that is self-reinforcing called “positive” feedback, even though its effects are undesirable. Even when the positive feedback is insufficient to cause actual oscillation, its presence can lead to excessive distortion and strange effects on the tuning of the amplifier and it, therefore, should be eliminated or at least reduced. The deliberate

se of “negative” feedback in amplifiers to increase linearity is discussed briefly elsewhere in this chapter.

The power at the output of an amplifier will couple back to the input of the amplifier through any path it can find. It is a good practice to isolate the input and output circuits of an amplifier in separate shielded compartments. Wires passing between the two compartments should be bypassed to ground if possible. This prevents feedback via paths external to the tube.

However, energy can also pass back through the tube itself. To prevent this, a process called neutralization can be used. Neutralization seeks to prevent or to cancel out any transfer of energy from the plate of the tube back to its input, which will be either the grid or the cathode. An effective way to neutralize a tube is to provide a grounded shield between the input and the output. In the grounded grid connection, the grid itself serves this purpose. For best neutralization, the grid should be connected through a low inductance conductor to a point that is at RF ground. Ceramic external tube types may have multiple low inductance leads to ground to enhance the shielding effect. Older glass type tubes may have significant inductance inside the tube and in the socket, and this will limit the effectiveness of the shielding effect of the grid. Thus, using a grounded grid circuit with those tube types does not rule out the need for further efforts at neutralization, especially at the higher HF frequencies.

When tetrodes are used in a grounded cathode configuration, the screen grid acts as an RF shield between the grid and plate. Special

tube sockets are provided that provide a very low inductance connection to RF ground. These reduce the feed through from plate to grid to a very small amount, making the effective grid-to-plate capacitance a tiny fraction of one picofarad. If in doubt about amplifiers that will work over a large frequency range, use a network analyzer or impedance measuring instrument to verify how well grounded a “grounded” grid or screen really is. If at some frequencies the impedance is more than an ohm or two, a different grounding configuration may be needed.

For amplifiers to be used at only a single frequency, a series resonant circuit can be used at either the screen or grid to provide nearly perfect bypassing to ground. Typical values for a 50 MHz amplifier are shown in **Figure 17.27**.

For some tubes, at a certain frequency, the lead inductance to ground can just cancel the grid-to-plate capacitance. Due to this effect, some tube and socket combinations have a naturally self-neutralizing frequency based on the values of screen inductance and grid-to-plate capacitance. For example, the “self-neutralizing frequency” of a 4-1000 is about 30 MHz. This effect has been utilized in some VHF amplifiers.

### BRIDGE NEUTRALIZATION

When the shielding effect of a grid or screen bypassed to ground proves insufficient, other circuits must be devised to cancel out the remaining effect of the grid-to-plate or grid-to-cathode capacitance. These, in effect, add an additional path for negative feedback that will combine with the undesired positive feedback and cancel it. The most commonly used circuit is the “bridge neutralization” circuit shown in **Figure 17.28**. This method gets its name from the fact that the four important capacitance values can be redrawn as a bridge circuit, as shown in **Figure 17.29**. Clearly when the bridge is properly balanced, there

is no transfer of energy from the plate to the grid tanks. Note that four different capacitors are part of the bridge.  $C_{gp}$  is characteristic of the chosen tube, somewhat affected by the screen or grid bypass mentioned earlier. The other components must be chosen properly so that bridge balance is achieved.  $C1$  is the neutralizing capacitor. Its value should be adjustable to the point where

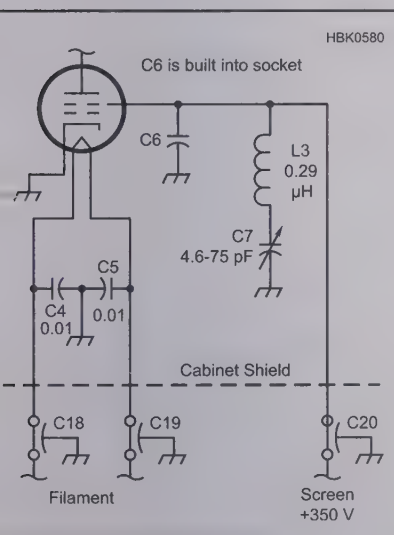

$$\frac{C1}{C3} = \frac{C_{gp}}{C_{IN}} \quad (8)$$

where

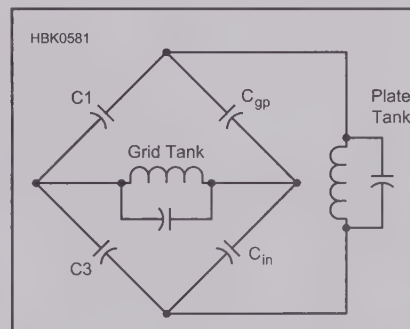

$C_{gp}$  = tube grid-plate capacitance  
 $C_{IN}$  = tube input capacitance

The tube input capacitance must include all strays directly across the tube.  $C3$  is not simply a bypass capacitor on the ground side of the grid tank, but rather a critical part of the bridge. Hence, it must provide a stable value of capacitance. Sometimes, simple bypass capacitors are of a type which change their value drastically with temperature. These are not suitable in this application.

Neutralization adjustment is accomplished

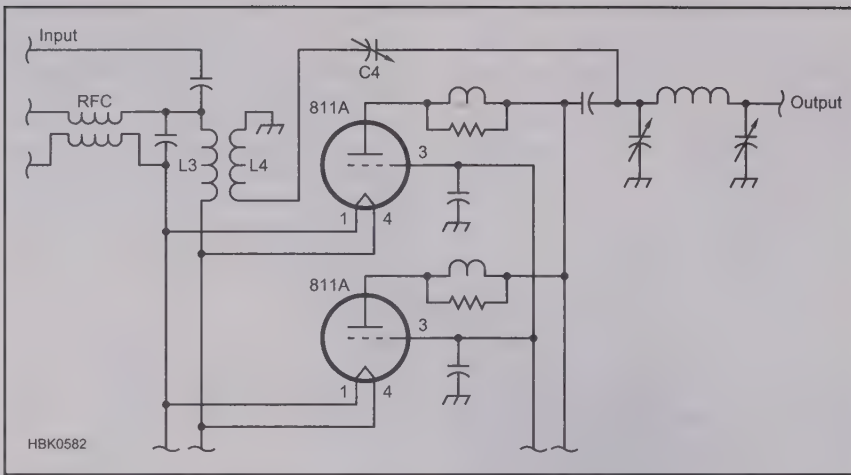

**Figure 17.27** — A series-resonant circuit can be used to provide nearly perfect screen or grid bypassing to ground. This example is from a single-band 50 MHz

**Figure 17.29** — The “bridge neutralization” circuit of **Figure 17.28** redrawn to show the capacitance values.

**Figure 17.28** — A neutralization circuit uses  $C1$  to cancel the effect of the tube internal capacitance.

**Figure 17.30** — In this neutralizing method, a broadband transformer (L3, L4) provides the needed out-of-phase signal. L3 is 6 turns of #14 wire close wound, ½ inch diameter. L4 is 5 turns of insulated wire over L3. C4 is 6 pF with 0.06-inch spacing. This circuit was originally featured in June 1961 *QST* and is still found in modern amplifiers using 811A tubes.

by applying energy to the output of the amplifier, and measuring the power fed through the input. Conversely, the power may be fed through the input and the output power measured. *with the power off*, the neutralization capacitor C1 is adjusted for minimum feed through, while keeping the output tuning circuit and the input tuning (if used) at the point of maximum response. Since the bridge neutralization circuit is essentially broad band, it will work over a range of frequencies. Usually, it is adjusted at the highest anticipated frequency of operation, where the adjustment is most critical.

### BROADBAND TRANSFORMER

Another neutralizing method is shown in **Figure 17.30**, where a broadband transformer provides the needed out of phase signal. C4 is adjusted so that the proper amount of negative feedback is applied to the input to just cancel the feedback via the cathode to plate capacitance. Though many 811A amplifiers have been built without this neutralization, its use makes tuning smoother on the higher bands. This circuit was featured in June 1961 *QST* and then appeared in the *RCA*

**Figure 17.31** — At A, typical VHF/UHF parasitic resonance in plate circuit. The HF tuning inductor in the pi network looks like an RF choke at VHF/UHF. The tube's output capacitance and series stray inductance combine with the pi-network tuning capacitance and stray circuit capacitance to create a VHF/UHF pi network, presenting a very high impedance to the plate, increasing its gain at VHF/UHF. At B, Z1 lowers the Q and therefore gain at parasitic frequency.

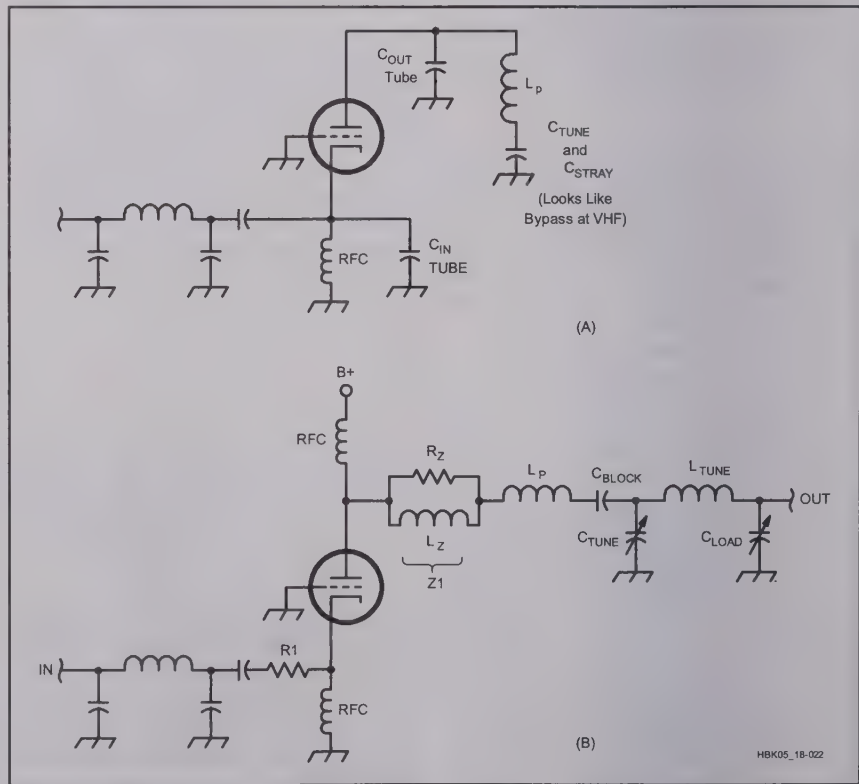

*Transmitting Tube Handbook*. Amplifiers featuring this basic circuit are still being manufactured in 2009 and are a popular seller. Many thousands of hams have built such amplifiers as well.

An alternate method of achieving stable operation is to load the grid of a grounded cathode circuit with a low value of resistance.

A convenient value is 50 Ω as it provides a match for the driver. This approach reduces the power being fed back to the grid from the output to a low enough level that good stability is achieved. However, the amplifier gain will be much less than without the grid load. Also, unlike the grounded grid circuit, where much of the power applied to the input feeds through to the output, with this “loaded grid” approach, the input power is lost in the load, which must be able to dissipate such power. Distortion may be low in that the driver stage sees a very constant load. In addition, no tuning of the input is required.

### 17.8.2 VHF and UHF Parasitic Oscillations

RF power amplifier circuits contain parasitic reactances that have the potential to cause so-called parasitic oscillations at frequencies far above the normal operating frequency. Nearly all vacuum-tube amplifiers designed for operation in the 1.8 to 29.7 MHz frequency range exhibit tendencies to oscillate somewhere in the VHF-UHF range — generally between about 75 and 250 MHz depending on the type and size of tube. A typical parasitic resonant circuit is shown in **Figure 17.31**. Stray inductance between the tube plate and the output tuning capacitor forms a high-Q resonant circuit with the tube's  $C_{OUT}$ .  $C_{OUT}$  normally is much smaller (higher  $X_C$ ) than

any of the other circuit capacitances shown. The tube's  $C_{IN}$  and the tuning capacitor  $C_{TUNE}$  essentially act as bypass capacitors, while the various chokes and tank inductances shown have high reactances at VHF. Thus, the values of these components have little influence on the parasitic resonant frequency.

Oscillation is possible because the VHF resonant circuit is an inherently high-Q parallel-resonant tank that is not coupled to the external load. The load resistance at the plate is very high and thus, the voltage gain at the parasitic frequency can be quite high, leading to oscillation. The parasitic frequency,  $f_r$ , is approximately:

$$f_r = \frac{1000}{2 \pi \sqrt{L_p C_{OUT}}} \quad (9)$$

where

$f_r$  = parasitic resonant frequency in MHz

$L_p$  = total stray inductance between tube plate and ground via the plate tuning capacitor (including tube internal plate lead) in  $\mu$ H.

$C_{OUT}$  = tube output capacitance in pF.

In a well-designed HF amplifier,  $L_p$  might be in the area of 0.2  $\mu$ H and  $C_{OUT}$  for an 8877 is about 10 pF. Using these figures, the equation above yields a potential parasitic resonant frequency of

$$f_r = \frac{1000}{2 \pi \sqrt{0.2 \times 10}} = 112.5 \text{ MHz}$$

For a smaller tube, such as the 3CX800A7 with  $C_{OUT}$  of 6 pF,  $f_r = 145$  MHz. Circuit details affect  $f_r$  somewhat, but these results do, in fact, correspond closely to actual parasitic oscillations experienced with these tube types. VHF-UHF parasitic oscillations can be prevented (*not* just minimized!) by reducing the loaded Q of the parasitic resonant circuit so that gain at its resonant frequency is insufficient to support oscillation. This is possible with any common tube, and it is especially easy with modern external-anode tubes like the 8877, 3CX800A7 and 4CX800A.

### PARASITIC SUPPRESSORS

Z1 of Figure 17.31B is a parasitic suppressor. Its purpose is to add loss to the parasitic circuit and reduce its Q enough to prevent oscillation. This must be accomplished without significantly affecting normal operation.  $L_z$  should be just large enough to constitute a significant part of the total parasitic tank inductance (originally represented by  $L_p$ ), and located right at the tube plate terminal(s). If  $L_z$  is made quite lossy, it will reduce the Q of the parasitic circuit as desired.

The inductance and construction of  $L_z$  depend substantially on the type of tube used.

Popular glass tubes like the 3-500Z and 4-1000A have internal plate leads made of wire. This significantly increases  $L_p$  when compared to external-anode tubes. Consequently,  $L_z$  for these large glass tubes usually must be larger in order to constitute an adequate portion of the total value of  $L_p$ . Typically a coil of 3 to 5 turns of #10 wire, 0.25 to 0.5 inches in diameter and about 0.5 to 1 inches long is sufficient. For the 8877 and similar tubes it usually is convenient to form a "horseshoe" in the strap used to make the plate connection. A "U" about 1-inch wide and 0.75 to 1 inch deep usually is sufficient. In either case,  $L_z$  carries the full operating-frequency plate current; at the higher frequencies this often includes a substantial amount of circulating tank current, and  $L_z$  must be husky enough to handle it without overheating even at 29 MHz. Figure 17.32 shows a typical parasitic suppressor.

Regardless of the form of  $L_z$ , loss may be introduced as required by shunting  $L_z$  with one or more suitable non-inductive resistors. In high-power amplifiers, two composition or metal film resistors, each 100  $\Omega$ , 2 W, connected in parallel across  $L_z$  usually are adequate. For amplifiers up to perhaps 500 W a single 47  $\Omega$ , 2 W resistor may suffice. The resistance and power capability required to prevent VHF/UHF parasitic oscillations, while not overheating as a result of normal plate circuit current flow, depend on circuit parameters. Operating-frequency voltage drop across  $L_z$  is greatest at higher frequencies, so it is important to use the minimum necessary value of  $L_z$  in order to minimize power dissipation in  $R_z$ .

The parasitic suppressors described above very often will work without modification, but in some cases it will be necessary to experiment with both  $L_z$  and  $R_z$  to find a suitable combination. Some designers use nichrome or other resistance wire for  $L_z$ .

In exceptionally difficult cases, particularly when using glass tetrodes or pentodes, additional parasitic suppression may be attained

by connecting a low value resistor (about 10 to 15  $\Omega$ ) in series with the tube input, near the tube socket. This is illustrated by R1 of Figure 17.31B. If the tube has a relatively low input impedance, as is typical of grounded-grid amplifiers and some grounded-cathode tubes with large  $C_{IN}$ , R1 may dissipate a significant portion of the total drive power.

### TESTING TUBE AMPLIFIERS FOR VHF-UHF PARASITIC OSCILLATIONS

Every high-power amplifier should be tested, before being placed in service, to insure that it is free of parasitic oscillations. For this test, nothing is connected to either the RF input or output terminals, and the band switch is first set to the lowest-frequency range. If the input is tuned and can be band switched separately, it should be set to the highest-frequency band. The amplifier control system should provide monitoring for both grid current and plate current, as well as a relay, circuit breaker or fast-acting fuse to quickly shut off high voltage in the event of excessive plate current. To further protect the tube grid, it is a good idea to temporarily insert in series with the grid current return line a resistor of approximately 1000  $\Omega$  to prevent grid current from soaring in the event a vigorous parasitic oscillation breaks out during initial testing.

Apply filament and bias voltages to the amplifier, leaving plate voltage off and/or cutoff bias applied until any specified tube warm-up time has elapsed. Then apply the lowest available plate voltage and switch the amplifier to transmit. Some idling plate current should flow. If it does not, it may be necessary to increase plate voltage to normal or to reduce bias so that at least 100 mA or so does flow. Grid current should be zero. Vary the plate tuning capacitor slowly from maximum capacitance to minimum, watching closely for any grid current or change in plate current, either of which would indicate a parasitic oscillation. If a tunable input net-

Figure 17.32 — Typical parasitic suppressor.

work is used, its capacitor (the one closest to the tube if a pi circuit) should be varied from one extreme to the other in small increments, tuning the output plate capacitor at each step to search for signs of oscillation. If at any time either the grid or plate current increases to a large value, shut off plate voltage immediately to avoid damage! If moderate grid current or changes in plate current are observed, the frequency of oscillation can be determined by loosely coupling an RF absorption meter or a spectrum analyzer to the plate area. It will then be necessary to experiment with parasitic suppression measures until no signs of oscillation can be detected under any conditions. This process should be repeated using each band switch position.

When no sign of oscillation can be found, increase the plate voltage to its normal operating value and calculate plate dissipation (idling plate current times plate voltage). If dissipation is at least half of, but not more than its maximum safe value, repeat the previous tests. If plate dissipation is much less than half of maximum safe value, it is desirable (but not absolutely essential) to reduce bias until it is. If no sign of oscillation is detected, the temporary grid resistor should be removed and the amplifier is ready for normal operation.

### LOW-FREQUENCY PARASITIC OSCILLATIONS

The possibility of self-oscillations at frequencies lower than VHF is significantly lower than in solid state amplifiers. Tube amplifiers will usually operate stably as long as the input-to-output isolation is greater than the stage gain. Proper shielding and dc-power-lead bypassing essentially eliminate feedback paths, except for those through the tube itself.

On rare occasions, tube-type amplifiers will oscillate at frequencies in the range of about 50 to 500 kHz. This is most likely with high-gain tetrodes using shunt feed of dc voltages to both grid and plate through RF chokes. If the resonant frequency of the grid RF choke and its associated coupling capacitor occurs close to that of the plate choke and its blocking capacitor, conditions may support a tuned-plate tuned-grid oscillation. For example, using typical values of 1 mH and 1000 pF, the expected parasitic frequency would be around 160 kHz.

Make sure that there is no low-impedance, low-frequency return path to ground through inductors in the input matching networks in series with the low impedances reflected by a transceiver output transformer. Usually, oscillation can be prevented by changing choke or capacitor values to insure that the input resonant frequency is much lower than that of the output.

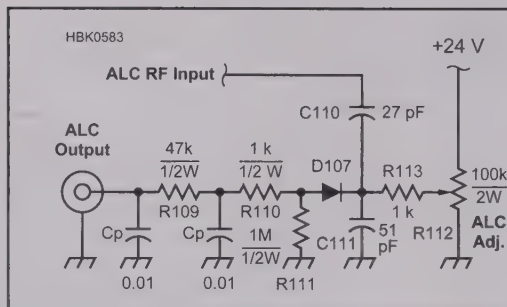

Figure 17.33 — An amplifier ALC circuit can be used to automatically limit the drive power from the transceiver to a safe level.

## Overshoot and Overdrive Protection

The ALC and power control circuits of numerous transceivers allow short excess power transients at the beginning of transmission. While tube amplifiers are fairly tolerant of short overloads, solid-state amplifiers are not. To avoid damaging your amplifier input, some kind of protection is necessary. The article “Amplifier Overshoot — Drive Protection” by Phil Salas, AD5X, shows how to use a gas-discharge tube to limit short over-power pulses. It is available as part of the downloadable supplemental information for this book.

### 17.8.3 Reduction of Distortion

As mentioned previously, a common cause of distortion in amplifiers is over drive (flat topping). The use of automatic level control (ALC) is a practical way of reducing the ill effects of flat topping while still being assured of having a strong signal. This circuit detects the voltage applied to the input of the amplifier. Other circuits are based on detecting the onset of grid current flow. In either case, when the threshold is reached, the ALC circuit applies a negative voltage to the ALC input of the transceiver and forces it to cut back on the driving power, thus keeping the output power within set limits. Most transceivers also apply an ALC signal from their own output stage, so the ALC signal from the amplifier will add to or work in parallel with that. See **Figure 17.33** for a representative circuit.

Some tube types have inherently lower distortion than others. Selection of a tube specifically designed for linear amplifier service, and operating it within the recommended voltage and current ranges is a good start. In addition, the use of tuned circuits in the input circuits when running class AB2 will help by maintaining a proper load on the driver stages over the entire 360° cycle, rather than letting the load change as the tube begins to draw grid current. Another way to accomplish this is with the “loaded grid,” the use of a rather low value of resistance from the grid to cathode. Thus, when grid current flows, the change in impedance is less drastic, having been swamped by the resistive load.

For applications where the highest linear-

ity is desired, operating class A will greatly reduce distortion but at a high cost in efficiency. Some solid state amateur transceivers have provision for such operation. The use of negative feedback is another way of greatly reducing distortion. High efficiency is maintained, but there is a loss of overall gain. Often, two stages of gain are used and the feedback applied around both stages. In this way, gain can be as high as desired, and both stages are compensated for any inherent nonlinearities. Amplifiers using RF negative feedback can achieve values of intermodulation distortion (IMD) as much as 20 dB lower than amplifiers without feedback.

It must be remembered that distortion tends to be a cumulative problem, with each nonlinear part of the transmission chain adding its part. It is not worthwhile to have a super clean transceiver if it is followed by an amplifier with poor linearity. In the same way, a very good linear will look bad if the transceiver driving it is poor. It is even possible to have a clean signal out of your amplifier, but have it spoiled by a ferrite core tuner inductor or balun that is saturated.

Distortion in a linear amplifier is usually measured with a spectrum analyzer while transmitting a two tone test. If the spectrum analyzer input is overloaded, this can also produce apparent distortion in the amplifier. Reducing the level so that the analyzer is not clipping the input signal is necessary to see the true distortion in the amplifier chain. Use of test equipment for various types of measurements is covered in the **Test Equipment and Measurements** chapter.

## 7.9 MOSFET Design for RF Amplifiers

There are two general classes of MOSFETs: high and low frequency designs. (See the **Circuits and Components** chapter for MOSFET basics.) The low frequency types are generally optimized for high volume commercial switching applications: computer power supplies, motor controllers, inverters, and so on. They have molded plastic packages, the die are made with aluminum top side metallization, they have maximum junction temperature ratings of 150 to 175°C. Most have polysilicon gate conductors. Polysilicon is easy to manufacture consistently and it's cheap. This works very well for applications up to 200 kHz, but the gate losses start to increase dramatically when they are used at higher frequencies.

A MOSFET gate is essentially a capacitor, but its folded structure is long and skinny. The gate in a 500 W device may be more than a meter long! ("Meter" is not a misprint.) If its conductor material is a lossy material like polysilicon, the gate becomes a long distributed RC network. If an RF signal does make all the way to the end it will be attenuated and no longer be in phase with the start. This effectively reduces the useful area of the device as frequency increases. It takes a lot of

RF current to feed the gate capacitance:  $I = CVf$ , where  $C$  is the gate capacitance,  $V$  is the peak gate voltage, and  $f$  is the operating frequency. If the gate capacitance is 500 pF and is being driven to 10 V at 30 MHz, the gate current is 150 mA RMS. While the current is directly proportional to the frequency, the power loss is  $I^2R$ . If the gate's top conductor is not low loss, it will fail due to  $I^2R$  losses at the gate bond pad (the metallization melts) when used at frequencies much higher than it was designed for.

There are two MOSFET manufacturers that use a metal gate instead of polysilicon for their switchmode devices, IXYS and Microsemi. While the die of these devices are quite capable of HF operation, their packaging (usually TO-247 or TO-264) does not provide an optimum HF layout. Because these are aimed at the switchmode market, their drain terminal is on the mounting surface and the source bond-wire length adds gain-killing degeneration at higher frequencies. But on the other hand, they are cheap in terms of cost per watt of dissipation and are acceptable for single-band designs through 20 meters.

When these same metal-gate MOSFET die are placed in packages that are specifically

for RF use, the source is often connected to the mounting surface of the package. The source bond wires are thus short, which improves the available gain at all frequencies. This is very convenient because the source is grounded in most RF power amplifier circuits. It also eliminates the need for a mounting insulator, which in turn improves the power dissipation capability.

In MOSFETs specifically designed for RF, the main distinguishing feature is the gate structure. The channels are "shorter" (there is less distance between the gate and source) which reduces the transit time for electrons. As the active area of a device is increased by making the channel "wider," its power dissipation capability is increased. At the same time, the intrinsic (inter-electrode) capacitances also get bigger. A larger device is more difficult to use at higher frequencies because the input impedance (mostly gate capacitance) becomes ever smaller, which makes it harder to drive. In order to solve the gate loss problem mentioned earlier, the long skinny gate is folded into a comb shape. (See **Figure 17.34**.) The gate signal now only has to travel to the end of each finger. The highest frequency designs use multiple combs

(A)

(B)

(C)

Figure 17.34 — A shows the layout of a multiple-die RF MOSFET (VRF157). B illustrates the comb structure of the gate. C is a closeup of the gate showing the interleaved source and gate finger structure. [Dick Frey, K4XU, photos]

with shorter fingers. Several of these comb structures are arrayed on the die and are connected in parallel when the die is wire-bonded in the package.

The top metallization for RF parts is either aluminum or gold. Aluminum is cheaper but gold is best because it has a higher operating temperature rating, up to 225 °C, and it is immune to power cycling failures due to its excellent ductility. The downside is that it is more expensive and the devices are much harder to manufacture because gold likes to dissolve into silicon. Its higher temperature rating means you can get more power from a small device, which offsets their higher cost somewhat.

### 17.9.1 LDMOS versus VDMOS

So far all the devices discussed are vertical MOSFETs, or VDMOS. Their gate and source electrodes are on the top surface of the die and the drain is on the bottom. For RF applications there is another type, LDMOS. This is a lateral device. Here the MOS structure is laid on edge and all the electrodes are on the top side of the die. Vertical p+ source connections are made through the die to make the bottom side of the die a source contact in order to get the optimum “common source” configuration. The channel area is low so the capacitances are smaller, especially the feedback capacitance,  $C_{GD}$ . However, the operating voltage capability is also low. There are none rated for more than 50 V operation. The gates are particularly sensitive to ESD and overdrive. However, they have spectacular high frequency capability and gain, and reasonable ruggedness. Your mobile phone would not work without LDMOS technology.

New RF amplifier designs are using LDMOS to replace bipolar transistors, which manufacturers are no longer making. The ability of LDMOS to operate at lower voltages is well suited for 12 V operation and, with its high gain and frequency response, providing 6 meter capability is simple. The downside is that these devices are not as linear as the bipolar transistor they replace.

Bipolar transistors need emitter ballasting resistors in each tiny bipolar cell so they can be paralleled in the die. The resistors also provide negative feedback, which improves linearity. MOSFETs do not require source resistors: paralleled cells will naturally share the load because their ON resistance has a positive temperature coefficient that prevents thermal runaway. As a result, LDMOS amplifiers require more negative feedback to provide comparable IMD performance, which offsets their higher gain advantage.

Regardless of the device type, the packaging is particularly important to an RF device. It must have low parasitics (see the **RF Techniques** chapter) and superior thermal

qualities. The package insulator is made of ceramics, beryllia BeO (which is toxic), and/or alumina  $Al_2O_3$ , for high temperature capability. The conductors are gold-plated copper or Kovar, and the base flanges are often copper-tungsten or copper-molybdenum. The package is the major determining factor in the cost of an RF part. Parasitic inductance introduced by gate and source bond wires limits the ultimate frequency capability of a VDMOS part. LDMOS parts have gate and drain bond wires. LDMOS devices have an advantage in terms of frequency and package cost because they are free of the gain degeneration caused by source wire inductance and their die may be soldered directly to a metal mounting flange.

### 17.9.2 Designing Amplifiers with MOSFETs

Designing an amplifier requires a systems approach. You will need to consider how much power supply is required, as well as the cooling and control systems needed to keep it happy. If you have the transistors and want to build them into an amplifier, the design procedure is a little different. The place to start in any case is with its transistor’s data sheet. This will show the voltage and power capabilities, and from these the circuit requirements can be calculated and the cooling system defined.

#### VOLTAGE RATINGS

Designing an amplifier with MOSFETs requires knowledge of the part being used. Generally, the cheap plastic-packaged switchmode parts will be best for single-band operation. Switchmode parts are rated by their drain breakdown voltage ( $BV_{DSS}$ ), ON resistance ( $R_{DS}$ ), and power dissipation. They are available in voltage ratings from as little as 5 V to over 1200 V. RF parts are sold by operating voltage,  $V_{DD}$ , power dissipation and frequency capability.

Select the part to suit your power supply requirements. A 500 V MOSFET will not work on a 12 V supply and will barely work at 50 V. This is because the MOSFET’s intrinsic capacitances are higher at low voltage. Between the drain and source of every MOSFET is a parasitic “body diode” as shown in **Figure 17.35**. It’s too slow to rectify RF, but like any diode, its capacitance changes with reverse bias voltage. This relationship is always given in the device’s C-V curves on its data sheet. (See **Figure 17.36**.) Data sheets can be found on manufacturer or distributor websites or perform an Internet search for the part number and “data sheet.”

In class AB operation, a MOSFET works best when operated at a little less than one-half of its rated breakdown voltage,  $BV_{DSS}$ . The drain voltage will swing up to 2 or even 3.562 times (for class E) the supply voltage. Under high VSWR, the drain voltage can be somewhat higher still. The RF voltage breakdown of a MOSFET is typically 20% higher than its data sheet value but is hard to specify

**Figure 17.36** — The capacitance versus voltage (C-V) curves for the Microsemi VRF151 RF MOSFET. (Illustration courtesy Microsemi Corp.)

**Figure 17.35** — All MOSFETs have parasitic capacitances as shown and a body diode between the drain and source in the cross-section and schematic symbol. The diode is shown for an N-channel device. It is reversed for P-channel devices.

reliability, so RF devices are rated by their dc operating voltages rather than  $BV_{DSS}$ . This takes into account the requirement for operating overhead.

RF parts are usually rated at a specific operating voltage such as 13.5 V, 28 V or 50 V. Originally these were common battery voltages for civilian and military vehicles and the tradition persists. The devices are optimized for their operating voltage. Choosing the operating voltage is a matter of considering many different parameters, not just the breakdown voltage.

**THERMAL DESIGN**

Suffice it to say that the thermal design of a high power transistor PA is often as challenging as the electrical design. It can be done “by the numbers” but the tricky part is making it fit into the available space. A thermal design example and an Advanced Power Technology application note by the author are provided with this book’s downloadable supplemental content.

A word of caution is in order: tubes used in power amplifiers have a great deal of “headroom” in their specifications and are quite forgiving of momentary operator errors. RF power transistors, because they are more expensive in terms of cost per watt, are specified much closer to their limits. These limits must be observed at all times. Even though the data sheet says the device can do X watts, the designer must observe the requirements for proper cooling in order to reach this level in practice. In addition, manufacturers rate the power dissipation in theoretical terms. You will be lucky to achieve half of it.

As with tubes, there are CW ratings and SSB ratings. For transistors, the ratings are based on average power. The difference is simply the size of the heat sink required, as the peak power is the same for each. Each transistor has a thermal rating expressed as  $R_{\theta JC}$ , the thermal resistance from the transistor junction to the bottom of its case. Since the device has an upper junction temperature limit, somewhere between 150 and 200 °C, the power dissipation is determined by the difference between the junction and the case temperature:

$$P_d = (T_J - T_C) / R_{\theta JC}$$

where  $P_d$  is the available power dissipation,  $T_J$  is junction and  $T_C$  is case temperature. What this says is that without any cooling, the transistor’s case will be almost the same as the junction temperature so its power dissipation capability is nearly zero. When placed on a heat sink, the case will be cooler and it then has power dissipation capability. It follows that the better the heat sink, the more power can be dissipated by the transistor.

There is another thermal consideration: the thermal resistance between the case of the transistor and the heat sink,  $R_{\theta CS}$ . Even if the base of the transistor and the heat sink are flat and smooth, microscopic air gaps still exist. These do not conduct heat and so reduce the net effectiveness of the heat sink. The solution is to use a thermal interface compound or *thermal grease*. The simplest and best is silicone oil loaded with zinc oxide powder. The oil does most of the work: the powder thickens it to a paste so it doesn’t run out of the joint. It is applied as a very thin coat between the heat sink and device. When using thermal grease, always wiggle the transistor around on the sink to insure a minimum of grease between the part and the sink. Remember, thermal grease is not a good thermal conductor, it’s just much better than air. Use it sparingly!

Most commercial high power broadcast amplifiers are cooled with circulated water, or a water-glycol mix if the minimum ambient temperature will be below 0 °C. While it has yet to be introduced to the amateur market, liquid cooling has great potential. The advances in plastic fittings, small pumps and heat exchangers driven by the high-performance computer market have great potential benefits to the amateur high power amplifier. Water is more than four times better than air for absorbing and moving heat. **Figure 17.37** illustrates both open- and closed-loop cooling systems. But regardless of where it is moved to, the heat must still be dissipated. It can warm the air in the shack, heat the rest of the house, or warm the septic tank.

**17.9.3 The Transistor Data Sheet**

Regardless of manufacturer, all data sheets contain the same basic information. The following should help make sense of what can

be very confusing to a first time user. Transistor specifications rely heavily on several ideal conditions that cannot happen in practice but since it is a common practice by all manufacturers, the numbers are very useful for comparing different devices. As long as you have the part number (and it is not a custom part), the corresponding data sheet can be found easily by searching for the part number and “data sheet.”

The Microsemi VRF151 N-channel enhancement-mode VDMOS transistor will be used as an example. It is used in the 250 W broadband amplifier project presented in this chapter. The following discussion assumes the reader has obtained a data sheet for this part (see the company website at [www.microsemi.com](http://www.microsemi.com)) and can refer to it.

**MINIMUM, TYPICAL AND MAXIMUM**

All of the specification parameters which the manufacturer guarantees are subject to either a minimum value or a maximum value. This is the worst case. As in an automobile, there is a maximum safe stopping distance and a minimum gas tank capacity. Most parameters also have a *typical* value that is generally representative of typical performance than the specified minimum or maximum. Some quantities have both upper and lower limits. Every parameter has specific test conditions under which it is measured.

**ABSOLUTE MAXIMUM RATINGS**

These are all dc ratings, easily verified with a variable power supply and a multimeter. If the manufacturer finds that any of these have been exceeded, any warranty claims are voided.

$V_{DSS}$  is the maximum drain to source voltage rating, with the gate is shorted to the source. Think of the device as a high voltage Zener diode. As soon as it draws any current,

**Figure 17.37 — Open- and closed-loop water cooling systems for solid-state amplifiers.**

power is dissipated, and temperature rises very quickly. Damage occurs either from puncturing through the junction or by arcing over the edge of the die.

Maximum drain current,  $I_D$ , is the current that will cause the device to dissipate its maximum rated power when fully turned on. Every device has an ON resistance called  $R_{DS(ON)}$ . The power dissipated is due to  $I_D^2 \times 2.5 R_{DS(ON)}$ . The factor of 2.5 accounts for  $R_{DS(ON)}$  having a positive temperature coefficient which causes it to roughly double by the point at which the junction temperature is 200 °C.

$V_{GS}$  is the maximum gate to source voltage. The gate is essentially a capacitor, with a  $\text{SiO}_2$  dielectric perhaps 400 to 1000 Angstroms ( $10^{-10}$  m) thick. The limit is lower on LDMOS than VDMOS, and cannot be exceeded without destroying the device. Because LDMOS devices have much lower  $V_{GS}$  ratings and thinner dielectrics, some LDMOS manufacturers build in diode protection to make them less susceptible to electrostatic discharge, ESD.

$P_D$  is the maximum power dissipation of the device under theoretical conditions: The bottom of the case at 25 °C and the junction at its maximum temperature,  $T_{jmax}$ . If not stated directly, the thermal resistance  $R_{\theta JC}$  is equal to  $P_D / (T_{jmax} - 25^\circ\text{C})$ .

Storage temperature is straightforward. Maximum  $T_J$  is the junction temperature above which things start to come unsoldered, or the reliability seriously impaired, or smoke emitted.

### STATIC ELECTRICAL CHARACTERISTICS

$V_{DSS}$  is specified again, this time showing the measurement conditions, the guaranteed minimum, and the typical production values.

$V_{DS(ON)}$  or sometimes  $R_{DS(ON)}$  is the minimum resistance between drain and source that is obtained when the device is fully ON and carrying half the rated current. It is more commonly specified on switchmode parts, but it is of particular importance in high-efficiency saturated modes like class D and E because it limits the maximum obtainable efficiency.

$I_{DSS}$  is the maximum drain current flowing with the gate shorted to the source. In an N-channel enhancement device one must apply a positive voltage to the gate to turn it on. The VRF151 will not conduct more than 1 mA at 100 V by itself without gate bias. This is a leakage current. In a perfect device it is zero.

Similarly,  $I_{GSS}$  is gate leakage current with the  $V_{DS} = 0$ . It represents a resistor in parallel with the gate capacitor. In this case, 1  $\mu\text{A}$  at 20 V is 20 M $\Omega$ . This does not sound like much but if the drain has voltage on it and there is no resistor across the gate, this leakage current will cause the gate to charge from the drain, eventually turning the device fully ON with bad consequences.

Forward transconductance,  $g_{fs}$ , is the dc gain of the device expressed in terms of change in drain current per change in gate volts measured at a particular drain current. It has only a mild relationship with RF gain and too high a  $g_{fs}$  can cause bias instability and/or parasitics.

$V_{TH}$  is the gate threshold specification. When  $V_{DS}$  is 10 V,  $V_{GS}$  of no less than 2.9 V and no more than 4.4 V will cause 100 mA of drain current to flow. A typical Class AB quiescent bias condition is 100 mA. Of all the parameters, this one has the widest window. Enough variation exists so that manu-

facturers sort parts into "bins" of value across the range, and assign letter codes each which are marked on the package. This allows one to make matched pairs within device type.

### THERMAL CHARACTERISTICS

$R_{\theta JC}$  is equal to  $P_{Dmax} / (T_{jmax} - 25^\circ\text{C})$ . Specifying the first two parameters ( $R_{\theta JC}$  and  $P_{Dmax}$ ) generates the third ( $T_{jmax}$ ). In this sense specifying  $T_{jmax}$  is redundant but it is often reiterated for those who are looking for the particular parameter.

Because thermal performance is just as important as RF performance, much of the information in the data sheet is concerned with it. In addition to the static thermal impedance,  $R_{\theta JC}$ , there is a dynamic thermal impedance  $Z_{\theta JC}$ . Transistor packages have thermal mass so the die temperature does not change instantaneously. For pulsed operation, the effective  $R_{\theta JC}$  can be much lower than it is for steady-state operation.

The dynamic thermal impedance is shown in Figure 17.38 (Figure 5 of the VRF151 data sheet). It shows how the device can be used for pulse operation at higher power than can be on CW because the effective thermal impedance is lower for short pulses. This has some application to SSB, but there are other constraints on peak power that boil down to just allowing a smaller heat sink when used only for intermittent service—a bad practice for amateur amplifiers!

### DYNAMIC CHARACTERISTICS

Somewhat of a misnomer, these are the parasitic capacitances between the gate, drain and gate. Except for the gate capacitance which is a fixed value based on device dime-

Figure 17.38 — Dynamic thermal impedance for the Microsemi VRF151 RF MOSFET. (Illustration courtesy Microsemi Corp.)

ns, the other two are a function of the drain stage, just like varactors (voltage-variable capacitors). Because it is rather difficult to measure these parameters, the parameters are defined in a common-source configuration.  $C_{GS}$  is the gate-to-source capacitance with the drain ac-short-circuited to the source. It is actually  $C_{GS}$  in parallel with  $C_{GD}$ . The three parameters are usually measured at the specified supply voltage with  $V_{GS}$  at zero. They are also usually displayed as in Figure 17.36 (Figure 3 of the data sheet), a graph of  $C$  vs.  $V_{GS}$ .

This voltage-varying capacitance is one of the causes of IMD in a transistor. Its effect is to impart some phase modulation (PM) on the signal. PM can be observed as unequal IMD products on each side of the carrier pair in a two-tone test. PM distortion generates products of odd-order carriers like AM distortion. The high side carriers are  $-180^\circ$  out of phase with the AM products. This causes them to reduce the level of amplitude products on the high side of the carrier pair and increase them on the lower side. (See the reference list entry for Sabin and Schoenike, *Single Sideband Systems and Circuits*.)

## TRANSFER CHARACTERISTICS

As discussed above,  $g_{fs}$  describes the gain of a MOSFET as the change in drain current per change in gate voltage:  $\Delta I_D / \Delta V_{GS}$ . This means that  $g_{fs}$  is the slope of the transfer curve. The transfer curve for the VRF151 is shown in Figure 17.39 (the data sheet's Figure 2). There are three curves in this graph, depicting the transfer characteristic at three different temperatures.

The three curves cross each other at the thermal neutral point." This is where the temperature coefficient of  $V_{TH}$  changes from negative to positive and it is usually at a current much higher than the part normally operates. This explains why MOSFETs must have thermally compensated gate bias. Below the crossover point, where the part would be used for class AB, the temperature coefficient of  $V_{TH}$  is negative. This means the gate voltage required for a given current goes down as the part heats up. Without thermal compensation we can have thermal runaway. The part will usually melt before it reaches the crossover point.

**Figure 17.39 — Transfer characteristics for the Microsemi VRF151 RF MOSFET. (Illustration courtesy Microsemi Corp.)**

The transfer curve also shows that the gain of the device is not constant. It is quite low at low current and increases to a nominal value over its linear range and then the curves flatten out at higher current as the part saturates. This demonstrates why very low distortion amplifiers are usually operated in class A.

## FUNCTIONAL CHARACTERISTICS

This section is where the RF performance is specified — how much gain at what frequency, IMD performance, and ruggedness. While gain and IMD are easily understood, ruggedness is more difficult and it is very poorly defined by most manufacturers. The VRF151 has a ruggedness specification at all phase angles of a 30:1 VSWR when putting out 150 W PEP at 30 MHz. The test circuit is shown on page 4 in the data sheet. Nothing is said about how long the test takes or how well the device is cooled. If the test time and cooling conditions are not given, the specification is inadequate to guarantee that a design will remain within the device power limits. In the author's experience, 90% of all VSWR-related failures are due to over-dissipation. This says that limiting the amplifier's drain current is a simple and effective means for VSWR protection.

## DATA SHEET EXTRAS

Test circuits are usually provided so cus-

tomers can duplicate the test conditions for gain, IMD and output power. Sometimes circuit layouts and complete part lists are also provided. Note however, that while most high power parts are usually used in push-pull circuits, parts in data sheets are always tested one at a time in single-ended circuits. The last page of the data sheet gives the mechanical outline and sometimes mounting information. The VRF151 is "binned" (sorted into similarly performing groups) for  $V_{TH}$  as it exits the final testing and the bin letter code is marked on the package. This allows very close matching of gate threshold which is important when used in a push-pull circuit with a common bias supply for both parts. Most designers use separate bias adjustments regardless of matching, but it insures a measure of gain matching also, especially if the parts are from the same lot date code.

## 17.9.4 Summary Observations

MOSFETs are not perfect devices.  $g_{fs}$ ,  $V_{TH}$ ,  $BV$  and  $R_{DS}$  are all affected by die temperature.  $g_{fs}$  goes down with increasing die temperature. While this might cause the output power to sag a bit as the amplifier gets hotter, it is generally a benefit. MOSFETs can be paralleled without requiring source resistors because as the one carrying more current heats up, it loses gain and its resistance goes up, allowing the others to share the load.  $R_{DS}$  rises with temperature, a useful trait in hard-switching applications using paralleled devices. Breakdown voltage,  $BV_{DSS}$ , increases with temperature and so is usually not a concern in a part that heats up as it is being used. It has implications in cases of extreme cold, as in satellites.

One caveat when paralleling MOSFETs: always be mindful that they will easily oscillate at UHF. The device's inter-electrode capacitances and bonding wire inductances conspire to form a cross-coupled multi-vibrator. The solution is to place a small resistor in series with the gate leads, 3.3  $\Omega$  will usually suffice. This lowers the circuit Q enough to prevent oscillation from starting. [ref: Motorola *Engineering Bulletin 104*, et al]

# 17.10 Solid State RF Amplifiers

## 17.10.1 Solid State vs Vacuum Tubes

Solid state amplifiers have become the norm in transceivers, but their use in external high power amplifiers has not. The primary reason is economic. It is more expensive to generate a kilowatt or more with transistors because they are smaller and have less dissipation capability. This is changing as the broadcast and industrial RF industry converts to solid state, making RF power transistors available for amateur use at lower prices. A number of legal-limit solid state Amateur Radio amplifiers are available.

## 17.10.2 Classes of Operation

This topic applies to transistors as well as tubes, and it was covered earlier in this chapter and also in the **RF Techniques** chapter. In communications amplifiers, Class A is used mainly for driver stages where linearity is desired and efficiency is not a concern.

Class B is usually passed over in favor of the more linear Class AB. Class AB offers RF amplifiers increased linearity, mainly in less crossover distortion, for a very small (perhaps 1% or 2%) reduction in efficiency. It is the most commonly used class of operation for linear power amplifiers that must cover a wide range of frequencies. Broadband solid state Class AB amplifiers typically achieve 50 to 60% efficiency.

Class C is used where efficiency is important and linearity and bandwidth or harmonics are not. FM transmitters are the most common application in communications. Single-band tuned amplifiers can be as much as 80% efficient. However, in a single-ended amplifier they require a tank circuit. Class C amplifiers are *not* suitable for on-off keyed modes like CW without extensive pre-distortion of the driving signal in order to prevent key clicks.

Class D and E are most efficient, up to 95% in practical circuit applications. But both of these both require a narrow band tuned tank circuit to achieve this efficiency. They are not linear; their output is essentially either on or off. They can be used quite effectively for linear amplification by the process of EER (envelope elimination and restoration) but it is always in a single-band circuit. On-off keying can be employed if the power supply is keyed with a properly shaped envelope. EER is difficult to do well and requires very complex circuitry. Without careful system design, EER results in poor SSB performance.

## 17.10.3 Modeling Transistors

The design method using performance curves that was detailed earlier in this chap-

ter is more applicable to vacuum tube amplifier design than solid state. The most common method used with solid state is electronic design analysis (EDA, also called computer-aided design, or CAD) using electronic models. *SPICE* or S-parameter models are available for some high power transistors, and simple amplifiers can be readily designed with the aid of an appropriate analysis program. (See the **Computer-Aided Circuit Design** chapter for more information on *SPICE* and related modeling techniques.)

Full-featured circuit design and analysis programs are expensive, and the resulting designs are only as good as the accuracy of the transistor models they use. A complicating factor is that any design relies heavily on models for all the passive components in the circuit. While passive part models can be obtained for some commercial components, many others — such as ferrite-loaded transformers — must also be designed before the circuit can be modeled. It is not unusual for the electronic design to take much longer and cost more than the benefits are worth.

As detailed in the **Computer-Aided Circuit Design** chapter, many of the EDA vendors offer free or inexpensive “student versions” of their products. These are fully capable up to a certain level of circuit complexity. Although they usually are not big enough to analyze a whole amplifier, student versions are still particularly useful for looking at parts of the whole.

Electronic design is very useful for getting the circuit design “in the ballpark.” The design will be close enough that it will work when built, and any necessary fine tuning can be done easily once it is constructed. Computer modeling is very useful for evaluating the stresses on the circuit’s passive components so they can be properly sized. Another very helpful use of CAD is in the development of the output filters. *SVC Filter Designer* by Jim Tonne, W4ENE, available with this book’s downloadable supplemental content, is exceptional in this regard.

## 17.10.4 Impedance Transformation — “Matching Networks”

Aside from the supply voltage, there is little difference between the operation of a tube amplifier and a transistor amplifier. Each amplifies the input signal, and each will only work into a specific load impedance. In a tube amplifier, the proper plate load impedance is provided by an adjustable pi or pi-L plate tuning network, which also transforms the impedance down to 50  $\Omega$ .

A single-transistor amplifier can be made

in the same way, and in fact most single-band VHF amplifier “bricks” are. A tuned matching network provides the proper load impedance for the transistor and transforms it up to 50  $\Omega$ . The major difference is that the proper load impedance for a transistor, at any reasonable amount of power, is much *lower* than 50  $\Omega$ . For vacuum tubes it is much *higher* than 50  $\Omega$ .

## BROADBAND TRANSFORMERS

Broadband transformers are often used in matching to the input impedance or optimum load impedance in a power amplifier. Unlike the tuned matching circuits, transformers can provide constant impedance transformation over a wide range of frequency without tuning. Multi-octave power amplifier performance can be achieved by appropriate application of these transformers. The input and output transformers are two of the most critical components in a broadband amplifier. Amplifier efficiency, gain flatness, input SWR, and even linearity all are affected by transformer design and application.

There are two basic RF transformer types as described in the **RF Techniques** and **Transmission Lines** chapters: the conventional transformer and the transmission line transformer. More information on RF transformers is included with this book’s downloadable supplemental content.

The conventional transformer is wound much the same way as a power transformer. Primary and secondary windings are wound around a high-permeability core, usually made from a ferrite or powdered-iron material. Coupling between the secondary and primary is made as tight as possible to minimize leakage inductance. At low frequencies the coupling between windings is predominantly magnetic. As the frequency rises, core permeability decreases and leakage inductance increases; transformer losses increase as well.

Typical examples of conventional transformers are shown in **Figure 17.40**. In **Figure 17.40A**, the primary winding consists of brass or copper tubes inserted into ferrite sleeves. The tubes are shorted together at one end by a piece of copper-clad circuit board material forming a single turn loop. The secondary winding is threaded through the tubes. Since the low-impedance winding is only a single turn, the impedance transformation ratio is limited to the squares of integers — 1, 4, 9, 16 and so on.

The lowest effective transformer frequency is determined by the inductance of the one turn winding. It should have a reactance, at the lowest frequency of intended operation, at least four times greater than the impedance

(A)

(B)

Figure 17.40 — The two methods of constructing the transformers outlined in the text. At A, the one-turn loop is made from brass tubing; at B, a piece of coaxial cable braid is used for the loop.

is connected to. The coupling coefficient between the two windings is a function of the primary tube diameter and its length, and the secondary diameter and insulation thickness of the secondary winding. These are used in the high-impedance winding. For high impedance ratios, greater than 36:1, one would use large-diameter secondary windings. Miniature coaxial cable (using only the shield as the conductor) works well. Another method for coaxial cable braid is illustrated in Figure 17.40B. Instead of using tubing for the primary winding, the secondary winding is threaded through copper braid. Because of the increased coupling between the primary and secondary of the transformer made with multiple pieces of coax, leakage reactance is reduced and bandwidth performance is increased.

The cores used must be large enough so that the core material will not saturate at the power level applied to the transformer. Core saturation can cause permanent changes to the core permeability, as well as overheating. Transformer nonlinearity also develops at core saturation. Harmonics and other distortion products are produced — clearly an undesirable situation. Multiple cores can be used to increase the power capabilities of the transformer.

Transmission line transformers are similar to conventional transformers, but can be used over wider frequency ranges. In a conventional transformer, high-frequency performance deterioration is caused primarily by leakage inductance, the reactance of which rises with frequency. In a transmission line transformer, the windings are arranged so there is tight capacitive coupling between the two. A high coupling coefficient is maintained up to considerably higher frequencies than with conventional transformers.

The upper frequency limit of the transmission line transformer is limited by the length of the lines. As the lines approach  $\frac{1}{4}$  wavelength, they start to exhibit resonant line effects and the transformer action becomes erratic.

### MATCHING NETWORKS AND TRANSFORMERS

The typical tube amplifier tank circuit is an impedance transforming network in a pi or pi-L configuration. With reasonable loaded Q, it also functions as a low-pass filter to reduce the output signal harmonic levels below FCC minimums.

If a transistor amplifier uses a broadband transformer, it must be followed by a separate low-pass filter to achieve FCC harmonic suppression compliance. This is one reason broadband transistor amplifiers are operated in push-pull pairs. The balance between the circuit halves naturally discriminates against even harmonics, making the filtering job easier, especially for the second harmonic. The push-pull configuration provides double the power output when using two transistors, with very little increase in circuit complexity or component count. Push-pull pairs are also easier to match. The input and output impedance of a push-pull stage is twice that of a single-ended stage. The impedance is low, and raising it usually makes the matching task easier.

The transistor's low-impedance operation provides the opportunity to use a simple broadband transformer to provide the transformation needed from the transistor's load impedance up to 50  $\Omega$ . This low impedance also swamps out the effects of the device's output capacitance and, with some ferrite loading on the transformer, the amplifier can be made to operate over a very wide bandwidth without adjustment. This is not possible with tubes.

On the other hand, a tube amplifier with its variable output network can be adjusted for the actual output load impedance. The transistor amplifier with its fixed output network cannot be adjusted and is therefore much less forgiving of load variations away from 50  $\Omega$ . Circuits are needed to protect the transistor from damage caused by mis-

matched loads. These protection circuits generally operate “behind the scenes” without any operator intervention. They are essential for the survival of any transistor amplifier operating in the real world.

### CALCULATING PROPER LOAD IMPEDANCE

The proper load impedance for a single transistor (or a tube for that matter) is defined by  $R = E^2/P$ . Converting this from RMS to peak voltage, the formula changes to  $R = E^2/2P$ . If two devices are used in push-pull (with twice the power and twice the impedance) the formula becomes  $R = 2E^2/P$ .

There is a constraint. Transformer impedance ratios are the square of their turns ratios. Those with single turn primaries are limited to integer values of 1, 4, 9, 16 and so on. Real-world transformers quickly lose their bandwidth at ratios larger than 25:1 due to stray capacitance and leakage inductance. A design solution must be found which uses one of these ratios. We will use the ubiquitous 100 W, 12 V transceiver power amplifier as an example. Using the push-pull formula, the required load impedance is  $2 \times 12.5^2/100 = 3.125 \Omega$ . The required transformer impedance ratio is  $50/3.125 = 16$ , which is provided by a turns ratio of 4:1.

Transistor manufacturers, recognizing the broadband transformer constraint, have developed devices that operate effectively using automotive and military battery voltages and practical transformer ratios: 65 W devices for 12 V operation and 150 W devices for 48 V. Bigger 50 V devices have been designed (for example, the MRF154) that will put out 600 W, but practical transformer constraints limit 50 V push-pull output power to 900 W. There are higher voltage devices developed for the industrial markets and they are gradually finding their way into amateur designs. Being able to adjust the impedance to a convenient value for a common transformer turns ratio by adjusting the operating voltage is a powerful design option. These device and transformer limitations on output power can also be overcome by combining the outputs of several PA modules.

### 17.10.5 Combiners and Splitters

With some exceptions, practical solid state amplifiers have an upper power limit of about 500 W. This is a constraint imposed by the available devices and, to some extent, the ability to cool them. As devices are made more powerful by increasing the area of silicon die, the power density can become so high that only water cooling can provide adequate heat removal. Large devices also have large parasitic capacitances that make secur-

ing a broadband match over several octaves very difficult. By building a basic amplifier cell or “brick” and then combining several cells together, transmitter output powers are only limited by the complexity. Combiners and splitters have losses and add cost, so there are practical limits.

Broadband combiners usually take the form of an N-way  $0^\circ$  hybrid followed by an N:1 impedance transformer. The square ratio rule applies here too because the output impedance of a broadband combiner with N input ports is  $50/N \Omega$  — so combiners are usually 2, 4, 9 and 16-way. The higher the ratio, the lower the bandwidth will be.

Many types of combiners have been developed. The most common is the 4-way. It is easy to construct and has very good bandwidth. Most of the commercial “1 kW” broadband amplifiers use a 4-way combiner to sum the output of four 300 W push-pull modules operating on 48 V. Every combiner has loss. It may only be a few percent, but this represents a considerable amount of heat and loss of efficiency for a kilowatt output. This is a case where  $4 \times 300$  does not make 1200.

The combiner approach to make a 1 kW solid state amplifier uses a large number of individual parts. A comparable 1 kW tube amplifier requires relatively few. This makes the high-powered solid state unit more expensive and potentially less reliable.

There is an alternative. If we had higher voltage transistors, we could use the same output transformer network configuration to get more output because power rises with the square of the operating voltage. There are high voltage transistors that can operate on 200 V or more. The problem is that these transistors must be capable of handling the corresponding higher power dissipation. The downside of making bigger, more powerful devices is an increase in parasitic capacitance. These bigger transistors become harder to drive and to match over broad bandwidths. However, the circuit simplicity and elimination of the combiner and its losses makes the higher voltage approach quite attractive.

### TRANSMISSION LINE TRANSFORMERS AND COMBINERS

Figure 17.41 illustrates, in skeleton form, how transmission-line transformers can be used in a push-pull solid state power amplifier. The idea is to maintain highly balanced stages so that each transistor shares equally in the amplification in each stage. The balance also minimizes even-order harmonics so that low-pass filtering of the output is made much easier. In the diagram, T1 and T5 are current (choke) baluns that convert a grounded connection at one end to a balanced (floating) connection at the other end, with a high impedance to ground at both wires. T2 transforms the  $50 \Omega$  generator to the  $12.5 \Omega$  (4:1

impedance) input impedance of the first stage. T3 performs a similar step-down transformation from the collectors of the first stage to the gates of the second stage. The MOSFETs require a low impedance from gate to ground. The drains of the output stage require an impedance step up from  $12.5 \Omega$  to  $50 \Omega$ , performed by T4. Note how the choke baluns and the transformers collaborate to maintain a high degree of balance throughout the amplifier. Note also the various feedback and loading networks that help keep the amplifier frequency response flat.

Three methods are commonly used to combine modules: parallel ( $0^\circ$ ), push-pull ( $180^\circ$ ) and quadrature ( $90^\circ$ ). In RF circuit design, the combining is often done with special types of “hybrid” transformers called splitters and combiners. These are both the same type of transformer that can perform either function. The splitter is at the input, the combiner at the output.

Figure 17.42 illustrates one example of each of the three basic types of combiners. In a  $0^\circ$  hybrid splitter at the input the tight coupling between the two windings forces the voltages at A and B to be equal in amplitude and also equal in phase if the two modules are identical. The  $2R$  resistor between points A and B greatly reduces the transfer of power between A and B via the transformer, but only if the generator resistance is closely equal to R. The output combiner

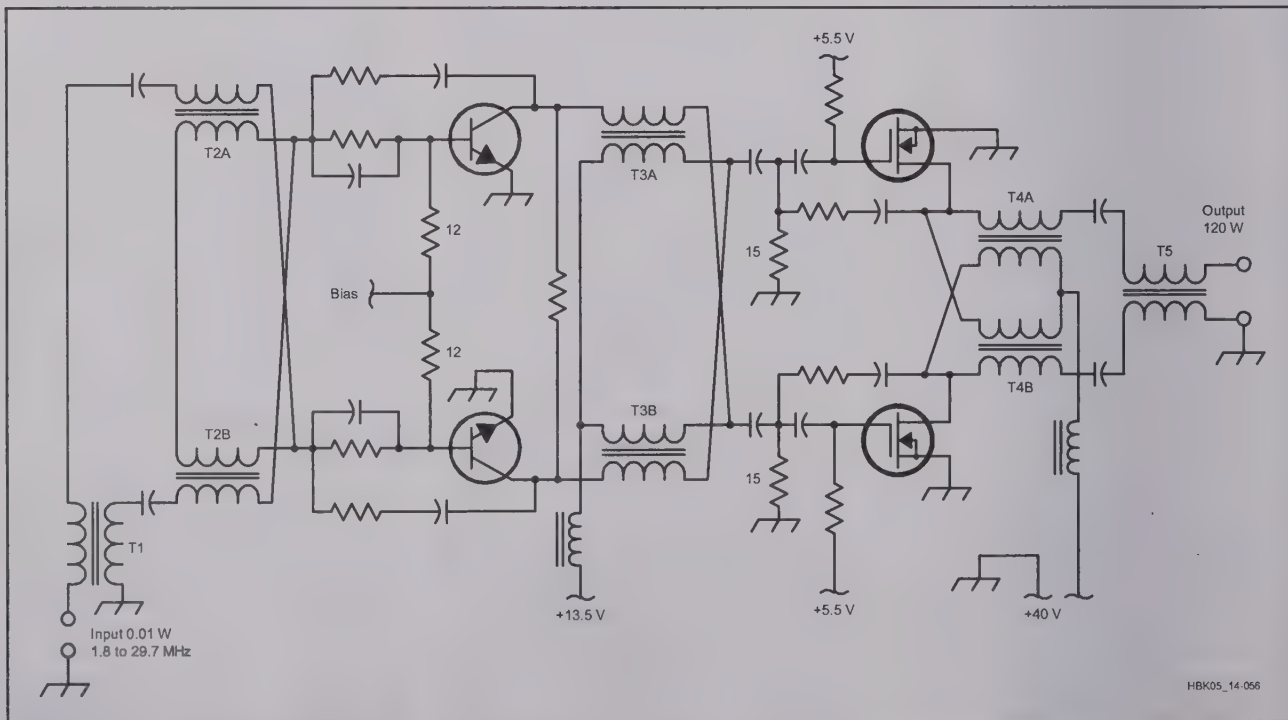

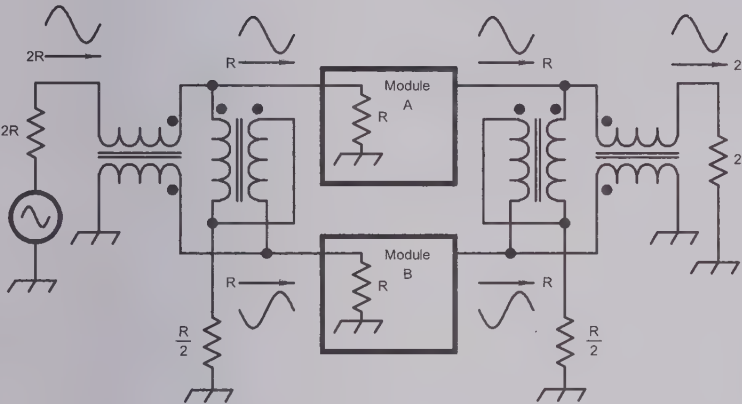

Figure 17.41 — Typical use of transmission line transformers as baluns and combiners in solid state power amplifiers.

separates the two outputs C and D from each other in the same manner, if the output load is equal to R, as shown. No power is lost in the 2R resistor if the module output levels are identical. This section covers the subject of combiners very lightly. We suggest that the reader consult the considerable literature for a deeper understanding and for techniques used at different frequency ranges.

### 17.10.6 Amplifier Stabilization

Purity of emissions and the useful life (or even survival) of the active devices in a tube or transistor circuit depend heavily on stability during operation. Oscillations can occur at or away from the operating frequency because of undesired positive feedback in the

amplifier. Unchecked, these oscillations pollute the RF spectrum and can lead to tube or transistor over-dissipation and subsequent failure. Each type of oscillation has its own cause and its own cure.

In a linear amplifier, the input and output circuits operate on the same frequency. Unless the coupling between these two circuits is kept to a small enough value, sufficient energy from the output may be coupled in phase back to the input to cause the amplifier to oscillate. Care should be used in arranging components and wiring of the two circuits so that there will be negligible opportunity for coupling external to the tube or transistor itself. A high degree of shielding between input and output circuits usually is required. All RF leads should be kept as short as possible and particular attention should be paid to the RF return paths from input and output tank circuits to emitter or cathode.

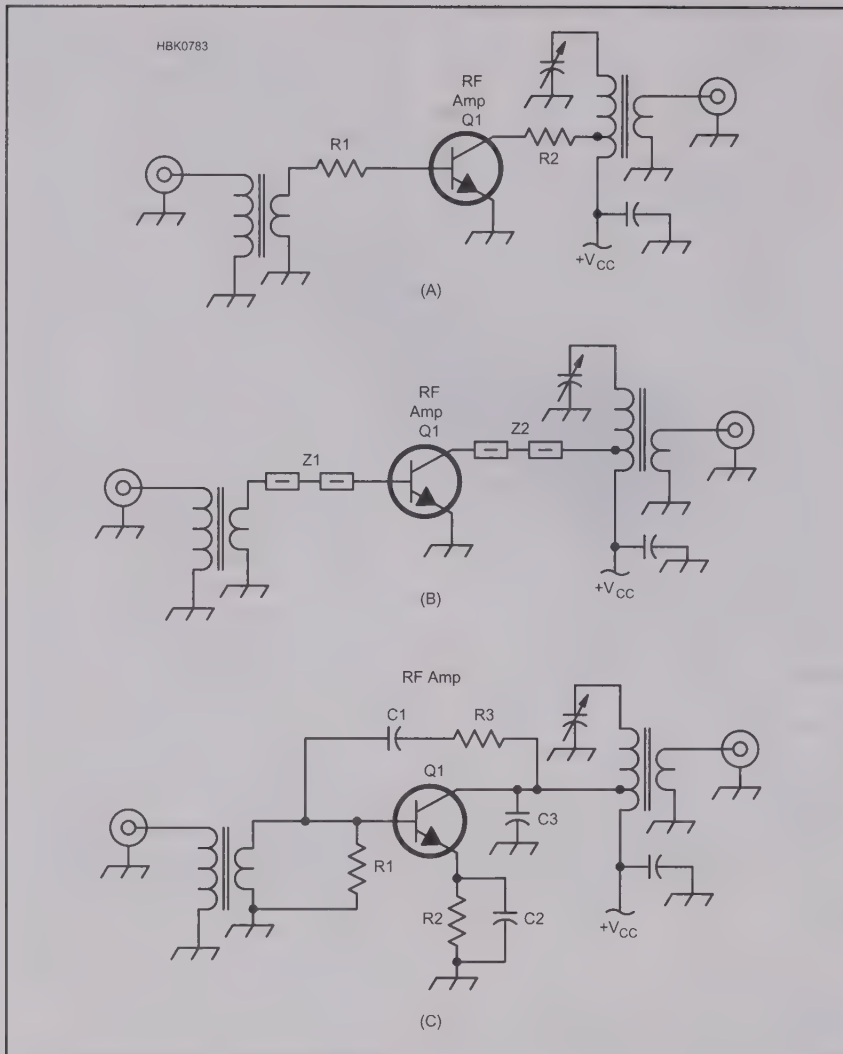

In general, the best arrangement using a tube is one in which the input and output circuits are on opposite sides of the chassis. Individual shielded compartments for the input and output circuitry add to the isolation. Transistor circuits are somewhat more forgiving, since all the impedances are relatively low. However, the high currents found on most amplifier circuit boards can easily couple into unintended circuits. Proper layout, the use of double-sided circuit boards (with one side used as a ground plane and low-inductance ground return), and heavy doses of bypassing on the dc supply lines often are sufficient to prevent many solid state amplifiers from oscillating.

### PARASITIC OSCILLATIONS

In low-power solid state amplifiers, parasitic oscillations can be prevented by using a small amount of resistance in series with the base or collector lead, as shown in Figure 17.43A. The value of R1 or R2 typically should be between 10 and 22  $\Omega$ . The use of both resistors is seldom necessary, but an empirical determination must be made. R1 or R2 should be located as close to the transistor as practical.

At power levels in excess of approximately 0.5 W, the technique of parasitic suppression shown in Figure 17.43B is effective. The voltage drop across a resistor would be prohibitive at the higher power levels, so one or more ferrite beads placed over connecting leads can be substituted (Z1 and Z2). A bead permeability of 125 presents a high impedance at VHF and above without affecting HF performance. The beads need not be used at both circuit locations. Generally, the terminal carrying the least current is the best place for these suppression devices. This suggests that the resistor or ferrite beads should be connected in the base lead of the transistor.

C3 of Figure 17.43C can be added to some

**Figure 17.43 — Suppression methods for VHF and UHF parasitics in solid state amplifiers. At A, small base and collector resistors are used to reduce circuit Q. B shows the use of ferrite beads to increase circuit impedance. In circuit C, C1 and R3 make up a high-pass network to apply negative feedback.**

power amplifiers to dampen VHF/UHF parasitic oscillations. The capacitor should be low in reactance at VHF and UHF, but must present a high reactance at the operating frequency. The exact value selected will depend upon the collector impedance. A reasonable estimate is to use an  $X_C$  of 10 times the collector impedance at the operating frequency. Silver-mica or ceramic chip capacitors are suggested for this application. An additional advantage is the resultant bypassing action for VHF and UHF harmonic energy in the collector circuit. C3 should be placed as close to the collector terminal as possible, using short leads.

The effects of C3 in a broadband amplifier are relatively insignificant at the operating

frequency. However, when a narrow-band collector network is used, the added capacitance of C3 must be absorbed into the network design in the same manner as the  $C_{OUT}$  of the transistor.

### LOW-FREQUENCY PARASITIC OSCILLATIONS

Bipolar transistors and MOSFETs exhibit a rising gain characteristic as the operating frequency is lowered. To preclude low-frequency instabilities because of the high gain, shunt and degenerative feedback are often used. In the regions where low-frequency self-oscillations are most likely to occur, the feedback increases by nature of the feedback network, reducing the amplifier gain. In the

circuit of Figure 17.43C, C1 and R3 provide negative feedback, which increases progressively as the frequency is lowered. The network has a small effect at the desired operating frequency but has a pronounced effect at the lower frequencies. The values for C1 and R3 are usually chosen experimentally. C1 will usually be between 220 pF and 0.0015  $\mu$ F for HF-band amplifiers while R3 may be a value from 51 to 5600  $\Omega$ .

R2 of Figure 17.43C develops emitter degeneration at low frequencies. The bypass capacitor, C2, is chosen for adequate RF bypassing at the intended operating frequency. The impedance of C2 rises progressively as the frequency is lowered, thereby increasing the degenerative feedback caused by R2. This lowers the amplifier gain. R2 in a power stage is seldom greater than 10  $\Omega$  and may be as low as 1  $\Omega$ . It is important to consider that under some operating and layout conditions R2 can cause instability. This form of feedback should be used only in those circuits in which unconditional stability can be achieved.

R1 of Figure 17.43C is useful in swamping the input of an amplifier. This reduces the chance for low-frequency self-oscillations but has an effect on amplifier performance in the desired operating range. Values from 3 to 27  $\Omega$  are typical. When connected in shunt with the normally low base impedance of a power amplifier, the resistors lower the effective device input impedance slightly. R1 should be located as close to the transistor base terminal as possible, and the connecting leads must be kept short to minimize stray reactances. The use of two resistors in parallel reduces the amount of inductive reactance introduced compared to a single resistor.

### 17.10.7 Amplifier “Pallet” Modules

Since the early RF amplifier transistors were introduced by Motorola, TRW, and RCA, marketing of these devices was done by having applications engineers design them into functional amplifier modules. The schematic and parts list was provided in the devices' data sheet or in a separate published Application Note. The first and most famous applications engineer was Motorola's Helge Granberg, K7ES. He was inventive and had a very clear and engaging writing style. As more companies entered the RF transistor market, they adopted the same strategy. Even as the technology has evolved from bipolar to VDMOS and LDMOS devices, this is still a valid strategy.

The manufacturers want these applications circuits to demonstrate the capabilities of their products but are understandably reluctant about building, selling, and warranting

them. This has provided a business opportunity for other companies to bundle the difficult-to-source components and devices and sell them as semi-kits. Some entrepreneurs go further and build up amplifier modules or “pallets,” either from the manufacturer’s application notes or of their own design. This has resulted in a wide variety of available kits and pallets. The oldest of these is Communications Concepts in Ohio, but there are many others. Some are listed at the end of this section.

Modules are available in a wide range of power levels, operating voltage, and frequency ranges. They come in two forms: single-band amplifiers using a single-ended topology typically used at VHF or UHF, and broadband amplifiers using balanced “push-pull” topology for HF and even up to 2 meters. **Figure 17.44** shows a 1 kW output pallet designed for HF use.

It is not difficult to read some of these application notes and become excited about having one of them to use on the air. It seems so easy — buy a module, hook up a power supply, your exciter, an antenna and you are on the air! Well, in your dreams. Buying an RF amplifier “brick” and thinking it will be a complete system is more like buying a car engine without the rest of the car. The pallet in **Figure 17.44** can be made into a complete amplifier at significant extra cost for supporting electronics. There are many things that are crucially important to comprehend and address before you can put it on the air and have it survive in the typical amateur station.

### USING PALLETS IN AN AMPLIFIER

The first concern is stability. Pallets are rated for a 50  $\Omega$  load and are seldom characterized for output harmonics. The pallet in **Figure 17.44** requires a low-pass filter to operate legally, for example. Some are wildly unstable when operated with real-world VSWR, or when terminated with a low-pass filter that reflects all the harmonic energy back into the module. Oscillation of any sort is a device killer.

The amplifier must meet FCC regulations for harmonic output. This necessitates a low-pass filter. Filters are designed for a specific input and load impedance, usually 50  $\Omega$ . The filter may become less effective as the load impedance deviates from 50  $\Omega$  but more importantly, a bad load at full power can damage the filter due to high current or voltage stress on the capacitors. The amplifier’s efficiency changes as the load changes. While certain non-50  $\Omega$  loads may actually cause the amplifier to be more efficient than at 50  $\Omega$ , they can still overstress the filter and need to be avoided. Well-designed protection will start to act when the load VSWR exceeds 1.5:1 and absolutely trip at 2:1.

The amplifier needs a power supply with

**Figure 17.44** — Typical HF amplifier “pallet” designed by Jim Klitzing, W6PQL ([www.w6pql.com/index.htm](http://www.w6pql.com/index.htm)). This design is capable of 1 kW output power and uses the NXB BLF188XR LDMOS amplifier transistor module. [Jim Klitzing, W6PQL, photo]

a regulated output that keeps the voltage within 3% of nominal. Voltage sag under load causes flat-topping. It must also have an absolute limit at 125% of normal current. This alone is insufficient to protect an amplifier but will go a long way to prevent “collateral damage” in the event of a circuit failure. There are several reputable manufacturers of small lightweight switchmode supplies available through electronic supply houses and online. Some of these have built-in cooling fans, good regulation and current limiting. Be sure to check that any switchmode supply is RF-quiet when running without a load. Some can generate RF hash in your receiver. Some designs can be keyed, remaining in standby when not powering the amplifier. For such designs, check the wake-up time to ensure it responds quickly enough not to degrade CW keying waveforms.

Many of the currently available commercial amplifiers use a microprocessor-based protection and control system. This provides lots of flexibility, communications capability with the transceiver, and even remote control. If this route is chosen, care must be taken to ensure it is fast enough. VSWR trips must be enabled within 15 ms to be safe. (See the following discussion on transient thermal protection.) Some multi-channel A-to-D circuits take far longer and are not suitable. The controller designed for the 250 W solid-state amplifier in this chapter represents a suitable means of total analog protection. Its fast and simple circuitry can be adapted easily to fit just about any amplifier.

### COOLING A PALLET MODULE

Cooling must be provided and at these power levels is not trivial. Most often the amplifiers are tested on a water-cooled heat-sink for which a description and specification are not supplied. However, Granberg did write several expanded application notes describing complete amplifiers that were subsequently published in *QST*. (See the References and Bibliography section at the end of this chapter for articles by Granberg.) Even so, these are lacking by today’s standards for ruggedness, operability, safety, and “ham-proofing.”

By far the most common cause (> 95%) of expensive RF device failure is thermal overstress when the transistors got too hot and melted before something could be done to relieve the stress — regardless of the cause. There is very little silicon inside an RF transistor (see **Figure 17.34**). A typical transistor die is less than 0.2-inch square and perhaps 4 mils thick. Thinner is better because all of the heat is produced in the top 0.3 mils and all the heat has to travel through the silicon and through the base of the package header before it reaches the heat sink. Heat transfer takes time, so even if there is a thermal sensor on the heat sink, it will indicate a problem far too late to save the device. Recall that the available device dissipation is related to the difference between the maximum allowed junction temperature and the device’s mounting flange. Heat sink temperature sensing is required to limit the long-term accumulated

heat in high duty cycle operation, not protect transistor junctions.

Proper thermal protection recognizes all of the possible causes of sudden thermal stress: overdrive, high VSWR (possibly causing poor efficiency), over-current, incorrect low-pass filter selection, and others. The thermal protection system needs to quickly determine when the input power (RF + dc) minus the RF output power exceeds the allowable power dissipation, then disable the amplifier. Disabling can be as simple as opening the PTT line, removing the RF drive, or as enlightened as switching in a 3 dB pad on the input. (Reducing input power might possibly allow you to stay on the air at half power until the transistor cools down.) In any case, disabling the amplifier must be accomplished quickly and in proper sequence — the drive must be removed before the output is disconnected — without “hot switching” of the output.

Thermal protection for transient loads is one thing. Thermal design of the cooling system is another. As covered in the section on MOSFET Design for Amplifiers, the amplifier needs a heat sink with enough cooling capacity to continuously dissipate a power equal to the output power. Above 100 W a fan is needed to ensure adequate airflow over

## RF Safety

High-power amplifiers generate strong RF fields, especially near a tube or transistor and around the output circuits. These fields are particularly hazardous above 30 MHz and microwave power amplifiers can be especially dangerous. Avoid exposing yourself to intense RF fields when adjusting or measuring energized equipment, including high-gain microwave antennas. Follow the RF exposure guidelines for yourself and others. See the **Safety Practices** chapter for more information.

the heat sink. A proportional speed control is recommended. It can be off when the sink is below 100 °F and full speed when the sink reaches 140 °F. This will reduce the harmful dust buildup on the fins in standby and low duty cycle operation. Design of proportional fan controls is covered in articles such as “Why and How to Control Fan Speed for Cooling Electronic Equipment” by Mary Burke from Analog Devices ([www.analog.com/en/analog-dialogue/articles/how-to-control-fan-speed.html](http://www.analog.com/en/analog-dialogue/articles/how-to-control-fan-speed.html)).

Some of the available amplifier modules have adequate heat spreaders, others have none. This is very important. Considering that all of the power dissipation comes from a very small device footprint, a good layer of copper the same size as the heat sink fin protrusion area ensures the sink is adequately “illuminated.”

## CURRENT SUPPLIERS OF RF PALLET MODULES

These are not the only manufacturers providing pallet modules and more vendors are entering the market. This list is intended to provide a sample of current sources for RF pallet modules.

# Repeaters

For decades, FM has been a mainstay of Amateur Radio operation. FM and repeaters fill the VHF and UHF bands, and most hams have at least one handheld or mobile FM radio. Thousands of repeaters throughout the country provide reliable communication for amateurs operating from portable, mobile and home stations. Digital voice systems are now beginning to dominate new installations. Along with the well-established D-STAR (now offered by Kenwood as well as Icom), Yaesu's System Fusion, and Digital Mobile Radio (DMR) are two popular new systems. DMR makes extensive use of the Internet to build hybrid systems similar to the trunking systems used by public service agencies. A whole new era of repeater-based communications is at hand.

The first part of this chapter, by Paul M. Danzer, N1II, describes FM voice repeaters. Later sections, contributed by Jim McClellan, N5MIJ, and Pete Loveall, AE5PL, of the Texas Interconnect Team, cover more recent developments in D-STAR digital voice and data repeaters. Gary Pearce, KN4AQ, maintains the chapter's basic material. John Burningham, W2XAB, contributed the section on DMR and Cory Sickles, WA3UVV, updated the System Fusion section for this edition.

## 18.1 A Brief History

Few hams today don't operate at least some VHF/UHF FM, and for many hams, FM *is* Amateur Radio. That wasn't always the case.

Until the late 1960s, the VHF and UHF Amateur Radio bands were home to a relatively small number of highly skilled operators who used CW and SSB for long distance communication and propagation experiments. This operation used just a small fraction of the spectrum available at 50 MHz and above. A somewhat larger number of hams enjoyed low power, local operation with AM transceivers on 6 and 2 meters. Our spectrum was underutilized, while public safety and commercial VHF/UHF two-way operation, using FM and repeaters, was expanding rapidly.

The business and public-safety bands grew so rapidly in the early 1960s that the FCC had to create new channels by cutting the existing channels in half. Almost overnight, a generation of tube-type, crystal-controlled FM equipment had to be replaced with radios that met the new channel requirements. Surplus radios fell into the hands of hams for pennies on the original dollar. This equipment was designed to operate around 150 MHz and 450 MHz, just above the 2 meter and 70 cm amateur bands. It was fairly easy to order new crystals and retune them to operate inside the ham bands. Hams who worked in the two-way radio industry led the way, retuning radios and building repeaters that extended coverage. Other hams quickly followed, attracted by the noise-free clarity of FM audio, the inexpensive equipment, and the chance to do something different.

That initial era didn't last long. The surplus commercial equipment was cheap, but it was physically large, ran hot and consumed lots of power. By the early 1970s, manufacturers recognized an untapped market and began building solid-state equipment specifically for the Amateur Radio FM market. The frequency synthesizer, perfected in the mid-1970s, eliminated the need for crystals. The stage was set for an explosion that changed the face of Amateur Radio. Manufacturers have added plenty of new features to equipment over the years, but the basic FM operating mode remains the same.

In the 1980s, hams experimenting with data communications began modulating their FM radios with tones. *Packet radio* spawned a new system of *digirepeaters* (digital repeaters).

Digitized audio has been popular since audio compact discs (CDs) were introduced in the 1980s. In the 1990s, technology advanced enough to reduce the bandwidth needed for digital audio, especially voice, to be carried over the Internet and narrowband radio circuits. The first digital-voice public safety radio systems (called APCO-Project 25) appeared and a variety of Internet voice systems for conferencing and telephone-like use were developed.

Hams are using VHF/UHF digital voice technology, too. The Japan Amateur Radio League (JARL) developed a true ham radio standard called D-STAR, a networked VHF/UHF repeater system for digital voice and data that is beginning to make inroads around the world. Yaesu has developed a hybrid analog/digital system called System Fusion. Another digital voice system, generically known as DMR (Digital Mobile Radio) and by the Motorola trade name MOTOTRBO, is being adapted from commercial service to the ham bands. Hams are also using surplus Project 25 (or just P25) radios.

## 18.2 Repeater Overview

Amateurs learned long ago that they could get much better use from their mobile and portable radios by using an automated relay station called a *repeater*. Home stations benefit

as well — not all hams are located near the highest point in town or have access to a tall tower. A repeater, whose basic idea is shown in **Figure 18.1**, can be more readily located where the antenna system is as high as possible and can therefore cover a much greater area.

### 18.2.1 Types of Repeaters

The most popular and well-known type of amateur repeater is an FM voice system on the 144 or 440 MHz bands. Amateurs operate many repeaters on the 29, 50, 222, 902, and 1240 MHz bands as well, but 2 meters and 70 cm are the most popular. Tens of thousands of hams use mobile and handheld radios for casual ragchewing, emergency communications, public service activities or just staying in touch with their regular group of friends during the daily commute.

While the digital voice modes are gaining ground, FM is still the most popular mode for voice repeaters. Operations are *channelized* — all stations operate on specific, planned frequencies, rather than the more or less random frequency selection employed in CW and SSB operation. In addition, since the repeater receives signals from mobile or fixed stations and retransmits these signals simultaneously, the transmit and receive frequencies are different, or *split*. Direct contact between two or more stations that listen and transmit on the same frequency is called operating *simplex*.

Individuals, clubs, emergency communications groups and other organizations all sponsor repeaters. Anyone with a valid amateur license for the band can establish a repeater in conformance with the FCC rules. No one owns specific repeater frequencies, but nearly all repeaters are *coordinated* to minimize repeater-to-repeater interference. Frequency coordination and interference are discussed later in this chapter. Operational aspects are covered in more detail in *The ARRL Operating Manual*. Special operating notes for the digital repeaters are included in the sections on each mode.

### 18.2.2 Advantages of Using a Repeater

When we use the term *repeater* we are almost always talking about transmitters and receivers on VHF or higher bands, where radio-wave propagation is normally line of sight. Don't take "line of sight" too literally. VHF/UHF radio signals do refract beyond what you can actually see on the horizon, but the phrase is a useful description. (See the **Propagation of Radio Signals** chapter for more information on these terms.)

We know that the effective range of VHF and UHF signals is related to the height of

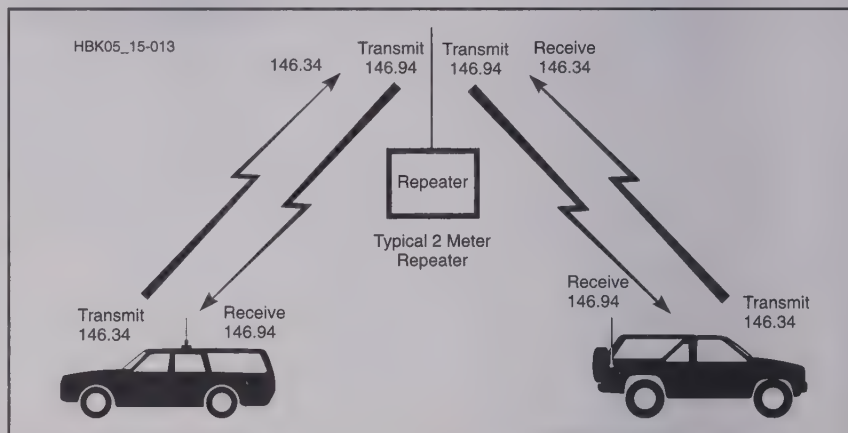

each antenna. Since repeaters can usually be located at high points, one great advantage of repeaters is the extension of coverage area from low-powered mobile and portable transceivers.

**Figure 18.2** illustrates the effect of using a repeater in areas with hills or mountains. The same effect is found in metropolitan areas, where buildings provide the primary blocking structures.

Siting repeaters at high points can also have disadvantages. Since most repeaters have co-channel neighbors (other repeaters operating on the same channel) less than 150 miles away, there may be times when your transceiver can receive both. But since

it operates FM, the *capture effect* usually ensures that the stronger signal will capture your receiver and the weaker signal will not be heard — at least as long as the stronger repeater is in use.

It is also simpler to provide a very sensitive receiver, a good antenna system, and a slightly higher power transmitter at just one location — the repeater — than at each mobile, portable or home location. A superior repeater system compensates for the low power (5 W or less), and small, inefficient antennas that many hams use to operate through them. The repeater maintains the range or coverage we want, despite our equipment deficiencies. If both the handheld

**Figure 18.1** — Typical 2 meter repeater, showing mobile-to-mobile communication through a repeater station. Usually located on a hill or tall building, the repeater amplifies and retransmits the received signal on a different frequency.

**Figure 18.2** — In the upper diagram, stations A and B cannot communicate because their mutual coverage is limited by the mountains between them. In the lower diagram, stations A and B can communicate because the coverage of each station falls within the coverage of repeater C, which is on a mountaintop.

transceiver and the repeater are at high elevations, for example, communication is possible over great distances, despite the low output power and inefficient antenna of the transceiver (see **Figure 18.3**).

Repeaters also provide a convenient meeting place for hams with a common interest. It's usually geographic — your town, or your club. A few repeaters are dedicated to a particular interest such as DX or passing traffic. Operation is channelized, and usually in any area you can find out which channel — or repeater — to pick to ragchew, get highway information or whatever your need or interest is. The conventional wisdom is that you don't have to tune around and call CQ to make a contact, as on the HF bands. Simply call on a repeater frequency — if someone is there and they want to talk, they will answer you. But with a few dozen repeaters covering almost any medium size town, you probably use the scan function in your radio to seek activity.

### EMERGENCY OPERATIONS

When there is a weather-related emergency or a disaster (or one is threatening), most repeaters in the affected area immediately spring to life. Emergency operation and traffic always take priority over other ham activities, and many repeaters are equipped with emergency power sources just for these occasions. See **Figure 18.4**.

Almost all Amateur Radio emergency organizations use repeaters to take advantage of their extended range, uniformly good coverage and visibility. Most repeaters are well known — everyone active in an area with suitable equipment knows the local repeater frequencies.

### 18.2.3 Digital Voice Repeaters on VHF/UHF

Digital voice transmits digitized audio speech as a digital data stream over the RF or wired media. The process of converting between analog voice and the digital data stream utilizes a vocoder (voice encoder). A package of software or firmware that performs the encoding and decoding of the speech is called a codec (coder-decoder).

The transmitted digital voice data stream is encapsulated inside a protocol which handles the addressing and communication management. For a sender and receiver to communicate both must be using the same vocoder and protocol. Additional information on the digital voice modes is available in the **Digital Protocols and Modes** chapter and at the websites listed in the References and Bibliography section of this chapter.

The primary digital voice technologies utilized in the amateur VHF/UHF bands are D-STAR (Digital Smart Technologies for Amateur Radio), DMR (Digital

Mobile Radio), System Fusion and P25. Both D-STAR and System Fusion were designed specifically for the amateur radio market. Developed by the European Telecommunications Standards Institute (ETSI) for government and commercial users, DMR has been adapted for Amateur Radio use.

D-STAR is supported by Icom and Kenwood according to the standard originally developed for the Japanese Amateur

Radio League (JARL). Yaesu is the only manufacturer for System Fusion. There are over a dozen manufacturers producing DMR compatible equipment including Motorola Solutions, Hytera, Vertex Standard, TYT, Connect Systems, BFDX, Kirisun, and Kenwood.

D-STAR and System Fusion protocols both include the amateur's call sign in the transmitted digital data, DMR utilizes a Radio ID number for users and repeaters which amateurs must obtain from DMR-MARC (Motorola Amateur Radio Club) which serves as a central registry for worldwide amateur users.

### DIGITAL VS ANALOG

If you are used to operating on analog FM repeaters, you will have noticed that the audio quality degrades gradually. As a station's signal into the repeater gets weaker; there is an increase in noise bursts mixed with the audio until the signal gets so weak that the station can no longer access the repeater or you cannot understand the audio because of noise. Similarly, as you move further from the repeater you will start hearing the same noise as the repeater's transmitted signal gets weaker. A combination of a station's weak signal into a repeater and a repeater's weak signal to the listener degrades usability faster.

For digital repeaters the audio quality remains the same for both input and output to the edge of the coverage range. At that point,

**Figure 18.3** — In the Rocky Mountain west, handheld transceivers can often cover great distances, thanks to repeaters located atop high mountains. [Photo courtesy Rachel Witte, KCØETU, and Bob Witte, KØNRJ]

**Figure 18.4** — Repeaters provide communication over a wide area to support disaster relief, emergency communication, and public service. They allow portable and mobile stations to communicate effectively with each other and with served agencies and event management. The operators shown here (F-B AE5MT, KE5YBC, and KE5NCR) are supporting an Oklahoma City marathon, getting valuable training while providing a service to the community. (Photo by Frank Tassone, KE5KQL)

the audio becomes broken (missing portions of the speech) caused by lost packets in the digital protocol. Further signal degradation causes complete signal loss. (The same effect is seen on digital television (DTV) as the image becomes pixilated and finally is dropped completely.) The Internet can also drop packets used for transferring the audio data stream between repeaters and bridges, causing the same broken audio affect.

All of major digital voice technologies include Forward Error Correction (FEC) which can correct limited errors, slightly extending the usable range and improving communication quality. Better quality receivers can operate at a lower noise floor, higher power transmitters, and higher gain antenna systems will also extend coverage of both analog and digital systems.

### 18.2.4 Non-Voice Repeater Uses

In addition to FM voice, there are several other types of ham radio repeaters.

**ATV (amateur TV)** — ATV repeaters are used to relay wideband television signals in the 70 cm and higher bands. They are used to extend coverage areas, just like voice repeaters. ATV repeaters are often set up for *crossband* operation, with the input on one band (say, 23 cm) and the output on another (say, 70 cm). More information on ATV repeaters may be found in the **Image Communications** chapter in the downloadable supplement.

**Digipeaters** — Digital repeaters are used primarily for packet communications, including APRS (the Amateur Packet/position Reporting System). They can use a single channel (single port) or several channels (multi-port) on one or more VHF and UHF bands. See the **Digital Protocols and Modes** chapter and the **Digital Communications** chapter in the *Handbook's* downloadable supplemental information for details of these systems.

**Multi-channel (wideband)** — Amateur satellites are the best-known examples. Wide bandwidth (perhaps 50 to 200 kHz) is selected to be received and transmitted so all

signals in bandwidth are heard by the satellite (repeater) and retransmitted, usually on a different VHF or UHF band. See the **Space Communications** chapter in the *Handbook's* downloadable supplemental information for details.

### 18.2.5 Repeaters and FCC Regulations

Repeaters are specifically authorized by the FCC rules. For a brief period when the repeater concept was new in the amateur service, the FCC required special repeater licenses identified by a “WR” call sign prefix and a fairly complex application process. While that complexity is gone, repeaters are still restricted to certain band segments and have lower maximum power limits. But most of the “rules” that make our repeater systems work are self-imposed and voluntary. Hams have established frequency coordination, band plans, calling frequencies, digital protocols and rules that promote efficient communication and interchange of information.

FCC rules on prohibited communication have also been somewhat relaxed, allowing hams to communicate with businesses, and allowing employees of emergency-related agencies and private companies to participate in training and drills while “on the clock.” There are significant restrictions to this operation, so for the latest rules and how to interpret them, see *QST* and the ARRL website, [www.arrl.org](http://www.arrl.org).

### FREQUENCY COORDINATION AND BAND PLANS

Since repeater operation is channelized, with many stations sharing the same frequency pairs, the amateur community has formed coordinating groups to help minimize conflicts between repeaters and among repeaters and other modes. Over the years, the VHF and UHF bands have been divided into repeater and non-repeater sub-bands. These frequency-coordination groups maintain lists of available frequency pairs in their areas (although in most urban areas,

**Table 18.1**  
**Standard Frequency Offsets for Repeaters**

Band	Offset
29 MHz	-100 kHz
52 MHz	Varies by region -500 kHz, -1 MHz, -1.7 MHz
144 MHz	+ or -600 kHz
222 MHz	-1.6 MHz
440 MHz	+ or -5 MHz
902 MHz	12 MHz
1240 MHz	12 MHz

there are no “available” pairs on 2 meters and 70 cm pairs are becoming scarce). A complete list of frequency coordinators, band plans and repeater pairs is included in the *ARRL Repeater Directory*.

Each VHF and UHF repeater band has been subdivided into repeater and non-repeater channels. In addition, each band has a specific *offset* — the difference between the transmit frequency and the receive frequency for the repeater. While most repeaters use the standard offsets, others use “oddball splits.” These nonstandard repeaters are generally also coordinated through the local frequency coordinator. **Table 18.1** shows the standard frequency offsets for each repeater band.

FM repeater action isn’t confined to the VHF and UHF bands. There are a large handful of repeaters on 10 meters around the US and the world. “Wideband” FM is permitted on above 29.0 MHz, and there are four band-plan repeater channels (outputs are 29.62, 29.66 and 29.68 MHz), plus the simple channel 29.60 MHz. Repeaters on 10 meters use a 100 kHz offset, so the corresponding inputs are 29.52, 29.54, 29.56 and 29.58 MHz. During band openings, you can keep up a repeater thousands of miles away, but that also creates the potential for interference generated when multiple repeaters are keyed up at the same time. CTCSS would help reduce the problem, but not many 10 meter repeater owners use it and too many leave their machines on “carrier access.”

## 18.3 FM Voice Repeaters

Repeaters normally contain at least the sections shown in **Figure 18.5**. Repeaters consist of a receiver and transmitter plus a couple more special devices. One is a *controller* that routes the audio between the receiver and transmitter, keys the transmitter and provides remote control for the repeater licensee or designated control operators.

The second device is the *duplexer* that lets the repeater transmit and receive on the same antenna. A high power transmitter and a sensitive receiver, operating in close proximity within the same band, using the same antenna, present a serious technical challenge. You might think the transmitter would just blow the receiver away. But the duplexer keeps the transmit energy out of the receiver with a series of tuned circuits. Without a duplexer, the receiver and transmitter would need separate antennas, and those antennas would need to be 100 or more feet apart on a tower. Some repeaters do just that, but most use duplexers. A 2 meter duplexer is about the size of a two-drawer filing cabinet. See **Figure 18.6**.

Receiver, transmitter, controller, and duplexer: the basic components of most

repeaters. After this, the sky is the limit on imagination. As an example, a remote receiver site can be used to extend coverage (**Figure 18.7**).

The two sites can be linked either by telephone (“hard wire”) or a VHF or UHF link. Once you have one remote receiver site, it is natural to consider a second site to better hear those “weak mobiles” on the other side of town (**Figure 18.8**). Some of the stations using the repeater are on 2 meters while others are on 70 cm? Just link the two repeaters! (See **Figure 18.9**).

For even greater flexibility, you can add an auxiliary receiver, perhaps for a NOAA weather channel (**Figure 18.10**).

The list goes on and on. Perhaps that is why so many hams have put up repeaters.

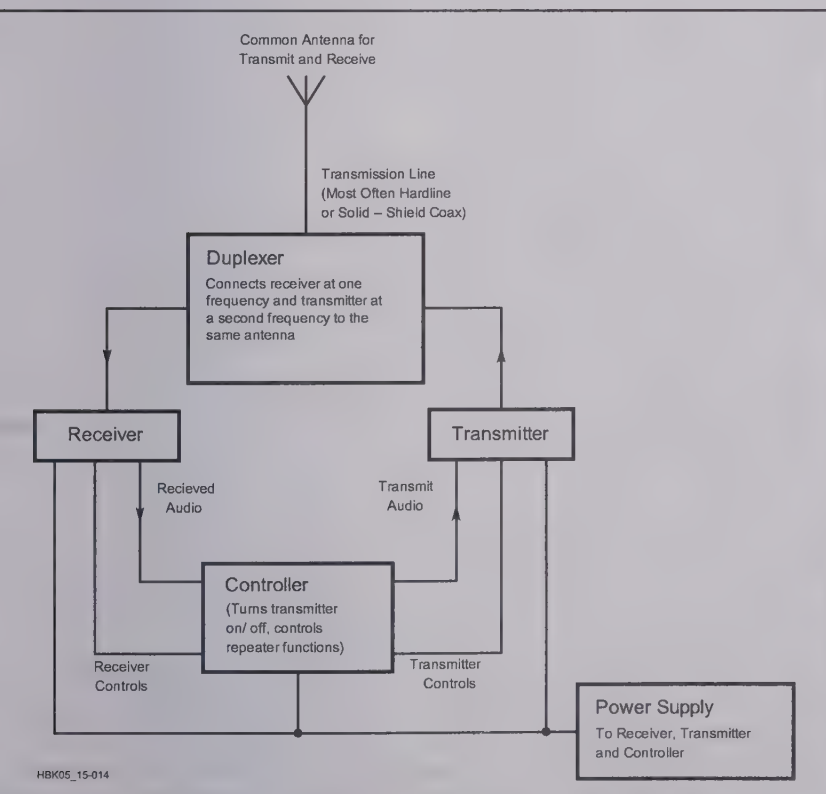

### 18.3.1 FM Repeater Operation

There are almost as many operating procedures in use on repeaters as there are repeaters. Only by listening can you determine the customary procedures on a particular machine. A number of common

operating techniques are found on many repeaters, however.

One such common technique is the transmission of *courtesy tones*. Suppose several stations are talking in rotation — one following another. The repeater detects the end of a transmission of one user, waits a few seconds, and then transmits a short tone or beep. The next station in the rotation waits until the beep before transmitting, thus giving any other station wanting to join in a brief period to transmit their call sign. Thus the term *courtesy tone* — you are politely pausing to allow other stations to join in the conversation.

Another common repeater feature that encourages polite operation is the *repeater timer*. A 3-minute timer is actually designed to comply with an FCC rule for remotely controlled stations, but in practice the timer serves a more social function. Since repeater

**Figure 18.5** — The basic components of a repeater station. In the early days of repeaters, many were home-built. Today, most are commercial, and are far more complex than this diagram suggests.

**Figure 18.6** — The W4RNC 2 meter repeater includes the repeater receiver, transmitter and controller in the rack. The large object underneath is the duplexer. [Photo courtesy Gary Pearce, KN4AQ]

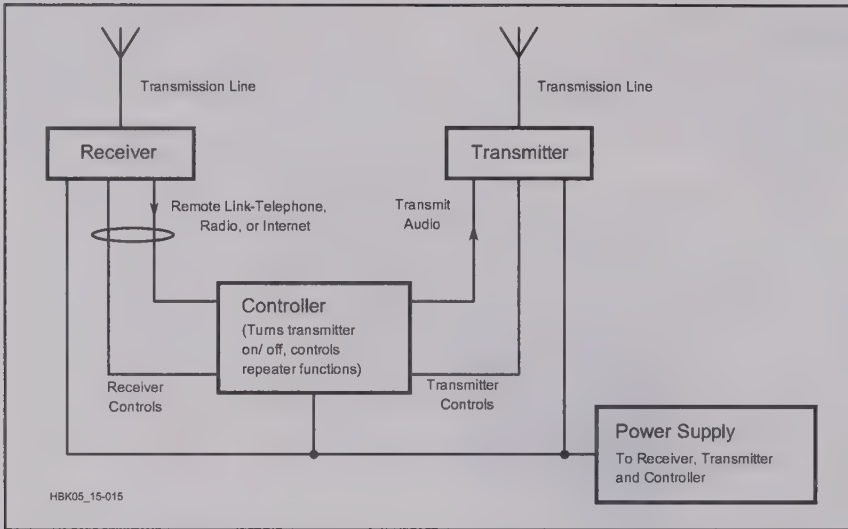

Figure 18.7 — Separating the transmitter from the receiver can extend the repeater's coverage area. The remote receiver can be located on a different building or hill, or consist of a second antenna at a different height on the tower.

Figure 18.9 — Two repeaters using different bands can be linked for added convenience.

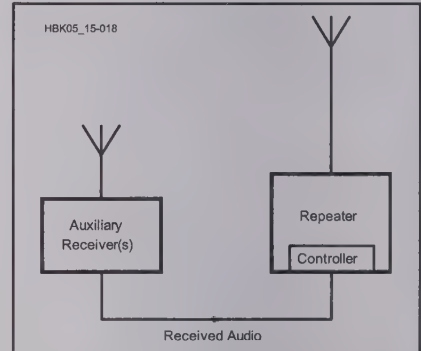

Figure 18.10 — For even greater flexibility, you can add an auxiliary receiver.

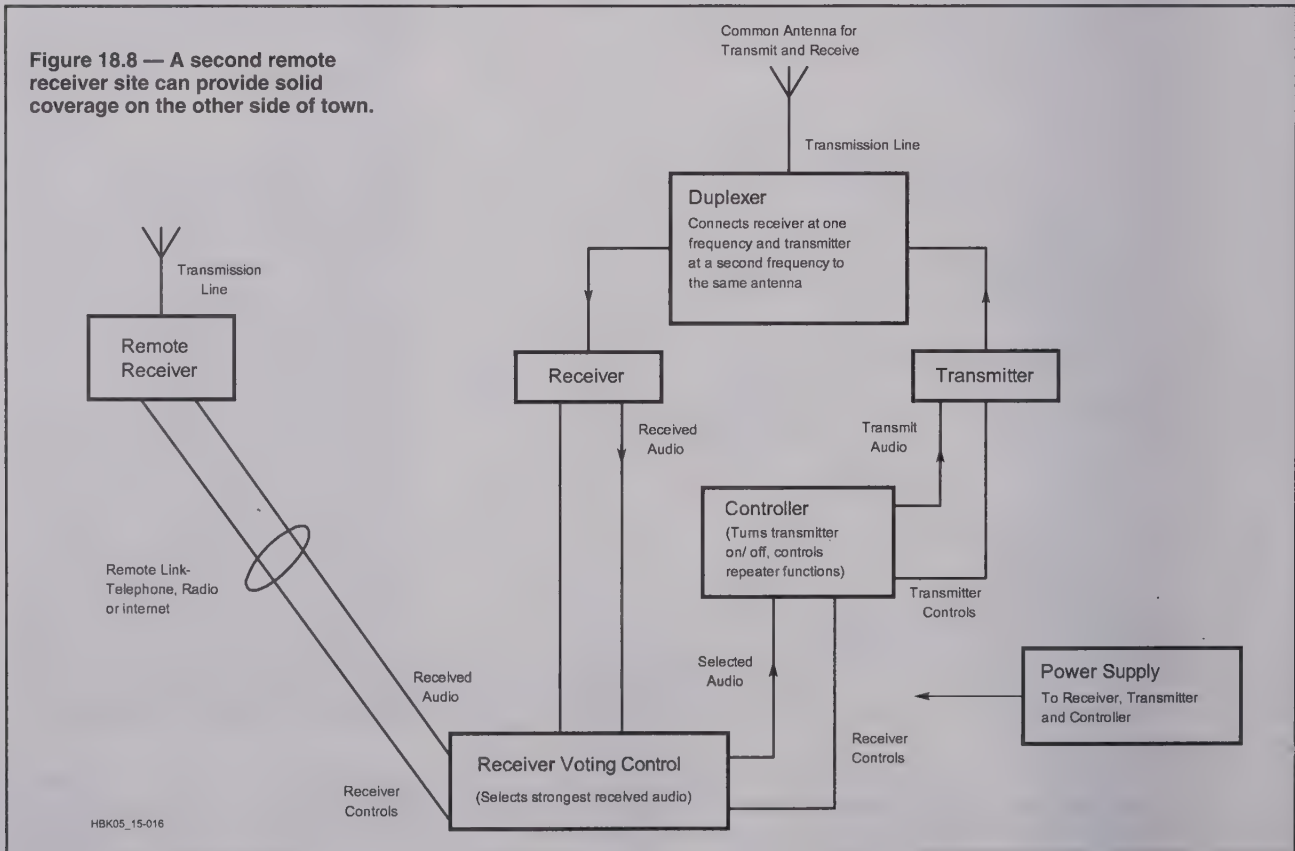

Figure 18.8 — A second remote receiver site can provide solid coverage on the other side of town.

operation is channelized — allowing many stations to use the same frequency — it is polite to keep your transmissions short. If you forget this little politeness many repeaters simply cut off your transmission after 2 or 3 minutes of continuous talking. If the repeater “times out,” it remains off the air until the station on the input frequency stops transmitting.

A general rule, in fact law — both internationally and in areas regulated by the FCC — is that emergency transmissions always have priority. These are defined as relating to life, safety and property damage. Many repeaters are voluntarily set up to give mobile stations priority, at least in checking into the repeater. If there is going to be a problem requiring help, the request will usually come from a mobile station. This is particularly true during rush hours; some repeater owners request that fixed stations limit their use of the repeater during these hours.

Some parts of the country have one or more *closed repeaters*. These are repeaters whose owners wish, for any number of reasons, to not make them available for general use. Often they require transmission of a *subaudible* or *CTCSS* tone (discussed later). Not all repeaters requiring a CTCSS tone are closed — many open repeaters use tones to minimize interference among machines in adjacent areas using the same frequency pair. Other closed repeaters require the transmission of a special tone sequence to turn on. It is desirable that all repeaters, including generally closed repeaters, be made available at least long enough for the presence of emergency information to be made known.

Repeaters have many uses. In some areas they are commonly used for formal traffic nets, replacing or supplementing HF nets. In other areas they are used with tone alerting for severe weather nets. Even when a particular repeater is generally used for ragchewing it can be linked for a special purpose. As an example, an ARRL volunteer official may hold a periodic section meeting across her state, with linked repeaters allowing both announcements and questions directed back to her.

One of the most common and important uses of a repeater is to aid visiting hams. Since repeaters are listed in the *ARRL Repeater Directory* and other directories, hams traveling across the country with mobile or handheld radios often check into local repeaters asking for travel route, restaurant or lodging information. Others just come on the repeater to say hello to the local group. In most areas courtesy prevails — the visitor is given priority to say hello or get the needed help.

Detailed information on repeater operating

techniques is included in a full chapter of the *ARRL Operating Manual*.

### 18.3.2 Home, Mobile and Handheld Equipment

There are many options available in equipment used on repeaters. A number of these options are shown in **Figure 18.11**.

#### HANDHELD TRANSCEIVERS

A basic handheld radio with an output power of 500 mW to 5 W can be used almost anywhere — in a building, walking down a street, or in a car.

Several types of antennas can be used in the handheld mode. The smallest and most convenient is a rubber flex antenna, known as a “rubber duck,” a helically wound antenna encased in a flexible tube. Unfortunately, to obtain the small size the use of a wire helix or coil produces a very low efficiency.

A quarter-wave whip, which is about 19 inches long for the 2 meter band, is a good choice for enhanced performance. The rig and your hand act as a ground plane and a reasonably efficient result is obtained. A longer antenna, consisting of several electrical quarter-wave sections in series, is also commercially available. Although this antenna usually produces extended coverage, the mechanical strain of 30 or more inches of antenna mounted on the radio’s antenna connector can cause problems. After several months, the strain may require replacement of the connector.

Most newer handheld radios are supplied with lithium-ion (Li-ion) batteries. These high-capacity batteries are lightweight and allow operation for much longer periods than the classic NiCd battery pack. Charging is accomplished either with a “quick” charger in an hour or less or with a trickle charger overnight. See the **Power Sources** chapter for more information on batteries.

Power levels higher than 7 W may cause a safety problem on handheld units, since the antenna is usually close to the operator’s head and eyes. See the **Safety** chapter for more information.

For mobile operation, an external antenna provides much greater range than the “rubber duck” as discussed in the following Mobile Equipment section. A power cord plugs into the vehicle cigarette lighter so that the battery remains charged, and a speaker-microphone adds convenience. In addition, commercially available “brick” amplifiers can be used to raise the output power level of the handheld radio to 50 W or more. Many hams initially go this route, but soon grow tired of frequently connecting and disconnecting all the accessories from the handheld and install a permanent mobile radio.

#### MOBILE EQUIPMENT

Compact mobile transceivers operate from 11-15 V dc and generally offer several transmit power levels up to about 50 W. They can operate on one or more bands. Most common are the single band and dual-band transceivers. “Dual-band” usually means 2 meters and 70 cm, but other combinations are available, as are radios that cover three or more bands.

Mobile antennas range from the quick and easy magnetic mount to “drill through the car roof” assemblies. The four general classes of mobile antennas shown in the center section of **Figure 18.11** are the most popular choices. Before experimenting with antennas for your vehicle, there are some precautions to be taken.

*Through-the-glass antennas:* Rather than trying to get the information from your dealer or car manufacturer, test any such antenna first using masking tape or some other temporary technique to hold the antenna in place. Some windshields are metalized for defrosting, tinting and car radio reception. Having this metal in the way of your through-the-glass antenna will seriously decrease its efficiency.

*Magnet-mount or “mag-mount” antennas* are convenient if your car has a metal roof or trunk. The metal also serves as the ground plane. They work well, but are not a good long-term solution. Eventually they’ll scratch the car’s paint, and the coax run through a door can be subject to flexing or crimping and can eventually fail.

*Through-the-roof antenna mounting:* Most hams are reluctant to drill a hole in their car roof, unless they intend to keep the car for a long time. This mounting method provides the best efficiency, however, since the (metal) roof serves as a ground plane. Before you drill, carefully plan and measure how you intend to get the antenna cable down under the interior car headliner to the radio. Be especially careful of side-curtain air bags. Commercial two-way shops can install antennas and power cables, usually for a reasonable price.

*Trunk lip and clip-on antennas:* These antennas are good compromises. They are usually easy to mount and they perform acceptably. Cable routing must be planned. If you are going to run more than a few watts, do not mount the antenna close to one of the car windows — a significant portion of the radiated power may enter the car interior.

More information on mobile equipment may be found in the **Assembling a Station** and **Antennas** chapters.

#### HOME STATION EQUIPMENT

Most “base station” FM radios are actually mobile rigs, powered either from rechargeable batteries or ac-operated power

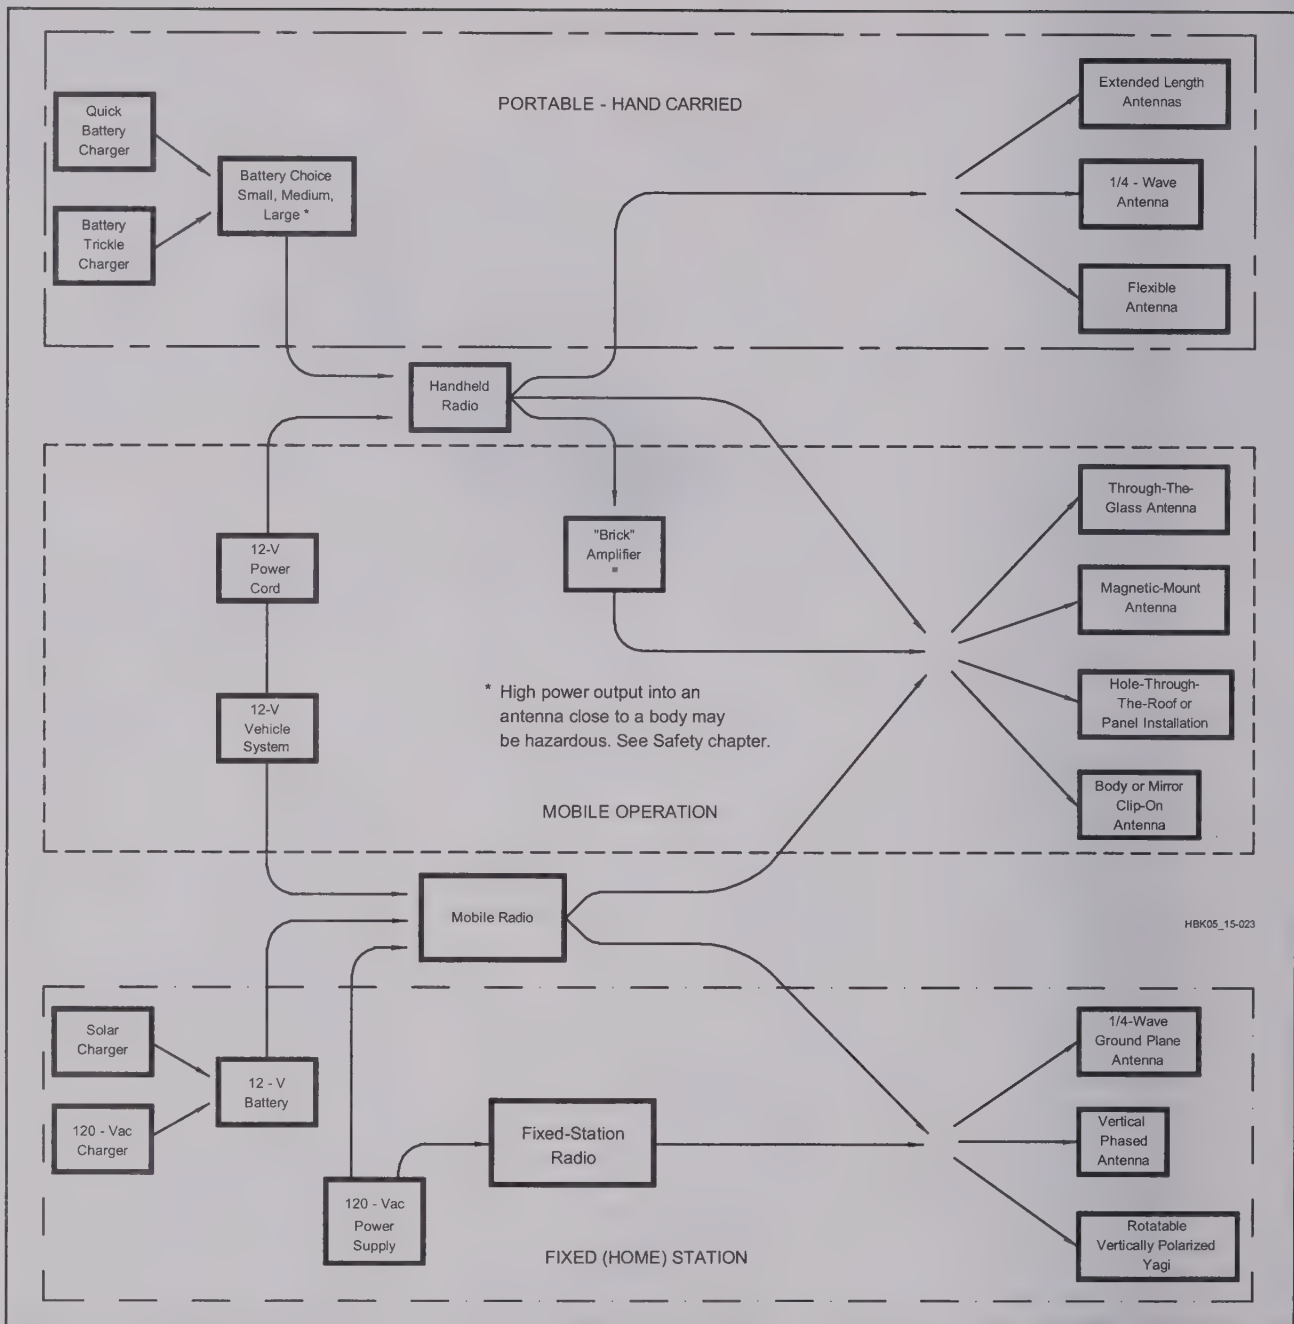

Figure 18.11 — Equipment choices for use with repeaters are varied. A handheld transceiver is perhaps the most versatile type of radio, as it can be operated from home, from a vehicle and from a mountaintop.

supplies. Use of batteries has the advantage of providing back-up communications ability in the event of a power interruption. Some HF transceivers designed for fixed-station use also offer operation on the VHF or VHF/UHF bands, using SSB and CW in addition to FM. Using them means that you will not be able to monitor a local FM frequency while operating HF.

The general choice of fixed-location

antennas is also shown in Figure 18.11. Most hams use an omnidirectional vertical, but if you are in an area between two repeaters on the same channel, a rotatable Yagi may let you pick which repeater you will use without interfering with the other repeater. Vertical polarization is the universal custom, since it is easiest to accomplish in a mobile installation. VHF/UHF SSB operation is customarily horizontally polarized. An operator with

a radio that does both has a tough choice, as there can be a serious performance hit between stations using cross-polarized antennas.

Both commercial and homemade  $\frac{1}{4}\lambda$  and larger antennas are popular for home use. A number of these are shown in the **Antennas** chapter. Generally speaking,  $\frac{1}{4}\lambda$  sections may be stacked up to provide more gain on any band. As you do so, however, more

and more power is concentrated toward the horizon. This may be desirable if you live in a flat area. See **Figure 18.12**.

### 18.3.3 Coded Squelch and Tones

*Squelch* is the circuit in FM radios that turns off the loud rush of noise with no signal present. Most of the time, hams use *noise squelch*, also called *carrier squelch*, a squelch circuit that lets any signal at all come through. But there are ways to be more selective about what signal gets to your speaker or keys up your repeater. That's generically known as *coded squelch*, and more than half of the repeaters on the air require you to send coded squelch to be able to use the repeater.

#### CTCSS

The most common form of coded squelch has the generic name *CTCSS* (Continuous

Tone Coded Squelch System), but is better known by the nickname "tone." Taken from the commercial services, subaudible tones are generally not used to keep others from using a repeater but rather are a method of minimizing interference from users of the same repeater frequency. CTCSS tones are sine-wave audio tones between 67 and 250 Hz, that are added to the transmit audio at a fairly low level. They are *subaudible* only because your receiver's audio circuit is supposed to filter them out. A receiver with CTCSS will remain silent to all traffic on a channel unless the transmitting station is sending the correct tone. Then the receiver sends the transmitted audio to its speaker.

For example, in **Figure 18.13** a mobile station on hill A is nominally within the normal coverage area of the Jonestown repeater (146.16/76). The Smithtown repeater, also on the same frequency pair, usually cannot hear stations 150 miles away. The mobile is

on a hill and so he is in the coverage area of both Jonestown and Smithtown. Whenever the mobile transmits both repeaters hear him.

The common solution to this problem, assuming it happens often enough, is to equip the Smithtown repeater with a CTCSS decoder and require all users of the repeater to transmit a CTCSS tone to access the repeater. Thus, the mobile station on the hill does not come through the Smithtown repeater, since he is not transmitting the required CTCSS tone.

**Table 18.2** shows the available CTCSS tones. Most radios built since the early 1980s have a CTCSS encoder built in, and most radios built since the early 1990s also have a CTCSS decoder built in. Newer radios have a "tone scan" feature that will hunt the tone, if the repeater output includes a tone. Most repeaters that require tone also transmit their tone, but they don't have to. Listings in the *ARRL Repeater Directory* include the CTCSS tone required, if any.

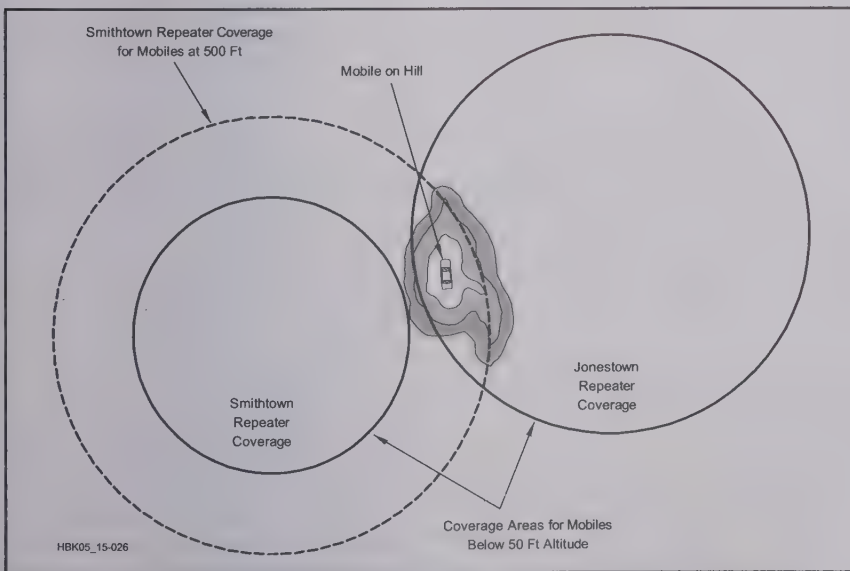

If your local repeater sends a CTCSS tone, you can use your decoder to monitor just that repeater, and avoid hearing the co-channel neighbor, intermod or the annoying fizzes of nearby consumer electronics. Radios typically store CTCSS frequency and mode in their memory channels.

#### DIGITAL-CODED SQUELCH (DCS)

A newer form of coded squelch is called *DCS* (Digital-Coded Squelch). DCS appeared in commercial service because CTCSS didn't

**Figure 18.12** — As with all line-of-sight communications, terrain plays an important role in how your signal gets out.

**Figure 18.13** — When two repeaters operate on the same frequencies, a well-situated operator can key up both repeaters simultaneously. A directional antenna may help.

**Table 18.2**  
**CTCSS Tone Frequencies**

The purpose of CTCSS is to reduce cochannel interference during band openings. CTCSS equipped repeaters would respond only to signals having the CTCSS tone required for that repeater. These repeaters would not respond to weak distant signals on their inputs and correspondingly not transmit and repeat to add to the congestion. The standard ANSI/EIA frequency codes, in hertz, are as follows:

67.0	118.8	179.9
69.3	123.0	183.5
71.9	127.3	186.2
74.4	131.8	189.9
77.0	136.5	192.8
79.7	141.3	199.5
82.5	146.2	203.5
85.4	151.4	206.5
88.5	156.7	210.7
91.5	159.8	218.1
94.8	162.2	225.7
97.4	165.5	229.1
100.0	167.9	233.6
103.5	171.3	241.8
107.2	173.8	250.3
110.9	177.3	254.1
114.8		

provide enough tones for the many users. DCS adds another 100 or so code options. DCS started showing up in Amateur Radio transceivers several years ago and is now a standard feature in most new radios. Open repeaters generally still use CTCSS rather than DCS, since many older radios still in use don't have DCS.

### DTMF

In the days before widespread use of cell phones, one of the most attractive features of repeaters was the availability of autopatch services that allowed a mobile or portable station to use a standard telephone DTMF (dual-tone multi-frequency, or Touch-Tone) key pad to connect the repeater to the local telephone line and make outgoing calls.

Although autopatches see less use today, DTMF key pads are still used for sending control signals. DTMF can also be used as a form of squelch, to turn a receiver on, though it's more often used to control various functions such as autopatch and talking S meters. Some repeaters that require CTCSS have a DTMF "override" that puts the repeater into carrier-squelch mode for a few minutes if you send the proper digits. Other applications for DTMF tones include controlling linked repeaters, described in a later section.

Table 18.3 shows the DTMF tones. Some keyboards provide the standard 12 sets of tones corresponding to the digits 0 through 9 and the special signs # and \*. Others include the full set of 16 pairs, providing special keys A through D. The tones are arranged in two groups, usually called the low tones and high tones. Two tones, one from each group, are required to define a key or digit. For example, pressing 5 will generate a 770-Hz tone and a 1336-Hz tone simultaneously.

The standards used by the telephone company require the amplitudes of these two tones to have a certain relationship.

### 18.3.4 Narrowbanding

We noted in the previous section that in most urban areas, there are no "available" frequencies for new repeaters. And you might recall from our short history section at the beginning of this chapter that the Amateur Radio FM boom began when the business

and public-safety services ran out of room and had to buy all new radios. Their solution to overcrowding, mandated by the FCC, was to reduce the spectrum used for each channel. In the 1960s, that meant reducing the modulation ("deviation") of FM signals from 15 kHz to 5 kHz, and splitting each channel in two. Hams inherited the 15 kHz deviation radios (called "wideband" at the time), but soon adopted the 5 kHz "narrowband" standard.

History is repeating itself. Our spectrum neighbors are again out of room, and the FCC is again requiring them to reduce deviation, from 5 kHz (now called "wideband"), to 2.5 kHz (the new "narrowband"). It's been postponed for several years, but is finally happening.

Will hams follow suit and create space for more repeaters in our own crowded bands? So far, the answer is "no." While most Amateur Radio FM equipment built in the past decade has a "narrow" option that reduces the deviation and incorporates tighter receive filters, we still have a lot of legacy equipment in the field, and no corporate or municipal budget to draw on to replace it. Most of our repeaters are still made of old hardware converted from commercial service. Few repeater councils have seriously considered adjusting frequency coordination to accommodate narrowbanding. No one expects the FCC to require hams to adopt narrowbanding.

What is happening is the placement of D-STAR digital repeaters, which are especially "narrow" already, in between the channels occupied by analog FM repeaters. Since there is still some spectrum overlap, the D-STAR repeaters must also be a good distance away from their new adjacent-channel neighbors — 30 to 50 miles — to reduce the field strength of all the signals involved.

To help you understand how this all works, we'll explain that the terminology "5 kHz" and "2.5 kHz" deviation for analog FM signals is misleading. It refers to the peak frequency shift a modulated signal takes in one direction from the center frequency. But the FM signal moves both up and down from that center, and has some sidebands as well. The actual spectrum used by a "5 kHz" FM signal peaks at 16 kHz and the "narrow" 2.5

kHz signal hits 11 kHz on peaks — not much of a savings. The digital D-STAR signal is about 6.25 kHz wide. The digital signals fill their spectrum completely, all the time, and don't vary with modulation.

Narrowbanding may become a voluntary practice in Amateur Radio, though your use would be "mandated" by remaining compatible with narrowbanded repeaters. It's not on the horizon as of this edition of the *Handbook*.

### 18.3.5 Linked Repeater

Most repeaters are standalone devices, providing their individual pool of coverage and that's it. But a significant number of repeaters are linked — connected to one or more other repeaters. Those other repeaters can be on other bands at the same location, or they can be in other locations, or both. Linked repeaters let users communicate between different bands and across wider geographic areas than they can on a single repeater. Figure 18.14 shows an example.

There are many ways to link repeaters. Repeaters on the same tower can just be wired together, or they may even share the same controller. Repeaters within a hundred miles or so of each other can use a radio link — separate link transmitters and receivers at each repeater, with antennas pointed at each other. Multiple repeaters, each still about 100 miles apart, can "daisy-chain" their links to cover even wider territory. There are a few linked repeater systems in the country that cover several states with dozens of repeaters, but most radio-linked repeater systems have more modest ambitions, covering just part of one or two states.

Repeater linking via the Internet has created the ability to tie repeaters together around the world and in nearly unlimited number. We'll talk more about Internet linking in the next section.

There are several ways linked repeaters can be operated, coming under the categories of *full-time* and *on demand*. Full-time linked repeaters operate just as the name implies — all the repeaters in a linked network are connected all the time. If you key up one of them, you're heard on all of them, and you can talk to anyone on any of the other repeaters on the network at any time. You don't have to do anything special to activate the network, since it's always there.

In an on-demand system, the linked repeaters remain isolated unless you take some action, usually by sending a code by DTMF digits, to connect them. Your DTMF sequence may activate all the repeaters on the network, or the system may let you address just one specific repeater, somewhat like dialing a telephone. When you're finished, another DTMF code drops the link, or a timer

**Table 18.3**  
Standard Telephone (DTMF) Tones

	Low Tone Group		High Tone Group	
	1209 Hz	1336 Hz	1477 Hz	1633 Hz
697 Hz	1	2	3	A
770 Hz	4	5	6	B
852 Hz	7	8	9	C
941 Hz	*	0	#	D

**Figure 18.14** — Repeater linking can greatly expand VHF/UHF communication distances. Repeater links are commonly made via dedicated radio hardware or via the Internet.

**Figure 18.15** — A diagram of a VoIP simplex node. If a control operator is not physically present at the station location and the node is functioning with wireless remote control, the control link must follow the rules for *auxiliary* operation.

may handle that chore when the repeaters are no longer in use.

### INTERNET LINKING

The Internet and *Voice over Internet Protocol* (VoIP) has expanded repeater linking exponentially, making worldwide communication through a local repeater commonplace. Two Internet linking systems, IRLP and EchoLink, have reached critical mass in the US and are available almost everywhere. The D-STAR and DMR digital systems also have a significant Internet linking component. A brief overview is included here; more information may be found in the **Digital Communications** downloadable supplement.

### IRLP

The Internet Radio Linking Project (IRLP) is the most “radio” based linking system. User access is only via radio, using either simplex or repeater stations, while linking is done using VoIP on the Internet. An IRLP system operator establishes a *node* by interfacing his radio equipment to a computer with an

Internet connection, and then running IRLP software. Once that’s set up, repeater users send DTMF tones to make connections, either directly to other individual repeater or simplex nodes (**Figure 18.15**), or to *reflectors* — servers that tie multiple nodes together as one big party line.

The direct connections work like on-demand linked repeaters. You dial in the node number you want to connect to and access code (if required), and you are connected to the distant repeater. Once connected, everyone on both ends can communicate. When finished, another DTMF sequence takes the link down. Someone from a distant repeater can make a connection to you as well.

Reflectors work like a hybrid between on-demand and full-time linked repeaters. You can connect your local repeater to a reflector and leave it there all day, or you can connect for a special purpose (like a net), and drop it when the event is over.

### EchoLink

EchoLink requires a PC with sound card and appropriate software. It allows repeater connections like IRLP, and it has Conference

Servers, similar to IRLP reflectors that permit multiple connections. The big difference is that EchoLink allows individuals to connect to the network from their computers, without using a radio.

The EchoLink conference servers all have more or less specific functions. Some are just regional gathering places, while some are region, topic or activity based (SKYWARN and National Hurricane Center Nets, Jamboree on the Air, and so on).

You can connect your EchoLink-enabled computer to your base station radio fairly easily through a sound card, and create an on-air node. Don’t pipe EchoLink to a local repeater without permission from the repeater owner, though.

If you decide to create a full-time link from a computer to a repeater, consider using a dedicated UHF link frequency rather than just a base station on the repeater input. This applies to IRLP connections as well. Of course, the Internet is infrastructure dependent, and both power and Internet access can be interrupted during storms or other disasters.

## 18.4 D-STAR Repeater Systems

D-STAR is a digital protocol developed by the Japan Amateur Radio League (JARL) that takes Amateur Radio into the 21st century. D-STAR is a bit-streaming protocol able to encapsulate voice and low speed data (DV) or higher speed Ethernet data (DD). Because the protocol is entirely digital (GMSK modulation is used for amateur station transceivers and the respective repeaters), signaling is carried entirely out-of-band (ie, control codes are a separate part of the data stream from the voice or Ethernet information). When looking at the D-STAR repeater systems, it is important to keep that aspect in mind. Amateurs are more familiar with in-band signaling (DTMF tones, for example) in the analog world. Additional information on D-STAR may be found in the **Digital Communications** downloadable supplement.

### 18.4.1 D-STAR Station IDs

The D-STAR specification defines a protocol that can be used for simplex communication or repeater operations. When used simplex, the D-STAR radios function similarly to analog radios with the additional capability to enable selective listening based on station ID (call sign and a character or space). To operate through a repeater, you must know the repeater's station ID as well as the frequency the repeater is on. In this case, consider the repeater's station ID equivalent to a unique CTCSS tone in the analog world.

The D-STAR specification defines all station IDs as seven upper-case alphanumeric characters (space padded) and one upper-case alphanumeric station identifier (which may

also be a space). In other words, W1AW can operate multiple D-STAR stations where the first seven characters of the station ID are "W1AW<space><space><space>" (three space characters follow W1AW) and the eighth character may be a space or upper-case alphanumeric. The G2 gateway software restricts the eighth character to a space or upper-case alphanumeric. For instance, two stations could operate at the same time using "W1AW<space><space><space>" and "W1AW<space><space><space>P".

To talk to someone via D-STAR, you need to set your radio with four station IDs:

- your station ID (MYCALL)
- their station ID (URCALL)
- your local repeater station ID (RPT1)
- your local gateway station ID (RPT2).

MYCALL is always set to your call sign, followed by a character or space. RPT1 is set to your local repeater's station ID (the repeater call sign, followed by a character or space).

If you want to talk locally through the repeater:

- Set URCALL to CQCQCQ.
- Set RPT2 to your local gateway station ID (this isn't needed for local communication, but allows some new network functions to operate, and has become the default recommendation).

The power of the D-STAR protocol becomes evident when D-STAR *gateways* are implemented, providing interconnectivity between repeater systems. This interconnectivity is the same whether you are using voice or Ethernet data.

To talk to someone elsewhere in the D-STAR world, beyond your local area:

- Set URCALL to the other station's ID.
- Set RPT2 to your local gateway station ID.

The RPT2 setting is very important. You don't need to know where the other station is. You simply tell your local repeater to send your bit stream (everything is digital) to the local gateway so that gateway can determine where to send it next. The local gateway looks at URCALL (remember, this is part of the bit stream) and determines where that station was heard last. It then sends the bit stream on to that remote gateway, which looks at URCALL again to determine which repeater at the far end should transmit the bit stream.

Sounds complex? Yes, the implementation can be complex but the user is shielded from all of this by simply setting the four station IDs. **Figure 18.16** shows an example.

### 18.4.2 Station Routing

There are several different ways to set the destination station ID using URCALL:

- If URCALL is set to CQCQCQ, this means "don't go any farther."
- If URCALL is set to the remote station's ID and RPT2 is set to the local gateway, this means "gateway, send my bit stream to be transmitted out the repeater that the remote station was last heard on."
- If URCALL is set to/followed by a remote *repeater* station ID, and RPT2 is set to the local gateway, this means "gateway, send my bit stream to be transmitted out the repeater designated."

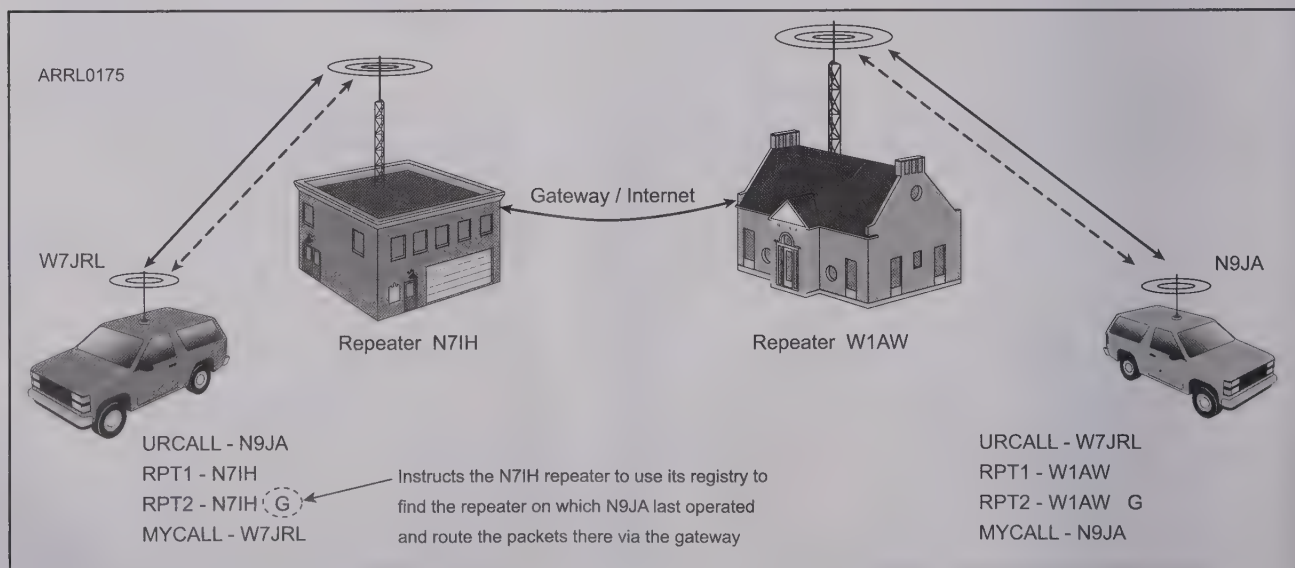

Figure 18.16 — The necessary call sign set to make a call on a remote D-STAR repeater by using a gateway.

# D-STAR Network Overview

The D-STAR specification defines the repeater controller/gateway communications and defines the general D-STAR network architecture. The diagram shown here as Figure 18.A1 is taken from the English translation of the D-STAR specification:

The Comp. IP and Own IP are shown for reference if this were a DD communications. As they do not change and are not passed as part of the D-STAR protocol, they can safely be ignored for the purposes of the following explanation.

Headers 1 through 4 are W\$1QQQ calling W\$1WWW. Headers 5 through 8 are W\$1WWW calling W\$1QQQ. Note that "Own Callsign" and "Companion Callsign" are never altered in either sequence. The "Destination Repeater Callsign" and the "Departure Repeater Callsign" are changed between the gateways. This is so the receiving gateway and repeater controller know which repeater to send the bit stream to. It also makes it easy to create a "One Touch" response as ICOM has done by simply

placing the received "Own Callsign" in the transmitted "Companion Callsign", the received "Destination Repeater Callsign" in the transmitted "Departure Repeater Callsign", and the received "Departure Repeater Callsign" in the transmitted "Destination Repeater Callsign".

Use of the "special" character "/" at the beginning of a call sign indicates that the transmission is to be routed to the repeater specified immediately following the slash. For instance, entering "/K5TIT B" in the "Companion Callsign" would cause the transmission to be routed to the "K5TIT B" repeater for broadcast. Using the above example, W\$1QQQ would put "/W\$1SSS" in the "Companion Callsign" for the same sequence 1 through 4 to occur. At the W\$1VVV gateway, however, the "/W\$1SSS" in the "Companion Callsign" would be changed to "CQCQCQ". All stations within range of W\$1SSS would see the transmission as originating from W\$1QQQ and going to CQCQCQ just like that station was local (but the "Departure Repeater

Callsign" would be "W\$1VVV" and the "Destination Repeater Callsign" would be "W\$1SSS"). Replying would still be done the same way as before since the received "Companion Callsign" is ignored when programming the radio to reply.

Every "terminal" (station) has an IP address assigned to it for DD purposes. The address is assigned from the 10.0.0/8 address range. The D-STAR gateway is always 10.0.0.2. The router to the Internet is always 10.0.0.1. The addresses 10.0.0.3-31 are reserved for local-to-the-gateway (not routable) use. What this makes possible is the ability to send Ethernet packets to another station by only knowing that terminal's IP address and the remote station can directly respond based solely on IP address. This is because the gateway software can correlate IP address with call sign and ID. This makes it possible to route DD Ethernet packets based on the "Companion Callsign" or based on IP address with "Companion Callsign" set to "CQCQCQ". — Pete Loveall, AE5PL

Figure of System constitution

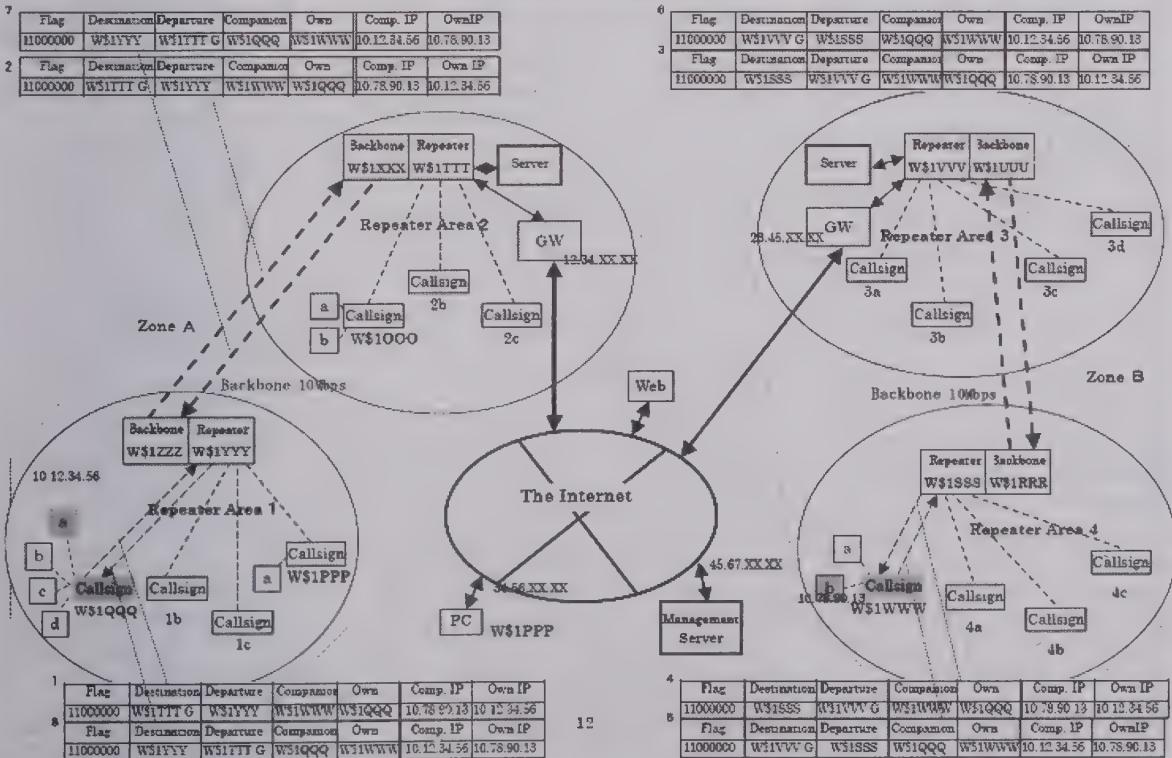

Figure 18.A1 — A D-STAR system overview.

Some people mistakenly call this “call sign routing.” In fact, this is “station routing” because you are specifying the station you want to hear your bit stream (voice or Ethernet data). This is not source routing because the source station is only defining what station they want to talk to; it is up to the gateways to determine routing (very similar to Internet routers).

You can specify a destination but you have no guarantee that:

- 1) The designated station is on the air to receive your transmission.

- 2) The repeater that the designated station is using is not busy.

- 3) Other factors will not prevent your bit stream from reaching the designated station.

Station routing is similar to your address book. In your address book you may have a work number, home number, cell number, fax number and email address for a person. How do you know which one to contact them at? Maybe the email address is best if you want to send them data (equivalent to the station ID for their Ethernet data radio). Maybe the cell phone number if that is what they normally have with them (equivalent to their hand-held transceiver station ID).

How do I know if they heard me? When they talk (or send Ethernet data) back to you. D-STAR is connectionless. Therefore, there is no equivalence in D-STAR to repeater linking as we think of it in the analog world. However, there have been independent implementations of linking of repeaters similar to the linking we see with IRLP (see the section on *DPlus*).

In all cases of D-STAR repeater use, all digital voice (DV) signals with a proper RPT1 are always repeated so everyone hears your transmission through the repeater, regardless of the other settings. Ethernet data (DD) signals are not repeated on frequency because the “repeater” is actually a half-duplex Ethernet bridge operating on a single frequency.

For more details, see the sidebar, “D-STAR Network Overview.”

### 18.4.3 Enhancing D-STAR Operation with *DPlus*

Because D-STAR is a true digital protocol, repeaters have no need for decoding the audio transmitted as bits from each radio. As mentioned previously, this requires all signaling to be out-of-band (with regard to the voice or Ethernet data).

Applications can be built to work with this out-of-band signaling to implement enhancements to the base product without modifying those products. One of these applications is *DPlus*, software that runs on the D-STAR Gateway computer at the repeater site. It provides many capabilities

and more are being added as the software develops.

A key concept is the capability to link repeaters either *directly* (everything heard on one repeater is heard on another) or *indirectly* through a *reflector* (everything sent to a reflector is reflected back out to all linked repeaters). A reflector is a special version of *DPlus* that runs on a standalone computer that is not part of a repeater system. Linking and unlinking a repeater is done by altering the contents of URCALL according to the *DPlus* documentation. (These features continue to evolve, so specific operating commands are not covered here.)

There is no way to directly link two DD “repeaters.” Because DD is Ethernet bridging, however, full TCP support is available, allowing each individual station to make connections as needed to fit their requirements.

For a station to make use of a linked repeater, the station must have URCALL set to CQCQCQ and RPT2 set to the local gateway. If RPT2 is not set to the local gateway, *DPlus* running on the local gateway computer will never see the bit stream and therefore not be able to forward the bit stream to the linked repeater or reflector. This is why setting RPT2 for your local gateway should be your default setting.

If your radio is set for automatic low-speed data transmission, remember that low-speed data is carried as part of the digital voice bit stream and is not multiplexed. Therefore, any low-speed data transmission will block the frequency for the time the transmission is occurring. Caution: if you are using a linked repeater or if you have set URCALL to something other than CQCQCQ, your bit stream will be seen by all stations that are on the other end of that transmission. A reflector could have over 100 other repeaters listening to your transmission.

### 18.4.4 D-STAR Repeater Hardware

D-STAR repeaters are a bit different from the FM repeaters with which we’re all familiar. A quick comparison will help to illustrate.

A complete FM repeater such as in **Figure 18.17** consists of at least three identifiable components. A receiver receives the original signal and demodulates it. The demodulated audio is routed to a controller, where it is mixed with other audio. The resulting combined audio signal is routed back to one or more transmitters. At least one additional source of audio is present in the controller, as it is a legal requirement to ID the repeater transmitter correctly. A well-constructed system includes validation that the levels and frequency response of the processed

**Figure 18.17** — A full rack of D-STAR equipment on the bench of Jim McClellan, N5MIJ. Top to bottom: ICOM IP-RPC2 controller, ID-RP2V 1.2-GHz voice repeater, ID-RP4000 440 MHz voice and data repeater, a blank panel and an ID-RP2000 146 MHz voice and data repeater.

audio are consistent and true to the originally transmitted signals.

A D-STAR repeater’s block diagram (**Figure 18.18**) looks very similar, but functions very differently. A receiver receives the original signal and demodulates it. That signal is passed to a controller, which then drives one or more transmitters. The most significant difference is that there is no audio involved! D-STAR is a digital protocol. All required manipulation of information is performed in the digital domain, including the necessary ID functions. Most existing D-STAR repeaters do not contain the vocoders necessary to recover audio information, so there exists no local speaker or microphone. There is also no level-setting to consider with D-STAR.

### D-STAR REPEATER OPTIONS

There is much discussion about “homebrew” D-STAR repeaters. The two most common approaches are to modify an existing FM repeater to pass the digital signal, or to wire two radios back-to-back. Both approaches provide the desired extended RF coverage, but fail to accurately process the digital signal. Thus both approaches fall short in either functional capability or in legality of the transmitted signal.

It is relatively simple to modify an existing FM repeater to pass the digital signal. The limitations of this approach are that there can be no additional capability added (for example, a D-STAR Gateway), since the digital signal is never decoded. Additionally, this method lacks the ability to encapsulate the ID for the repeater transmitter into the transmitted data.

It is also very simple to wire two D-STAR radios back-to-back, such that the incoming signals are retransmitted. Again, the functionality is limited by the inability to process the entire data stream. This approach presents an additional consideration, as the radio used as a transmitter does not process the data stream as is done in the D-STAR repeater system, and the ID of the originating transmitter is lost, replaced by the ID of the “repeater” transmitter.

Current commercially produced D-STAR repeaters are designed to be used across a broad frequency range. They do not have some of the tight front-end filtering provided by our familiar FM repeaters, so repeater builders must provide that front-end filtering externally. Installing additional band-pass filters between the antenna and the repeater will significantly improve the performance of the system. This is true for both digital voice (DV) repeaters and digital data (DD) access points.

Following good engineering practices will ensure good performance of the

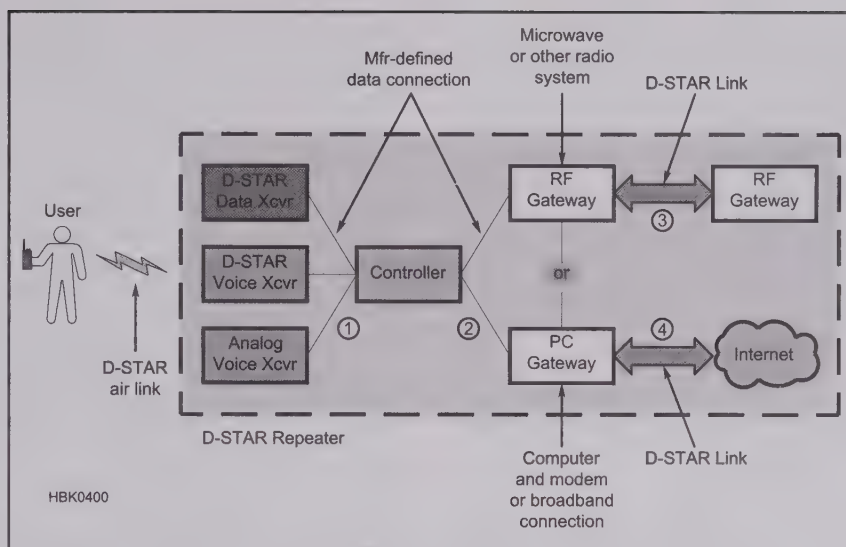

Figure 18.18 — Internal and external connections of a D-STAR repeater stack.

system. A properly constructed and installed D-STAR repeater can exhibit performance improvements of 15% or more in range, as compared to a comparably constructed FM repeater. This performance gain comes from the combination of the forward error correction (FEC) contained in the transmitted signal, and the fact that the radiated power is contained within a narrower bandwidth.

D-STAR is an exciting new system for the amateur community, providing significant

opportunities for us to develop applications and implementations using capabilities we’ve never had before. We truly are limited only by our imaginations. The growth of the world-wide D-STAR network illustrates the level of interest in the technology by both amateurs and our served agencies. Amateurs are once again developing at the leading edge of technology. What we do with the new tools is up to us. How will you use D-STAR?

## 18.5 Digital Mobile Radio (DMR)

The following sections are contributed by John Burningham, W2XAB, from “Amateur Radio Guide to Digital Mobile Radio” (see Reference section).

Digital Mobile Radio (DMR) was developed by the European Telecommunications Standards Institute (ETSI) and is used worldwide by professional mobile radio users. It supports both fully-digital and dual-mode (analog/digital) operation.

Amateurs have implemented DMR with over 3,400 repeaters and 49,000 users registered worldwide as of March 2017. Majority of the repeaters are interconnected via the Internet. There are a number of US amateur international, regional and state networks. Most are interconnected with the DMR-MARC (Motorola Amateur Radio

Club) DMRX core servers, Brandmeister, and DMR-Plus.

In the early era of amateur analog repeaters, most amateurs used modified (“retuned”) surplus commercial equipment. Over time, equipment designed for Amateur Radio reached the marketplace. Today you can find used commercial DMR gear, but new DMR radios are now available with street prices within the range of a typical ham budget (\$100 to \$800). DMR mobile and handheld radios are referred to as “user radios” to distinguish them from repeaters.

### 18.5.1 DMR Standards

DMR is divided into three tiers. Tier I is a single channel specification originally for the

European unlicensed dPMR446 service. It is a single-channel FDMA 6.25 kHz bandwidth; the standard supports peer-to-peer (mode 1), repeater (mode 2) and linked repeater (mode 3) configurations. The use of the Tier I standard has been expanded into radios for use in other than the unlicensed dPMR446 service.

Tier II is a 2-slot TDMA 4FSK 12.5 kHz wide peer-to-peer and repeater mode specification, resulting in a spectrum efficiency of 6.25 kHz per channel. Each time slot can be either voice and/or data depending upon system needs. Most Amateur Radio implementations of DMR are using voice on both time slots.

Tier III builds upon Tier II, adding trunking operation involving multiple repeaters at a single site. Not all manufacturers’ trunking

implementation is compatible with Tier III. Vendor-specific protocols have expanded trunking to multiple-site operations. Any Tier III-capable radio will also work on Tier II systems but neither will work on Tier I.

DMR Tier II is being implemented in amateur MOTOTRBO and Hytera infrastructure networks along with homebrew repeaters. The IP-based protocols used by the different repeater manufacturers are not compatible. It is doubtful the equipment manufacturers will ever standardize for business reasons but conversion (a "bridge") between the two vendor protocols is possible. Any DMR (Tier II) user (mobile or handheld) radio will work on any Tier II system, although some manufacturers offer proprietary features for their infrastructure.

### DMR VOCODER

The current implementation of DMR utilizes the DSVI AMBE+2 vocoder by agreement of the manufacturers; it is not specified in the ESTI standard. Many of the radio manufacturers have implemented the vocoder in licensed software, while others use a DSVI IC. The AMBE+2 vocoder is more recent technology than the AMBE vocoder used by D-STAR.

### DMR NETWORKS

Amateur MOTOTRBO and Hytera DMR networks operate the same from the end user perspective. Amateur MOTOTRBO networks are much larger, cover many more areas, and most are interconnected. Not all the amateur DMR repeaters are connected to the wide area networks; some are standalone either because they have yet to obtain an ISP connection at their repeater site or because the repeater is only intended for local communications. Some standalone systems are operating in dual-mode (analog/digital) which allows the repeater to support both digital and legacy analog users. MOTOTRBO repeaters operating in dual-mode do not support interconnection via the Internet using the IPSC proprietary protocol.

Some hams have installed DMR repeaters in a vehicle, using 3G/4G cellular wireless services for Internet access. Others have implemented remote bases to interconnect to other networks or radios; it is important to remember that the wide area network typically have policies prohibiting interconnected traffic, but what is implemented locally and stays local is acceptable. FCC regulations regarding commercial and business traffic must be followed when transferring content to and from the Internet.

### TWO-SLOT TDMA

DMR Tier II/Tier III occupies a 12.5 kHz bandwidth shared between two channels using Time-Division Multiple Access (TDMA),

resulting in a spectrum efficiency of 6.25 kHz per channel. Each time slot can carry either voice and/or data depending on system design. The time slots are called Time Slot 1 (TS1) and Time Slot 2 (TS2). You can think of the two time slots as separate channels.

For the amateur, this means one repeater allows two separate channels at the same time. Currently most amateur DMR repeater system implementations utilize both channels for voice and some limited text messaging. Normally one time slot is used for wide-area and the second is local and regional.

For repeater operators, a single two-slot TDMA repeater offers a significant savings over two standalone repeaters to obtain two separate communication channels as only one repeater and one antenna system is required.

The two-slot TDMA implemented in DMR uplinks (portable/mobile to repeater) uses a 30-ms window for each time slot, the 30-ms is further divided into a 27.5-ms frame and a 2.5-ms gap. This means when transmitting, your transmitter is only turned on for 27.5 ms every 60 ms, resulting in about a 40% battery savings on transmit.

The DMR repeater transmits a continuous data stream even if only one timeslot is being used; the 2.5-ms uplink gap is replaced with a CACH burst (Common Announcement Channel) that is used for channel management and low-speed signaling.

The 27.5-ms frame consists of a total of 264 bits; a 108-bit payload, 48-bit SYNC or embedded signaling, and a second 108-bit payload for a total of 216-bits of payload per frame. The vocoder must compress 60 ms of audio with FEC (forward error correction) into 216 bits of data for transmission. The 2.5 ms gap is used as guard time to allow for PA ramping (turn-on time) and propagation delay.

### IPSC AND BRIDGES

IP Site Connect (IPSC) is a vendor-specific repeater feature offered by some manufacturers. Note that MOTOTRBO repeaters will only interconnect over the Internet with other MOTOTRBO repeaters because it is not part of the ETSI specifications and the manufacturers don't want to interconnect their infrastructures. IP Site Connect (IPSC) is not part of the current ETSI standards.

The Motorola Solutions MOTOTRBO IPSC implementation allows up to 15 MOTOTRBO repeaters operating in DMR mode to be connected on a fully meshed IPv4 network, with one of the repeaters or a bridge serving as a Master and the others are Peers. Any traffic originating on one of the interconnected repeaters is relayed over the IP network to each of the other repeaters. The Peers will first establish a connection with the Master and obtain the database of

the other Peers along with their IPv4 and port addresses.

The more repeaters in this fully-meshed IPSC network, the more IP network bandwidth is required for each repeater. To expand beyond the limits of basic IPSC network requires the utilization of a bridge to interconnect the different IPSC networks. Rayfield Communications (*c-Bridge*) and BridgeCom Systems (*TL-Net*) are the current commercial preference in North America. In the European market, *SmartPIT* is common. These bridges require static IPv4 addresses and larger network bandwidths than individual repeaters. Besides the commercial bridging products, Brandmeister and DMR Plus are available.

## 18.5.2 DMR Structure

### TALK GROUPS (TG)

Talk Groups (TG) are a way for groups of users to share a time slot without distracting and disrupting other users of the time slot. It should be noted that only one TG can be using a time slot at one time on a repeater. If your radio is not programmed to listen to a TG, you will not hear that TG's traffic. In this regard it is similar to coded squelch, discussed earlier in this chapter. Talk Groups can be considered as conference bridges that are used to interconnect multiple users together, other technologies use the term *reflectors*, or *rooms*.

The DMR-MARC MOTOTRBO network supports many Talk Groups on TS1 including World Wide (TG1), North America (TG3), World Wide English (TG13), and DMR-Plus USA (TG133). TS2 is for local, state, and regional traffic. Check with your local repeater operator to find out what Talk Groups/Time Slots are available on a repeater. Other networks such as Brandmeister and DMR Plus have their own assignment of TGs.

There are TGs implemented for individual states and regional on many networks. Some TGs are available all the time, while others only at preprogrammed times or require a local user to PTT on the TG to activate it for a programmed time. Since only one TG can be transmitting at a time on a time slot, many systems will disable other TGs when a local user is active on a different TG on the time slot. Be courteous and try to use TGs that tie up the fewest number of repeaters if you are going to have a long QSO. Further information about specific Talk Groups can be found on the DMR-MARC, DMRX, Brandmeister, DMR-PLUS and regional group websites.

### ZONES

User DMR radios support *zones*. Zones are a way to organize channels, much like file

folders or directories on your computer. A zone is just a grouping of individual channels. Some model radios may limit the number of channels per zone and the number of zones allowed.

You could program zones for local channels (DMR or analog), another zone for a neighboring state, and a zone for business and government channels. For example, you could program a zone to include all of the NWS Weather Channels. If you do program non-amateur channels in your radio, make sure they are receiver-only unless you are licensed to use them as required by FCC 90.427(b) to avoid committing a violation.

### ENCRYPTION AND DMR

The DMR standard also supports private calls (one-to-one), encryption, and data. Private calls are not allowed by most of the amateur networks and many consider private calls inappropriate for Amateur Radio. Private calls can tie up large number of repeaters across the network and can't be heard by other users. Encryption is not legal for Amateur Radio in the US and in most other parts of the world. Data and text messaging is supported on some networks.

### 18.5.3 DMR Channels

On a DMR radio, a channel is a combination of frequency, CC, TS, and TG. A single repeater may occupy six or more programmed channels depending on the number of TGs available.

### COLOR CODES

DMR repeaters use Color Codes (CC) much like analog repeaters use CTCSS or DCS. To access a repeater, you must program your radio to use the same CC as the repeater. There are 16 different CCs (CC0-CC15). The use of Color Codes is not optional on DMR systems. If your Color Code is not set correctly, you will not be able to access the repeater. Many repeater councils are assigning CCs with frequency assignments.

### ADMIT CRITERIA

The Admit Criteria determines when your radio can transmit. The recommended setting for repeater channels is COLOR CODE FREE; this configures your radio to be polite to your own digital system. You should configure the radio in Call Criteria to FOLLOW ADMIT CRITERIA. Simplex channels should be configured as ALWAYS for both Admit Criteria and ALWAYS or FOLLOW TX for in Call Criteria.

### 18.5.4 DMR Equipment

#### USER RADIOS

There are many sources of new and used

DMR radios. Presently all DMR radios are professional (commercial) radios marketed primarily to commercial radio users. If you want to purchase a new DMR radio for ham use, you can easily find a dealer. Some dealers are "ham friendly" and will offer reasonable discounts to hams. Check with other DMR users or on DMR related websites for further information.

You can also search on eBay and other online flea markets for both new and used radios. Larger hamfests may also have DMR dealers or sellers in their flea markets or vendor areas. Here are a few things you need to know before buying a DMR radio:

**New or Used** — For used DMR radios, it is buyer beware! Just remember that you will not be able to repair a non-working DMR radio unless you have the technical skills and necessary test equipment, and that test equipment can cost hundreds of times the cost of the radio. The street price for new DMR radios is \$100 to \$800. Arguably higher quality, name brand radios, such as those bearing the name Motorola or Hytera, typically sell for more used than brand new radios cost from newer entrants into the DMR market. Higher priced radios usually have more features, are better constructed and can handle more abuse than less expensive radios. For the average amateur, one of the new lower-cost radios is a good initial radio.

**VHF, UHF, or 900 MHz** — UHF is the most commonly used band for DMR, but because of military radar in some US areas, VHF repeaters may be the local choice. There are only few amateur 902-928 MHz DMR repeaters in the US. If you are purchasing UHF equipment, make sure it covers the amateur band (420-450 MHz) from the factory.

**Programming Software** — Some manufacturers supply programming software free. Motorola Solutions charges ~\$175 for a three-year subscription (which covers all their models within a region) to their software and updates. Many DMR radios typically do not allow keyboard programming because they are sold in the professional market. If a vendor charges for the programming software, do not ask another ham to bootleg a copy for you. If you have a legal copy, you may program radios for others, but you cannot legally distribute the software.

**Programming Cable** — Some radios use standard USB cables for programming, while others use cables that can cost upward of \$80.

**Number of Channels** — Some radios have as few as two channels while others have as more than 1,000 channels. You will need a channel for each combination of frequency, CC, TS, and TG. You can easily use six or more memory channels for each DMR repeater.

**Display or Non-Display** — Some radios

have only a channel selector knob, while others have displays (monochrome or color) that will show TG and ID information. Some displays only show channel numbers.

**Visually Impaired Operators** — Consideration must be given to the channel selection knob on the radios. Most of the non-display models have channel selection knobs that have fixed stops instead of 360° continuous rotation to allow the operator to find channel one. Some LCD display models also have fixed stops on the channel selector knob; these include some Hytera and CSI radios. Many models offer programmable voice announcements.

**DTMF Keypad** — Some radios have a 12-button DTMF keypad. MOTOTRBO repeaters support an optional proprietary autopatch feature (Digital Telephone Interconnect) that only works with MOTOTRBO radios.

**GPS** — GPS is available on some models, but DMR does not natively support APRS (Amateur Packet Reporting System). On professional networks, one of the time slots is typically allocated for location reporting and is interconnected to server-based dispatch applications. GPS will shorten battery life if it is enabled.

**Bluetooth and Wi-Fi** — Some higher end radios have Bluetooth built in for wireless headsets and programming, Wi-Fi is also available on some models. This is a great feature at work and home to listen without bothering others. Some radios with Bluetooth support data and programming via the Bluetooth wireless connection to the radio. Some models have Bluetooth adapters available as options. Bluetooth and Wi-Fi will shorten battery life if enabled.

**Analog** — Most radio models support analog FM. Current FCC rules require narrowband for most commercial/government services. For DMR radios from some manufacturers, this requires a programming entitlement key or a different version of the programming software if you require wide-band FM that is still used on many amateur analog repeaters.

**External Antenna on Portable** — Not all portable radios support the connection of an external antenna, except for testing and alignment purposes. Using an adapter to connect an external antenna can place undue stress on the portable antenna connector which may result in premature equipment failure and expensive repair. If you are going to use an external antenna adapter, use an adapter cable that uses miniature coaxial cable to reduce stress on the radio's connector. Some MOTOTRBO models support an external microphone with an antenna mounted on the top.

**Portable (Handheld) or Mobile** — Portable models are available in the 2-5 W

range. Mobiles are available with a maximum of 10-45 W. A portable is recommended as a first DMR radio unless you live beyond the handheld coverage of your local DMR repeater. If you spend significant time in your vehicle commuting, you will find a mobile a good investment. Mobiles can also be used as a base station with the addition of an external power supply.

**External Amplifier** — Many external amplifiers will not work with DMR radios unless they are specifically designed to meet the fast switching requirements of TDMA on DMR.

### CODE PLUGS

A *code plug* is simply a radio's configuration file, the user programs their code plug from scratch or starts with one made available by a local group. This file is uploaded to the radio and typically should also be saved on your computer as a backup. You can also download the code plug from a radio to modify it. Building a code plug can take many hours, especially if you want to program hundreds of channels. The code plug can also contain a contact list of Radio IDs, call signs, and names to be displayed. You can find copies of configured code plugs online for different models of radio; check first with your local group. All DMR radios with an alpha/numeric display support a limited number of entries in the Contact List, radio without an alpha/numeric display do not support Contact Lists.

## 18.5.5 DMR Operation

### SIMPLEX

On the professional side of DMR, *Talk-Around* refers to operating simplex on a repeater output channel. This allows a direct communication while still being able to hear the repeater. This allows users to directly contact other users listening on the repeater output frequency. Amateurs typically

**Table 18.4**

### Recommended Simplex DMR Frequencies and Configuration

	Frequency (MHz)
UHF	441.000, 446.500, 446.075, 433.450
VHF	145.790, 145.510

Channel configuration: TG99 / CC1 / TS1 / Admit Criteria: Always / In Call Criteria: TX or Always

use dedicated simplex channels so as not to interfere with repeaters. The amateur DMR community has published a list of recommended simplex frequencies to be used instead of operating simplex on repeater outputs. **Table 18.4** shows recommended simplex DMR frequencies and configuration.

*Avoid creating conflict with non-DMR analog users.* Do not use 146.520 or 446.000; the national analog simplex channels. Avoid repeater inputs and outputs, locally-used non-DMR simplex channels, satellite sub-bands, and any other frequencies that could disrupt other amateur communications.

### ACCESSING A DMR REPEATER

To access a DMR repeater, have the frequency, CC, TS, and TG set correctly. When a transmitted is keyed, an access-request signal is sent to the repeater and the repeater responds to permit transmitting. If a repeater's acknowledgement is not received, the radio will stop transmitting and a negative confirmation tone will be heard. This is one of the advantages of TDMA: allowing bidirectional communications between user radio and the repeater when transmitting. The repeater can also signal the radio to stop transmitting if there is contention on the network because more than one station is transmitting at a time.

Not all DMR repeaters are interconnected on the Internet. Internet connectivity may not be available at the repeater site, or not available at a reasonable cost. Some repeater operators may just prefer to keep their repeater for local usage only without connecting to the larger regional and worldwide networks.

### OPERATING USING DMR

If you are unsure of "DMR etiquette," spend some time listening to other operate. Be considerate and learn the preferred operating style. This is good practice for learning any new mode, system, or protocol. Listen, listen, listen.

To place a call to another station, or to make a general call, announce your Talk Group because some users may be scanning or have radios without a display. Avoid calling CQ.

When you are talking on one of the wide area TGs, hundreds of repeaters will be tied up. If you are unable to move to a more localized TG, be considerate of the other users on the network. When one TG is active; other TGs on the same time slot will be blocked. Leave time between transmissions so others can break in. Remember that emergency traffic always has priority over all other traffic.

### HOT SPOTS

A "hotspot" is an interface constructed with a very low power transceiver that interconnects to the Internet through an attached computer that is external or integrated to the hotspot. This is similar to a Wi-Fi access point. Some of the units currently available include the DV4mini, openSPOT, DVMEGA, and Micro Node Nano-DV. Beside supporting DMR most will also support D-STAR, System Fusion, NXDN, and P25 protocols. The hot spot allows a user outside the coverage of a repeater to access parts of the network using their radio. The hot spot then connects to the desired repeater via the Internet, similarly to EchoLink. Hot spots are supported by both the Brandmeister and DMR-Plus networks and offer connectivity to other networks.

# 18.6 System Fusion

Yaesu released the initial specification for System Fusion in 2013. System Fusion supports digital voice and data in a 12.5 kHz narrow-band channel at 9600 bps, using C4FM modulation over VHF (144~148 MHz) and UHF (440~450 MHz). System Fusion's low-level modulation and packet structure are discussed in the **Digital Modes and Protocols** chapter. Unless noted otherwise, references to "System Fusion" in this section apply to all versions of System Fusion equipment.

All System Fusion repeaters are configurable for VHF (144~148 MHz) or UHF (440~450 MHz) operation. VHF and UHF operation can be selected as required. All repeater models are configured through a touch-screen interface to set call sign, input frequency, output frequency, CTCSS or DCS setting, power level, mode selection, and so on. By using the lowest (5 W) power setting and a suitable attenuator, a variety of power amplifiers can be used.

Firmware upgrades are available for transceivers, including discontinued models, manufactured prior to the release of System Fusion II in 2017. Specific support levels of

DG-ID memories (see below) and accessibility varies by transceiver. All updated transceivers can access and control unrestricted WIRES-X nodes.

## CALL SIGN IDENTIFICATION

Call sign identification is embedded within the digital transmission packets. When powered up for the first time, a System Fusion transceiver prompts the user to enter their call sign. This establishes station identification. There is no requirement for advance call sign registration or a subscriber ID.

### 18.6.1 System Fusion Versions

#### SYSTEM FUSION I

The original DR-1 repeater was produced in 2014 for a beta testing program. The DR-1X repeater was then released as the production model. There is a significant difference between the internal controllers in the DR-1 and DR-1X. Note that while many DR-1 (beta) repeaters are installed and in daily use

as standalone assets, they were not designed to be directly connected to external controller and networking interfaces, in the same manner as the DR-1X (production). The DR-1X is the appropriate choice for new installations and upgrades from the DR-1. System Fusion I is supported by DR-1 and DR-1X repeaters.

#### System Fusion II

System Fusion II adds new features and configuration options and is supported by DR-2X repeaters and enhanced controllers for DR-1X repeaters. Factory-upgraded or refurbished DR-1X models have been designated DR-1XFR and examination of the firmware version is necessary to determine the actual model. DR-2X repeaters were released in 2017, along with an upgraded internal controller for DR-1X repeaters. DR-2X repeaters also upgrade thermal control for higher duty-cycle operation at full-power. DR-2X repeaters feature a second receiver and additional over-the-air controls.

DSQ (Digital Squelch) has been renamed DG-ID (Digital Group IDentification) and provides a means of adding selective access

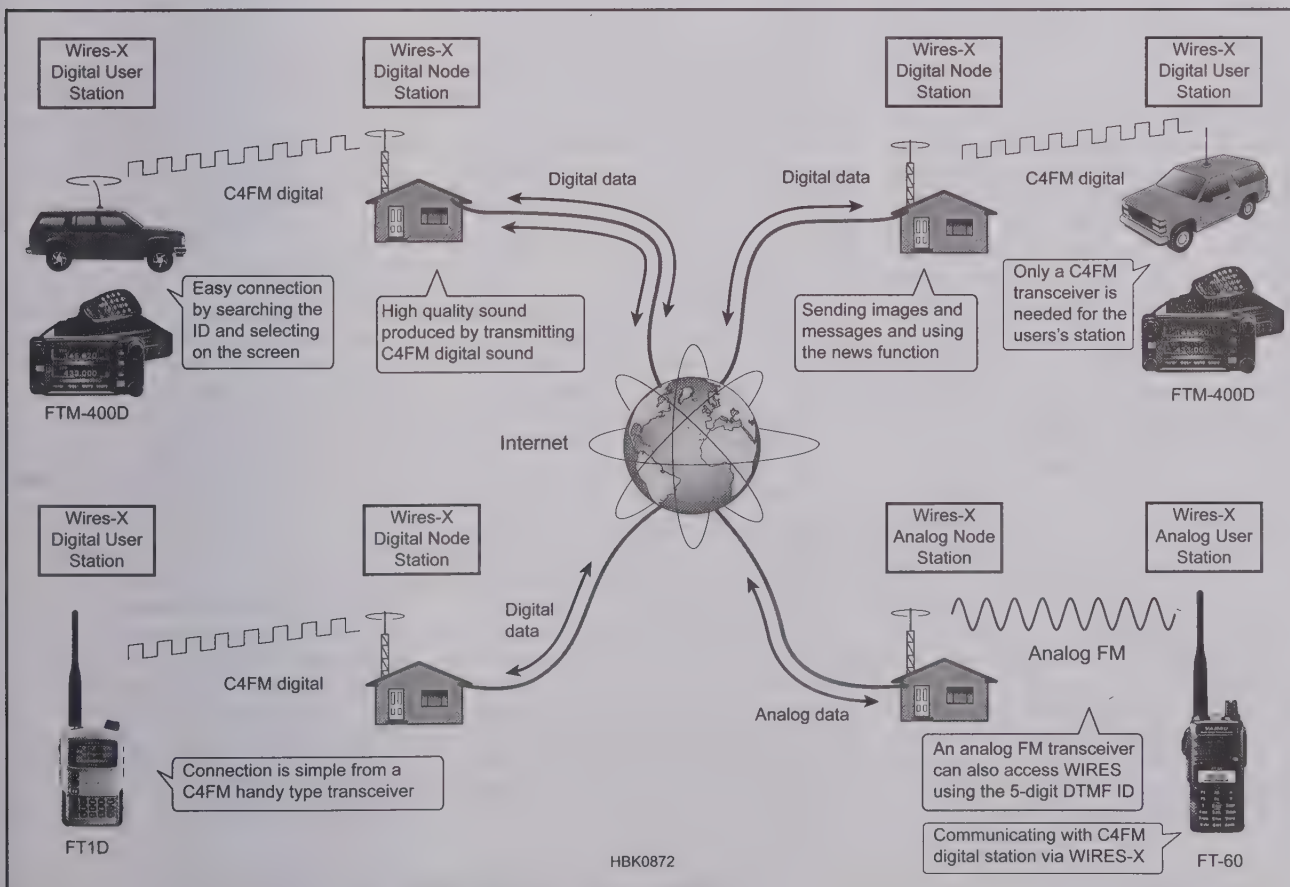

Figure 18.19 — System Fusion I configuration. (graphic courtesy of Yaesu)

for individual repeaters, repeater groups, and WIRES-X nodes. The DG-ID mantissa is 0 ~ 99, with 0 used as a “hear all” setting.

DP-ID (Digital Personal Identification) is transceiver-specific and may be used to designate authorized control operators on a given DR-2X, by inclusion within that repeater’s white list. DP-ID can also be used on an ad-hoc basis to aggregate sets of radios together, within a given DG-ID designation.

### 18.6.2 System Fusion Modes

System Fusion supports three modes of operation: voice full rate (Voice FR) mode, data full rate (Data FR) mode, or voice/data (V/D) mode. Voice FR mode is typically displayed on System Fusion transceivers as “VW” and Voice/Data as “DN.” The two full-rate modes use the entire 9600 bps channel for their respective voice or data payloads, whereas the V/D mode splits the channel into two 4800 bps streams, with voice information on one and data on the other. Data is currently limited to image files and internally-generated data such as GPS, call sign, and routing elements. There is no external access to the data stream.

System Fusion repeaters can be configured in a combination of modes. While the older DR-1X repeaters are capable of operation in a purely analog mode, this prevents digitally-equipped users from accessing the repeater. The repeaters can also be configured to allow analog or digital reception, while forcing the output to analog only. While this configuration allows both analog and digital users to coexist, it does so in a constrained fashion. Analog-output mode strips away GPS, call sign and other information from a digital-mode input signal. Operating in purely digital mode is also possible, effectively locking out analog FM operation. This is typically implemented when there is more than one System Fusion repeater operating in a given area.

### AMS CONFIGURATION

The hybrid Automatic Mode Select (AMS) operates in both FM analog and System Fusion digital modes. This supports both analog FM in to analog FM out and digital in to digital out. In this configuration, analog users are not suddenly “disconnected” from a repeater and other analog-only capable operators. Also, digital users are free to take full advantage of available features.

When configured in AMS, digital users can hear an analog call placed on the repeater in between transmission exchanges. The transceivers will switch to analog, automatically allowing them to communicate with

the analog station. This allows both analog and digital users to share a repeater and does not require all users to switch to digital simultaneously.

Analog FM users can avoid hearing digital transmissions by enabling their transceiver’s TONE SQUELCH feature to match the repeater’s transmitted continuous tone coded subaudible squelch (CTCSS) or digital coded squelch (DCS) signal. Watching for a visual “channel busy” indicator on the analog users’ transceivers or enabling a BUSY CHANNEL LOCKOUT feature will prevent accidental interference when digital communications are taking place.

Repeater networking options allow remote nodes or “points of presence” in cases where internet connectivity is not locally available. This enables systems without internet service to be integrated into a repeater network. Further, digital and analog signaling is supported throughout the WIRES-X (Wide-coverage Internet Repeater Enhancement System) networking protocols.

### 18.6.3 System Fusion Network

#### WIRES-X NETWORK OPERATION

WIRES-X nodes normally consist of a transceiver, a Windows-based computer executing the WIRES-X node software, and the WIRES-X interface. Alternately, a “local” configuration is possible, using the repeater as a replacement for the transceiver. With the acquisition of the HRI-200 WIRES-X interface, a node registration is required in order to enable secure communications to the network. A WIRES-X network map is presented in **Figure 18.19**.

WIRES-X presently supports nodes and “rooms.” Each is assigned a number, although rooms can have alphanumeric identifiers (“America Link,” “All Delaware,” and so on). Compatible digital transceivers can select rooms and nodes with scrollable menus. Analog FM transceivers operating through analog WIRES-X nodes can access rooms and other nodes through use of the numeric identifiers, using the DTMF pad on a suitable microphone or portable radio. (See IMRS section below.)

Transceivers with enhanced feature sets allow for the ad-hoc selection of different rooms. In a digital setting, room lists may be scrolled through the display and selected, as desired. In an analog setting, rooms are not listed, but may be selected through a direct entry of the desired room’s numeric identi-

fier. Although not as popular, mixed rooms — supporting both analog and digital audio — are supported.

### Internet-linked Multiple Repeater System (IMRS)

IMRS is a networking structure supported by System Fusion II DR-2X controllers. While WIRES-X is server-based, IMRS utilizes a peer-to-peer architecture using TCP/IP. IMRS allows a number of repeaters to be interconnected and accessed via DG-ID entries assigned to individual repeaters depending on how the overall repeater group’s system administrator configures the repeater network. Some examples: A DG-ID of 01 may be used to access only a local DR-2X. A DG-ID of 11 may access a group of DR-2X repeaters within a county. A DG-ID 21 may access DR-2X repeaters across a region, state, province, and so on.

In System Fusion II, WIRES-X nodes, through the use of DG-ID, can be used to bridge normally non-connected IMRS groups together or to add the users of a room into an IMRS group. The DR-2X can support IMRS or direct connection of the HRI-200 for WIRES-X, but not both at the same time, due to shared signal lines. Use with a remote node avoids this limitation.

### 18.6.4 Third-Party Enhancements and Options

External repeater controllers can be attached via the repeater signal and control interface connections. Adapter cable sets are available that enable a microcontroller to read and assert the correct sequence of signals required for Automatic Mode Select configuration.

Following publication of the Common Air Interface (CAI) specification for System Fusion, a number of third-party additions have been offered for the repeaters. Protocol converters, typically operating in conjunction with Raspberry Pi3 and Arduino single-board computers, may allow the support of other DV functions with the DR-1X. DR-2X design enhancements may not support a given third-party protocol converter. Interfacing with analog repeater controllers is unaffected.

Other products in the “hot spot” category allow System Fusion repeaters and transceivers to connect through alternate networking schemes. As such, it is possible to use a System Fusion transceiver and network interface to communicate with other DV methodologies, while staying completely within the digital domain.

## 18.7 Other Digital Voice Repeater Technologies

P25 (or APCO Project 25) is a digital voice system designed for public safety (police, fire, EMS, and so on). It was developed in the 1990s to update the FM infrastructure. After about 10 years, the first P25 radios were retired and acquired by hams, who

built P25 repeaters around the country. So far, though, they have not developed a digital P25 network.

Until recently there were no open-source vocoders that could generate a good-quality voice signal at the low bit-rates required for

the narrowband digital voice technologies. As described in the **Digital Protocols and Modes** chapter, *CODEC2* is an open-source vocoder developed by VK5DGR that provides good performance without licensing fees. It has been implemented for both HF and VHF/UHF operation.

## 18.8 Glossary of FM and Repeater Terminology

**Access code** — One or more numbers and/or symbols that are keyed into the repeater with a DTMF tone pad to activate a repeater function, such as an autopatch.

**Autopatch** — A device that interfaces a repeater to the telephone system to permit repeater users to make telephone calls. Often just called a “patch.”

**Carrier-operated relay (COR)** — A device that causes the repeater to transmit in response to a received signal. Solid state versions may be called COS (carrier-operated switch).

**Channel** — The pair of frequencies (input and output) used by a repeater, or a single frequency used for simplex.

**Channel step** — The difference (in kHz) between FM channels. The common steps are 15 and 20 kHz for 2 meter repeaters, 20 kHz for 222 MHz repeaters, and 25 kHz for 440 MHz repeaters. Closer spacing is beginning to be used in some congested areas.

**Closed repeater** — A repeater whose access is limited to a select group (see *open repeater*).

**Control operator** — The Amateur Radio operator who is designated to “control” the operation of the repeater, as required by FCC regulations.

**Courtesy tone** — An audible indication that a repeater user may go ahead and transmit.

**Coverage** — The geographic area within which the repeater provides communications.

**Crossband** — A repeater with its input on one band and output on another.

**CTCSS** — Abbreviation for continuous tone-controlled squelch system, a subaudible tone sent with an FM voice transmission to access a repeater.

**DCS** — Digital Coded Squelch. A newer version of CTCSS that uses a subaudible digital code instead of an analog tone to selectively open a receiver’s squelch.

**Digipeater** — A packet radio (digital) repeater, usually using store-and-forward on a single frequency.

**DTMF** — Abbreviation for *dual-tone multifrequency*, commonly called Touch Tone, the series of tones generated from a keypad on a ham radio transceiver (or a regular telephone).

**Duplex or full duplex** — A mode of communication in which a user transmits on one frequency and receives on another frequency simultaneously (see *half duplex*).

**Duplexer** — A device that allows the repeater transmitter and receiver to use the same antenna simultaneously.

**Frequency coordinator** — An individual or group responsible for assigning frequencies to new repeaters without causing interference to existing repeaters.

**Full quieting** — A received signal that contains no noise.

**Half duplex** — A mode of communication in which a user transmits at one time and receives at another time.

**Handheld** — A small, lightweight portable transceiver small enough to be carried easily.

**Hang time** — A few seconds of repeater carrier following a user transmission that allows others who want to access the repeater a chance to do so; the *courtesy beep* sounds during the hang time.

**Input frequency** — The frequency of the repeater’s receiver (and your transceiver’s transmitter).

**Intermod** — **Intermodulation distortion (IMD)**, the unwanted mixing of two strong RF signals that causes a signal to be received on an unintended frequency.

**Key up** — To turn on a repeater by transmitting on its input frequency.

**Li-ion** — Lithium-ion battery. Longer life, smaller and lighter than NiCd, Li-ion batteries are becoming more popular for use with handheld radios.

**Machine** — A repeater system.

**Mag mount** — Magnetic mount, an antenna with a magnetic base that permits quick installation and removal from a motor vehicle or other metal surface.

**NiCd** — A nickel-cadmium battery that may be recharged many times; often used to power portable transceivers. Pronounced *NYE-cad*.

**NiMH** — Nickel-metal-hydride battery; rechargeable, offers more capacity and lighter weight than an NiCd battery. Often used to power portable transceivers.

**Offset** — the spacing between a repeater’s input and output frequencies.

**Open repeater** — a repeater whose access is not limited.

**Output frequency** — the frequency of the repeater’s transmitter (and your transceiver’s receiver).

**Over** — A word used to indicate the end of a voice transmission.

**Repeater Directory** — An annual ARRL publication that lists repeaters in the US, Canada and other areas.

**Separation** — The difference (in kHz) between a repeater’s transmitter and receiver frequencies, also called the *offset*, or *split*. Repeaters that use unusual separations, such as 1 MHz on 2 meters, are sometimes said to have “oddball splits.”

**Simplex** — A mode of communication in which users transmit and receive directly on the same frequency.

**Squelch tail** — The noise burst heard in a receiver that follows the end of an FM transmission, before the squelch circuit turns off the speaker.

**Time-out** — To cause the repeater or a repeater function to turn off because you have transmitted for too long.

**Timer** — A device that measures the length of each transmission and causes the repeater or a repeater function to turn off after a transmission has exceeded a certain length.

**Tone pad** — An array of 12 or 16 numbered keys that generate the standard telephone dual-tone multifrequency (**DTMF**) dialing signals. Resembles a standard telephone keypad. (see *autopatch*).

# Propagation of Radio Signals

Radio waves, like light waves — all other forms of electromagnetic radiation — normally travel in straight lines. Obviously this does not happen all the time, because long-distance communication depends on radio waves traveling beyond the horizon. In free space, radio waves propagate in other than straight-line paths is a complicated subject, but one that need not be a mystery. This chapter, originally by W. H. R. Poole, W3EP, with updates by W. H. R. Poole, W3EP, and Lutzelschwab, K9LA, provides a clear understanding of the principles of electromagnetic radiation, the structure of the Earth's atmosphere and its interaction with radio waves. For a working knowledge of radio propagation. The section on VHF/UHF propagation was contributed by Alan Bloom, N1AL. More detailed discussions and the underlying mathematics of radio propagation physics can be found in the references listed at the end of this chapter.

## 19.1 Fundamentals of Radio Waves

Radio belongs to a family of electromagnetic radiation that includes infrared (radiation heat), visible light, ultraviolet, X-rays and the even shorter-wavelength gamma and cosmic rays. Radio has the longest wavelength and thus the lowest frequency of this group. See **Table 19.1**.

Electromagnetic waves are composed of an inter-related electric and magnetic field. The electric and magnetic components are oriented at right angles to each other and are also perpendicular to the direction of travel. The polarization of a radio wave is usually designated the same as the orientation of its electric field. This relationship can be visualized in **Figure 19.1**. Unlike sound waves or ocean waves, electromagnetic waves need no propagating medium, such as air or water. This property enables electromagnetic waves to travel through the vacuum of space.

### 19.1.1 Velocity

Radio waves, like all forms of electromagnetic radiation, travel nearly 300,000 km (186,400 miles) per second in a vacuum. Radio waves travel more slowly through any other medium. The decrease in speed through the atmosphere is so slight that it is usually ignored, but sometimes even this small difference is significant. The speed of a radio wave in a piece of wire, by contrast, is about 95% that in free space, and the speed can be even slower in other media.

The speed of a radio wave is always the product of wavelength and frequency, whatever the medium. That relationship can be stated simply as:

$$c = f \lambda$$

where

$c$  = speed in meters/second

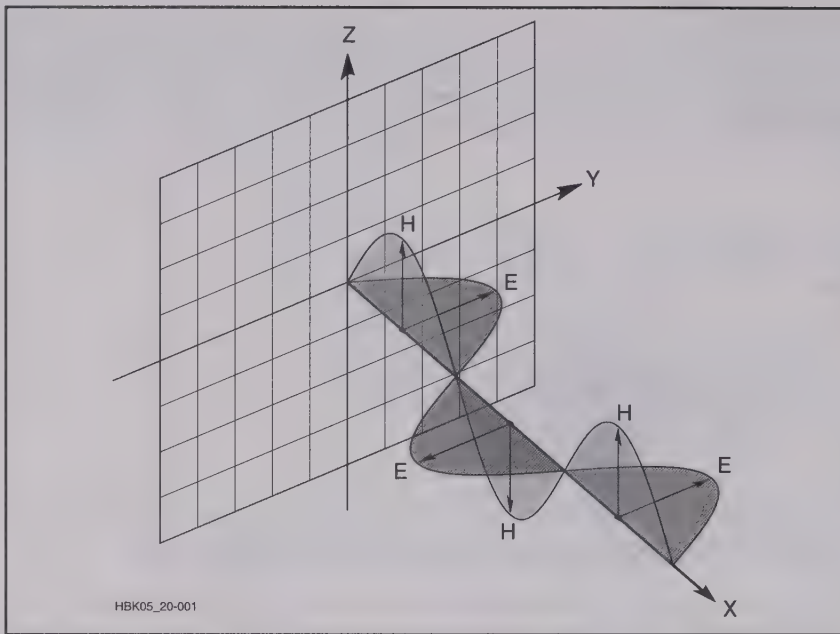

$f$  = frequency in Hz

$\lambda$  = wavelength in meters

The wavelength ( $\lambda$ ) of any radio frequency can be determined from this simple formula by rearranging the above equation to  $\lambda = c/f$ . For example, in free space the wavelength of a 30 MHz radio signal is thus 10 meters. A simplified equation in metric units is  $\lambda$  in meters = 300 divided by the frequency in MHz. Alternately in English units,  $\lambda$  in feet = 984 divided by

**Table 19.1**  
**The Electromagnetic Spectrum**

<i>Radiation</i>	<i>Frequency</i>	<i>Wavelength</i>
Radio	10 kHz – 300 GHz	30 km – 1 mm
Infrared	300 GHz – 428.6 THz	1 mm – 700 nm
Visible light	428.6 THz – 750 THz	700 nm – 400 nm
Ultraviolet	750 THz – $3 \times 10^3$ THz	400 nm – 100 nm
Extreme Ultraviolet	$3 \times 10^3$ THz – $3 \times 10^4$ THz	100 nm – 10 nm
“Soft” X-ray	$3 \times 10^4$ THz – $3 \times 10^5$ THz	10 nm – 1 nm
“Hard” X-ray	$3 \times 10^5$ THz – $3 \times 10^6$ THz	1 nm – 0.1 nm

**Figure 19.1** — Electric and magnetic field components of the electromagnetic wave. The polarization of a radio wave is the same direction as the plane of its electric field.

the frequency in MHz.

Wavelength decreases in other media because the propagating speed is slower. In a piece of wire, the wavelength of a 30 MHz signal shortens to about 9.5 meters. This factor must be taken into consideration in antenna designs, in transmission line designs, and in other applications.

### 19.1.2 Free Space Attenuation and Absorption

Free-space attenuation results from the spherical spreading of radio energy from its source. See **Figure 19.2**. Attenuation grows rapidly with distance because signal strength decreases with the square of the distance from the source. (The signal's field strength in V/m decreases linearly with distance and its power

**Figure 19.2** — Radio energy disperses as the square of the distance from its source. For the change of one distance unit shown the signal's power per unit of area is only one quarter as strong. Each spherical section has the same surface area.

density in  $W/m^2$  decreases with the square of the distance.) In free space, if the distance between transmitter and receiver is increased from 1 km to 10 km (0.6 to 6 miles), the signal power will be reduced by a factor of 100. Attenuation increases with frequency as well. Free space attenuation (path loss) is

$$L_{fs} = 32.45 + 20 \log d + 20 \log f$$

where

$$L_{fs} = \text{free space path loss in dB}$$

$$d = \text{distance in km}$$

$$f = \text{frequency in MHz}$$

Free-space attenuation is a major factor governing signal strength, but in the real world radio signals undergo other losses and enhancements. Energy is lost to absorption when radio waves travel through media other than a vacuum. Radio waves propagate through the ionosphere or solid material (like a wire) by exciting electrons, which then reradiate energy at the same frequency. The amount of radio energy lost depends on the characteristic of the medium and on the frequency. Attenuation in the atmosphere is minor to 3 GHz, but at higher frequencies, absorption due to water vapor and oxygen can be high. Enhancements (especially at VHF and above) can be due to multi-path and scattering. Thus in the real world, the equation above may not be valid.

Radio energy is also lost during refraction, diffraction and reflection — the very phenomena that allow long-distance propagation. Indeed, any form of useful propagation

is accompanied by attenuation. This may be from the slight losses encountered by reflection from sporadic E clouds near the maximum usable frequency, to the more considerable losses involved with tropospheric forward scatter (not enough ionization for refraction or reflection, but enough to send weak electromagnetic waves off into varied directions) or D layer absorption in the lower HF band. These topics will be covered later. In some circumstances, total losses can become so great that radio signals become too weak for communication (they are below the sensitivity of a receiver or receiving system).

### 19.1.3 Refraction Below the Ionosphere

Electromagnetic waves travel in straight lines until they are deflected by something. Radio waves are *refracted*, or bent, slightly when traveling from one medium to another. Radio waves behave no differently from other familiar forms of electromagnetic radiation in this regard. The apparent bending of a partially immersed in a glass of water demonstrates this principle quite dramatically.

Refraction is caused by a change in the velocity of a wave when it crosses the boundary between one propagating medium and another. If this transition is made at an angle, one portion of the wavefront slows down (or speeds up) before the other, thus bending the wave slightly. This is shown schematically in **Figure 19.3**.

The amount of bending increases with the ratio of the *refractive indices* of the two media. Refractive index is simply the velocity of a radio wave in free space divided by its velocity in the medium. The refractive properties of a medium may be calculated from temperature, moisture

**Figure 19.3** — Radio waves are refracted as they pass at an angle between dissimilar media. The lines represent the crests of a moving wave front and the distance between them is the wavelength. The direction of the wave changes because one end of the wave slows down before the other as it crosses the boundary between the two media. The wavelength is simultaneously shortened but the wave frequency (number of crests that pass a certain point in a given unit of time) remains constant.

atmospheric pressure. The index of refraction of air, at a very wide range of frequencies, can be calculated from:

$$\frac{77.6 p}{T} + \frac{3.73 \times 10^5 e}{T^2}$$

$n$  = index of refraction, N units (number of millionths by which the index of refraction exceeds 1.0)

$p$  = atmospheric pressure, millibars (mb)

$e$  = partial pressure of water vapor, millibars

$T$  = temperature, K

that the index of refraction below the ionosphere is greater than 1, causing more bending. The refraction of radio signals is a function of the change in the index of refraction with altitude.  $N$  varies between 290 and 400 at the Earth's surface and normally diminishes with altitude at the rate of 40  $N$  units per kilometer in the first few kilometers.

Radio waves are commonly refracted when they travel through different layers of the atmosphere, whether the highly charged ionospheric layers roughly 100 km (60 miles) and above, or the weather-sensitive area near the Earth's surface. When the ratio of the refractive indices of two media is great enough, radio waves can be reflected, just like light waves striking a mirror. The Earth is a rather lossy reflector, but a metal surface works well if it is several wavelengths in diameter.

## 19.1.4 Scattering

The direction of radio waves can also be changed through *scattering*. The effect seen by a beam of light attempting to penetrate fog is a good example of light-wave scattering. On a clear night, a highly directional flashlight is visible due to a small amount of atmospheric scattering perpendicular to the beam. Radio waves are similarly scattered when they encounter randomly arranged objects of wavelength size or smaller, such as molecules of electrons or water droplets. When the density of scattering objects becomes great enough, they behave more like a propagating medium with a characteristic refractive index. If the scattering objects are arranged in some pattern or order, scattering takes place only at certain angles. A rainbow provides a good analogy for *field-aligned scattering* of light waves. The arc of a rainbow can be seen only at a precise angle away from the Sun, while the colors result from the variance in scattering across the light-wave frequency range. Atmospheric electrons can be field-aligned by magnetic forces in auroras and under other unusual circumstances. Scattering in such cases is most perpendicular to the Earth's magnetic lines.

## 19.1.5 Reflection

At amateur frequencies above 30 MHz, reflections from a variety of large objects, such as water towers, buildings, airplanes, mountains and the like, can provide a useful means of extending over-the-horizon paths several hundred km. Two stations need only beam toward a common reflector, whether stationary or moving.

Maximum range is limited by the radio line-of-sight distance of both stations to the reflector and by reflector size and shape. The reflectors must be many wavelengths in size and ideally have flat surfaces. Large airplanes make fair reflectors and may provide the best opportunity for long-distance contacts. The calculated limit for airplane reflections is 900 km (560 miles), assuming the largest jets fly no higher than 12,000 meters (40,000 ft), but actual airplane reflection contacts are likely to be considerably shorter.

## 19.1.6 Knife-Edge Diffraction

Radio waves can also pass behind solid objects with sharp upper edges, such as a mountain range, by *knife-edge diffraction*. This is a common natural phenomenon that affects light, sound, radio and other coherent waves, but it is difficult to comprehend. **Figure 19.4** depicts radio signals approaching an idealized knife-edge. The portion of the radio waves that strike the base of the knife-edge is entirely

blocked, while that portion passing several wavelengths above the edge travel on relatively unaffected. It might seem at first glance that a knife-edge as large as a mountain, for example, would completely prevent radio signals from appearing on the other side but that is not quite true. Something quite unexpected happens to radio signals that pass just over a knife-edge.

Normally, radio signals along a wave front interfere with each other continuously as they propagate through unobstructed space, but the overall result is a uniformly expanding wave. When a portion of the wave front is blocked by a knife-edge, the resulting interference pattern is no longer uniform. This can be understood by visualizing the radio signals right at the knife-edge as if they constituted a new and separate transmitting point, but in-phase with the source wave at that point. The signals adjacent to the knife-edge still interact with signals passing above the edge, but they cannot interact with signals that have been obstructed below the edge. The resulting *interference pattern* no longer creates a uniformly expanding wave front, but rather appears as a pattern of alternating strong and weak bands of waves that spread in a nearly 180° arc behind the knife-edge.

The crest of a range of hills or mountains 50 to 100 wavelengths long can produce knife-edge diffraction at UHF and microwave frequencies. Hillcrests that are clearly defined and free of trees, buildings and

**Figure 19.4** — VHF and UHF radio waves, light and other waves are diffracted around the sharp edge of a solid object that is large in terms of wavelengths. Diffraction results from interference between waves right at the knife-edge and those that are passing above it. Some signals appear behind the knife-edge as a consequence of the interference pattern. Hills or mountains can serve as natural knife-edges at radio frequencies.

## Propagation Summary, by Band

### LOW FREQUENCY (LF) BANDS AND MEDIUM FREQUENCY (MF) BANDS

#### 135.7-137.8 kHz (2200 meters) and 472-479 kHz (630 meters)

See section 19.8 for a discussion of propagation on these bands.

#### 1.8-2.0 MHz (160 meters)

160 meters suffers from daytime D layer absorption. Daytime communication is limited to ground-wave coverage and a single E hop out to about 1500 km for well equipped stations (running the full legal limit, quarter-wave verticals with a good ground system, and a low noise receiving environment). At night, the D layer quickly disappears and worldwide 160 meter communication becomes possible via  $F_2$  layer skip and ducting. Atmospheric and man-made noise limits propagation. Tropical and mid latitude thunderstorms cause high levels of static in summer, making winter evenings the best time to work DX at 1.8 MHz. A proper choice of receiving antenna (Beverage, 4-square, small loop) can often significantly reduce the amount of received noise to improve the signal-to-noise ratio.

#### HIGH FREQUENCY (HF) BANDS (3-30 MHz)

A wide variety of propagation modes are useful on the HF bands. The lowest two bands in this range share many daytime characteristics with 160 meters. The transition between bands primarily useful at night or during the day appears around 10 MHz. Most long-distance contacts are made via  $F_2$  layer skip. Above 21 MHz, more exotic propagation, including TE, sporadic E, aurora and meteor scatter, begins to be practical.

#### 3.5-4.0 MHz (80 meters for the lower end, 75 meters for the higher end)

The lowest HF band is similar to 160 meters in many respects. Daytime absorption is significant, but not quite as extreme as at 1.8 MHz. At night, signals are often propagated halfway around the world. As at 1.8 MHz, atmospheric noise is a nuisance, making winter the most attractive season for the 80/75 meter DXer.

#### 5.3-5.4 MHz (60 meters)

The distance covered during daytime propagation will fall in between that achievable on the 80 meter and 40 meter bands. At night, worldwide propagation is possible in spite of the relatively low power limit. Signal strengths will typically be higher than on 80 meters but not as high as on 40 meters.

#### 7.0-7.3 MHz (40 meters)

The popular 40 meter band has a clearly defined skip zone during the day due to insufficient ionization to refract high angles. D layer absorption is not as severe as on the lower bands, so short-distance skip via the E and F layers is possible. During the day, a typical station can cover a radius of approximately 800 km (500 miles). At night, reliable worldwide communication via  $F_2$  is common on the 40 meter band.

Atmospheric noise is much less troublesome than on 160 and 80 meters, and 40 meter DX signals are often of sufficient strength to override even high-level summer static. For these reasons, 40 meters is the lowest-frequency amateur band considered reliable for DX communication in all seasons. Even during the lowest point in the solar cycle, 40 meters may be open for worldwide DX throughout the night.

#### 10.1-10.15 MHz (30 meters)

The 30 meter band is unique because it shares characteristics of both daytime and nighttime bands. D layer absorption is not a significant factor. Communication up to 3000 km (1900 miles) is typical during the daytime, and this extends halfway around the world via all-darkness paths. The

band is generally open via  $F_2$  on a 24-hour basis, but during a solar minimum, the MUF on some DX paths may drop below 10 MHz at night. Under these conditions, 30 meters adopts the characteristics of the daytime bands at 14 MHz and higher. The 30 meter band shows the least variation in conditions over the 11-year solar cycle, thus making it generally useful for long-distance communication anytime.

#### 14.0-14.35 MHz (20 meters)

The 20 meter band is traditionally regarded as the amateur's primary long-haul DX favorite. Regardless of the 11-year solar cycle, 20 meters can be depended on for at least a few hours of worldwide  $F_2$  propagation during the day. During solar-maximum periods, 20 meters will often stay open to distant locations throughout the night. Skip distance is usually appreciable and is always present to some degree. Daytime E layer propagation may be detected along very short paths. Atmospheric noise is not a serious consideration, even in the summer. Because of its popularity, 20 meters tends to be very congested during the daylight hours.

#### 18.068-18.168 MHz (17 meters)

The 17 meter band is similar to the 20 meter band in many respects, but the effects of fluctuating solar activity on  $F_2$  propagation are more pronounced. During the years of high solar activity, 17 meters is reliable for daytime and early-evening long-range communication, often lasting well after sunset. During moderate years, the band may open only during sunlight hours and close shortly after sunset. At solar minimum, 17 meters will open to middle and equatorial latitudes, but only for short periods during midday on north-south paths.

#### 21.0-21.45 MHz (15 meters)

The 15 meter band has long been considered a prime DX band during solar cycle maxima, but it is sensitive to changing solar activity. During peak years, 15 meters is reliable for daytime  $F_2$  layer DXing and will often stay open well into the night. During periods of moderate solar activity, 15 meters is basically a daytime-only band, closing shortly after sunset. During solar minimum periods, 15 meters may not open at all except for infrequent north-south transequatorial circuits. Sporadic E is observed occasionally in early summer and mid winter, although this is not common and the effects are not as pronounced as on the higher frequencies.

#### 24.89-24.99 MHz (12 meters)

This band offers propagation that combines the best of the 10 and 15 meter bands. Although 12 meters is primarily a daytime band during low and moderate sunspot years, it may stay open well after sunset during the solar maximum. During years of moderate solar activity, 12 meters opens to the low and middle latitudes during the daytime hours, but it seldom remains open after sunset. Periods of low solar activity seldom cause this band to go completely dead, except at higher latitudes. Occasional daytime openings, especially in the lower latitudes, are likely over north-south paths. The main sporadic E season on 24 MHz lasts from late spring through summer and short openings may be observed in mid-winter.

#### 28.0-29.7 MHz (10 meters)

The 10 meter band is well known for extreme variations in characteristics and a variety of propagation modes. During solar maxima, long-distance  $F_2$  propagation is so efficient that very low power can produce strong signals halfway around the globe. DX is abundant with modest equipment. Under these conditions, the band is usually open from sunrise to a few

hours past sunset. During periods of moderate solar activity, 10 meters usually opens only to low and transequatorial latitudes around noon. During the solar minimum, there may be no  $F_2$  propagation at any time during the day or night.

Sporadic E is fairly common on 10 m, especially May through August, although it may appear at any time. Short skip, as sporadic E is sometimes called on the HF bands, has little relation to the solar cycle and occurs regardless of F layer conditions. It provides single-hop communication from 300 to 800 km (190 to 1400 miles) and multiple-hop opportunities of 500 km (2800 miles) and farther.

Ten meters is a transitional band in that it also shares some of the propagation modes more characteristic of VHF. Meteor scatter, aurora, auroral E and transequatorial propagation provide the means of making contacts out to 2300 km (1400 miles) and farther, but these modes often go unnoticed on 28 MHz. Techniques similar to those used at VHF can be very effective on 10 meters, as signals are usually stronger and more persistent. These exotic modes can be more fully exploited, especially during the solar minimum when  $F_2$  DXing has waned.

### VERY HIGH FREQUENCY (VHF) BANDS (30-300 MHz)

A wide variety of propagation modes are useful in the VHF range. F layer skip appears on 50 MHz during solar cycle peaks. Sporadic E and several other E layer phenomena are most effective in the VHF range. Still other forms of VHF ionospheric propagation, such as field-aligned irregularities (FAI) and transequatorial propagation (TE), are rarely observed on VHF. Tropospheric propagation, which is not a factor at HF, becomes increasingly important above 50 MHz.

#### 30-54 MHz (6 meters)

The lowest amateur VHF band shares many of the characteristics of both lower and higher frequencies. In the absence of any favorable ionospheric propagation conditions, well-equipped 50 MHz stations work regularly over a radius of 800 km (190 miles) via tropospheric scatter, depending on terrain, power, receiver capabilities and antenna. Weak-signal troposcatter allows the best stations to make 500 km (310 mile) contacts nearly any time. Weather effects may extend the normal range by a few hundred km, especially during the summer months, but true tropospheric ducting is rare.

During the peak of the 11-year sunspot cycle (especially during the winter months), worldwide 50 MHz DX is possible via the  $F_2$  layer during daylight hours.  $F_2$  backscatter provides an additional propagation mode for contacts as far as 4000 km (2500 miles) when the MUF is just below 50 MHz. TE paths as long as 8000 km (5000 miles) across the magnetic equator are common around the spring and fall equinoxes of peak solar cycle years.

Sporadic E is probably the most common and certainly the most popular form of propagation on the 6 meter band. Single-hop E-skip openings may last many hours for contacts from 300 to 2300 km (370 to 1400 miles), primarily during the spring and early summer. Multiple-hop  $E_s$  provides transcontinental contacts several times a year, and contacts between the US and South America, Europe and Japan via multiple-hop E-skip occur nearly every summer.

Other types of E layer ionospheric propagation make 6 meters an exciting band. Maximum distances of about 800 km (1400 miles) are typical for all types of E layer modes. Propagation via FAI often provides additional hours of contacts immediately following sporadic E events. Auroral propagation often makes its appearance in late afternoon when the geomagnetic field is disturbed. Closely related auroral E propagation may extend the 6 meter range to 4000 km (2500 miles) and sometimes farther across the northern states and

Canada, usually after midnight. Meteor scatter provides brief contacts during the early morning hours, especially during one of the dozen or so prominent annual meteor showers.

#### 144-148 MHz (2 meters)

Ionospheric effects are significantly reduced at 144 MHz, but they are far from absent. F layer propagation is unknown except for TE, which is responsible for the current 144 MHz terrestrial DX record of nearly 8000 km (5000 miles). Sporadic E occurs as high as 144 MHz less than a tenth as often as at 50 MHz, but the usual maximum single-hop distance is the same, about 2300 km (1400 miles). Multiple-hop sporadic E contacts greater than 3000 km (1900 miles) have occurred from time to time across the continental US, as well as across Southern Europe.

Auroral propagation is quite similar to that found at 50 MHz, except that signals are weaker and more Doppler-distorted. Auroral E contacts are rare. Meteor-scatter contacts are limited primarily to the periods of the great annual meteor showers and require much patience and operating skill. Contacts have been made via FAI on 144 MHz, but its potential has not been fully explored.

Tropospheric effects improve with increasing frequency, and 144 MHz is the lowest VHF band at which terrestrial weather plays an important propagation role. Weather-induced enhancements may extend the normal 300 to 600 km (190 to 370 mile) range of well-equipped stations to 800 km (500 miles) and more, especially during the summer and early fall. Tropospheric ducting extends this range to 2000 km (1200 miles) and farther over the continent and at least to 4000 km (2500 miles) over some well-known all-water paths, such as that between California and Hawaii.

#### 222-225 MHz (135 cm)

The 135 cm band shares many characteristics with the 2 meter band. The normal working range of 222 MHz stations is nearly as far as comparably equipped 144 MHz stations. The 135 cm band is slightly more sensitive to tropospheric effects, but ionospheric modes are more difficult to use. Auroral and meteor-scatter signals are somewhat weaker than at 144 MHz, and sporadic E contacts on 222 MHz are extremely rare. FAI and TE may also be well within the possibilities of 222 MHz, but reports of these modes on the 135 cm band are uncommon. Increased activity on 222 MHz will eventually reveal the extent of the propagation modes on the highest of the amateur VHF bands.

### ULTRA-HIGH FREQUENCY (UHF) BANDS (300-3000 MHz) AND HIGHER

Tropospheric propagation dominates the bands at UHF and higher, although some forms of E layer propagation are still useful at 432 MHz. Above 10 GHz, atmospheric attenuation increasingly becomes the limiting factor over long-distance paths. Reflections from airplanes, mountains and other stationary objects may be useful adjuncts to propagation at 432 MHz and higher.

#### 420-450 MHz (70 cm)

The lowest amateur UHF band marks the highest frequency on which ionospheric propagation is commonly observed. Auroral signals are weaker and more Doppler distorted; the range is usually less than at 144 or 222 MHz. Meteor scatter is much more difficult than on the lower bands, because bursts are significantly weaker and of much shorter duration. Although sporadic E and FAI are unknown as high as 432 MHz and probably impossible, TE may be possible.

Well-equipped 432 MHz stations can expect to work over a radius of at least 300 km (190 miles) in the absence of any propagation enhancement. Tropospheric refraction is more pronounced at 432 MHz and provides the most frequent and useful means of extended-range contacts. Tropospheric ducting supports contacts of 1500 km (930 miles) and farther over land.

The current 432 MHz terrestrial DX record of more than 4000 km (2500 miles) was accomplished by ducting over water.

### 902-928 MHz (33 cm) and Higher

Ionospheric modes of propagation are nearly unknown in the bands above 902 MHz. Auroral scatter may be just within amateur capabilities at 902 MHz, but signal levels will be well below those at 432 MHz. Doppler shift and distortion will be considerable, and the signal bandwidth may be quite wide. No other ionospheric propagation modes are likely, although high-powered research radars have received echoes from auroras and meteors as high as 3 GHz.

Almost all extended-distance work in the UHF and microwave bands is accomplished with the aid of tropospheric enhancement. The frequencies above 902 MHz are very sensitive to changes in the weather. Tropospheric ducting occurs more frequently than in the VHF bands and the

potential range is similar. At 1296 MHz, 2000 km (1200 mile) continental paths and 4000 km (2500 mile) paths between California and Hawaii have been spanned many times. Contacts of 1000 km (620 miles) have been made on all bands through 10 GHz in the US and over 1600 km (1000 miles) across the Mediterranean Sea. Well-equipped 903 and 1296 MHz stations can work reliably up to 300 km (190 miles), but normal working ranges generally shorten with increasing frequency.

Other tropospheric effects become evident in the GHz bands. Evaporation inversions, which form over very warm bodies of water, are usable at 3.3 GHz and higher. It is also possible to complete paths by scattering from rain, snow and hail in the lower GHz bands. Above 10 GHz, attenuation caused by atmospheric water vapor and oxygen become the most significant limiting factors in long-distance communication.

other clutter make the best knife-edges, but even rounded hills may serve as a diffracting edge. Alternating bands of strong and weak signals, corresponding to the interference pattern, will appear on the surface of the Earth behind the mountain, known as the *shadow zone*. The phenomenon is generally reciprocal, so that two-way communication can be established under optimal conditions. Knife-edge diffraction can make it possible to complete paths of 100 km or more that might otherwise be entirely obstructed by mountains or seemingly impossible terrain.

### 19.1.7 Ground Wave

A *ground wave* is the result of a special form

of diffraction that primarily affects longer-wavelength vertically polarized radio waves. It is most apparent in the 80 and 160 meter amateur bands, where practical ground-wave distances may extend beyond 200 km (120 miles). It is also the primary mechanism used by AM broadcast stations in the medium-wave bands. The term ground wave is often mistakenly applied to any short-distance communication, but the actual mechanism is unique to the longer-wave bands.

Radio waves are bent slightly as they pass over a sharp edge, but the effect extends to edges that are considerably rounded. At medium and long wavelengths, the curvature of the Earth looks like a rounded edge. Bending results when the lower part of the wave front

loses energy due to currents induced in the ground. This slows down the lower part of the wave, causing the entire wave to tilt forward slightly. This tilting follows the curvature of the Earth, thus allowing low- and medium-wave radio signals to propagate over distances well beyond line of sight.

Ground wave is most useful during the day at 1.8 and 3.5 MHz, when D layer absorption makes skywave propagation more difficult. Vertically polarized antennas with excellent ground systems provide the best results. Ground-wave losses are reduced considerably over saltwater and are highest over dry and rocky land.

## 19.2 Sky-Wave Propagation and the Sun

The Earth's atmosphere is composed primarily of nitrogen (78%), oxygen (21%) and argon (1%), with smaller amounts of a dozen other gases. Water vapor can account for as much as 5% of the atmosphere under certain conditions. This ratio of gases is maintained until an altitude of about 80 km (50 miles), when the mix begins to change. At the highest levels, helium and hydrogen predominate.

Solar radiation acts directly or indirectly on all levels of the atmosphere. Adjacent to the surface of the Earth, solar warming controls all aspects of the weather, powering wind, rain and other familiar phenomena. *Solar ultraviolet (UV) radiation* creates small concentrations of ozone (O<sub>3</sub>) molecules between 10 and 50 km (6 and 30 miles). Most UV radiation is absorbed by this process and never reaches the Earth.

At even higher altitudes, EUV (Extreme UV) and X-ray radiation partially ionize atmospheric gases. Electrons freed from gas atoms eventually recombine with positive ions to recreate neutral gas atoms, but this takes some time. In the low-pressure environment at the highest altitudes, atoms are spaced far

apart and the gases may remain ionized for many hours. At lower altitudes, recombination happens rather quickly, and only constant radiation can keep any appreciable portion of the gas ionized.

### 19.2.1 Structure of the Earth's Atmosphere

The atmosphere, which reaches to more than 600 km (370 miles) altitude, is usually divided into a number of regions based on a transitioning characteristic of the atmosphere — like temperature. For propagation purposes, the important regions are shown in **Figure 19.5**. The weather-producing *troposphere* lies between the surface and an average altitude of 10 km (6 miles). Between 10 and 50 km (6 and 30 miles) are the *stratosphere* and the embedded *ozonosphere*, where ultraviolet-absorbing ozone reaches its highest concentrations. About 99% of atmospheric gases are contained within these two lowest regions.

Above 50 km to about 600 km (370 miles) is the *ionosphere*, notable for its effects on radio

propagation. At these altitudes, atomic oxygen, molecular oxygen, molecular nitrogen and nitric oxide predominate under very low pressure and are the important species to consider for propagation. High-energy solar EUV and X-ray radiation ionize these constituents, creating a broad region where ions are created in relative abundance. The ionosphere is subdivided into distinctive D, E and F regions.

The *magnetosphere* begins around 600 km (370 miles) and extends as far as 160,000 km (100,000 miles) into space. The predominant component of atmospheric gases gradually shifts from atomic oxygen, to helium and finally to hydrogen at the highest levels. The lighter gases may reach escape velocity and be swept off the atmosphere by the *solar wind* (electrically charged particles emitted by the Sun and traveling through space). About 3200 and 16,000 km (2000 and 9900 miles, respectively), the Earth's magnetic field traps energetic electrons and protons in two bands, known as the *Van Allen belts*. These have only a minor effect on terrestrial radio propagation.

## 19.2.2 The Ionosphere

The ionosphere plays a basic role in long-distance communications in all the amateur bands from 1.8 MHz to 30 MHz. The effects of the ionosphere are less apparent at the very high frequencies (30-300 MHz), but they persist east through 432 MHz. As early as 1902,

Oliver Heaviside and Arthur E. Kennelly independently suggested the existence of a layer in the upper atmosphere that could account for the long-distance radio transmissions made the previous year by Guglielmo Marconi and others. Edward Appleton confirmed the existence of the Kennelly-Heaviside layer in publications

beginning in 1925 and used the letter E on his diagrams to designate the strength of the electric field of the waves that were apparently reflected from the layer he measured.

In late 1927 Appleton reported the existence of an additional layer in the "ionosphere." (Robert Watson-Watt coined the term "ionosphere", but it wasn't commonly used until 1932.) The additional higher-altitude layer was named "F" and subsequently another was termed "D." For a time during the 1930s, a "C" layer was proposed, and later discarded. Appleton was reluctant to alter this arbitrary nomenclature for fear of discovering yet other lower layers, so it has stuck to the present day. The basic physics of ionospheric propagation was largely worked out by the 1930s, yet both amateur and professional experimenters made further discoveries during the 1930s, 1940s and 1950s. Sporadic E, aurora, trans-equatorial, meteor scatter and several types of field-aligned scattering were among additional ionospheric phenomena that required explanation.

Although the term "layer" is used in this chapter, this could lead to the erroneous assumption that the ionosphere consists of distinct thin sheets separated by emptiness in between. This is not so, and as we'll see later in the chapter the ionosphere is a continuous electronic density versus altitude, with definite peaks and inflection points that define the D, E, F<sub>1</sub> and F<sub>2</sub> regions. Studies have shown that the height of the various layers may also vary by latitude. Research into ionospheric physics is ongoing in an attempt to better understand the variability of the ionosphere.

Figure 19.5 — Regions of the lower atmosphere and the ionosphere.

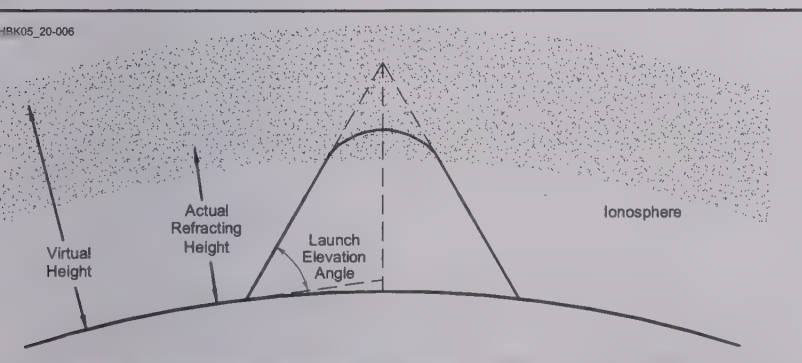

Figure 19.6 — Gradual refraction in the ionosphere allows radio signals to be propagated long distances. It is often convenient to imagine the process as a reflection on an imaginary reflection point at some virtual height above the actual refracting ion. The other figures in this chapter show ray paths as equivalent reflections, but should keep in mind that the actual process is a gradual refraction.

## 19.2.3 Ionospheric Refraction

The refractive index of an ionospheric layer decreases from a value of 1.00 as the density of free-moving electrons increases (this is opposite from the refractive index in the troposphere since the ionosphere is a dispersive medium). In the densest regions of the F layer, that density can reach a trillion electrons per cubic meter ( $10^{12} \text{ e/m}^3$ ). Even at this high level, radio waves are refracted gradually over a considerable vertical distance, usually amounting to tens of km. Radio waves become useful for terrestrial propagation only when they are refracted enough to bring them back to Earth. See Figure 19.6.

Although refraction is the primary mechanism of ionospheric propagation, it is usually more convenient to think of the process as a reflection. The *virtual height* of an ionospheric layer is the equivalent altitude of a reflection that would produce the same effect as the actual refraction. The virtual height of any ionospheric layer can be determined using an ionospheric sounder, or *ionosonde*, a sort of vertically oriented radar. The ionosonde sends pulses that sweep over a wide frequency range, generally from 2 MHz to 20 MHz or

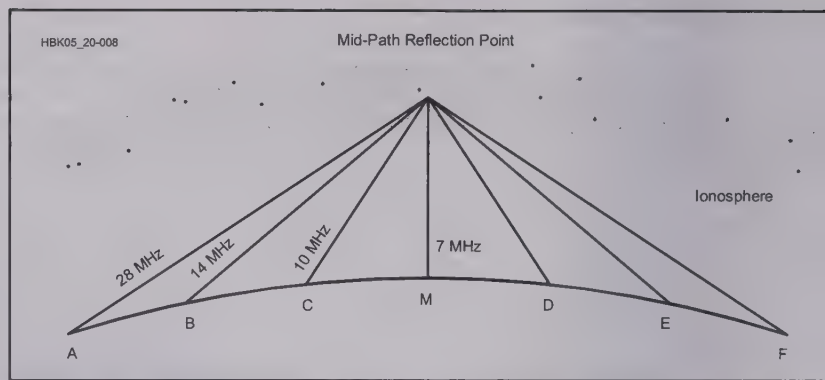

**Figure 19.7** — Simplified vertical incidence ionogram showing echoes returned from the E, F<sub>1</sub> and F<sub>2</sub> layers. The critical frequencies of each layer (4.1, 4.8 and 6.8 MHz) can be read directly from the ionogram scale.

higher, straight up into the ionosphere. The frequencies of any echoes are recorded against time and then plotted as distance on an *ionogram*. **Figure 19.7** depicts a simple ionogram. Real-time ionograms can be found online at the Digital Ionogram Database, sponsored by the University of Massachusetts Lowell (<http://umlcdr.uml.edu/DIDBase/>). For an extensive discussion of ionogram interpretation, download *UAG-23A: URSI Handbook of Ionogram Interpretation and Reduction* from the Australian IPS (Ionospheric Prediction Service) website at [www.ips.gov.au/IPSHosted/INAG/uag\\_23a/uag\\_23a.html](http://www.ips.gov.au/IPSHosted/INAG/uag_23a/uag_23a.html). For more information about ionospheric sounding, see [k9la.us/Measuring\\_the\\_Ionosphere.pdf](http://k9la.us/Measuring_the_Ionosphere.pdf).

The highest frequency that returns echoes from the E and F regions at vertical incidence is known as the *vertical incidence or critical frequency*. (There is a D region critical frequency, but its value is well below 1 MHz and thus has minimal impact on our Amateur Radio bands.) The critical frequency is a function of ion density. The higher the ionization at a particular altitude, the higher becomes the critical frequency. Strictly speaking, the critical frequency is the term applicable to the peak electron density of a region. Physicists call any electron density in any part of the ionosphere a *plasma frequency*, because technically gases in the ionosphere are in a plasma, or partially ionized state. F layer critical frequencies commonly range from about 1 MHz to as high as 15 MHz.

### 19.2.4 Maximum and Lowest Usable Frequencies

When the frequency of a vertically incident signal is raised above the critical frequency of an ionospheric layer, that portion of the signal is unable to refract the signal

**Figure 19.8** — The relationships between critical frequency, maximum usable frequency (MUF) and skip zone can be visualized in this simplified, hypothetical case. The critical frequency is 7 MHz, allowing frequencies below this to be used for short-distance ionospheric communication by stations in the vicinity of point M. These stations cannot communicate by the ionosphere at 14 MHz. Stations at points B and E (and beyond) can communicate because signals at this frequency are refracted back to Earth because they encounter the ionosphere at an oblique angle of incidence. At greater distances, higher frequencies can be used because the MUF is higher at the larger angles of incidence (low launch angles). In this figure, the MUF for the path between points A and F, with a small launch angle, is shown to be 28 MHz. Each pair of stations can communicate at frequencies at or below the MUF of the path between them, but not below the LUF — see text.

back to Earth. However, a signal above the critical frequency may be returned to Earth if it enters the layer at an *oblique angle*, rather than at vertical incidence. This is fortunate because it permits two widely separated stations to communicate on significantly higher frequencies than the critical frequency. See **Figure 19.8**.

The highest frequency supported by the ionosphere between two stations is the *maximum usable frequency (MUF)* for that path. If the separation between the stations is increased, a still higher frequency can be supported at lower launch angles. The MUF for this longer path is higher than the MUF for the shorter path because more refraction can occur for electromagnetic waves that encounter the ionosphere

at more oblique angles. When the distance increased to the maximum one-hop distance the launch angle of the signals between two stations is zero (that is, the ray path tangential to the Earth at the two stations) and the MUF for this path is the highest that can be supported by that layer of the ionosphere at that location. This maximum distance is about 4000 km (2500 miles) for the F<sub>2</sub> layer and about 2000 km (1250 miles) for the E layer. See **Figure 19.9**.

The MUF is a function of path, time of day, season, location, solar UV and X-ray radiation levels and ionospheric disturbances. For vertically incident waves, the MUF is the same as the critical frequency. For path lengths at the limit of one-hop propagation, the MUF can

**Figure 19.9** — Signals at the MUF propagated at a low angle to the horizon provide the longest possible one-hop distances. In this example, 28 MHz signals entering the ionosphere at higher angles are not refracted enough to bring them back to Earth.

several times the critical frequency. The ratio between the MUF and the critical frequency is known as the *M-factor*.

The M-factor can be estimated using simple geometry in a spherical model of the Earth-ionosphere system. The angle of incidence on the ionosphere of an electromagnetic wave launched from the ground depends on the launch angle and the height of the ionospheric region. Due to the spherical geometry of the Earth-ionosphere system, the angle of incidence on the ionosphere does not approach zero as the launch angle approaches zero — it is limited to approximately 19° and 11° for the F<sub>2</sub> and E regions, respectively, which then limits the M-factor to approximately 3 and 2 for these two regions (from the equation  $MUF = 1 / \text{the sine of the angle of incidence in the ionosphere}$ ). See **Table 19.2** for typical M-factors of the various regions.

The term *skip zone* is closely related to MUF. When two stations are unable to communicate with each other on a particular frequency because the ionosphere is unable to refract the signal enough from one to the other through the required angle — that is, the operating frequency is above the MUF — the stations are said to be in the skip zone for that frequency. Stations within the skip zone may be able to work each other on a lower frequency, or by ground wave or other mechanisms if they are close enough. There is no skip zone at frequencies below the MUF.

The MUF at any time on a particular path is just that — the *maximum* usable frequency. Frequencies below the MUF will also propagate along the path, but ionospheric absorption and noise at the receiving location (due to man-made noise and/or noise from local or distant thunderstorms) may make the received signal-to-noise ratio too low to be usable. In this case, the frequency is said to be below the *lowest usable frequency* (LUF). This occurs most frequently below 10 MHz, where atmospheric and man-made noises are most troublesome.

The LUF can be lowered somewhat by the use of high power and directive antennas, or through the use of communication modes that permit reduced receiver bandwidth or are less demanding of SNR — CW or PSK31 instead of

SSB, for example. This is not true of the MUF, which is limited by the physics of ionospheric refraction, no matter how high your transmitter power or how narrow your receiver bandwidth. The LUF can be higher than the MUF. This is a common occurrence on 160 meters during the day due to too much absorption; another scenario would be too much noise on the higher bands due to thunderstorm activity or man-made noise. When the LUF is higher than the MUF, there is no frequency that supports communication on the particular path at that time.

### 19.2.5 NVIS Propagation

In the previous section, the statement was made that *stations within the skip zone may be able to work each other at a lower frequency, or by ground wave if they are close enough*. This statement summarizes the purpose of *Near Vertical Incidence Skywave (NVIS)* propagation — to bridge the gap between where ground wave is too weak and where the skip zone ends. By going to lower frequencies, communications can be maintained over these relatively short distances.

Propagation over short distances means high elevation angles — this is not DXing in which lower angles in general are most effective. For example, a path from San Francisco to Sacramento is 75 miles, and requires an average elevation angle of 78 degrees. To radiate maximum energy at these higher angles, relatively low height antennas need to be used.

In the December 2005 issue of *QST*, Dean Straw N6BV used the *VOACAP* propagation prediction program to analyze a variety of NVIS paths centered on San Francisco. His analysis showed area coverage maps (signal strength contours versus distance from the transmitter) and elevation patterns of antennas at various heights. His analysis allowed him to formulate a very nice summary: *As a rule-of-thumb, for ham band NVIS, I would recommend that 40 meters be used during the day; 80 meters during the night*. Additionally, during a winter night near solar minimum, changing to 160 meters may be necessary. Tom Kamp, DF5JL, also studied NVIS on the 60 meter band in Germany. See the References section entry for his article in *CQ DL*.

### 19.2.6 Ionospheric Fading

HF signal strengths typically rise and fall over periods of a few seconds to several minutes, and rarely hold at a constant level for very long. Fading is generally caused by the interaction of several radio waves from the same source arriving along different propagation paths. Waves that arrive in-phase combine to produce a stronger signal, while those out-of-phase cause destructive interference and lower net signal strength. Short-term variations in ionospheric conditions may change individual path lengths or signal strengths enough to cause fading. Even signals that arrive primarily over a single path may vary as the propagating medium changes. Fading may be most notable at sunrise and sunset, especially near the MUF, when the ionosphere undergoes dramatic transformations. Other ionospheric traumas, such as auroras and geomagnetic storms, also produce severe forms of HF fading.

### 19.2.7 Polarization at HF

Although the ionosphere varies on a short-term basis and results in somewhat random polarization, there is more order to polarization than realized. The ionosphere is immersed in the Earth's magnetic field, and the result of an electromagnetic wave propagating through an ionized medium (called a plasma, which is what our ionosphere is) immersed in a magnetic field is the propagation of two characteristic waves: the ordinary wave (O-wave) and the extraordinary wave (X-wave). Ordinary and extraordinary are terms borrowed from the science of optics. These two waves are generally elliptically polarized (the tip of the polarization vector traces out an ellipse), and are orthogonal to each other.

Upon entering the ionosphere, and depending on the location and the heading, a linearly polarized wave (from our horizontal or vertical antenna) will either couple all of its energy into the O-wave, all of its energy into the X-wave, or divide its energy into the O-wave and X-wave. Our horizontal antenna will couple best into one characteristic wave, and our vertical antenna will couple best into the other characteristic wave. The same coupling issue is present when the characteristic waves exit the ionosphere. The bottom line is that on the HF bands of 80 meters and higher, both characteristic waves generally propagate with similar absorption, and thus the use of a vertical or horizontal antenna is not too critical with respect to polarization. One of the characteristic waves will couple into whichever antenna is being used.

On 160 meters, though, the X-wave is heavily absorbed, leaving the O-wave. In general, vertical polarization is best for those of us in North America and at high northern latitudes. However, 160 meter operators have observed that under some conditions,

**Table 19.2**  
Maximum Usable Frequency Factors (M-factors) for 2000 km E Hops and 2000 km F Hops

Layer	Maximum Critical Frequency (MHz)	M-factor	Useful Operating Frequencies (MHz)
F <sub>2</sub>	15.0	3.3-4.0	1-60
F <sub>1</sub> *	5.5	4.0	10-20
E*	4.0	4.8	5-20
3000 MUFs	30.0	5.3	20-160

Daylight only

horizontally polarized antennas outperform vertically polarized antennas.

## 19.2.8 The 11-Year Solar Cycle

The density of ionospheric layers depends on the amount of solar radiation reaching the Earth, but solar radiation is not constant. Variations result from daily and seasonal motions of the Earth, the Sun's own 27-day rotation and the 11-year cycle of solar activity. One visual indicator of both the Sun's rotation and the solar cycle is the periodic appearance of dark spots on the Sun, which have been observed continuously since the mid-18th century. On average, the number of *sunspots* reaches a maximum every 10.7 years, but the period has varied between 7 and 17 years. Cycle 19 peaked in 1958, with a smoothed sunspot number of 201, the highest recorded to date. **Figure 19.10** shows the smoothed sunspot numbers (these values are the new Version 2.0 sunspot data) for the past six cycles.

Sunspots are cooler areas on the Sun's surface associated with high magnetic activity. Active regions adjacent to sunspot groups, called *plages*, are capable of producing great flares and sustained bursts of radiation in the radio through X-ray spectrum. During the peak of the 11-year solar cycle, average solar radiation increases along with the number of flares and sunspots. The ionosphere becomes more intensely ionized as a consequence, resulting in higher critical frequencies, particularly in the F<sub>2</sub> layer. The possibilities for long-distance communications are considerably improved during solar maxima, especially in the higher-frequency bands.

One key to forecasting F layer critical

frequencies, and thus long-distance propagation, is the intensity of ionizing UV and X-ray radiation. Until the advent of satellites, UV and X-ray radiation could not be measured directly, because they were almost entirely absorbed in the upper atmosphere during the process of ionization. The sunspot number provided the most convenient approximation of general solar activity. The sunspot number is not a simple count of the number of visual spots, but rather the result of a complicated formula that takes into consideration size, number and grouping. The smoothed sunspot number (equivalent to a running average of monthly mean sunspot numbers from 6 months before to 6 months after the desired month) varies from near zero during the solar cycle minimum to over 200 during an extremely active solar cycle.

Another method of gauging solar activity is the *solar flux*, which is a measure of the intensity of 2800 MHz (10.7 cm) radio noise coming from the Sun ( $10^{-22} \text{ W m}^{-2} \text{ Hz}^{-1}$ ). The smoothed 2800 MHz radio flux is an indication of the intensity of ionizing UV and X-ray radiation and provides a convenient alternative to sunspot numbers, as shown in **Figure 19.11** (note that this is only valid for converting between smoothed values). The Dominion Radio Astrophysical Observatory, Penticton, British Columbia, measures the 2800 MHz solar flux three times a day (centered on local noon). (A supplemental article, "The Penticton Solar Flux Receiver" from February 2013 *QST* is with the downloadable supplemental content.) Radio station WWV broadcasts the latest solar-flux index at 18 minutes after each hour; WWVH does the

**Figure 19.11 — Approximate conversion between solar flux and sunspot number. Note that this is for smoothed values of Solar Flux and Sunspot Numbers.**

same at 45 minutes after the hour. Solar flux and other useful data is also available online at [www.swpc.noaa.gov](http://www.swpc.noaa.gov).

The Penticton solar flux is employed in a wide variety of other applications. Daily, weekly, monthly and even smoothed solar flux readings are commonly used in propagation predictions (but be aware that our HF propagation predictions are based on the correlation between smoothed solar flux or smoothed sunspot number and monthly median ionospheric parameters — more on this later in the chapter).

High flux values generally result in higher MUFs, but the actual procedures for predicting the MUF at any given hour and path are quite complicated. Solar flux is not the sole determinant, as the angle of the Sun to the Earth, season, time of day, exact location of the radio path and other factors must all be taken into account. MUF forecasting a few days or months ahead involves additional variables and even more uncertainties.

### TRENDS IN SOLAR CYCLES

If one looks at all 23 recorded solar cycles, three characteristics stand out. First, we see the cyclic nature to the maximum smoothed sunspot numbers. Second, we've been through three high cycle periods of 50 years or so (consisting of several solar cycles) and two low cycle periods of 50 years or so (again consisting of several solar cycles), and we appear to be headed into a third low cycle period. Third, we've lived through the highest period of high cycle activity (but this is currently being challenged by solar scientists through an in-depth review of old sunspot records), which has allowed excellent worldwide propagation on the higher frequency bands and provided great enjoyment for radio amateurs.

If we look at solar cycles prior to recorded history through various proxies for solar

**Figure 19.10 — Smoothed sunspot numbers (SSN) through December 2019 for solar cycles 19 to 25.**

# Status of Solar Cycle 24

(This information was prepared in early February 2020 by Carl Luetzelshwab, K9LA)

We are nearing solar minimum. The NOAA/NASA Solar Cycle International Panel met in early December last year and they predict that solar minimum will be in April 2020 ( $\pm 6$  months). All we can do right now is wait and see if that actually happened.

As for Cycle 25 sunspots, we have seen several of them already. The first Cycle 25 sunspot occurred in December 2016, but it was so small and of such a short duration that it was not assigned an AR (Active Region) number. Similar small and short duration Cycle 25 sunspots occurred in April 2018, November 2018, May 2019 and early July 2019. None of these were assigned an AR number, either.

Later in July 2019 another Cycle 25 sunspot appeared. It was big enough and lasted long enough to be assigned AR2744. This is likely the first official Cycle 25 sunspot. More Cycle 25 sunspots occurred in November 2019 (AR2750, AR2751), December 2019 (AR2753, AR2754) and January 2020 (AR2755, AR2756). Cycle 25 is alive!

**Figure 19.A1** shows the monthly mean and smoothed sunspot numbers for the last solar minimum between Cycles 23 and 24. It shows that an old solar cycle and a new solar cycle overlap. Solar scientists can tell if a sunspot is from the old cycle or the new cycle by where the sunspot emerges on the solar disk (old cycle sunspots emerge near the solar equator and new cycle sunspots emerge at higher latitudes) and by the polarity of the sunspot region (the orientation of the white and black areas on a magnetogram).

Also note that during the last solar minimum, the first sunspot of the new cycle was seen about a year before solar minimum. Extrapolating this to the current solar minimum between Cycles 24 and 25 says we may see solar minimum in mid 2020. This falls in line with the Cycle 25 prediction from the NOAA/NASA Solar Cycle International Panel cited above.

**Figure 19.A2** shows the monthly mean and smoothed sunspot numbers for the current solar minimum between Cycles 24 and 25 (monthly means through January 2020).

The NOAA/NASA Solar Cycle International Panel also predicts that the peak of Cycle 25 will occur in July 2025 ( $\pm 8$  months) at a smoothed sunspot

**Figure 19.A1** — Monthly mean and smoothed sunspot numbers for the solar minimum between Cycles 23 and 24.

**Figure 19.A2** — Monthly mean and smoothed sunspot numbers for the solar minimum between Cycles 24 and 25.

number of 115. This makes it similar to Cycle 24 in magnitude. Again, all we can do is wait and see.

Until Cycle 25 starts its ascent in earnest, stay active on the low bands. On the higher frequency bands, 20 meters (and 17 meters to a lesser extent) should be open worldwide during the day and early evening. Look for occasional

north-south openings and openings to VK/ZL on 15 meters, 12 meters and 10 meters (thanks to the robust equatorial ionosphere). Don't forget sporadic-E on 10 meters and 6 meters in the summer months and in December. And take advantage of the better SNR performance of the digital modes.

activity (for example, carbon-14 in trees and beryllium-10 in ice cores), we'll see extended periods of very low solar activity referred to as Grand Minima (for example, the Maunder Minimum between 1640 and 1710 AD). It's likely that we'll again enter one of these extended periods, but trying to predict when this

will happen is, at best, a wild guess. With respect to solar minimum periods between solar cycles, historical data shows a great variation. The average length of solar minimum, for example defined as the number of months in which the smoothed sunspot number is below 20, is around 37 months. Using

this definition, the shortest minimum was 17 months (between Cycles 1 and 2) and the longest minimum was 96 months (between Cycles 5 and 6). The minimum period between Cycle 23 and Cycle 24 turned out to be 56 months. Interestingly, up until the minimum between Cycle 23 and Cycle 24, in our lifetimes we

have experienced minimum periods of approximately 24 months — much shorter than the average. This leads us to believe this recent solar minimum period was unusual. But historical data, with its great amount of variation, says otherwise.

### 19.2.9 The Sun's 27-Day Rotation

Sunspot observations also reveal that the Sun rotates on its own axis. The Sun is composed of extremely hot gases and does not turn uniformly (it is essentially a fluid). At the equator, the period is just over 25 days, but it approaches 35 days at the poles. Sunspots that affect the Earth's ionosphere, which appear almost entirely within 35° of the Sun's equator, take about 26 days for one rotation. After taking into account the Earth's movement around the Sun, the apparent period of solar rotation is about 27 days.

Active regions must face the Earth in the proper orientation to have an impact on the ionosphere. They may face the Earth only once before rotating out of view, but they often persist for several solar rotations. The net effect is that solar activity often appears in 27-day cycles corresponding to the Sun's rotation, even though the active regions themselves may last for several solar rotations.

The downloadable supplemental content includes articles about observing solar phenomena, including a *QST* article by Mark Spencer, WA8SME on building your own radio telescope. Numerous online sources such as [solar-center.stanford.edu/observe](http://solar-center.stanford.edu/observe) explain how to view the Sun for yourself. When observing the Sun, be sure to follow safe viewing practices as described in the online *Sky and Telescope* article "Safe Solar Viewing" by Jeff Medkeff ([www.skyandtelescope.com/observing/objects/sun/3309106.html](http://www.skyandtelescope.com/observing/objects/sun/3309106.html)).

### 19.2.10 Disturbances to Propagation

Like a campfire that occasionally spits out a flaming ember, our Sun sometimes erupts spasmodically — but on a much grander scale than a summer campfire here on Earth. After all, any event that violently releases as much as 10 billion tons of solar material traveling up to four and a half million miles per hour or releases large amounts of electromagnetic radiation at extremely short wavelengths has to be considered pretty impressive!

Following the lead of the Space Weather Prediction Center, there are three types of disturbances to propagation: geomagnetic storms (designated G), solar radiation storms (designated S) and radio blackouts (designated R). For more details and the scaling associated with these designators, visit [www.swpc.noaa.gov/noaa-scales-explanation](http://www.swpc.noaa.gov/noaa-scales-explanation).

## GEOMAGNETIC STORMS

Geomagnetic storms are generally caused by *coronal mass ejections* and high speed wind streams from *coronal holes*. A *coronal mass ejection* (CME) originates in the Sun's outer atmosphere — its corona. With several sophisticated satellites launched in the mid 1990s, we have gained powerful new tools to monitor the intricacies of solar activity. Using the latest satellite technology (and also some re-engineered earthbound instruments), scientists have observed many CMEs, greatly expanding our knowledge about them. Previously, the only direct observations we had of coronal activity were during solar eclipses — and eclipses don't occur very often. CMEs are observed with an instrument called a *coronagraph*, which has an occulting disk to block out the main portion of the Sun. In essence a coronagraph creates an artificial eclipse.

A *coronal hole* is a region on the Sun where the magnetic field is open to the interplanetary magnetic field (IMF) and ionized particles can escape into the solar wind. Normally the solar wind blows at approximately 400 km per second. During CMEs and coronal holes, solar wind speeds can increase to 2000 km per second.

Coronal holes and coronal mass ejections that are Earth-directed (these are also called full halo CMEs, as the explosion surrounds the occulting disk of a coronagraph) concurrent with the IMF oriented in a southerly direction result in the most disturbance to propagation. It usually takes up to a couple days for a CME or the effects of a coronal hole to reach and impact the Earth's ionosphere, so this generally gives us ample warning of the impending disturbance.

### SOLAR RADIATION STORMS AND RADIO BLACKOUTS

Solar radiation storms and radio blackouts are caused by large *solar flares*. When a large solar flare erupts from the Sun's surface, it can launch out into space a wide spectrum of electromagnetic energy. Since electromagnetic energy travels at the speed of light, the first indication of a solar flare reaches the Earth in about eight minutes. A large flare shows up as an increase in visible brightness near a sunspot group, accompanied by increases in UV and X-ray radiation and high levels of noise in the VHF radio bands. It is the X-ray radiation that results in radio blackouts on the daytime side of the Earth due to increased D region absorption, and this is called a *sudden ionospheric disturbance* (SID). The lower frequencies are affected for the longest period. In extreme cases, nearly all background noise will be gone as well. SIDs may last up to an hour, after which ionospheric conditions return to normal.

A large solar flare can also release matter

**Figure 19.12 — Geomagnetic activity (measured as the A index) also follows an 11-year cycle. Average values over the past few cycles show that geomagnetic activity peaks before and after the peak of solar flux.**

into space, mainly in the form of very energetic protons. These cause solar radiation storms, whereby increased absorption in the polar cap (that area inside the auroral oval) degrades over-the-pole paths. This is called a *polar cap absorption* (PCA) event. A PCA event may last for days, dramatically affecting transpolar HF propagation. An interesting fact with respect to PCAs is that they do not necessarily affect the northern and southern polar regions similarly. Thus if the short path between two points is degraded over one pole, the long path may still be available over the other pole.

At one time, scientists believed that solar flares and CMEs were causally related, but now they recognize that many CMEs occur without an accompanying flare. And while many flares do result in an ejection of some solar material, many do not. It now seems clear that flares don't cause CMEs and vice versa.

Since geomagnetic storms have the most impact to propagation, it is instructive to understand their occurrence statistics. The number of geomagnetic storms varies considerably from year to year, but peak geomagnetic activity follows the peak of solar activity. See **Figure 19.12**. Also, geomagnetic activity affects the ionosphere mostly in the equinox months (March and September).

**Table 19.3**  
**Geomagnetic Storms**

Typical Kp	Description	Days per Solar Cycle
9	Extreme	4
8	Severe	60
7	Strong	130
6	Moderate	360
5	Minor	900

## MONITORING GEOMAGNETIC ACTIVITY

Geomagnetic activity is monitored by devices known as *magnetometers*. These may be as simple as a magnetic compass rigged to record its movements. Small variations in the geomagnetic field are scaled to two measures known as the *K* and *A* indices. The *K* index provides an indication of magnetic activity on a finite logarithmic scale of 0-9, and it is updated every three hours. Very quiet conditions are reported as 0 or 1, while geomagnetic storm levels begin at 4. See **Table 19.3** for the latest NOAA descriptions of geomagnetic storms.

A worldwide network of magnetometers constantly monitors the Earth's magnetic field, because the Earth's magnetic field varies with location. *K* indices that indicate average planetary conditions are indicated as  $K_p$ . Daily geomagnetic conditions are also summarized by the open-ended linear *A* index, which corresponds roughly to the cumulative *K* index values (it's the daily average of the eight *K* indices after converting the *K* indices to a linear scale). The *A* index commonly varies between 0 and 30 during quiet to active conditions, and up to 100 or higher during geomagnetic storms.

At 18 minutes past the hour, radio station WWV broadcasts the solar flux measured at 2000 UTC, the prior day's planetary *A* Index and the latest mid latitude *K* Index. In addition, they broadcast a descriptive account of the condition of the geomagnetic field and a forecast for the next three hours. For more details about WWV broadcasts, visit [www.nist.gov/pml/div688/grp40/wwv\\_format.cfm](http://www.nist.gov/pml/div688/grp40/wwv_format.cfm). You should keep in mind that the *A* Index is a description of what happened yesterday. Strictly speaking, the *K* Index is valid only for mid latitudes. However, the trend of the *K* Index is very important for propagation analysis and forecasting. A rising *K* foretells worsening HF propagation conditions, particularly for transpolar paths. At the same time, a rising *K* alerts VHF operators to the possibility of enhanced auroral activity, particularly when the *K* Index rises above 3. Another source of useful information about solar disturbances is [www.spaceweather.com](http://www.spaceweather.com).

### 19.2.11 D Layer Propagation

The *D* layer is the lowest region of the ionosphere, situated between 55 and 90 km (30 and 60 miles). See **Figure 19.13**. It is ionized primarily by the strong emission of solar hydrogen at 121.5 nanometers and short-wavelength X-rays (so-called hard X-rays), both of which penetrate through the upper atmosphere to ionize nitric oxide (radiation at 121.5 nm) and all other constituents (hard X-rays). The *D* layer exists only during daylight, because constant radiation is needed to replenish ions that quickly recombine into neutral molecules. The *D* layer abruptly disappears at night so far

as amateur MF and HF signals are concerned. *D* layer ionization varies a small amount over the solar cycle. It is unsuitable as a refracting medium for MF and HF radio signals, but it is very important for VLF signals.

During daylight hours, radio energy as high as 5 MHz is effectively absorbed by the *D* layer, severely limiting the range of daytime 1.8- and 3.5 MHz signals. Signals at 7 MHz and 10 MHz pass through the *D* layer and on to the *E* and *F* layers only at relatively high angles. Low-angle waves, which must travel a much longer distance through the *D* layer, are subject to greater absorption. As the frequency increases above 10 MHz, radio waves pass through the *D* layer with increasing ease (less absorption).

*D* layer ionization falls 100-fold as soon as the Sun sets and the source of ionizing radiation is removed. Low-band HF signals are then free to pass through to the *E* layer (also greatly diminished at night) and on to the *F* layer, where the MUF is almost always high enough to propagate 1.8 and 3.5 MHz signals half way around the world. Long-distance propagation at 7 and 10 MHz generally improves at night as well, because absorption is less and low-angle waves are able to reach the *F* layer.

### 19.2.12 E Layer Propagation

The *E* layer lies between 90 and 150 km (60 and 90 miles) altitude, but a narrower region centered at 95 to 120 km (60 to 70 miles) is more important for radio propagation. In the *E* layer nitric oxide and molecular oxygen are ionized by short-wavelength UV and long-wavelength X-ray radiation (so-called soft X-rays). The normal *E* layer exists primarily during daylight hours, because like the *D* layer, it requires a constant source of ionizing radiation. Recombination

is not as fast as in the denser *D* layer and absorption is much less. The *E* layer has a daytime critical frequency that varies between 3 and 4 MHz with the solar cycle. At night, the normal *E* layer decays to a minimum critical frequency of 0.3 – 0.5 MHz, which is still enough to refract low elevation angle 1.8 MHz signals.

### DAYTIME E LAYER

The *E* layer plays a small role in propagating HF signals but can be a major factor limiting propagation during daytime hours. Its usual critical frequency of 3 to 4 MHz, with an *M*-factor of about 5, suggests that single-hop *E* layer skip might be useful between 5 and 20 MHz at distances up to 2300 km (1400 miles). In practice this is not the case, because the potential for *E* layer skip is severely limited by *D* layer absorption. Signals radiated at low angles at 7 and 10 MHz, which might be useful for the longest-distance contacts, are largely absorbed by the *D* layer. Only high-angle signals pass through the *D* layer at these frequencies, but high-angle *E* layer skip is typically limited to 1200 km (750 miles) or so. Signals at 14 MHz penetrate the *D* layer at lower angles at the cost of some absorption, but the casual operator may not be able to distinguish between signals propagated by the *E* layer or higher-angle *F* layer propagation.

An astonishing variety of other propagation modes find their home in the *E* layer, and this perhaps more than makes up for its ordinary limitations. Each of these other modes — sporadic *E*, field-aligned irregularities, aurora, auroral *E* and meteor scatter — are related forms of *E* layer propagation with unique characteristics. They are primarily useful only on the highest HF and lower VHF bands.

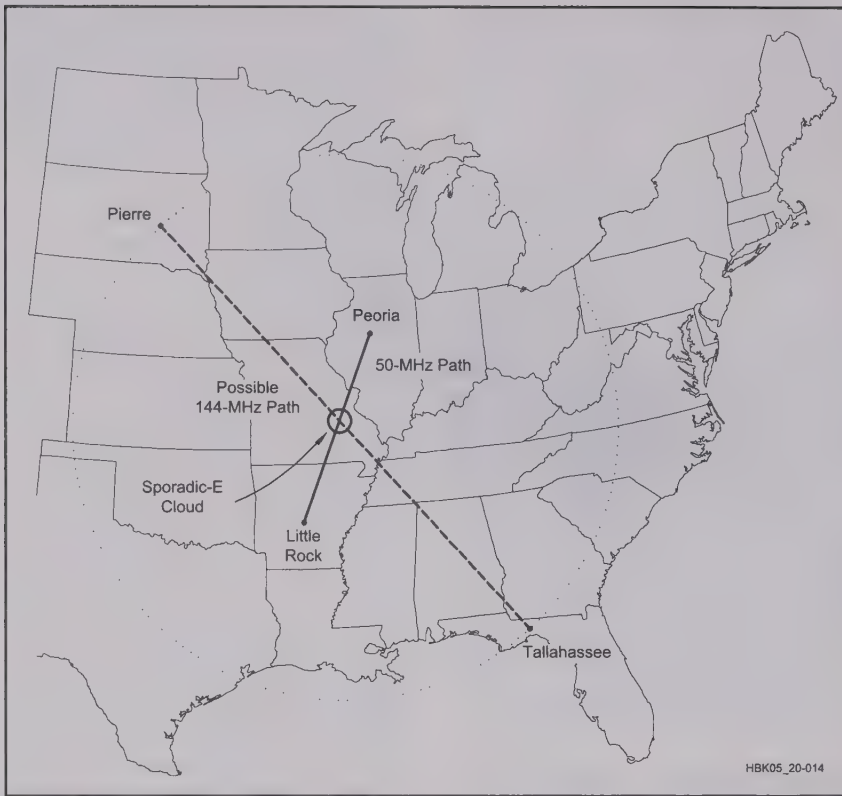

### SPORADIC E

*Short skip*, long familiar on the 10 meter band during the summer months, affects the VHF bands as high as 222 MHz. *Sporadic E* ( $E_s$ ), as this phenomenon is properly called, commonly propagates 28, 50 and 144 MHz radio signals between 500 and 2300 km (300 and 1400 miles). Signals are apt to be exceedingly strong, allowing even modest stations to make  $E_s$  contacts. At 21 MHz, the skip distance may only be a few hundred km. During the most intense  $E_s$  events, skip may shorten to less than 200 km (120 miles) on the 10 meter band and disappear entirely on 15 meters. Multiple-hop  $E_s$  has supported contacts up to 10,000 km (6200 miles) on 28 and 50 MHz and more than 3000 km (1900 miles) on 144 MHz. The first confirmed 220 MHz  $E_s$  contact was made in June 1987, but such contacts are likely to remain very rare.

Sporadic *E* at mid latitudes (roughly 15° to 45°) may occur at any time, but it is most common in the Northern Hemisphere during May, June and July, with a less-intense season

**Figure 19.13** — Typical electron densities for the various ionospheric regions.

**Figure 19.14** — 50 MHz sporadic E contacts of 700 km (435 miles) or shorter (such as between Peoria and Little Rock) indicate that the MUF on longer paths is above 144 MHz. Using the same sporadic E region reflecting point, 144 MHz contacts of 2200 km (1400 miles), such as between Pierre and Tallahassee, should be possible.

at the end of December and early January. Its appearance is independent of the solar cycle. Sporadic E propagation is most likely to occur from 9 AM to noon local time and again early in the evening between 5 PM and 8 PM. Mid latitude E<sub>s</sub> events may last only a few minutes or can persist for many hours. In contrast, sporadic E is an almost constant feature of the polar regions at night and the equatorial belt during the day.

Efforts to predict mid latitude E<sub>s</sub> have not been successful, probably because its causes are complex and not well understood. Studies have demonstrated that thin and unusually dense patches of ionization in the E layer, between 100 and 110 km (60 and 70 miles) altitude and 10 to 100 km (6 to 60 miles) in extent, are responsible for most E<sub>s</sub> reflections. Sporadic E clouds may form suddenly, move quickly from their birthplace, and dissipate within a few hours. Professional studies have recently focused on the role of heavy metal ions, probably of meteoric origin, and wind shears as two key factors in creating the dense patchy regions of E layer ionization.

Sporadic E clouds exhibit an MUF that can rise from 28 MHz through the 50 MHz band and higher in just a few minutes. When the skip distance on 28 MHz is as short as 400

or 500 km (250 or 310 miles), it is an indication that the MUF has reached 50 MHz for longer paths at low launch angles. Contacts at the maximum one-hop sporadic E distance, about 2300 km (1400 miles), should then be possible at 50 MHz. *E-skip* (yet another term for sporadic E) contacts as short as 700 km (435 miles) on 50 MHz, in turn, may indicate that 144 MHz contacts in the 2300 km (1400 mile) range can be completed. See **Figure 19.14**. Sporadic E openings occur about a tenth as often at 144 MHz as they do at 50 MHz and for much shorter periods.

Sporadic E can also have a detrimental effect on HF propagation by masking the F<sub>2</sub> layer from below. HF signals may be prevented from reaching the higher levels of the ionosphere and the possibilities of long F<sub>2</sub> skip. Reflections from the tops of sporadic E clouds can also have a masking effect, but they may also lengthen the F<sub>2</sub> propagation path with a top-side intermediate hop that never reaches the Earth.

### E LAYER FIELD-ALIGNED IRREGULARITIES

Amateurs have experimented with a little-known scattering mode known as *field-aligned irregularities* (FAI) at 50 and 144 MHz since

1978. FAI commonly appears directly after sporadic E events and may persist for several hours. Oblique-angle scattering becomes possible when electrons are compressed together due to the action of high-velocity ionospheric acoustic (sound) waves. The resulting irregularities in the distribution of free electrons are aligned parallel to the Earth's magnetic field, in something like moving vertical rods. A similar process of electron field-alignment takes place during radio aurora, making the two phenomena quite similar.

Most reports suggest that 8 PM to midnight may be the most productive time for FAI. Stations attempting FAI contacts point their antennas toward a common scattering region that corresponds to an active or recent E<sub>s</sub> reflection point. The best direction must be probed experimentally, for the result is rarely along the great-circle path. Stations in south Florida, for example, have completed 144 MHz FAI contacts with north Texas when participating stations were beamed toward a common scattering region over northern Alabama.

FAI-propagated signals are weak and fluttery, reminiscent of aurora signals. Doppler shifts of as much as 3 kHz have been observed in some tests. Stations running as little as 100 W and a single Yagi should be able to complete FAI contacts during the most favorable times, but higher power and large antennas may yield better results. Contacts have been made on 50 and 144 MHz, and 222 MHz FAI seems probable as well. Expected maximum distances should be similar to other forms of E layer propagation, or about 2300 km (1400 miles).

### AURORA

Radar signals as high as 3000 MHz have been scattered by the *aurora borealis* or northern lights (*aurora australis* in the Southern Hemisphere), but amateur aurora contacts are common only from 28 through 432 MHz. By pointing directional antennas generally northward toward the center of aurora activity, oblique paths between stations up to 2300 km (1400 miles) apart can be completed. See **Figure 19.15**. High power and large antennas are not necessary. Stations with small Yagis and a little as 10 W output have used auroras on frequencies as high as 432 MHz, but contacts at 902 MHz and higher are exceedingly rare. Auroral propagation works just as well in the Southern Hemisphere, in which case antennas must be pointed south.

The appearance of auroras is closely linked to solar activity. During massive geomagnetic storms, low energy particles that were trapped in the magnetosphere flow into the atmosphere near the polar regions, where they ionize the gases of the E layer and higher. This unusual ionization produces spectacular visual aurora displays, which often spread southward into the mid latitudes. Higher energy electrons ge-

## AURORAL E

HBK05\_20-015

**Figure 19.15 — Point antennas generally north to make oblique long-distance contacts on 28 through 432 MHz via aurora scattering. Optimal antenna headings may shift considerably to the east or west depending on the location of the aurora. This necessitates moving your antenna azimuth direction for best propagation, and continuing to do so as the aurora progresses.**

down to lower altitudes to cause auroral ionization (via collisions with neutral particles) in the E layer, and this scatters radio signals in the VHF and UHF ranges.

In addition to scattering radio signals, auroras have other effects on worldwide radio propagation. Communication below 20 MHz is disrupted in high latitudes, primarily by absorption, and is especially noticeable over polar and near-polar paths. Signals on the AM broadcast band through the 40 meter band late in the afternoon may become weak and watery. The 20 meter band may close down altogether. Satellite operators have also noticed that 144 MHz downlink signals are often weak and distorted when satellites pass near the polar regions. At the same time, the MUF in equatorial regions may temporarily rise dramatically, including an enhancement of transequatorial paths at frequencies as high as 50 MHz.

Auroras occur most often around the spring and fall equinoxes (March-April and September-October), but auroras may appear in any month. Auroral activity generally peaks about two years before and after solar cycle maximum (the “before” generally due to CMEs and the “after” generally due to high-speed wind streams from coronal holes). Radio aurora activity is usually heard first in late afternoon and may reappear later in the evening. Auroras may be anticipated by following the A and K indices reports on WWV. A K index of five or greater and an A index of at least 30 are indications that a geomagnetic storm is in progress and an aurora likely. The probability, intensity and southerly extent of auroras increase as the two index numbers

rise. Stations north of 42° latitude in North America experience many auroral openings each year, while those in the Gulf Coast states may hear auroral signals no more than once a year, if that often.

Aurora-scattered signals are easy to identify. On 28- and 50 MHz SSB, signals sound very distorted and somewhat wider than normal; at 144 MHz and above, the distortion may be so severe that only CW is useful. Auroral CW signals have a distinctive note variously described as a buzz, hiss or mushy sound. This characteristic auroral signal is due to Doppler broadening, caused by the movement of electrons within the aurora. An additional Doppler shift of 1 kHz or more may be evident at 144 MHz and several kilohertz at 432 MHz. This second Doppler shift is the result of massive electrical currents that sweep electrons toward the Sun side of the Earth during magnetic storms. Doppler shift and distortion increase with higher frequencies, while signal strength dramatically decreases.

It is not necessary to see an aurora to make auroral contacts. Useful auroras may be 500-1000 km (310-620 miles) away and below the visual horizon. Antennas should be pointed generally north and then probed east and west to peak signals, because auroral ionization is field aligned. This means that for any pair of stations, there is an optimal direction for aurora scatter. Offsets from north are usually greatest when the aurora is closest and often provide the longest contacts. There may be some advantage to antennas that can be elevated, especially when auroras are high in the sky.

Radio auroras may evolve into a propagation mode known as *auroral E* at 21, 28, 50 and rarely 144 MHz. Auroral E is essentially sporadic E in the auroral zone. Doppler distortion disappears and signals take on the characteristics of sporadic E. The most effective antenna headings shift dramatically away from oblique aurora paths to direct great-circle bearings. The usual maximum distance is 2300 km (1400 miles), typical for E layer modes, but 28 and 50 MHz auroral E contacts of 5000 km (3100 miles) are sometimes made across Canada and the northern US, apparently using two hops. Contacts at 50 MHz between Alaska and the east coasts of Canada and the northern US have been completed this way. Transatlantic 50 MHz auroral E paths are also likely.

Typically, 28 and 50 MHz auroral E appears across the northern third of the US and southern Canada when aurora activity is diminishing. This usually happens after midnight on the eastern end of the path. Auroral E signals sometimes have a slightly hollow sound to them and build slowly in strength over an hour or two, but otherwise they are indistinguishable from sporadic E. Auroral E paths are almost always east-west oriented, perhaps because there are few stations at very northern latitudes to take advantage of this propagation. A common auroral E path on 28 MHz and 21 MHz is from North America in the late afternoon hours in the autumn months to the Scandinavian countries. This path is open when normal F layer propagation is not possible — even to more southern locations in Europe.

Auroral E may also appear while especially intense auroras are still in progress, as happened during the great aurora of March 1989. On that occasion, 50 MHz propagation shifted from Doppler-distorted aurora paths to clear-sounding auroral E over a period of a few minutes. Many 6 meter operators as far south as Florida and Southern California made single- and double-hop auroral E contacts across the country. At about the same time, the MUF reached 144 MHz for stations west of the Great Lakes to the Northeast, the first time auroral E had been reported so high in frequency.

## METEOR SCATTER

Contacts between 800 and 2300 km (500 and 1400 miles) can be made at 28 through 432 MHz via reflections from the ionized trails left by meteors as they travel through the atmosphere. The kinetic energy of meteors no larger than grains of rice are sufficient to ionize a column of air 20 km (12 miles) long in the E layer. The particle itself evaporates and never reaches the ground, but the ionized column may persist for a few seconds to a minute or more before it dissipates. This is enough time

**Figure 19.16** — The relative velocity of meteors that meet the Earth head-on is increased by the rotational velocity of the Earth in orbit. Fast meteors strike the morning side of the Earth because their velocity adds to the Earth's rotational velocity, while the relative velocity of meteors that "catch up from behind" is reduced.

to make very brief contacts by reflections from the ionized trails. Millions of meteors enter the Earth's atmosphere every day, but few have the required size, speed and orientation to the Earth to make them useful for meteor-scatter propagation.

Radio signals in the 30 to 100 MHz range are reflected best by meteor trails, making the 50 MHz band prime for meteor-scatter work. The early morning hours around dawn are usually the most productive, because the morning side of the Earth faces in the direction of the planet's orbit around the Sun. The relative velocity of meteors that head toward the Earth's

morning side are thus increased by up to 30 km/sec, which is the average rotational speed of the Earth in orbit. See **Figure 19.16**. The maximum velocity of meteors in orbit around the Sun is 42 km/sec. Thus when the relative velocity of the Earth is considered, most meteors meet between 12 and 72 km/sec.

Meteor contacts ranging from a second or two to more than a minute can be made nearly any morning at 28 or 50 MHz. Meteor-scatter contacts at 144 MHz and higher are more difficult because reflected signal strength and duration drop sharply with increasing frequency. A meteor trail that provides 30 seconds of communication at 50 MHz will last only a few seconds at 144 MHz, and less than a second at 432 MHz.

Meteor scatter opportunities are somewhat better during July and August for North America because the average number of meteors entering the Earth's atmosphere peaks during those months. The best times are during one of the great annual *meteor showers*, when the number of useful meteors may increase ten-fold over the normal rate of five to ten per hour. See **Table 19.4**. A meteor shower occurs when the Earth passes through a relatively dense stream of particles, thought to be the remnants of a comet in orbit around the Sun. The most-productive showers are relatively consistent from year to year, although several can occasionally produce great storms.

Because meteors provide only fleeting moments of communication even during one of the great meteor showers, special operating techniques are often used to increase the chances of completing a contact. Prearranged schedules between two stations establish times, frequencies and precise operating standards. Usually, each station transmits on alternate 15-second periods until enough information is pieced together a bit at a time to confirm contact. High-speed Morse code of several hundred words per minute, generated and slowed down by special computer programs, can make effective use of very short meteor bursts. Non-scheduled random meteor contacts are common on 50 MHz and 144 MHz, but short transmissions and alert operating habits are required.

It is helpful to run several hundred watts to a single Yagi, but meteor-scatter can be used by modest stations under optimal conditions. During the best showers, a few watts and a small directional antenna are sufficient at 28 or 50 MHz. At 144 MHz, at least 100 W output and a long Yagi are needed for consistent results. Proportionately higher power is required for 222 and 432 MHz even under the best conditions.

A technique allowing even

smaller VHF/UHF stations to take advantage of meteor scatter and other modes (ionospheric scatter and even moonbounce) is available in software called *WSJT*. This software uses the sound card in a PC and a variety of modulation and coding techniques to allow reception of signals up to 10 dB below your noise level. For more information, visit [www.physics.princeton.edu/pulsar/K1JT/](http://www.physics.princeton.edu/pulsar/K1JT/).

### 19.2.13 F Layer Propagation

The region of the *F layers*, from 150 km (90 miles) to over 400 km (250 miles) altitude, is by far the most important for long-distance HF communications. F-region oxygen atoms are ionized primarily by ultraviolet radiation. During the day, ionization reaches maxima in two distinct layers. The *F<sub>1</sub>* layer forms between 150 and 250 km (90 and 160 miles), is most prevalent in the summer months, and disappears at night. The *F<sub>2</sub>* layer extends above 250 km (160 miles), with a peak of ionization around 300 km (190 miles). At night, F-region ionization collapses into one broad layer at 300-400 km (190-250 miles) altitude. Ions recombine very slowly at these altitudes, because atmospheric density is relatively low. Maximum ionization levels change significantly with time of day, season and year of the solar cycle.

#### F<sub>1</sub> LAYER

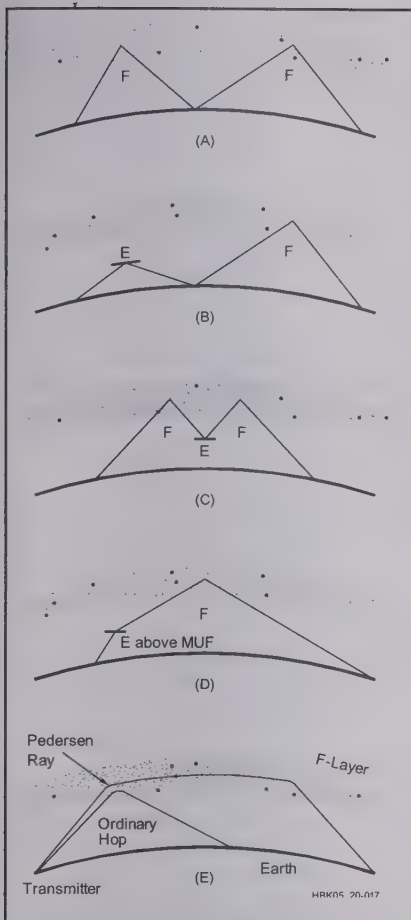

The daytime *F<sub>1</sub>* layer is not very important to HF communication. In reality it is an inflection point in the electron density profile, not a peak. It exists only during daylight hours and is largely absent in winter. Radio signals below 10 MHz are not likely to reach the *F<sub>1</sub>* layer, because they are either absorbed by the D layer or refracted by the E layer. Signals higher than 20 MHz that pass through both of the lower ionospheric regions are likely to pass through the *F<sub>1</sub>* layer as well, because the *F<sub>1</sub>* MUF rarely rises above 20 MHz. Absorption diminishes the strength of any signals that continue through to the *F<sub>2</sub>* layer during the day. Some useful *F<sub>1</sub>* layer refraction may take place between 10 and 20 MHz during summer days, yielding paths as long as 3000 km (1900 miles), but these would be practically indistinguishable from *F<sub>2</sub>* skip.

#### F<sub>2</sub> AND NIGHTTIME F LAYERS

The *F<sub>2</sub>* layer forms between 250 and 400 km (160 and 250 miles) during the daytime and persists throughout the night as a single consolidated F region 50 km (30 miles) higher in altitude. Typical ion densities are the highest of any ionospheric layer, with the possible exception of some unusual E layer phenomenon. In contrast to the other ionospheric layers, *F<sub>2</sub>* ionization varies considerably with time of day, season and position in the solar cycle, but it is never altogether

**Table 19.4**  
**Major Annual Meteor Showers**

Name	Peak Dates	Approximate Rate (meteors/hour)
Quadrantids	Jan 3	50
Arietids	Jun 7-8	60
Perseids	Aug 11-13	80
Orionids	Oct 20-22	20
Geminids	Dec 12-13	60

**Figure 19.17** — Multihop paths can take many different configurations, including a mixture of E and F layer hops. (A) Two F layer hops. Five or more consecutive F layer hops are possible. (B) An E layer hookup to the F layer. (C) A top-side E layer reflection can shorten the distance of two F layer hops. (D) Refraction in the E layer above the MUF is insufficient to return the signal to Earth, but it can go on to be refracted in the F layer. (E) The Pedersen Ray, which originates from a signal launched at a relatively high angle above the horizon into the E or F region, may result in a single-hop path, 5000 km (3100 miles) or more. This is considerably further than the normal 4000 km (2500 mile) maximum F-region single-hop distance, where the signal is launched at a very low takeoff angle. The Pedersen Ray can easily be disrupted by any sort of ionospheric gradient or irregularity. Not shown in this figure is a chordal hop — since chordal hops are most prevalent in the equatorial ionosphere, refer to Figure 19.21 and Figure 19.22.

the maximum  $F_2$  region electron density, and requires a fairly stable ionosphere. Pedersen ray paths are most evident over high-latitude east-west paths at frequencies near the MUF. They appear most often about noon local time at mid-path when the geomagnetic field is very quiet. Pedersen ray propagation may be responsible for 50 MHz paths between the US Northeast and Western Europe, for example, when ordinary MUF analysis could not explain the 5000 km contacts. See part E in Figure 19.17.

At any given location on Earth, in general both  $F_2$  layer ionization and MUF at that point build rapidly at sunrise, usually reaching a maximum after local noon, and then decrease to a minimum at night prior to the next sunrise. Depending on the season, the MUF is generally highest within  $20^\circ$  of the equator and lower toward the poles. For this reason, transequatorial paths may be open at a particular frequency when all other paths are closed.

In contrast to all the other ionospheric layers, daytime ionization in the winter  $F_2$  layer averages four times the level of the summer at the same period in the solar cycle, doubling the MUF. This so-called *winter anomaly* is caused by a seasonal increase in the ratio of atoms to molecules at  $F_2$  layer heights (atoms are instrumental in the production of electrons, whereas molecules are instrumental in the loss of electrons). Winter daytime  $F_2$  conditions are much superior to those in summer, because the MUF is much higher.

### MULTIHOP F LAYER PROPAGATION

Most HF communication beyond 4000 km (2500 miles) takes place via multiple ionospheric hops. Radio signals are reflected from the Earth back toward space for additional

ionospheric refractions. A series of ionospheric refractions and terrestrial reflections commonly create paths half-way around the Earth. Each hop involves additional attenuation and absorption, so the longest-distance signals tend to be the weakest. Even so, it is possible for signals to be propagated completely around the world and arrive back at their originating point. Multiple reflections within the F layer may at times bypass ground reflections altogether, creating what are known as *chordal hops*, with lower total attenuation. It takes a radio signal about 0.14 seconds to make an around-the-world trip.

Multihop paths can take on many different configurations, as shown in the examples of Figure 19.17. E layer (especially sporadic E) and F layer hops may be mixed. In practice, multi-hop signals arrive via many different paths, which often increases the problems of fading. Analyzing multi-hop paths is complicated by the effects of D and E layer absorption, possible reflections from the tops of sporadic E layers, disruptions in the auroral zone and other phenomena.

In general, when a band is opening and closing as the MUF changes, extremely low elevation angles are dictated (less than  $5^\circ$ ). During the main part of the opening, the elevation angle is higher — generally in the range of  $5^\circ$  to  $20^\circ$ . This is why stations with extremely high antennas (which have higher gain at lower takeoff angles) perform better at band openings and closings.

### F LAYER LONG PATH

Most HF communication takes place along the shortest great-circle path between two stations. Short-path propagation is always less than 20,000 km (12,000 miles) — halfway around the Earth. Nevertheless, it may be possible at times to make the same contact in exactly the opposite direction via the *long path*. The long-path distance will be 40,000 km (25,000 miles) minus the short-path length. Signal strength via the long path is usually considerably less than the more direct short-path. When both paths are open simultaneously, there may be a distinctive sort of echo on received signals. The time interval of the echo represents the difference between the short-path and long-path distances.

Sometimes there is a great advantage to using the long path when it is open, because signals can be stronger and fading less troublesome, or because fewer interfering signals lie along the path between the stations. There are times when the short path may be closed or disrupted by E layer *blanketing* (when the E-region ionization is high enough to keep waves from penetrating, regardless of elevation angle), D layer absorption or F layer gaps, especially when operating just below the MUF. Long paths that predominantly cross the night side of the Earth, for example, are sometimes

absent. These two characteristics make the  $F_2$  layer the most important for long-distance HF communications.

The  $F_2$  layer MUF is nearly a direct function of ultraviolet (UV) solar radiation, which in turn closely follows the solar cycle. During the lowest years of the cycle, the daytime MUF may climb above 14 MHz for only a few hours a day. In contrast, the MUF may rise beyond 50 MHz during peak years and stay above 14 MHz throughout the night. The virtual height of the  $F_2$  region averages 330 km (210 miles), but varies between 200 and 400 km (120 and 250 miles). Maximum one-hop distance is about 4000 km (2500 miles). Near-vertical incidence skywave propagation just below the critical frequency provides reliable coverage out to 200-300 km (120-190 miles) with no skip zone. It is most often observed on 7 MHz during the day.

The extremely high-angle *Pedersen ray* can create effective single-hop paths of 5000 to 12,000 km under certain conditions, but most operators will not be able to distinguish Pedersen Ray paths from normal F layer propagation. A Pedersen ray is a path that follows the contour of the Earth near the height of

**Figure 19.18** — The gray line encircles the Earth, but the tilt at the equator to the poles varies over 46° with the seasons. Long-distance contacts on 1.8 MHz and 3.5 MHz at more than halfway around the Earth can be enabled by the gray line, putting both ends of the path near darkness and allowing RF to cut across the dark ionosphere with minimal absorption. The strength of the signals indicates that multiple Earth-ionosphere hops are not the likely mode of propagation, since losses in many such hops would be prohibitive. Ducting in the electron density valley above the E region peak in the dark ionosphere is the likely mechanism.

useful because they generally avoid blanketing and absorption problems. Daylight-side long paths may take advantage of higher F layer MUFs that occur over the sunlit portions of the Earth.

### F LAYER GRAY-LINE

*Gray-line* paths can be considered a special form of long-path propagation that takes into account the unusual ionospheric configuration along the twilight region between night and day. The gray line, as the twilight region is sometimes called, extends completely around the world. It is not precisely a line, for the distinction between daylight and darkness is a gradual transition due to atmospheric scattering. On one side, the gray line heralds sunrise and the beginning of a new day; on the opposite side, it marks sunset and the end of the day.

The ionosphere undergoes a significant transformation between night and day. As day begins, the highly absorbent D and E layers are recreated, while the F layer MUF rises from its pre-dawn minimum. At the end of the day, the D and E layers quickly disappear, while the F layer MUF continues its slow decline from late afternoon. For a brief period just along the gray-line transition, the D and E layers are not well formed, yet the F<sub>2</sub> MUF usually remains higher than 5 MHz. This would normally provide a special opportunity for stations at

**Figure 19.19** — Schematic of a simple backscatter path. Stations A and B are too close to make contact via normal F layer ionospheric refraction. Signals scattered back from a distant point on the Earth's surface (S), often the ocean, may be accessible to both and create a backscatter circuit.

**Figure 19.20** — Backscatter path across the gray line. Stations A and B are too close to make contact via normal ionospheric refraction, but may hear each other's signals scattered from point S. Station A makes use of a high-angle refraction on the day side of the gray line, where the MUF is high. Station B makes use of a night-time refraction, with a lower MUF and lower angle of propagation. Note that station A points away from B to complete the circuit.

1.8 and 3.5 MHz but for:

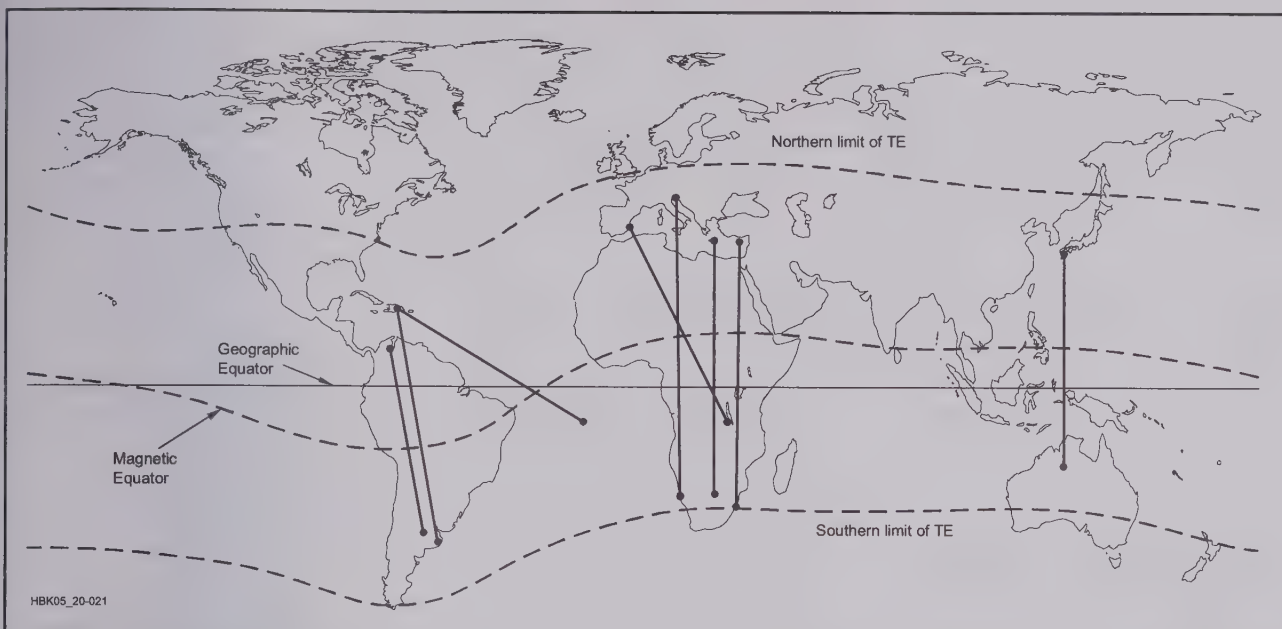

- ionospheric absorption is still high on these bands in this twilight region from an understanding of the physics of absorption, and
- the electron density gradient across the gray line (also known as the terminator) skews RF away from the day ionosphere into the night ionosphere (shown by ray tracing studies taking into account the Earth's magnetic field and the electron-neutral collision frequency).

What this means is that contrary to decades of popular belief, propagation along the terminator on the low bands is not efficient and it is not possible for RF on these bands to even follow the terminator. This is supported by the fact that there has never been a report of enhanced propagation on these bands along a short path that is aligned with the gray line.

Normally, long-distance communication on these two amateur bands takes place only via all-darkness paths because of daytime D layer absorption. The gray-line propagation

path extends completely around the world. See **Figure 19.18**. Thus what's important about gray line is that it puts both ends of the path very near darkness. What really appears to be happening is that the RF is taking a short cut across the dark ionosphere. This requires a skew point to join the two great circle paths in the dark ionosphere. This requires a skew point to join the two great circle paths in the dark ionosphere. This requires a skew point to join the two great circle paths in the dark ionosphere. For an investigation of this phenomena, read the article *Gray Line Propagation, or Florida to Cocos (Keeling) on 80m* with the downloadable supplemental content.

To take advantage of these paths, you need to understand the mechanics of gray line. The gray line generally runs north-south, but it varies by 23° either side of true north as measured at the equator over the course of the year. This variation is caused by the tilt in the Earth's axis. The gray line is exactly north-south through the poles at the equinoxes (March 21 and September 21) and is at its 23° extremes on June 21 and December 20.

**Figure 19.21** — Transequatorial propagation takes place between stations equidistant across the geomagnetic equator. Distances up to 8000 km (5000 miles) are possible on 28 through 432 MHz. Note the geomagnetic equator is considerably south of the geographic equator in the Western Hemisphere.

Over a one-year period, the gray line crosses a 46° sector of the Earth north and south of the equator, providing optimum paths to slightly different parts of the world each day. Many commonly available computer programs plot the gray line on a flat map or globe.

A web-based application to calculate worldwide sunrise and sunset times is available at [aa.usno.navy.mil/data/docs/RS\\_OneDay.html](http://aa.usno.navy.mil/data/docs/RS_OneDay.html). An alternative method of determining sunrise and sunset times, along with seeing great circle paths on the same plot, is W6EL's *W6ELProp* software, available free at [www.qsl.net/w6elprop](http://www.qsl.net/w6elprop). For an online gray line map, visit [dx.qsl.net/propagation/greyline.html](http://dx.qsl.net/propagation/greyline.html).

## F LAYER BACKSCATTER AND SIDESCATTER

Special forms of F layer scattering can create unusual paths within the skip zone. *Backscatter* and *sidescatter* signals are usually observed just below the MUF for the direct path and allow communications not normally possible by other means. Stations using backscatter point their antennas toward a common scattering region at the one-hop distance, rather than toward each other. Backscattered signals are generally weak and have a characteristic hollow sound. Useful communication distances range from 100 km (60 miles) to the normal one-hop distance of 4000 km (2500 miles).

Backscatter and sidescatter are closely related and the terminology does not precisely distinguish the two. Backscatter usually refers to single-hop signals that have been scattered by the Earth or the ocean at some

distant point back toward the transmitting station. Two stations spaced a few hundred km apart can often communicate via a backscatter path near the MUF. See **Figure 19.19**.

Sidescatter usually refers to a circuit that is oblique to the normal great-circle path and is sometimes referred to as *skew path*. Two stations can make use of a common side-scattering region well off the direct path, often toward the south. European and North American stations sometimes complete 28 MHz contacts via a scattering region over Africa. U.S. and Finnish 50 MHz operators observed a similar effect early one morning in November 1989 when they made contact by beaming off the coast of West Africa.

When backscattered signals cross an area where there is a sharp gradient in ionospheric density, such as between night and day, the path may take on a different geometry, as shown in **Figure 19.20**. In this case, stations can communicate because backscattered signals return via the day side ionosphere on a shorter hop than the night side. This is possible because the dayside MUF is higher and thus the skip distance shorter. The net effect is to create a backscatter path between two stations within the normal skip zone.

## TRANSEQUATORIAL PROPAGATION

Discovered by Amateur Radio operators in 1947, *transequatorial propagation* (commonly abbreviated TE or TEP) supports propagation between 5000 and 8000 km (3100 and 5000 miles) across the magnetic equator from 28 MHz to as high as 432 MHz. Stations attempting TE contacts must be nearly equidistant

from the geomagnetic equator. Many contacts have been made at 50 and 144 MHz between Europe and South Africa, Japan and Australia and the Caribbean region and South America. Fewer contacts have been made on the 222 MHz band, and TE signals have been heard at 432 MHz.

Unfortunately for most continental US stations, the *geomagnetic equator* dips south of the geographic equator in the Western Hemisphere, as shown in **Figure 19.21**, making only the most southerly portions of Florida and Texas within TE range. TE contacts from the southeastern part of the country may be possible with Argentina, Chile and even South Africa.

Transequatorial propagation peaks between 5 PM and 10 PM during the spring and fall equinoxes, especially during the peak years of the solar cycle. The lowest probability is during the summer. Quiet geomagnetic conditions are required for TE to form. High power and large antennas are not required to work TE, as VHF stations with 100 W and single long Yagis have been successful.

TE propagation depends on bulges of intense F<sub>2</sub> layer ionization on both sides of the geomagnetic equator. This field-aligned ionization forms shortly after sunset via a process known as the *fountain effect* in an area 100-200 km (60-120 miles) north and south of the geomagnetic equator and 500-3000 km (310-1900 miles) wide. It moves west with the setting Sun. The MUF may increase to twice its normal level 15° either side of the geomagnetic equator. See **Figure 19.22**. For

**Figure 19.22 — Cross-section of a transequatorial signal path, showing the effects of ionospheric bulging and a double refraction above the normal MUF.**

an overview of transequatorial propagation, read *F-Region Propagation and the Equatorial Ionosphere Anomaly* with the downloadable supplemental content.

### 19.2.14 Emerging Theories of HF and VHF Propagation

Although much is known about the ionosphere and propagation, there are still many instances of unusual propagation that cannot be easily explained with our textbook knowledge. It is encouraging to note that Amateur Radio operators continue to be at the forefront of trying to understand many of these unusual modes. Several recent studies have included:

1) The tie between polar mesospheric summer echoes and 6 meter propagation in “Polar Mesospheric Summer Echoes,” [k9la.us/PMSE\\_and\\_Propagation\\_at\\_50\\_MHz.pdf](http://k9la.us/PMSE_and_Propagation_at_50_MHz.pdf). These summer echoes are also called SSSP (summer solstice short path), a mode that Japanese amateurs have noted.

2) Theta aurora and 6 meter propagation

across the polar cap in “More Alaska to EU on 6 m,” at [k9la.us/More\\_Alaska\\_to\\_Europe\\_on\\_6m.pdf](http://k9la.us/More_Alaska_to_Europe_on_6m.pdf).

3) The impact of galactic cosmic rays on 160 meter *ducting* in “A Theory on the Role of Galactic Cosmic Rays in 160-Meter Propagation,” *CQ*, Nov 2008. *Ducting* refers to an electromagnetic wave successively refracting between a lower boundary and an upper boundary (for example, between the top of the E region and the bottom of the F region for 160 meters at night)

4) Discovery of single-day enhancements in the F<sub>2</sub> region that do not be appear to be tied to geomagnetic activity. This came from an interesting paper that was published in the *Journal of Geophysical Research* in late 2010. The paper was by Michael David and Jan J. Sojka, who were with the Center for Atmospheric and Space Sciences at Utah State University. The title of the paper is “Single-day dayside density enhancements over Europe: A survey of a half-century of ionosonde data.”

5) Although not a propagation issue, there is

## 19.3 MUF Predictions

F layer MUF prediction is key to forecasting HF communications paths at particular frequencies, dates and times, but forecasting is complicated by several variables. Solar radiation varies over the course of the day, season, year and solar cycle. Additionally, the ionization at any given point in the world depends on geomagnetic field activity and events in the lower atmosphere coupling up to the ionosphere. These regular intervals provide the main basis for prediction, yet recurrence is far from reliable. In addition, forecasts are predicated on a quiet geomagnetic field, but the condition of the Earth’s magnetic field is most difficult to predict weeks or months ahead. For professional users of HF communications, uncertainty is a nuisance for maintaining reliable communications paths, while for many amateurs it provides an aura of mystery and chance that adds to the fun of DXing. Nevertheless, many amateurs want to know what to expect on the HF bands to make best

use of available on-the-air time, plan contest strategy, ensure successful net operations or engage in other activities.

### 19.3.1 MUF Forecasts

Long-range forecasts several months ahead provide only the most general form of prediction. A series of 48 charts on the members-only ARRL website ([www.arrl.org/propagation](http://www.arrl.org/propagation)), similar to **Figure 19.23**, forecast average propagation for a one-month period over specific paths. The charts assume a single average solar flux value for the entire month and they assume that the geomagnetic field is undisturbed.

The uppermost curve in **Figure 19.23** shows the highest frequency that will be propagated on at least 10% of the days in the month. The given values might be exceeded considerably on a few rare days. On at least half the days, propagation should be possible on frequencies as high as the middle curve.

evidence that we may have missed a small solar cycle way back in the 1790 time frame. See [k9la.us/Did\\_We\\_Lose\\_a\\_Solar\\_Cycle.pdf](http://k9la.us/Did_We_Lose_a_Solar_Cycle.pdf).

6) Another topic not tied directly to propagation is the on-going research into better models of the ionosphere. We already pretty much understand solar radiation and we’ve recently developed a much better model of how elevated geomagnetic indices affect the ionosphere (it’s not simply applying a single K index). Research is on-going to better understand the physics behind events in the lower atmosphere coupling up to the ionosphere. Understanding these three processes is leading the way towards a true daily model of the ionosphere.

### 19.2.15 WSJT-X

*WSJT-X* (Weak Signal Communication, see [physics.princeton.edu/pulsar/k1jt/wsjt.html](http://physics.princeton.edu/pulsar/k1jt/wsjt.html)) is a suite of digital protocols optimized for weak signal communications on HF and VHF/UHF. See the **Digital Modes and Protocols** chapter’s section on Structured Digital Modes and this chapter’s section on E Layer Propagation. This software provides a wide variety of modes tailored for specific types of propagation. For example, FT8 is optimized for use at HF and 50 MHz; JT65 for EME on the VHF and UHF bands; JT4 for microwave bands; and JT9 especially for LF and MF. Any of these modes can be used on the HF bands to make worldwide contacts with a few watts and compromise antennas. The WSPR mode implements a protocol specially designed for probing potential propagation paths with low power transmissions.

Propagation will exceed the lowest curve on at least 90% of the days. The exact MUF on any particular day cannot be determined from these statistical charts, but you can determine when you should start monitoring a band to see if propagation actually does occur that day — particularly at frequencies above 14 MHz.

Short-range forecasts of a few days ahead are marginally more reliable than long-range forecasts, because underlying solar indices and geomagnetic conditions can be anticipated with greater confidence. The tendency for solar disturbances to recur at 27-day intervals may enhance short-term forecasts. Daily forecasts may not be any better, as the ionosphere does not instantly react to small changes in solar flux (or sunspot number) and geomagnetic field indices. Regardless of these limitations, it is always good to know the current solar and geophysical data, as well as understanding warnings provided by observations of the

East Coast to Eastern Europe

Figure 19.23 — Propagation prediction chart for East Coast to Eastern Europe from the ARRL web members-only site for April 2001. An average 2800 MHz (10.7 m) solar flux of 159 was assumed for the month. On 10% of the days, the highest frequency propagated is predicted to be at least as high as the uppermost curve, the Highest Possible Frequency, or HPF, approximately 33 MHz, and for 50% of the days as high as the middle curve, the MF. The lowest curve shows the Lowest Usable Frequency (LUF) for a 1500-W CW transmitter.

...in the visual to X-ray range.  
 The CD-ROM bundled with *The ARRL Antenna Book* contains even more detailed propagation-prediction tables from more than 50 locations around the world for six levels of solar activity, for the 12 months of the year. Again, keep in mind that these long-range forecasts assume quiet geomagnetic conditions. Real-time MUF forecasts are also available in a variety of text and graphical forms on the web. Forecasts can also be made by individuals using one of several popular programs for personal computers, including *ASAPS*, *OACAP*, and *W6ELProp*. (See the sidebar, "MUF Prediction on the Home Computer.")

### 19.3.2 Statistical Nature of Propagation Predictions

The model of the ionosphere in propagation prediction software is a monthly median model — thus the results (usually MUF and signal strength) are statistical over a month's time frame. The median aspect means that the predicted value will actually occur on at least half the days of the month — but unfortunately it's tough to tell which are the "better" days and which are the "worse" days.

This monthly median model came about due to the efforts of scientists to correlate what the ionosphere was doing to what the Sun was doing. The best correlation was between smoothed solar index (smoothed sunspot number or smoothed 10.7 cm solar flux) and monthly median ionospheric parameters. Thus our propagation prediction software was never

intended to give daily predictions. One good way to achieve somewhat better short-term predictions is to use the concept of an effective sunspot number — SSNe.

### EFFECTIVE SUNSPOT NUMBER (SSNe)

The concept of SSNe is quite simple. The  $F_2$  layer critical frequency data from worldwide ionosondes is monitored, and then the sunspot number in an  $F_2$  layer model of the ionosphere is varied until it provides a best fit to the monitored data. The current SSNe comes from Northwest Research Associates in Tucson (AZ), and can be found at [www.nwra.com/spawx/ssne.html](http://www.nwra.com/spawx/ssne.html). By plugging the current SSNe into your favorite propagation prediction program, you will have a better (but not perfect) picture of what the ionosphere is doing "now."

### 19.3.3 Direct Observation

Propagation conditions can be determined directly by listening to the HF bands. The simplest method is to tune higher in frequency until no more long-distance stations are heard. This point is roughly just above the MUF to anywhere in the world at that moment. The highest usable amateur band would be the next lowest one. If HF stations seem to disappear around 23 MHz, for example, the 15 meter band at 21 MHz might make a good choice for DXing. By carefully noting station locations as well, the MUF in various directions can also be determined quickly.

The shortwave broadcast bands (see **Table 19.5**) are most convenient for MUF browsing, because there are many high-powered stations on regular schedules. Take care to ensure that programming is actually transmitted from the originating country. A Radio Moscow or BBC program, for example, may be relayed to a transmitter outside Russia or England for retransmission. An excellent guide to shortwave broadcast stations is the *World Radio TV Handbook*, available through the ARRL.

**Table 19.5**  
**Shortwave Broadcasting Bands**

Frequency (MHz)	Band (meters)
2.300-2.495	120
3.200-3.400	90
3.900-4.000	75
4.750-5.060	60
5.959-6.200	49
7.100-7.300	41
9.500-9.900	31
11.650-12.050	25
13.600-13.800	22
15.100-15.600	19
17.550-17.900	16
21.450-21.850	13
25.600-26.100	11

### 19.3.4 WWV and WWVH

The standard time stations WWV (Fort Collins, Colorado) and WWVH (Kauai, Hawaii), which transmit on 2.5, 5, 10, 15 and 20 MHz, are also popular for propagation monitoring. They transmit 24 hours a day. Daily monitoring of these stations for signal strength and quality can quickly provide a good basic indication of propagation conditions. In addition, each hour they broadcast the geomagnetic A and K indices, the 2800 MHz (10.7 cm) solar flux, and a short forecast of conditions for the next day. These are heard on WWV at 18 minutes past each hour and on WWVH at 45 minutes after the hour. The same information, along with a lot more space weather information, is available at various websites, such as [www.swpc.noaa.gov](http://www.swpc.noaa.gov) or [www.spaceweather.com](http://www.spaceweather.com). The K index is updated every three hours, while the A index and solar flux are updated after 2100 UTC. These data are useful for making predictions on home computers, especially when averaged over several days of solar flux observations.

### 19.3.5 Beacons

Automated *beacons* in the higher amateur bands can also be useful adjuncts to propagation watching. Beacons are ideal for this purpose because most are designed to transmit 24 hours a day.

One of the best organized beacon systems is the International Beacon Project, sponsored by the Northern California DX Foundation (NCDXF) and International Amateur Radio Union (IARU). The beacons operate 24 hours a day at 14.100, 18.110, 21.150, 24.930 and 28.200 MHz. Eighteen beacons on five continents transmit in successive 10-second intervals (each beacon transmits once every 3 minutes). More on this system can be found at the Northern California DX Foundation website [www.ncdxf.org](http://www.ncdxf.org) (click on the *Beacons* link on the left).

A network of automated SDR receivers called the Reverse Beacon Network ([www.reversebeacon.net](http://www.reversebeacon.net)) has been created to monitor the HF CW subbands for signals that are automatically decoded by *CW Skimmer* software by VE3NEA ([www.dxatlas.com/cwskimmer](http://www.dxatlas.com/cwskimmer)). The network logs signal strength and location for the received signals, providing real-time information on HF propagation.

A list of many 28 MHz beacons can be found on the 10-10 International website, [www.ten-ten.org](http://www.ten-ten.org) (look for *Beacons* under the Resources link). Beacons often include location as part of their automated message, and many can be located from their call sign. Thus, even casual scanning of beacon subbands can be useful. **Table 19.6** provides the frequencies where beacons useful to HF propagation are most commonly placed.

There are also many beacons on VHF and higher bands. "G3USF's Worldwide List of

## MUF Prediction on the Home Computer

Like predicting the weather, predicting HF propagation — even with the best computer software available — is not an exact science. The processes occurring as a signal is propagated from one point on the Earth to another are enormously complicated and subject to an incredible number of variables. Experience and knowledge of propagation conditions (as related to solar activity, especially unusual solar activity, such as flares or coronal mass ejections) are needed when you actually get on the air to check out the bands. Keep in mind, too, that ordinary computer programs are written mainly to calculate propagation for great-circle paths via the F layer. Scatter, skew-path, auroral and other such propagation modes may provide contacts when computer predictions indicate no contacts are possible.

What follows is some brief information about commercially available propagation-prediction programs for the IBM PC and compatible computers. See **Table 19.A**. These programs generally allow predictions from 3 to 30 MHz. Unfortunately prediction programs are not available on 160 meters (because of an incomplete understanding of the lower ionosphere and ducting mechanisms that contribute to propagation on that band) and on 6 meters (because of an incomplete understanding of openings when the MUF is not predicted to be high enough). As a general guideline, you should look for 160 meter openings when the path to your target station is in darkness and around sunrise/sunset, and you should look for 6 meter F<sub>2</sub> openings in the daytime during winter months near solar maximum.

You may find an article that appeared in the Summer 2008 issue of *CQ VHF* to be helpful with your 6m endeavors: "Predicting 6-meter F<sub>2</sub> Propagation," by Carl Luetzelschwab, K9LA.

### ASAPS Version 7

An agency of the Australian government has developed the ASAPS program, which stands for Advanced Stand-Alone Prediction System. It rivals *IONCAP* (see below) in its analysis capability and in its prediction accuracy. It is a *Windows* program that interacts reasonably well with the user, once you become accustomed to the acronyms used. If you change transmit power levels, antennas and other parameters, you can see the new results almost instantly without further menu entries. Available from IPS Radio and Space Services. See [www.sws.bom.gov.au/Products\\_and\\_Services/1/2](http://www.sws.bom.gov.au/Products_and_Services/1/2).

50 MHz Beacons" may be found at [www.keele.ac.uk/depts/por/50.htm](http://www.keele.ac.uk/depts/por/50.htm). Information on North American beacons on 144 MHz and up is maintained by Ron Klimas, WZ1V, at [www.newsvhf.com/beacons2.html](http://www.newsvhf.com/beacons2.html).

### 19.3.6 Other Methods for Real-Time Assessment of the Ionosphere

Since our propagation predictions are statistical in nature over a month's time frame, determining what the ionosphere is doing in real time can be important. In addition to using the effective sunspot number, making direct observations of our bands, monitoring WWV/WWVH on their five frequencies, and monitoring the IARU/NCDXF and other beacons as discussed previously, there are other ways to get a real-

**Table 19.6**  
**Popular Beacon Frequencies**

(MHz)	Comments
14.100, 18.110, 21.150, 24.930, 28.200	Northern California DX Foundation beacons
28.2-28.3	Several dozen beacons worldwide
50.0-50.1	Most US beacons are within 50.06-50.08 MHz
70.03-70.13	Beacons in England, Ireland, Gibraltar and Cyprus

time picture of the ionosphere.

An emerging method is to use the Reverse Beacon Network (RBN — briefly discussed previously) to construct maps of F<sub>2</sub> region critical frequencies (foF<sub>2</sub>). Applying some simple rules will allow MUFs (maximum useable frequencies) to be easily estimated. See the RBN article with the downloadable supplemental content for general information

about the RBN. Also expect to see a technical article about foF<sub>2</sub> maps generated from RBN data in the future.

Watching the worldwide spotting network is another way to assess real-time propagation. An extension of this is to plot the paths from the spots on a worldwide map. One such presentation is at [www.dxmaps.com/spots/map.php](http://www.dxmaps.com/spots/map.php).

### IONCAP and VOACAP

*IONCAP*, short for Ionospheric Communications Analysis and Prediction, was written by an agency of the US government and has been under development for about 30 years in one form or another. The *IONCAP* program has a well-deserved reputation for being difficult to use, since it came from the world of Fortran punch cards and mainframe computers.

*VOACAP* is a version of *IONCAP* adapted to Voice of America predictions, but this one includes a sophisticated *Windows* interface. The Voice of America (VOA) started work on *VOACAP* in the early 1990s and continued for several years before funding ran out. The program was maintained by a single, dedicated computer scientist, Greg Hand, at NTIA/ITS (Institute for Telecommunication Sciences), an agency of the US Department of Commerce in Boulder, Colorado. Greg Hand is now retired, but considerable documentation can be found at the website referenced below, along with links to other *VOACAP*-related websites. Although *VOACAP* is not specifically designed for amateurs (and thus doesn't include some features that amateurs are fond of, such as entry of locations by ham radio call signs and multiple receiving antennas), it is available for free by downloading from [www.its.bldrdoc.gov/resources/radio-propagation-software/high-frequency/high-frequency-propagation-models.aspx](http://www.its.bldrdoc.gov/resources/radio-propagation-software/high-frequency/high-frequency-propagation-models.aspx).

### W6ELProp, Version 2.70

In 2001, W6EL (SK) ported his well known *MINIPROP PLUS* program into the *Windows* world. It uses the same Fricker-based F<sub>2</sub> region computation engine as its predecessor. (This method was developed by Raymond Fricker of the BBC.) *W6ELProp* has a highly intuitive, ham-friendly user interface. It produces detailed output tables, along with a number of useful charts and maps, including the unique and useful "frequency map," which shows the global MUFs from a given transmitting location for a particular month/day/time and solar-activity level. *W6ELProp* is available for free by downloading from [www.qsl.net/w6elprop](http://www.qsl.net/w6elprop).

### PropLab Pro, Version 3.0

*PropLab Pro* by Solar Terrestrial Dispatch represents the high end of propagation-prediction programs. It is the only commercial program presently available that can do complete 3D ray tracing through the ionosphere, even taking complex geomagnetic effects and electron-neutral collisions (what causes

absorption) into account. The number of computations is huge, especially in the full-blown 3D mode and operation can be slow and tedious. The *Windows* based user interface is easier to use than previous versions, which were complex and difficult to learn.

It is fascinating to see exactly how a signal can bend off-azimuth or how it can split into the ordinary and extraordinary waves. It is best considered a propagation analysis tool, as opposed to a propagation prediction program. See [www.spacew.com/proplab](http://www.spacew.com/proplab).

**19.3.7 Space Weather Information**

Living in the space age results in a wealth of information about the Sun-Earth environment. Not only do we have measurements available, but we also have extensive tutorials available on what is being measured, how it is measured, and its general impact to propagation.

**SPACE WEATHER SATELLITES**

Three of the most beneficial satellites for propagation information are the Advanced Composition Explorer (ACE), the Solar and Heliospheric Observatory (SOHO), and the STEREO mission.

ACE is on a line from the Earth to the Sun, and is about 1 million miles from the Earth. Its primary purpose is to measure solar wind characteristics. For example, it measures the direction of the IMF (interplanetary magnetic

field), the solar wind speed, and the dynamic solar wind pressure. More detailed information about ACE can be found at [www.srl.caltech.edu/ACE/](http://www.srl.caltech.edu/ACE/).

SOHO moves around the Sun in step with Earth — it always faces the Sun. Its primary purpose is to study the Sun. For example, it views coronal mass ejections, and in conjunction with the Michelson Doppler Imager (MDI), allows scientists to “see” sunspots on the far side of the Sun. More detailed information about SOHO and MDI can be found at [sohowww.nascom.nasa.gov](http://sohowww.nascom.nasa.gov) and [soli.stanford.edu](http://soli.stanford.edu), respectively.

The STEREO mission consists of two spacecraft that are in heliocentric orbits leading and lagging the Earth. Each spacecraft provides a unique observing vantage point, and taken together, they enable a stereoscopic view of the Sun, solar activity, and the solar environment between the Sun and Earth. More information

can be found at [stereo.gsfc.nasa.gov/](http://stereo.gsfc.nasa.gov/).

More satellite data can be found at [www.swpc.noaa.gov](http://www.swpc.noaa.gov) and at [www.spaceweather.com](http://www.spaceweather.com).

**19.3.8 Online Predictions**

In addition to propagation predictions on your home PC, you can make predictions online. Two such websites to do this are [www.voacap.com/p2p/index.html](http://www.voacap.com/p2p/index.html) and [rsgb.org/main/about-us/committees/propagation-studies-committee/projects/iturhf-prop-propagation-prediction-engine/](http://rsgb.org/main/about-us/committees/propagation-studies-committee/projects/iturhf-prop-propagation-prediction-engine/).

The first website is by Jari Perkiömäki, OH6BG/OG6G, and uses *VOACAP*. The second web site is by Gwyn Williams, G4FKH, a member of the RSGB’s Propagation Studies Committee. Both websites have instructions on how to input your data to generate the desired prediction.

# 19.4 Propagation in the Troposphere

All radio communication involves propagation through the troposphere for at least part of the signal path. Radio waves traveling through the lowest part of the atmosphere are subject to refraction, scattering and other phenomena, much like ionospheric effects. Tropospheric conditions are rarely significant below 30 MHz, but they are very important at 50 MHz and higher. Much of the long-distance work on the VHF, UHF and microwave bands depends on some form of tropospheric propagation. Instead of watching solar activity and geomagnetic indices, those who use tropospheric propagation are much more concerned about terrestrial weather as opposed to space weather.

## 19.4.1 Line of Sight

At one time it was thought that communications in the VHF range and higher would be restricted to line-of-sight paths. Although this has not proven to be the case even in the microwave region, the concept of line of sight is still useful in understanding tropospheric propagation. In the vacuum of space or in a completely homogeneous medium, radio waves do travel essentially in straight lines, but these conditions are almost never met in terrestrial propagation.

Radio waves traveling through the troposphere are ordinarily refracted slightly earthward. The normal drop in temperature, pressure and water-vapor content with increasing altitude change the index of refraction of the atmosphere enough to cause refraction. Under average conditions, radio waves are refracted toward Earth enough to make the horizon appear 1.15 times farther away than the visual horizon. Under unusual conditions, tropospheric refraction may extend this range significantly.

A simple formula can be used to estimate the distance to the radio horizon under average conditions:

$$d = \sqrt{2h}$$

where

d = distance to the radio horizon, miles  
h = height above average terrain, ft.

and

$$d = \sqrt{17h}$$

where

d = distance to the radio horizon, km  
h = height above average terrain, m.

The distance to the radio horizon for an antenna 30 meters (98 ft) above average terrain

Figure 19.24 — Attenuation caused by oxygen and water vapor at 10 grams per cubic meter (equivalent to 40% humidity at 25 °C). There is little attenuation caused by atmospheric gases at 10 GHz and lower. Note that the 24 GHz band lies near the center of a peak of water vapor absorption and the 120 GHz band is near a peak of oxygen absorption.

Figure 19.25 — Tropospheric-scatter path geometry. The lower boundary of the common scattering volume is limited by the take-off angle of both stations. The upper boundary of 10 km (6 miles) altitude is the limit of efficient scattering in the troposphere. Signal strength increases with the scattering volume.

is thus 22.6 km (14 miles). A station on top of a 1000 meter (3280 ft) mountain has a radio horizon of 130 km (80 miles).

## ATMOSPHERIC ABSORPTION

Atmospheric gases, most notably oxygen and water vapor, absorb radio signals, but neither is a significant factor below 10 GHz. See **Figure 19.24**. Attenuation from rain becomes important at 3.3 GHz, where signals passing through 20 km (12 miles) of heavy showers incur an additional 0.2 dB loss. That same rain would impose 12 dB additional losses at 10 GHz and losses continue to increase with frequency. Heavy fog is similarly a problem only at 5.6 GHz and above.

### 19.4.2 Tropospheric Scatter

Contacts beyond the radio horizon out to a working distance of 100 to 500 km (60-310 miles), depending on frequency, equipment and local geography, are made every day without the aid of obvious propagation enhancement. At 1.8 and 3.5 MHz, local communication is due mostly to ground wave. At higher frequencies, especially in the VHF range and above, the primary mechanism is scattering in the troposphere, or *troposcatter*.

Most amateurs are unaware that they use troposcatter even though it plays an essential role in most local communication. Radio signals through the VHF range are scattered primarily by wavelength sized gradients in the index of refraction of the lower atmosphere due to turbulence, along with changes in temperature. Radio signals in the microwave region can also be scattered by rain, snow, fog, clouds and dust. That tiny part that is scattered forward and toward the Earth creates the over-the-horizon paths. Troposcatter path losses are considerable and increase with frequency.

The maximum distance that can be linked via troposcatter is limited by the height of a scattering volume common to two stations, shown schematically in **Figure 19.25**. The highest altitude for which scattering is efficient at amateur power levels is about 10 km (6 miles). An application of the distance-to-the-horizon formula yields 800 km (500 miles) as the limit for troposcatter paths, but typical maxima are about half that. Tropospheric scatter varies little with season or time of day, but it is difficult to assess the effect of weather on troposcatter alone. Variations in tropospheric refraction, which is very sensitive to the weather, probably account for most of the observed day-to-day differences in troposcatter signal strength.

Troposcatter does not require special operating techniques or equipment, as it is used unwittingly all the time. In the absence of all other forms of propagation, especially at VHF and above, the usual working range is essentially the maximum troposcatter distance. Ordinary

working range increases most dramatically with antenna height, because that lowers the take-off angle to the horizon. Working range increases less quickly with antenna gain and transmitter power. For this reason, a mountaintop is the choice location for extending ordinary troposcatter working distances.

### RAIN SCATTER IN THE TROPOSPHERE

Scatter from raindrops is a special case of troposcatter practical in the 3.3 to 24 GHz range. Stations simply point their antennas toward a common area of rain. A certain portion of radio energy is scattered by the raindrops, making possible over-the-horizon or obstructed-path contacts, even with low power. The theoretical range for rain scatter is as great as 600 km (370 miles), but the experience of amateurs in the microwave bands suggests that expected distances are less than 200 km (120 miles). Snow and hail make less efficient scattering media unless the ice particles are partially melted. Smoke and dust particles are too small for extraordinary scattering, even in the microwave bands.

### 19.4.3 Refraction and Ducting in the Troposphere

Radio waves are refracted by natural gradients in the index of refraction of air with altitude, due to changes in temperature, humidity and pressure. Refraction under standard atmospheric conditions extends the radio horizon somewhat beyond the visual line of sight. Favorable weather conditions further enhance normal tropospheric refraction, lengthening

the useful VHF and UHF range by several hundred kilometers and increasing signal strength. Higher frequencies are more sensitive to refraction, so its effects may be observed in the microwave bands before they are apparent at lower frequencies.

*Ducting* takes place when refraction is so great that radio waves are bent back to the surface of the Earth. When tropospheric ducting conditions exist over a wide geographic area, signals may remain very strong over distances of 1500 km (930 miles) or more. Ducting results from the gradient created by a sharp increase in temperature with altitude, quite the opposite of normal atmospheric conditions. A simultaneous drop in humidity contributes to increased refractivity.

Normally the temperature steadily decreases with altitude, but at times there is a small portion of the troposphere in which the temperature increases and then again begins decreasing normally. This is called an *inversion*. Useful temperature inversions form between 250 and 2000 meters (800-6500 ft) above ground. The elevated inversion and the Earth's surface act something like the boundaries of a natural open-ended waveguide. Radio waves of the right frequency range caught inside the duct will be propagated for long distances with relatively low losses. Several common weather conditions can create temperature inversions.

### RADIATION INVERSIONS IN THE TROPOSPHERE

*Radiation inversions* are probably the most common and widespread of the various weather conditions that affect propagation. Radiation inversions form only over land after

**Figure 19.26** — Temperature and dew point profile of an early-morning radiation inversion is shown at A. Fog may form near the ground. The midday surface temperature would be at least 30 °C. At B, temperature and humidity profile across an elevated duct at 1000 meters altitude. Such inversions typically form in summertime high-pressure systems. Note the air is very dry in the inversion.

sunset as a result of progressive cooling of the air near the Earth's surface. As the Earth cools by radiating heat into space, the air just above the ground is cooled in turn. At higher altitudes, the air remains relatively warmer, thus creating the inversion. A typical radiation-inversion temperature profile is shown in **Figure 19.26A**.

The cooling process may continue through the evening and predawn hours, creating inversions that extend as high as 500 meters (1500 ft). Deep radiation inversions are most common during clear, calm, summer evenings. They are more distinct in dry climates, in valleys and over open ground. Their formation is inhibited by wind, wet ground and cloud cover. Although radiation inversions are common and widespread, they are rarely strong enough to cause true ducting. The enhanced conditions so often observed after sunset during the summer are usually a result of this mild kind of inversion.

### HIGH-PRESSURE WEATHER SYSTEMS

Large, sluggish, high-pressure systems (or *anticyclones*) create the most dramatic and widespread tropospheric ducts due to *subsidence*. Subsidence inversions in high-pressure systems are created by air that is sinking. As air descends, it is compressed and heated. Layers of warmer air — temperature inversions — often form between 500 and 3000 meters (1500-10,000 ft) altitude, as shown in **Figure 19.26B**. Ducts usually intensify during the evening and early morning hours, when surface temperatures drop and suppress the tendency for daytime ground-warmed air to rise. In the Northern Hemisphere, the longest and strongest radio paths usually lie to the south of high-pressure centers. See **Figure 19.27**.

Sluggish high-pressure systems likely to contain strong temperature inversions are common in late summer over the eastern half of the US. They generally move southeastward out of Canada and linger for days over the Midwest, providing many hours of extended propagation. The southeastern part of the country and the lower Midwest experience the most high-pressure openings; the upper Midwest and East Coast somewhat less frequently; the western mountain regions rarely.

Semi-permanent high-pressure systems, which are nearly constant climatic features in certain parts of the world, sustain the longest and most exciting ducting paths. The Eastern Pacific High, which migrates northward off the coast of California during the summer, has been responsible for the longest ducting paths reported to date. Countless contacts in the 4000 km (2500 mile) range have been made from 144 MHz through 5.6 GHz between California and Hawaii. The *Bermuda High* is a nearly permanent feature of the Caribbean area, but

during the summer it moves north and often covers the southeastern US. It has supported contacts in excess of 2800 km (1700 miles) from Florida and the Carolinas to the West Indies, but its full potential has not been exploited. Other semi-permanent highs lie in the Indian Ocean, the western Pacific and off the coast of western Africa.

### WAVE CYCLONE

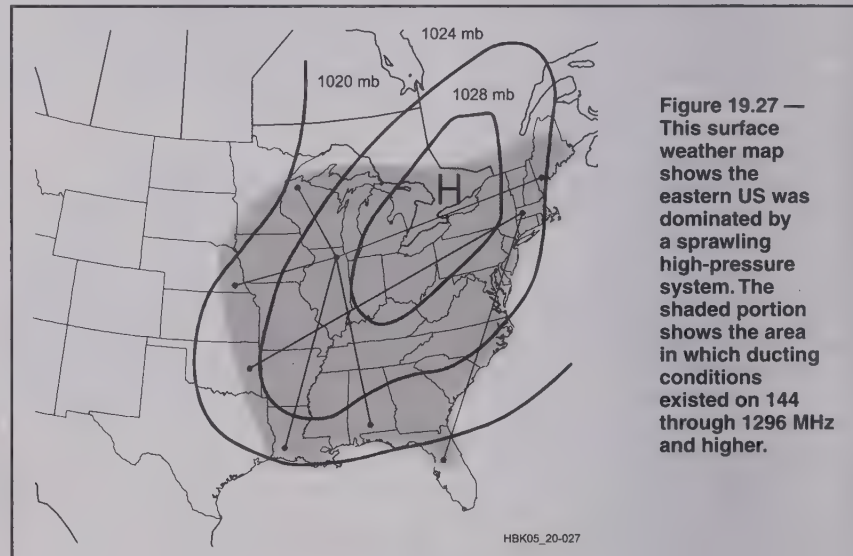

The *wave cyclone* is a more dynamic weather system that usually appears during the spring over the middle part of the American continent. The wave begins as a disturbance along a boundary between cooler northern and warmer southern air masses. Southwest of the disturbance, a cold front forms and moves rapidly eastward, while a warm front moves slowly northward on the eastward side. When the wave is in its open position, as shown in

**Figure 19.28**, north-south radio paths 1500 km (930 miles) and longer may be possible in the area to the east of the cold front and south of the warm front, known as the warm sector. East-west paths nearly as long may also open in the southerly parts of the warm sector.

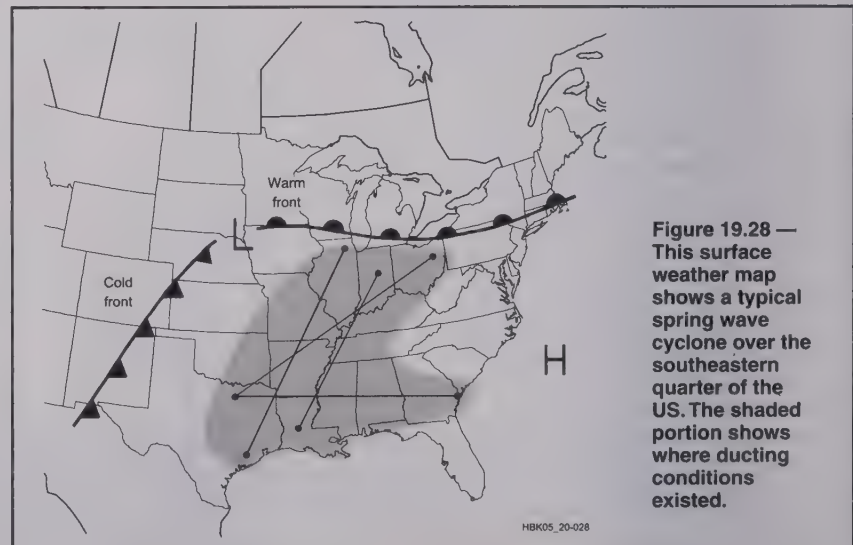

Wave cyclones are rarely productive for more than a day in any given place, because the eastward-moving cold front eventually closes off the warm sector. Wave-cyclone temperature inversions are created by a southwesterly flow of warm, dry air above 1000 meters (3200 ft) that covers relatively cooler and moister Gulf air flowing northward near the Earth's surface. Successive waves spaced two or three days apart may form along the same frontal boundary.

### WARM FRONTS AND COLD FRONTS

Warm fronts and cold fronts sometimes bring enhanced tropospheric conditions, but rarely

**Figure 19.27** — This surface weather map shows the eastern US was dominated by a sprawling high-pressure system. The shaded portion shows the area in which ducting conditions existed on 144 through 1296 MHz and higher.

**Figure 19.28** — This surface weather map shows a typical spring wave cyclone over the southeastern quarter of the US. The shaded portion shows where ducting conditions existed.

true ducting. A warm front marks the surface boundary between a mass of warm air flowing over an area of relatively cooler and more stationary air. Inversion conditions may be stable enough several hundred kilometers ahead of the warm front to create extraordinary paths.

A cold front marks the surface boundary between a mass of cool air that is wedging itself under more stationary warm air. The warmer air is pushed aloft in a narrow band behind the cold front, creating a strong but highly unstable temperature inversion. The best chance for enhancement occurs parallel to and behind the passing cold front.

## OTHER CONDITIONS ASSOCIATED WITH DUCTS

Certain kinds of wind may also create useful inversions. The *Chinook* wind that blows off the eastern slopes of the Rockies can flood the Great Plains with warm and very dry air, primarily in the springtime. If the ground is cool or snow-covered, a strong inversion can extend as far as Canada to Texas and east to the Mississippi River. Similar kinds of *foehn* winds, as these mountain breezes are called, can be found in the Alps, Caucasus Mountains and other places.

The *land breeze* is a light, steady, cool wind that commonly blows up to 50 km (30 miles) inland from the oceans, although the distance may be greater in some circumstances. Land breezes develop after sunset on clear summer evenings. The land cools more quickly than the adjacent ocean. Air cooled over the land flows near the surface of the Earth toward the

ocean to replace relatively warmer air that is rising. See **Figure 19.29**. The warmer ocean air, in turn, travels at 200-300 meters (600-1000 ft) altitude to replace the cool surface air. The land-sea circulation of cool air near the ground and warm air aloft creates a mild inversion that may remain for hours. Land-breeze inversions often bring enhanced conditions and occasionally allow contacts in excess of 800 km (500 miles) along coastal areas.

In southern Europe, a hot, dry wind known as the *sirocco* sometimes blows northward from the Sahara Desert over relatively cooler and moister Mediterranean air. Sirocco inversions can be very strong and extend from Israel and Lebanon westward past the Straits of Gibraltar. Sirocco-type inversions are probably responsible for record-breaking microwave contacts in excess of 1500 km (930 miles) across the Mediterranean.

## MARINE BOUNDARY LAYER EFFECTS

Over warm water, such as the Caribbean and other tropical seas, *evaporation inversions* may create ducts that are useful in the microwave region between 3.3 and 24 GHz. This inversion depends on a sharp drop in water-vapor content rather than on an increase in temperature to create ducting conditions. Air just above the surface of water at least 30°C is saturated because of evaporation. Humidity drops significantly within 3 to 10 meters (10 to 30 ft) altitude, creating a very shallow but stable duct. Losses due to water vapor absorption may be intolerable at the highest ducting

frequencies, but breezes may raise the effective height of the inversion and open the duct to longer wavelengths. Stations must be set up right on the beaches to ensure being inside an evaporation inversion.

## TROPOSPHERIC DUCTING FORECASTS

To help decide if weather conditions may support tropospheric ducting, visit "William Hepburn's Worldwide Tropospheric Ducting Forecasts" at [www.dxinfocentre.com/tropo.html](http://www.dxinfocentre.com/tropo.html). The principal content on this website is the forecast maps — 6-day preview as well as 42-hour preview (in 6-hour increments) maps for virtually every region of the world.

The purpose of these maps is to display potential duct paths for VHF, UHF and microwave signals, indicated by the color shading on the maps using the Hepburn Tropo Index. This index indicates the degree of tropospheric bending forecast to occur over a particular area. It is an indication of the overall tropospheric radio signal strength on a linear scale from 0 to 10 (with 10 representing an "extremely intense opening" for propagation by ducting).

Also shown on the maps are predicted "unstable signal areas" where weather conditions could potentially disrupt signal paths and cause unusual and sometimes rapid variations in signal strengths

### 19.4.4 Tropospheric Fading

Because the atmosphere is not homogeneous, radio signals are refracted slightly as they encounter variations in density and humidity. A signal may arrive at the receiver by two or more different paths simultaneously, causing addition or partial cancellation depending on the relative phases and amplitudes of the paths. As the wind blows, the paths change, which causes the net amplitude of the received signal to vary slowly, a process known as *scintillation fading*. This is the same process that causes the stars to twinkle in the visible portion of the electromagnetic spectrum. The higher the frequency and the longer the path length, the more pronounced the effect. While scintillation is generally not significant for short-range VHF/UHF repeater work, it can be the main limitation on power budgets for microwave point-to-point links.

*Fast-flutter fading* at 28 MHz and above is often the result of an airplane that temporarily creates a second propagation path. Flutter results as the phase relationship between the direct signal and that reflected by the airplane changes with the airplane's movement.

**Figure 19.29** — Land-breeze convection along a coast after sunset creates a temperature inversion over the land.

# 19.5 VHF/UHF Mobile Propagation

Most amateurs are aware that radio signals in free space obey the inverse-square law: the received signal power is inversely proportional to the square of the distance between the transmitting and receiving antennas. That law applies *only* if the transmitting and receiving antennas have an obstruction-free radio path between them.

Imagine two operators using hand-held 144 MHz radios, each standing on a mountaintop so that they have a direct line of sight. How far apart can they be and still maintain reliable communications? Assume 5 W transmitter power, 0 dBi antenna gain (2.15 dB worse than a dipole), 5 dB receiver noise figure, 10 dB S/N ratio and 12 kHz receiver bandwidth.

Ask experienced VHF mobile operators that question and you'll generally get guesses in the range of 20 to 30 miles because their experience tells them that's about the most you can expect when not communicating through a repeater. The correct answer, however, is over 9500 km (5938 miles) based on the parameters given in the previous paragraph! This also explains how some operators have been able to work the Amateur Radio station on the International Space Station using only a handheld transceiver.

The discrepancy is explained by the fact that the line-of-sight scenario is not realistic for a mobile station located close to ground level. At distances greater than a few miles, there usually is no line of sight — the signal is reflected at least once on its journey from transmitter to receiver. As a result, path loss is typically proportional to distance to the third or fourth power, not the second power as the inverse-square law implies.

## 19.5.1 Rayleigh Fading

Not only is the signal reflected, but it usually arrives at the receiver by several different paths simultaneously. See **Figure 19.30**. Because the length of each path is different, the signals are not in phase. If the signals on two paths happen to be 180° out of phase and at the same amplitude, they will cancel. If they are in phase then their amplitudes will add. As the mobile station moves about, the phases of the various paths vary in a random fashion. However they tend to be uncorrelated over distances greater than  $\lambda/4$  or so, which is about 20 inches on the 2 meter band. That is why if the repeater you are listening to drops out when you are stopped at a traffic light, you can often get it back again by creeping forward a few inches.

Because there are typically dozens of paths, it is rare for their amplitudes and phases to be such that they all cancel perfectly. Fades of 20 to 30 dB or more are common. The range of signal strengths has a *Rayleigh* distribution,

named after the physicist/mathematician who first derived the mathematical formula. That is why the phenomenon is called *Rayleigh fading*. **Figure 19.31** shows the relative probability of various signal strengths. **Figure 19.32** is the same graph plotted on a logarithmic (dB) scale, along with a typical plot of signal strength versus time as the mobile station moves down the road.

The closer a reflecting object is to the antenna the smaller is the path loss. A reflector that is close to the transmitter or receiver antenna gives a much stronger signal than one located halfway between. Even a weak reflector, such as a tree branch or telephone pole, is significant if it is close to the mobile station.

Because there are many such close-in reflectors, many rays arrive from all directions.

Rays arriving from in front of a forward moving vehicle experience a positive Doppler frequency shift and rays from the rear have a negative Doppler shift. Those from the sides are somewhere in-between, proportional to the cosine of the angle of arrival. The received signal is the sum of all those rays, which results in *Doppler spreading* of the signal as illustrated in **Figure 19.33**. At normal vehicle speeds on the 2 meter band, the Doppler spread is only plus and minus 10 or 15 Hz, calculated from

$$\text{Doppler frequency} = F_c v/c$$

**Figure 19.30** — At distances greater than a few miles, there normally is no line-of-sight path to the mobile station. Each path experiences at least one reflection. (Because the radio paths are reciprocal, propagation is the same for both receiving and transmitting.)

**Figure 19.31** — The horizontal axis is the Rayleigh probability density function (PDF), which is the relative probability of the different signal levels shown on the vertical axis. For this graph, an RMS value of 3.16  $\mu\text{V}$  has been selected to represent a typical average signal level in a marginal-coverage area.

**Figure 19.32** — The graph at the left is the same as **Figure 19.31** except that the vertical axis is logarithmic (proportional to dB). At the right is a typical Rayleigh-faded signal of the same RMS voltage level plotted using the same vertical scale.

Figure 19.33 — Rayleigh fading spectrum of a CW (unmodulated) signal. The maximum deviation ( $F_d$ ) from the center frequency is typically less than 10-15 Hz in the 144 MHz band.

where  
 $F_c$  = the carrier frequency  
 $v$  = the vehicle speed  
 $c$  = the speed of light

the same units for  $v$  and  $c$ . On an FM voice channel the only effect is a slight distortion of the audio, but Doppler spreading can severely affect digital signals, as will be discussed later.

### 19.5.2 Multipath Propagation

In addition to scattering by local reflectors, it is not uncommon also to have more than one main radio path caused by strong reflectors, such as large metal buildings located some distance away. See Figure 19.34. Each main path typically does not reach the mobile station directly, but is separately Rayleigh-faded by local reflectors.

As the mobile station moves around, the

shadowing of various paths by intervening hills, buildings and other objects causes the average signal level to fade in and out, but at a much slower rate than Rayleigh fading. This is called *shadowing* or *slow fading*. It is also called *log-normal fading* because the distribution of average signal levels tends to follow a log-normal curve. That means that the *logarithm* of the signal level (on a dB scale, if you will) has a *normal* distribution (the famous bell-shaped curve). This effect typically causes the average signal level on each path to vary plus and minus 10-20 dB (at two standard deviations) from the mean value. This is in addition to the signal variation due to Rayleigh fading.

### 19.5.3 Effect on the Receiver

Radio direction finding (RDF) enthusiasts have noticed that their RDF receivers usually do not give stable or accurate indications unless located on a hilltop or other location with a clear line of sight to the transmitter because of fading and reflections. The best technique is to record the bearing to the hidden transmitter from a high location clear of nearby reflecting objects, then drive in that direction and take the next reading from another (hopefully closer) hilltop. Only when close to the transmitter will the RDF equipment typically give good readings while the vehicle is in motion.

Under weak-signal conditions Rayleigh fading causes the signal to drop out periodically even though the average signal level would be high enough to maintain reliable communications if there were no fading. *Picket fencing*, as such rapid periodic dropout is called, is a

common occurrence when traveling in a weak-signal area at highway speeds. With analog modulation, normally the only solution is to stop at a location where the signal is strong. Moving the vehicle forward or backward a few inches is often enough to change an unreadable signal to solid copy.

Another possible solution is to employ *diversity reception*. If two (or more) mobile receiver antennas are spaced a half-wavelength or more apart, their Rayleigh fading will be almost entirely uncorrelated. That means it is relatively rare for both to experience a deep fade at the same time. The receiving system must have circuitry to determine which of the antennas has a stronger signal at any given time and to automatically combine the signals using some scheme that minimizes the probability of signal dropout. (One engineering text that has a fairly readable discussion of fading is *Cellular Radio Performance Engineering* by Asha Mehrotra; see the "References and Bibliography" section at the end of this chapter.)

One low-tech scheme is to use stereo headphones with each channel connected to a separate receiver and antenna. That method works better with linear modulation (AM, SSB, CW) than with FM because of the noise burst that occurs when the FM signal drops out.

Diversity antennas can also be used at a repeater site. The conditions are different because most repeater antennas are located in the clear with few local reflectors. The diversity antennas must be located much farther apart, typically on the order of 10 to 20 wavelengths, for the fading to be uncorrelated.

### FADING AND DIGITAL SIGNALS

Digitally-modulated signals, such as those used in the cellular telephone industry, use several techniques to combat Rayleigh fading. One is *error-correcting coding*, which adds redundant bits to the transmitted signal in a special way such that the receiver can "fill in" missing bits to obtain error-free reception. That technique does not work if the signal drops out completely for longer than a few consecutive bits. The solution often employed is called *interleaving*. This takes data bits that represent points close together in time in the original voice signal and shuffles them into several different time slots for transmission. That way, a single brief dropout does not affect all the bits for that time period. Instead, the lost data are scattered over several different time periods. Since only a few bits are missing at any one point, the error-correcting decoder in the receiver has enough information to reconstruct the missing information.

As the signal gradually gets weaker, the error correction in a digital receiver produces nearly-perfect voice quality until the signal gets too weak for the decoder to handle. At that point reception stops abruptly and the call

Figure 19.34 — When multipath propagation occurs, each main path is typically Rayleigh-faded by multiple reflectors close to the mobile station.

**Figure 19.35** — Multipath propagation can cause inter-symbol interference (ISI). At the symbol decision points, where the receiver decoder samples the signal, the path 2 data is often opposing the data on path 1.

is dropped. With an analog signal, reception gets scratchier as the signal gets weaker; this gives advance warning before the signal drops out completely.

The main paths of a multipath-faded signal can differ in length by several miles. A 10 km (6 mile) difference in path length results in a difference in propagation delay of

over 30  $\mu$ s. While that is not noticeable on an FM voice signal, it can wreak havoc with digital signals by causing *intersymbol interference (ISI)*. See **Figure 19.35**. If the delay difference is on the order of one symbol, the receiver sees adjacent symbols superimposed. In effect, the signal interferes with itself.

One solution is to use an *equalizer*. This is a special type of digital filter that filters the demodulated signal to remove the delay differences so that multiple paths become time-aligned. Since the path characteristics change as the mobile station moves around, a special *training sequence* is sent periodically so that the receiver can re-optimize the filter coefficients based on the known symbols in the training sequence.

ISI is an even bigger problem at HF than at VHF/UHF because the path lengths are much greater. It is not unusual to have path length differences up to 3000 km (1800 miles), which correspond to propagation delay differences of

up to 10 ms. That is why digital modes on HF with symbol periods of less than about 10 to 20 ms (that is, with symbol rates greater than 50 to 100 baud) are not very practical without some method of equalization.

There is much more detailed information available about mobile radio propagation but unfortunately most of it is written at an engineering level. For example, Keysight Technologies ([keysight.com](http://keysight.com)) offers fading simulator software that operates in conjunction with their N5182B MXG X-Series RF Vector Signal Generator.

For those who would like to explore the subject further, a *Mathcad* file with equation and explanatory text related to Rayleigh fading is available at [www.arrl.org/qst-in-depth](http://www.arrl.org/qst-in-depth). Look in the 2006 section for Bloom0806.zip. The file was used to generate some of the graphics in this section. For those without access to *Mathcad*, a read-only PDF version of the file is available in the same directory.

## 19.6 Propagation for Space Communications

Communication of all sorts into space has become increasingly important. Amateurs confront extraterrestrial propagation when accessing satellite repeaters or using the moon as a reflector. (More information on these modes may be found in the **Space Communications** section with the downloadable supplemental content.) Special propagation problems arise from signals that travel from the Earth through the ionosphere (or a substantial portion of it) and back again. Tropospheric and ionospheric phenomena, so useful for terrestrial paths, are unwanted and serve only as a nuisance for space communication. A phenomenon known as *Faraday rotation* may change the polarization of radio waves traveling through the ionosphere, presenting special problems to receiving weak signals. Cosmic noise also becomes an important factor when antennas are intentionally pointed into space.

### 19.6.1 Faraday Rotation

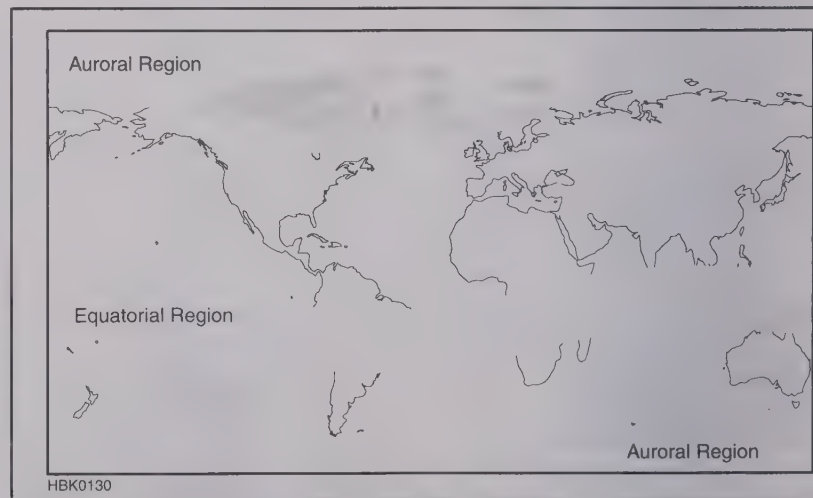

Magnetic and electrical forces rotate the polarization of radio waves passing through the ionosphere. For example, signals that leave the Earth as horizontally polarized and return after a reflection from the moon may not arrive with the same polarization. Additional path loss can occur when polarization is shifted by 90°, resulting in fading of the received signal.

Faraday rotation is difficult to predict and its effects change over time and with operating frequency. At 144 MHz, the polarization

of space waves may shift back into alignment with the antenna within a few minutes, so often just waiting can solve the Faraday problem. At 432 MHz, it may take half an hour or longer for the polarization to become realigned. Use of circular polarization completely eliminates this problem, but creates a new problem for EME paths. The sense of circularly polarized signals is reversed with reflection, so two complete antenna systems are normally required, one with left-hand polarization and one with right-hand polarization.

### 19.6.2 Scintillation

Extraterrestrial signals experience scintillation fading as they travel through the lower atmosphere, as described previously in the *Tropospheric Fading* section. However, they also experience scintillation fading as they traverse the ionosphere. The rule of thumb is that the ionosphere dominates below about 2 GHz, and the atmosphere is usually more significant above 2 GHz. Scintillation in the ionosphere is more complex than in the troposphere because, unlike the troposphere, the ionosphere

**Figure 19.36** — Regions of the world (shaded) where scintillation fading effects can be especially severe.

highly anisotropic and irregularities tend to be aligned with the Earth's magnetic field lines. Ionospheric scintillation varies with geographical location, time of day, the 11-year sunspot cycle, and the presence of geomagnetic storms. **Figure 19.36** shows the worldwide areas where scintillation occurs. The most intense and frequent disturbances are located within about 20 degrees of the Earth's magnetic equator. Fading depth in this region can be as much as 20 to 30 dB. Scintillation fading also is common within about 30 degrees of the magnetic poles, although fade depths are generally no more than 10 dB or so. At mid latitudes ionospheric scintillation is rarely an issue. Longitude is important as well. In South America, Africa and India, the frequency of occurrence is significantly lower in the southern hemisphere winter (May-August) than during summer, while the pattern is exactly opposite in the central Pacific.

In the polar regions disturbances occur at any time of day, but in the equatorial region they tend to start an hour or so after sunset and last a few hours, from perhaps 1900-2100 local time at the equinox. Fading events are sometimes intermittent, starting abruptly and ending abruptly some minutes later. The usual paths to slow-moving sources, such as the moon or geostationary satellites, tend to be about once or twice a second. While not much work has been done on characterizing ionospheric scintillation fading on low Earth

orbit (LEO) satellites, the fade rate should be more than an order of magnitude faster since the orbital period is typically on the order of 1.5 hours, much less than the Earth's 24-hour rotational period.

As might be expected, sunspots also are important. Ionospheric scintillation is much more severe and frequent near the peak of the 11-year solar cycle. Geomagnetic storms also have a major effect, principally in the polar regions.

### 19.6.3 Earth-Moon-Earth

Amateurs have used the moon as a reflector on the VHF and UHF bands since 1960. Maximum allowable power and large antennas, along with the best receivers, are normally required to overcome the extreme free-space and reflection losses involved in Earth-Moon-Earth (EME) paths. More modest stations make EME contacts by scheduling operating times when the moon is at perigee (on the horizon). The moon, which presents a target only one-half degree wide, reflects only 7% of the radio signals that reach it. Techniques have to be designed to cope with Faraday rotation, cosmic noise, Doppler shift (due to the moon's movements) and other difficulties. In spite of the problems involved, hundreds (and possibly thousands) of amateur stations have made contacts via the moon on all bands from 50 MHz to 10 GHz. The techniques of EME

communication are discussed in the **Space Communications** section with the downloadable supplemental content.

### 19.6.4 Satellites

Accessing amateur satellites generally does not involve huge investments in antennas and equipment, yet station design does have to take into account special challenges of space propagation. Free-space loss is a primary consideration, but it is manageable when satellites are only a few hundred kilometers distant. Free-space path losses to satellites in high-Earth orbits are considerably greater, and appropriately larger antennas and higher powers are needed.

Satellite frequencies below 30 MHz can be troublesome. Ionospheric absorption and refraction may prevent signals from reaching space, especially to satellites at very low elevations. In addition, man-made and natural sources of noise are high. VHF and especially UHF are largely immune from these effects, but free-space path losses are greater. Problems related to polarization, including Faraday rotation, intentional or accidental satellite tumbling and the orientation of a satellite's antenna in relation to terrestrial antennas, are largely overcome by using circularly polarized antennas. More on using satellites can be found in the **Space Communications** section with the downloadable supplemental content.

## 19.7 Noise and Propagation

Noise simply consists of unwanted electromagnetic radiation that interferes with desired communications. In some instances, noise imposes the practical limit on the lowest usable frequencies. Noise may be classified by its sources: man-made, terrestrial (atmospheric) and cosmic. Interference from other transmitting stations on adjacent frequencies is not usually considered noise and may be controlled, to some degree anyway, by careful station design or simply moving to a frequency further away from the interference. (Additional information on noise can be found in the **RF Techniques** and **Receiving** chapters.)

### 19.7.1 Man-Made Noise

Many unintentional radio emissions result from man-made sources. Broadband radio signals are produced whenever there is a spark, such as in contact switches, electric motors, gasoline engine spark plugs and faulty electrical connections. Household appliances, such as fluorescent lamps, microwave ovens, lamp dimmers and anything containing an electric motor may all produce

undesirable broadband radio energy. Devices of all sorts, especially computers and anything controlled by microprocessors, television receivers and many other electronics also emit radio signals that may be perceived as noise well into the UHF range. In many cases, these

sources are local and can be controlled with proper measures. See the **RF Interference** chapter.

High-voltage transmission lines and associated equipment, including transformers, switches and lightning arresters, can generate

**Figure 19.37** — Typical noise levels versus frequency for various environments. (This is man-made noise in a 500-Hz bandwidth, from Rec. ITU-R P.372.7, *Radio Noise*.)

high-level radio signals over a wide area, especially if they are corroded or improperly maintained. Transmission lines may act as efficient antennas at some frequencies, adding to the noise problem. Certain kinds of street lighting, neon signs and industrial equipment also contribute their share of noise.

Figure 19.37 shows typical noise levels versus frequency, in terms of power, for various noise environments. Note that man-made noise prevails below roughly 21 MHz for a Quiet Rural noise environment, and it, rather the sensitivity of your receiver (here depicted as the MDS — the minimum discernible signal), determines how weak a signal you can hear.

### 19.7.2 Lightning

Static is a common term given to the ear-splitting crashes of noise commonly heard on nearly all radio frequencies, although it is most severe on the lowest frequency bands. Atmospheric static is primarily caused by lightning and other natural electrical discharges. Static may result from close-by thunderstorms, but most static originates with tropical storms. Like any radio signals, lightning-produced static may be propagated

over long distances by the ionosphere. Thus static is generally higher during the summer, when there are more nearby thunderstorms, and at night, when radio propagation generally improves. Static is often the limiting factor on 1.8 and 3.5 MHz, making winter a more favorable time for using these frequencies. (Note that the quiet “winter” months in the Southern Hemisphere are June through August.)

### 19.7.3 Precipitation Static and Corona Discharge

Precipitation static is an almost continuous hash-type noise that often accompanies various kinds of precipitation, including snowfall. Precipitation static is caused by rain drops, snowflakes or even wind-blown dust, transferring a small electrical charge on contact with an antenna. Electrical fields under thunderstorms are sufficient to place many objects such as trees, hair and antennas, into corona discharge. Corona noise may sound like a harsh crackling in the radio — building in intensity, abruptly ending, and then building again, in cycles of a few seconds to as long as a minute. A corona

charge on an antenna may build to some critical level and then discharge in the atmosphere with an audible pop before recharging. Precipitation static and corona discharge can be a nuisance from LF to well into the VHF range.

### 19.7.4 Cosmic Sources

The Sun, distant stars, galaxies and other cosmic features all contribute radio noise well into the gigahertz range. These cosmic sources are perceived primarily as a more-or-less constant background noise at HF. In the VHF range and higher, specific sources of cosmic noise can be identified and may be a limiting factor in terrestrial and space communications. The Sun is by far the greatest source of radio noise, but its effects are largely absent at night. The center of our own galaxy is nearly as noisy as the Sun. Galactic noise is especially noticeable when high-gain VHF and UHF antennas, such as may be used for satellite or EME communications, are pointed toward the center of the Milky Way. Other star clusters and galaxies are also radio hot-spots in the sky. Finally, there is a much lower cosmic background noise that seems to cover the entire sky.

## 19.8 Propagation Below the AM Broadcast Band

Two bands in the LF/MF spectrum have been allocated for access by amateurs: 135.7-137.8 kHz and 472-479 kHz. It would be beneficial to review some fundamental issues with respect to propagation in these bands.

Three important parameters are involved in determining the likelihood of a signal getting from Point A to Point B. These parameters are refraction, absorption and polarization. Although propagation is certainly different on 160 meters and 6 meters, an electromagnetic wave on both of these bands follows the same laws of physics. Thus understanding how these three parameters change versus frequency will give us insight into propagation on our potentially new low frequency bands.

Figure 19.38 is a ray trace at night (0500 UTC) in mid-January at moderate solar activity for frequencies from 10.65 MHz down to 150 kHz. All rays are launched at a low elevation angle of 5 degrees. (This figure was made using *Proplab Pro V3* — see the section MUF Prediction on the Home Computer for more details on this software package.)

The MUF is not high enough for 10.65 MHz under these conditions, and it goes through the ionosphere. But frequencies of 8.9 MHz and lower are successively refracted at lower heights, which results in shorter

Figure 19.38 — Low frequency ray traces showing more bending as the frequency is lowered.

hops. So RF on 135.7-137.8 kHz and 472-479 kHz will take short hops.

**Table 19.7** summarizes absorption (data from the ray trace) on 5.4 MHz, 3.65 MHz, 1.9 MHz and 150 kHz for a 1500 km hop under the same conditions as the ray traces in Figure 19.38. Note that as the frequency decreases from 5.4 MHz to 1.9 MHz, the loss due to ionospheric absorption increases as expected. But at 150 kHz the absorption is significantly reduced. This is due to the wave not getting very high into the ionosphere—in fact, the residual nighttime D region ionization is sufficient to refract this low frequency with minimal absorption. So RF on 135.7-137.8 kHz and 472-479 kHz will not suffer

**Table 19.7**

**Absorption vs Frequency**

Frequency (MHz)	Absorption per Hop (dB)
5.4	0.8
3.65	2.3
1.9	17.8
0.150	4.0

as much absorption as on 160 meters.

In theory, highly elliptical polarization will prevail for these low frequencies. It is likely that most antennas for these bands will be vertically polarized, which should be a good

match to couple the most energy into the ordinary wave.

In summary, skywave propagation on 135.7-137.8 kHz and 472-479 kHz will be via short hops between the ionosphere and the D region, but with lower absorption than on 160 meters. Tempering this lower absorption are the lower antenna efficiencies and higher received noise levels. Thus these bands will be tough, but the Amateur Radio spirit will make the most of them.

This is a cursory look at propagation on our new bands. For a more detailed discussion, visit the December 2018 Monthly Feature at [k9la.us](http://k9la.us).

## 19.9 Glossary of Radio Propagation Terms

**A index** — An open-ended linear index that corresponds roughly to the cumulative **K index** values (it's the daily average of the eight K indices after converting the K indices to a linear scale). The A index commonly varies between 0 and 30 during quiet to active conditions, and up to 100 and higher during geomagnetic storms.

**Absorption** — The dissipation of the energy of a radio wave as it travels through a medium such as the ionosphere.

**Antipode** — Locations directly opposite each other on a globe.

**Atmosphere** — The mass of air surrounding the Earth. Radio signals travel through the atmosphere and different conditions in the atmosphere (in conjunction with the signal's frequency) affect how those signals travel or propagate.

**Aurora** — A disturbance of the atmosphere at high latitudes resulting from an interaction between electrically charged particles from the magnetosphere and the magnetic field of the Earth. *Auroral propagation* occurs when HF through UHF signals are reflected from the aurora to reach another station.

**Auroral E** — Sporadic E in the auroral zone.

**Backscatter** — Single-hop signals that have been scattered by the Earth or the ocean at some distant point back toward the transmitting station.

**Beacon station** — A station that transmits continuously, allowing other stations to assess propagation to and from the location of the beacon station.

**Coronal hole** — A region on the Sun where the magnetic field is open to the interplanetary magnetic field (IMF) and

ionized particles can escape into the solar wind.

**Critical angle** — The largest angle at which a radio wave of a specified frequency can be returned to Earth by the ionosphere.

**Critical frequency** — The highest frequency that returns echoes from the E and F regions at vertical incidence.

**D region** — The lowest region of the ionosphere. The D region (or layer) contributes very little to short-wave radio propagation. It absorbs energy from radio waves as they pass through it. This absorption has a significant effect on signals below about 7.5 MHz during daylight.

**Diffraction** — Bending of waves by an edge or corner.

**E region** — The second lowest ionospheric region, the E region (or layer) has its highest electron density during the day and falls to a much lower electron density during the night. The E region can refract radio waves enough to return them to Earth.

**Earth-Moon-Earth (EME) or Moonbounce** — A method of communicating with other stations by reflecting radio signals off the Moon's surface.

**Electromagnetic wave** — A wave of energy composed of an electric and magnetic field.

**Equinoxes** — One of two points in the orbit of the Earth around the Sun at which the Earth crosses a horizontal plane extending through the equator of the Sun. The vernal equinox marks the beginning of spring and the autumnal equinox marks the beginning of autumn.

**Furaday rotation** — A rotation of the polarization of radio waves when the waves

travel through an ionized medium that is immersed in a magnetic field (for example, the Earth's ionosphere).

**F region** — A combination of the two highest ionospheric regions (or layers), the F<sub>1</sub> and F<sub>2</sub> regions. The F region refracts radio waves and returns them to Earth. Its height varies greatly depending on the time of day, season of the year and amount of sunspot activity.

**Field-aligned irregularities (FAI)** — A propagation mechanism observed at 50 and 144 MHz that occurs when irregularities in the distribution of free electrons in the ionosphere are aligned parallel to the Earth's magnetic field.

**Free-space attenuation** — The dissipation of the energy of a radio wave that results from the spherical spreading of radio energy from its source.

**Gray-line** — A special form of **long-path** propagation that takes into account the unusual ionospheric configuration along the twilight region between night and day.

**Ground-wave propagation** — The method by which radio waves travel along the Earth's surface.

**High frequency (HF)** — The term used for the frequency range between 3 MHz and 30 MHz. The amateur HF bands are where you are most likely to make long-distance (worldwide) contacts.

**Ionosphere** — A region of electrically charged (ionized) gases high in the atmosphere. The ionosphere bends radio waves as they travel through it, returning them to Earth. Also see **sky-wave propagation**.

**K index** — A geomagnetic-field measurement that is updated every three hours at various observatories around the world. Changes in the K index can be used to indicate HF propagation conditions. Rising values generally indicate disturbed conditions while falling values indicate improving conditions.

**Line-of-sight propagation** — The term used to describe VHF and UHF propagation in a straight line directly from one station to another.

**Long-path propagation** — Propagation between two points on the Earth's surface that follows a path along the great circle between them, but in a direction opposite from the shortest distance between them.

**Lowest usable frequency (LUF)** — The frequency below the **maximum usable frequency (MUF)** at which ionospheric absorption and noise at the receiving location make the received signal-to-noise ratio too low to be usable.

**M-factor** — The ratio between the **maximum usable frequency (MUF)** and the critical frequency.

**Maximum usable frequency (MUF)** — The highest-frequency radio signal that will reach a particular destination using **sky-wave propagation**, or *skip*. The MUF may vary for radio signals sent to different destinations.

**Meteor-scatter communication** — A method of radio communication that uses the ionized trail of a meteor that burned up in the Earth's atmosphere to reflect, refract, or scatter radio signals back to Earth.

**Microwave** — Radio waves or signals with frequencies greater than 1000 MHz (1 GHz). This is not a strict definition, just a conventional way of referring to those frequencies.

**Moonbounce** — A common name for EME communication in which signals are bounced off the Moon before being received.

**Multihop propagation** — Long-distance radio propagation using several skips or hops between the Earth and the ionosphere.

**Multipath** — A fading effect caused by the transmitted signal traveling to the receiving station over more than one path.

**Near Vertical Incidence Skywave (NVIS) propagation** — A propagation mechanism that allows stations located within the **skip zone**, but too far apart for ground wave propagation, to maintain communications by going to a lower frequency.

**Path loss** — The total signal loss between transmitting and receiving stations relative to the total radiated signal energy.

**Pedersen ray** — A high-angle radio wave that penetrates deeper into the F region of

than a lower-angle wave, and thus for some distance parallels the Earth's surface in the F region, returning to Earth at a distance farther than normally expected for single-hop propagation.

**Polarization** — The orientation of the electrical-field of a radio wave. An antenna that is parallel to the surface of the Earth, such as a dipole, produces horizontally polarized waves. One that is perpendicular to the Earth's surface, such as a quarter-wave vertical, produces vertically polarized waves. An antenna that has both horizontal and vertical polarization is said to be circularly polarized.

**Propagation** — The process by which radio waves travel.

**Radio frequency (RF) signals** — RF signals are generally considered to be any electrical signals with a frequency higher than 20,000 Hz, up to 300 GHz.

**Radio horizon** — The position at which a direct wave radiated from an antenna becomes tangent to the surface of the Earth. Note that as the wave continues past the horizon, the wave gets higher and higher above the surface.

**Radiation inversion** — A weather condition that affects propagation at VHF and above. Radiation inversions form only over land after sunset as a result of progressive cooling of the air near the Earth's surface.

**Rain scatter** — A special case of tropospheric scatter practical in the 3.3 to 24 GHz range that is caused by scatter from raindrops.

**Reflection** — Signals that travel by **line-of-sight propagation** are reflected by large objects like buildings.

**Refraction** — Bending waves by changing the velocity of propagation. Radio waves refract as they travel through the ionosphere. If the radio waves refract enough they will return to Earth. This is the basis for long-distance communication on the HF bands.

**Scattering** — Radio wave propagation by means of multiple reflections in the layers of the atmosphere or from an obstruction. Scatter propagation also occurs in the ionosphere when there is not enough ionization for refraction or reflection, but enough to send weak electromagnetic waves off into varied directions.

**Scintillation fading** — Fading that occurs when a signal arrives at the receiver by two or more different paths simultaneously, causing addition or partial cancellation depending on the relative phases and amplitudes of the paths.

**Selective fading** — A variation of radio-wave intensity that changes over small frequency changes. It may be caused by

the wave is traveling or changes in transmission path, among other things.

**Short path** — The shorter of the two great circle paths between two stations.

**Skip** — Propagation by means of ionospheric refraction. Traversing the distance to the ionosphere and back to the ground is called a *hop*.

**Skip zone** — A ring-shaped area of poor radio communication, too distant for ground waves and too close for sky waves.

**Sky-wave propagation** — The method by which radio waves travel through the ionosphere and back to Earth. Sometimes called *skip*, sky-wave propagation has a far greater range than **line-of-sight** and **ground-wave propagation**.

**Solar cycle** — The approximate 11-year period of variation in solar activity.

**Solar flare** — An eruption on the surface of the Sun that launches a wide spectrum of electromagnetic energy into space, disrupting communications on Earth. A large flare can also release relativistic protons that cause additional absorption in the polar cap.

**Solar wind** — Electrically charged particles emitted by the Sun and traveling through space. Variations in the solar wind may have a sudden impact on radio communications when they arrive at the atmosphere of the Earth.

**Sporadic E** — A form of enhanced radio-wave propagation that occurs when radio signals are reflected from small, thin and dense ionization patches in the E region of the ionosphere. Sporadic E is observed on the 15, 10, 6 and 2 meter bands, and occasionally on the 1.25 meter band.

**Sunspot cycle** — The number of **sunspots** increases and decreases in a somewhat predictable cycle that lasts about 11 years.

**Sunspots** — Dark spots on the surface of the Sun. When there are few sunspots, long-distance radio propagation is poor on the higher-frequency bands. When there are many sunspots, long-distance HF propagation improves.

**Temperature inversion** — A condition in the atmosphere in which a region of cool air is trapped beneath warmer air.

**Transequatorial propagation** — A form of F layer ionospheric propagation, in which signals of higher frequency than the expected MUF are propagated across the Earth's magnetic equator.

**Troposphere** — The region in Earth's atmosphere just above the Earth's surface and below the ionosphere.

**Tropospheric bending** — When radio waves are bent in the troposphere, they return to Earth farther away than the visible horizon.

**Tropospheric ducting** — A type of VHF propagation that can occur when warm air overruns cold air (a temperature inversion).

**Tropospheric scatter** — A method of radio communication at VHF and above that takes advantage of scattering in the **troposphere** to allow contacts beyond the radio horizon out to a working distance of

100 to 500 km (60 to 310 miles), depending on frequency.

**Ultra high frequency (UHF)** — The term used for the frequency range between 300 MHz and 3000 MHz (3 GHz).

Technician licensees have full privileges on all Amateur UHF bands.

**Very high frequency (VHF)** — The term used for the frequency range between

30 MHz and 300 MHz. Technician licensees have full privileges on all Amateur VHF bands.

**Visible horizon** — The most distant point one can see by line of sight.

**WWV/WWVH** — Radio stations run by the US NIST (National Institute of Standards and Technology) to provide accurate time and frequencies.

# Transmission Lines

RF power is rarely generated right where it will be used. A transmitter and the antenna it feeds are a good example. The most effective antenna installation is outdoors and clear of ground and energy-absorbing structures. The transmitter, however, is most conveniently installed indoors, where it is out of the weather and is readily accessible. A *transmission line* is used to convey RF energy from the transmitter to the antenna. A transmission line should transport the RF from the source to its destination with as little loss as possible. Additional material on the topics covered in this chapter is available in the *ARRL Antenna Book*.

## 20.1 Transmission Line Basics

There are three main types of transmission lines used by radio amateurs: coaxial, open-wire and waveguide. The most common type is the *coaxial* line, usually called *coax*, shown in various forms in **Figure 20.1**. Coax is made up of a center conductor, which may be either stranded or solid wire, surrounded by a concentric outer conductor with a *dielectric* center insulator between the conductors. The outer conductor may be braided shield wire or a metallic sheath. A flexible aluminum foil or a second braided shield is employed in some coax to improve shielding over that obtainable from a standard woven shield braid. If the outer conductor is made of solid aluminum or copper, the coax is referred to as *hardline*.

The second type of transmission line uses parallel conductors, side by side, rather than the concentric ones used in coax. Typical examples of such *open-wire* lines are 300  $\Omega$  TV ribbon line or *twin-lead* and 450  $\Omega$  ladder line (sometimes called *window line*), also shown in **Figure 20.1**. Although open-wire lines are enjoying a sort of renaissance in recent years because of their inherently lower losses in simple multiband antenna systems, coaxial cables are far more prevalent because they are much more convenient to use.

The third major type of transmission line is the *waveguide*. While open-wire and coaxial lines are used from power-line frequencies to well into the microwave region, waveguides are used at microwave frequencies only. Waveguides will be covered at the end of this chapter.

### 20.1.1 Fundamentals

In either coaxial or open-wire line, currents flowing in the two conductors travel in opposite directions as shown in **Figs 20.1E** and **20.1I**. If the physical spacing between the two parallel conductors in an open-wire line,  $S$ , is small in terms of wavelength, the phase difference between the currents will be very close to  $180^\circ$ . If the two currents also have equal amplitudes, the field generated by each conductor will cancel that generated by the other, and the line will not radiate energy, even if it is many wavelengths long.

The equality of amplitude and  $180^\circ$  phase difference of the currents in each conductor in an open-wire line determine the degree of radiation cancellation. If the currents are for some reason unequal, or if the phase difference is not  $180^\circ$ , the line will radiate energy. How such imbalances occur and to what degree they can cause problems will be covered in more detail later.

In contrast to an open-wire line, the outer conductor in a coaxial line acts as a shield, confining RF energy within the line as shown in **Figure 20.1E**. Because of *skin effect* (see the **RF Techniques** chapter), current flowing in the outer conductor of a coax does so on the inner surface of the outer conductor. The fields generated by the currents flowing on the outer surface of the inner conductor and on the inner surface of the outer conductor cancel each other out, just as they do in open-wire line.

### VELOCITY FACTOR

In free space, electrical waves travel at the speed of light, or 299,792,458 meters per second. Converting to feet per second yields 983,569,082. The length of a wave in space may be related to frequency as wavelength =  $\lambda$  = velocity/frequency. Thus, the wavelength of a

**Figure 20.1** — Common types of transmission lines used by amateurs. Coaxial cable, or “coax,” has a center conductor surrounded by insulation. The second conductor, called the shield, covers the insulation and is, in turn, covered by the plastic outer jacket. Various types are shown at A, B, C and D. The currents in coaxial cable flow on the outside of the center conductor and the inside of the outer shield (E). Open-wire line (F, G and H) has two parallel conductors separated by insulation. In open-wire line, the current flows in opposite directions on each wire (I). Articles on splicing hard line and window line are included in the supplemental information available online.

1 Hz signal is 983,569,082 ft. Changing to a more useful expression gives:

$$\lambda = \frac{983.6}{f} \quad (1)$$

where

$$\lambda = \text{wavelength, in feet}$$

$$f = \text{frequency in MHz.}$$

Thus, at 14 MHz the wavelength is 70.25 ft.

Wavelength ( $\lambda$ ) may also be expressed in electrical degrees. A full wavelength is  $360^\circ$ ,  $\frac{1}{2} \lambda$  is  $180^\circ$ ,  $\frac{1}{4} \lambda$  is  $90^\circ$ , and so forth.

Waves travel slower than the speed of light in any medium denser than a vacuum or free space. A transmission line may have an insulator which slows the wave travel down. The actual velocity of the wave is a function of the dielectric characteristic of that insulator. We can express the variation of velocity as the *velocity factor* for that particular type of dielectric — the fraction of the wave’s velocity of propagation in the transmission line compared to that in free space. The velocity factor is related to the dielectric constant of the material in use.

$$VF = \frac{1}{\sqrt{\epsilon}} \quad (2)$$

where

$$VF = \text{velocity factor}$$

$$\epsilon = \text{dielectric constant.}$$

So the wavelength in a real transmission line becomes:

$$\lambda = \frac{983.6}{f} VF \quad (3)$$

As an example, many coax cables use polyethylene dielectric over the center conductor as the insulation. The dielectric constant for

polyethylene is 2.3, so the VF is 0.66. Thus, wavelength in the cable is about two-thirds as long as a free-space wavelength.

The VF and other characteristics of many types of lines, both coax and twin lead, are shown in the table "Nominal Characteristics of Commonly used Transmission Lines" in the Component Data and References chapter.

There are differences in VF from batch to batch of transmission line because there are some variations in dielectric constant during the manufacturing processes. When high accuracy is required, it is best to actually measure VF by using an antenna analyzer to measure the resonant frequency of a length of cable. (The antenna analyzer's user manual will describe the procedure.)

## CHARACTERISTIC IMPEDANCE

A perfectly lossless transmission line may be represented by a whole series of small inductors and capacitors connected in an infinitely long line, as shown in Figure 20.2A.

We first consider this special case because we need not consider how the line is terminated at its end, since there is no end.)

Each inductor in Figure 20.2A represents the inductance of a very short section of one wire and each capacitor represents the capacitance between two such short sections. The inductance and capacitance values per unit of line depend on the size of the conductors and the spacing between them. Each series inductor acts to limit the rate at which current can charge the following shunt capacitor, and in so doing establishes a very important property of a transmission line: its *surge impedance*, more commonly known as its *characteristic impedance*. This is usually abbreviated as  $Z_0$ ,

$$Z_0 \approx \sqrt{\frac{L}{C}}$$

where L and C are the inductance and capacitance per unit length of line.

The characteristic impedance of an air-insulated parallel-conductor line, neglecting the effect of the insulating spacers, is given by

$$Z_0 = \frac{120}{\sqrt{\epsilon}} \cosh^{-1} \frac{S}{d} \quad (4)$$

where

$Z_0$  = characteristic impedance

S = center to center distance between the conductors

d = diameter of conductors in the same units as S

When  $S \gg d$ , the approximation  $Z_0 = 276 \log_{10} (2S/d)$  may be used but for  $S < 2d$  gives values that are significantly higher than the correct value, such as is often the case when wires are twisted together to form a transmission line for impedance transformers. A more complete discussion of parallel-

Figure 20.2 — Equivalent circuit (A) of an infinitely long lossless transmission line using lumped circuit constants. The actual performance of transmission line varies with frequency as shown in (B). For precision uses, the exact value for  $Z_0$ , VF, and loss should be determined by measuring the cable.

conductor characteristic impedance for very small spacings is given in the *ARRL Antenna Book*, 24th edition.

The characteristic impedance of an air-insulated coaxial line is given by

$$Z_0 = 138 \log_{10} \left( \frac{b}{a} \right) \quad (5)$$

where

$Z_0$  = characteristic impedance

b = inside diameter of outer conductors

a = outside diameter of inner conductor (in same units as b).

It does not matter what units are used for S, d, a or b, as long as they are the *same* units. A line with closely spaced, large conductors will have a low characteristic impedance, while one with widely spaced, small conductors will have a relatively high characteristic impedance. Practical open-wire lines exhibit characteristic impedances ranging from about 200 to 800  $\Omega$ , while coax cables have  $Z_0$  values between 25 to 100  $\Omega$ . Except in special instances, coax used in Amateur Radio has an impedance of 50 or 75  $\Omega$ .

All practical transmission lines exhibit some power loss. These losses occur in the resistance that is inherent in the conductors that make up the line, and from leakage currents flowing in the dielectric material between the conductors. We'll next consider what happens when a real transmission line, which is not infinitely long, is terminated in an actual load impedance, such as an antenna.

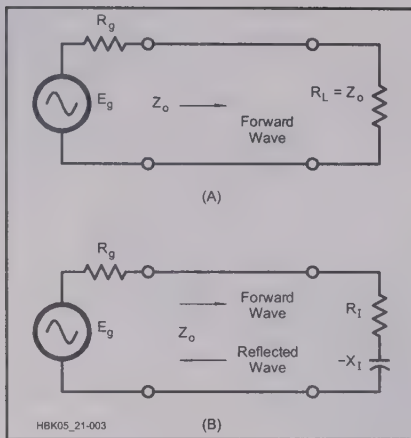

Practical lines also exhibit a fair amount of variation in characteristic impedance, VF, and line loss over wide frequency ranges. The simplified calculations given in this section make simplifying assumptions about conductor and insulation characteristics that give useful values at MF through low VHF. At lower and higher frequencies the actual values become significantly different. Figure 20.2B shows VF and line loss from 1-60 MHz for a RG11-type cable measured by Jim Brown, K9YC.

## 20.1.2 Matched and Mismatched Lines

Real transmission lines have a definite length and are connected to, or *terminate* in, a load (such as an antenna), as illustrated in Figure 20.3A. If the load is a pure resistance whose value equals the characteristic impedance of the line, the line is said to be *matched*. To current traveling along the line, such a load at the end of the line appears as though it were still more transmission line of the same characteristic impedance. In a matched transmission line, energy travels along the line from the source until it reaches the load, where it is completely absorbed (or radiated if the load is an antenna).

### MISMATCHED LINES

Assume now that the line in Figure 20.3B is terminated in an impedance  $Z_a$  which is not equal to  $Z_0$  of the transmission line. The line is now a *mismatched* line. Energy reaching the end of a mismatched line will not be fully

**Figure 20.3** — At A the coaxial transmission line is terminated with resistance equal to its  $Z_o$ . All power is absorbed in the load. At B, coaxial line is shown terminated in an impedance consisting of a resistance and a capacitive reactance. This is a mismatched line, and a reflected wave will be returned back down the line toward the generator. The reflected wave adds to the forward wave, producing a standing wave on the line. The amount of reflection depends on the difference between the load impedance and the characteristic impedance of the transmission line.

absorbed by the load impedance. Instead, part of the energy will be reflected back toward the source. The amount of reflected versus absorbed energy depends on the degree of mismatch between the characteristic impedance of the line and the load impedance connected to its end.

The reason why energy is reflected at a discontinuity of impedance on a transmission line can best be understood by examining some limiting cases. First, consider the rather extreme case where the line is shorted at its end. Energy flowing to the load will encounter the short at the end, and the voltage at that point will go to zero, while the current will rise to a maximum. Since the short circuit does not dissipate any power, the energy will all be reflected back toward the source generator.

If the short at the end of the line is replaced with an open circuit, the opposite will happen. Here the voltage will rise to maximum, and the current will by definition go to zero. The phase will reverse, and again all energy will be reflected back towards the source. By the way, if this sounds to you like what happens at the end of a half-wavelength dipole antenna, you are quite correct. However, in the case of an antenna, energy traveling along the antenna is lost by radiation on purpose, whereas a good transmission line will lose little energy to radiation because the fields from the conductors cancel outside the line.

For load impedances falling between the

extremes of short and open circuit, the phase and amplitude of the reflected wave will vary. The amount of energy reflected and the amount of energy absorbed in the load will depend on the difference between the characteristic impedance of the line and the impedance of the load at its end.

What actually happens to the energy reflected back down the line? This energy will encounter another impedance discontinuity, this time at the source. Reflected energy flows back and forth between the mismatches at the source and load. After a few such journeys, the reflected wave diminishes to nothing, partly as a result of finite losses in the line, but mainly because of partial absorption at the load each time it reaches the load. In fact, if the load is an antenna, such absorption at the load is desirable, since the energy is actually radiated by the antenna.

If a continuous RF voltage is applied to the terminals of a transmission line, the voltage at any point along the line will consist of a vector sum of voltages, the composite of waves traveling toward the load and waves traveling back toward the source generator. The sum of the waves traveling toward the load is called the *forward* or *incident* wave, while the sum of the waves traveling toward the generator is called the *reflected* wave.

### 20.1.3 Reflection Coefficient and SWR

In a mismatched transmission line, the ratio of the voltage in the reflected wave at any one point on the line to the voltage in the forward wave at that same point is defined as the *voltage reflection coefficient*. This has the same value as the current reflection coefficient. The reflection coefficient is a complex quantity (that is, having both amplitude and phase) and is generally designated by the Greek letter  $\rho$  (rho), or sometimes in the professional literature as  $\Gamma$  (Gamma). The relationship between  $R_L$  (the load resistance),  $X_L$  (the load reactance),  $Z_o$  (the line characteristic impedance, whose real part is  $R_o$  and whose reactive part is  $X_o$ ) and the complex reflection coefficient  $\rho$  is

$$\rho = \frac{Z_L - Z_o}{Z_L + Z_o} = \frac{(R_L \pm jX_L) - (R_o \pm jX_o)}{(R_L \pm jX_L) + (R_o \pm jX_o)} \quad (6A)$$

For most transmission lines the characteristic impedance  $Z_o$  is almost completely resistive, meaning that  $Z_o = R_o$  and  $X_o \cong 0$ . The magnitude of the complex reflection coefficient in equation 6A then simplifies to:

$$|\rho| = \sqrt{\frac{(R_L - R_o)^2 + X_L^2}{(R_L + R_o)^2 + X_L^2}} \quad (6B)$$

For example, if the characteristic imped-

ance of a coaxial line is  $50 \Omega$  and the load impedance is  $120 \Omega$  in series with a capacitive reactance of  $-90 \Omega$ , the magnitude of the reflection coefficient is

$$|\rho| = \sqrt{\frac{(120 - 50)^2 + (-90)^2}{(120 + 50)^2 + (-90)^2}} = 0.593$$

Note that if  $R_L$  in equation 6A is equal to  $R_o$  and  $X_L$  is 0, the reflection coefficient,  $\rho$ , is 0. This represents a matched condition, where all the energy in the incident wave is transferred to the load. On the other hand, if  $R_L$  is 0, meaning that the load is a short circuit and has no real resistive part, the reflection coefficient is 1.0, regardless of the value of  $R_o$ . This means that all the forward power is reflected since the load is completely reactive.

The concept of reflection is often shown in terms of the *return loss* (RL), which is given in dB and is equal to 20 times the log of the reciprocal of the reflection coefficient.

$$RL(\text{dB}) = -10 \log \left( \frac{P_r}{P_f} \right) = -20 \log(\rho) \quad (7)$$

In the example above, the return loss is  $20 \log(1/0.593) = 4.5$  dB. (See Table 22.65 in the **Component Data and References** chapter.)

If there are no reflections from the load, the voltage distribution along the line is constant or *flat*. A line operating under these conditions is called either a *matched* or a *flat* line. If reflections do exist, a voltage *standing-wave* pattern will result from the interaction of the forward and reflected waves along the line. For a lossless transmission line at least  $\frac{1}{4} \lambda$  long, the ratio of the maximum peak voltage anywhere on the line to the minimum value anywhere along the line is defined as the *voltage standing-wave ratio*, or VSWR. (The line must be  $\frac{1}{4} \lambda$  or longer for the true maximum and minimum to be created.) Reflections from the load also produce a standing-wave pattern of currents flowing in the line. The ratio of maximum to minimum current, or ISWR, is identical to the VSWR in a given line.

In amateur literature, the abbreviation SWR is commonly used for standing-wave ratio, as the results are identical when taken from proper measurements of either current or voltage. Since SWR is a ratio of maximum to minimum, it can never be less than one-to-one. In other words, a perfectly flat line has an SWR of 1:1. The SWR is related to the magnitude of the complex reflection coefficient and vice versa by

$$SWR = \frac{1 + |\rho|}{1 - |\rho|} \quad (8A)$$

and

$$|\rho| = \frac{SWR - 1}{SWR + 1} \quad (8B)$$

The definitions in equations 8A and 8B are

valid for any line length and for lines that are lossy, not just lossless lines longer than  $\frac{1}{4} \lambda$  at the frequency in use. Very often the load impedance is not exactly known, since an antenna usually terminates a transmission line. The antenna impedance may be influenced by a host of factors, including its height above ground, end effects from insulators, and the effects of nearby conductors. We may also express the reflection coefficient in terms of forward and reflected power, quantities that can be easily measured using a directional RF wattmeter. The reflection coefficient and SWR may be computed as

$$|\rho| = \sqrt{\frac{P_r}{P_f}} \quad (9A)$$

and

$$SWR = \frac{1 + \sqrt{\frac{P_r}{P_f}}}{1 - \sqrt{\frac{P_r}{P_f}}} \quad (9B)$$

where

$P_r$  = power in the reflected wave

$P_f$  = power in the forward wave.

If a line is not matched ( $SWR > 1:1$ ) the difference between the forward and reflected powers measured at any point on the line is the net power going toward the load from that point. The forward power measured with a directional wattmeter (often referred to as a reflected power meter or reflectometer) on a mismatched line will thus always appear greater than the forward power measured on a flat line with a 1:1 SWR.

The software program *TLW*, written by Dean Straw, N6BV, and included in the *ARRL Antenna Book* downloadable content, solves these complex equations. The characteristics of many common types of transmission lines are included in the software so that real antenna matching problems may be easily solved. Detailed instructions on using the program are included with it. *TLW* was used for the example calculations in this chapter.

### 20.1.4 Losses in Transmission Lines

A transmission line exhibits a certain amount of loss, caused by the resistance of the conductors used in the line and by dielectric losses in the line's insulators. The *matched-line loss* for a particular type and length of transmission line, operated at a particular frequency, is the loss when the line is terminated in a resistance equal to its characteristic impedance. The loss in a line is lowest when it is operated as a matched line.

Line losses increase when SWR is greater than 1:1. Each time energy flows from the generator toward the load, or is reflected at the load and travels back toward the genera-

tor, a certain amount will be lost along the line. The net effect of standing waves on a transmission line is to increase the average value of current and voltage, compared to the matched-line case. An increase in current raises  $I^2R$  (ohmic) losses in the conductors, and an increase in RF voltage increases  $E^2/R$  losses in the dielectric. Line loss rises with frequency, since the conductor resistance is related to skin effect, and also because dielectric losses rise with frequency.

*Matched-line loss* (ML) is stated in decibels per hundred feet at a particular frequency. The matched-line loss per hundred feet versus frequency for a number of common types of lines, both coaxial and open-wire balanced types, is shown graphically and as a table in the **Component Data and References** chapter. For example, RG-213 coax cable has a matched-line loss of 2.5 dB/100 ft at 100 MHz. Thus, 45 ft of this cable feeding a 50  $\Omega$  load at 100 MHz would have a loss of

$$\begin{aligned} \text{Matched line loss} &= \frac{2.5 \text{ dB}}{100 \text{ ft}} \times 45 \text{ ft} \\ &= 1.13 \text{ dB} \end{aligned}$$

If a line is not matched, standing waves will cause additional loss beyond the inherent matched-line loss for that line.

Total Mismatched Line Loss (dB)

$$= 10 \log \left[ \frac{a^2 - |\rho|^2}{a(1 - |\rho|^2)} \right] \quad (10)$$

where

$$a = 10^{ML/10}$$

ML = the line's matched loss in dB.

The effect of SWR on line loss is shown graphically in **Figure 20.4**. The horizontal axis is the SWR at the load end of the line. The family of curves is the matched loss of the length of transmission line in use. From the SWR value on the horizontal axis, proceed vertically to the curve representing the feed line's matched loss (loss with SWR of 1:1). At the intersection, the total loss can be read on the vertical axis.

#### Measuring Transmission Line Loss

The most obvious method is to use a calibrated wattmeter and dummy load. With the wattmeter at the input to the line and the dummy load at the output, apply power to the line and measure forward power,  $P_{IN}$ . (With the dummy load attached, there should be no reflected power.) Remove power and connect the input of the line directly to the power source. Connect the wattmeter between the output of the line and the dummy load. Apply the same amount of power and read forward power at the dummy load,  $P_{OUT}$ . The loss in the line is equal to  $10 \log(P_{OUT}/P_{IN})$ .

Without a wattmeter, loss can be measured by using a calibrated mismatch. Assuming a

**Figure 20.4**—Total insertion loss in a transmission line terminated in a mismatch. To use the chart, start with the SWR at the load. Find that value on the horizontal axis. From the SWR value on the horizontal axis, proceed vertically to the curve representing the feed line's matched loss (loss with SWR of 1:1). At the intersection, the total loss can be read on the vertical axis. (Courtesy of Joe Reisert, W1JR; see reference)

50- $\Omega$  system, select a non-inductive resistor between 150  $\Omega$  (3:1 SWR) and 270  $\Omega$  (5.4:1 SWR). Convert the resistor's expected SWR to return loss (RL), using the table "Reflection Coefficient, Attenuation, SWR and Return Loss" in the **Component Data and References** chapter. For example, a 220- $\Omega$  resistive load results in a 4.4:1 SWR which is a return loss of 4.0 dB. Connect the resistor to the output of the line. Make sure the resistor leads are very short so that they do not add a significant amount of inductance. Measure SWR at the input to the line and convert to return loss. The line loss is the difference between return loss at the line input and return loss of the load. For example, with the 220- $\Omega$  load (4.0 dB RL) and 100 feet of RG-58 coax at 10 MHz, the input SWR might be 3.0:1 (RL = 6.0 dB). The line loss at this frequency is 6.0 dB - 4.0 dB = 2.0 dB.

Some methods use an open or short circuit at the load end of the line (an infinite SWR and RL = 0) to measure line loss. Most amateur instrumentation is not well-calibrated at high SWR and will give an unreliable reading for SWR and RL. Using a moderate mismatch improves the accuracy of the final result. You can replace the feed line with in-line attenuators to check this more accurate method with the known amounts of loss. See the Reference entry for Stensby describing another method of calculating line loss by using measurements of mismatched impedance values.

## 20.1.5 Maximum Voltage and Current with SWR

It is useful to know what maximum voltage will occur on a transmission line with an SWR > 1:1. For example, if the line will be carrying the full legal power limit, voltage breakdown is a consideration if the SWR becomes significant, such as at a band edge far from the frequency of minimum SWR. Similarly, an open or short circuit will create high voltage at points along the line.

The following equation assumes P is the net input power, which on a directional wattmeter equals  $P_{\text{fwd}} - P_{\text{refl}}$ , and none of the reflected power is absorbed by the source

(such as a transmitter's output stage) or by line loss. In such a case, power is continually "pumped" into the line. If the termination is short or open, power is only dissipated by line loss and voltage can become very high. (See the *ARRL Antenna Book*, 24th edition for related versions of this calculation.)

$$E_{\text{max}} = \sqrt{P \times Z_0 \times \text{SWR}}; I_{\text{max}} = E_{\text{max}} / Z_0 \quad (11A)$$

$$E_{\text{min}} = E_{\text{max}} / \text{SWR}; I_{\text{min}} = I_{\text{max}} / \text{SWR} \quad (11B)$$

If  $P_{\text{fwd}} - P_{\text{refl}} = 100$  W of power is applied

to a 50-Ω line with an SWR at the load of 4:1, the maximum voltage is:

$$E_{\text{max}} = \sqrt{100 \times 50 \times 4} = 141.4 \text{ V}$$

In practice, when SWR is very high, line losses and transmitter output amplifier protection circuitry limit the peak line voltage caused by standing waves to a lower value.

$E_{\text{max}}$  and  $E_{\text{min}}$  are RMS values that would be measured with an ordinary RF voltmeter.  $E_{\text{max}}$  can be converted to an *instantaneous peak voltage* by multiplying by 1.414 and by 2.828 to find the *instantaneous peak-to-peak voltage*.

## 20.2 Choosing a Transmission Line

Making the best choice for a particular installation requires balancing the properties of the three common types of feed lines used by amateurs — coaxial, parallel-conductor or open-wire, and hardline — along with cost. The primary electrical considerations for feed line are characteristic impedance and loss. Mechanical concerns include weight, suitability for exposure to weather or soil, and interaction with other cables and conductors. When evaluating cost, be sure to include the cost of connectors and any auxiliary costs such as baluns and waterproofing materials.

The entire antenna system, composed of the feed line, tuners or matching networks and the antenna itself, must be included when evaluating what type of line to use. Along with loss, the effects of SWR on maximum voltage in the system must be considered if high power will be used, especially if high SWR is anticipated.

Multiband antenna systems, such as non-resonant wire antennas, can present quite a challenge because of the range of SWR values and the wide range of frequencies of use. As an example of the considerations involved, the article "Multiband Operation with Open-wire Line" is included with the downloadable supplemental content. By following the general process of modeling or calculation and evaluation with different types of feed line, reasonable choices can be made that result in satisfactory performance.

### 20.2.1 Effect of Loss

For most types of line and for modest values of SWR, the additional line loss due to SWR is of little concern. As the line's loss increases at higher frequencies, the total line loss (the sum of matched-line loss and additional loss due to SWR) can be surprisingly large at high values of SWR.

Because of losses in a transmission line, the measured SWR at the input of the line is lower than the SWR measured at the load end

of the line. This does *not* mean that the load is absorbing any more power. Line loss absorbs power as it travels to the load and again on its way back to the generator, so the difference between the generator output power and the power returning from the load is higher than for a lossless line. Thus,  $P_r/P_f$  is smaller than at the load and so is the measured SWR.

For example, RG-213 solid-dielectric coax

cable exhibits a matched-line loss at 28 MHz of 1.14 dB per 100 ft. A 250 ft length of this cable has a matched-line loss of  $1.14 \times 250/100 = 2.86$  dB. Assume that we measure the SWR at the load as 6:1, the total mismatched line loss from equation 10 is 5.32 dB.

The additional loss due to the 6:1 SWR at 28 MHz is  $5.32 - 2.86 = 2.46$  dB. The SWR at the input of the 250 ft line is only 2.2:1, because line loss has masked the true magnitude of SWR (6:1) at the load end of the line.

The losses increase if coax with a larger matched-line loss is used under the same conditions. For example, RG-58A coaxial cable is about one-half the diameter of RG-213, and it has a matched-line loss of 2.81 dB/100 ft at 28 MHz. A 250 ft length of RG-58A has a total matched-line loss of 7.0 dB. With a 6:1 SWR at the load, the additional loss due to SWR is 3.0 dB, for a total loss of 10.0 dB. The additional cable loss due to the mismatch reduces the SWR measured at the input of the line to 1.33:1. An unsuspecting operator measuring the SWR at his transmitter might well believe that everything is just fine, when in truth only about 10% of the transmitter power is getting to the antenna! Be suspicious of very low SWR readings for an antenna fed with a long length of coaxial cable, especially if the SWR remains

### Transmission Lines for Microwave Frequencies

While low-loss waveguide is generally used to carry microwave frequency signals for long distances, *semi-rigid* coaxial cable — essentially miniature hardline — is used for connections inside and between pieces of equipment in the shack. Working with this type of cable requires special techniques, addressed in the supplemental article "Microwave Plumbing" with this book's downloadable supplemental content. More information on microwave construction techniques is available in the **Construction Techniques** chapter and in the "Microwavelengths" columns by Paul Wade, W1GHZ in *QST*, available on-line to ARRL members.

**Table 20.1**  
Length in Feet for 1 dB of Matched Loss

MHz	1.8	3.6	7.1	14.2	21.2	28.4	50.1	144	440	1296
RG-58	179	122	83	59	50	42	30	18	9	5
RG-8X	257	181	128	90	74	63	47	27	14	8

\*Wireman #551, 400 Ω characteristic impedance

\*\*Conductors #12 AWG

low across a wide frequency range. Most antennas have narrow SWR bandwidths, and the SWR *should* change across a band.

On the other hand, if expensive  $\frac{7}{8}$  inch diameter 50  $\Omega$  hardline cable is used at 28 MHz, the matched-line loss is only 0.19 dB/100 ft. For 250 ft of this hardline, the matched-line loss is 0.475 dB, and the additional loss due to a 6:1 SWR is 0.793 dB. Thus, the total loss is 1.27 dB.

At the upper end of the HF spectrum, when the transmitter and antenna are separated by a long transmission line, the use of bargain coax may prove to be a very poor cost-saving strategy. Adding a 1500 W linear amplifier (providing 8.7 dB of gain over a 200 W transmitter), to offset the loss in RG-58A compared to hardline, would cost a great deal more than higher-quality coax. Furthermore, no *transmitting* amplifier can boost *receiver* sensitivity — loss in the line has the same effect as putting an attenuator in front of the receiver.

At the lower end of the HF spectrum, say 3.5 MHz, the amount of loss in common coax lines is less of a problem for the range of SWR values typical on this band. For example, consider an 80 meter dipole cut for the middle of the band at 3.75 MHz. It exhibits an SWR of about 6:1 at the 3.5 and 4.0 MHz ends of the band. At 3.5 MHz, 250 ft of RG-58A small-diameter coax has an additional loss of 2.1 dB for this SWR, giving a total line loss of 4.0 dB. If larger-diameter RG-213 coax is used instead, the additional loss due to SWR is 1.3 dB, for a total loss of 2.2 dB. This is an acceptable level of loss for most 80 meter operators.

The loss situation gets dramatically worse as the frequency increases into the VHF and UHF regions. At 146 MHz, the total loss in 250 ft of RG-58A with a 6:1 SWR at the load is 21.4 dB, 10.1 dB for RG-213A, and 2.7 dB for  $\frac{7}{8}$  inch, 50  $\Omega$  hardline. At VHF and UHF, a low SWR is essential to keep line losses low, even for the best coaxial cable. The length of transmission line must be kept as short as practical at these frequencies.

**Table 20.1** lists some commonly used coax cables showing feet per dB of loss vs frequency. The table can help with the selection of coax cable by comparing lengths that result in 1 dB of loss for different types of cable. The larger the value in the table, the less loss in the cable per unit length. (See also Table 23-3 and 23-4 in the *ARRL Antenna Book* for information on more types of cable.) Determine the length of line your installation requires and the maximum acceptable amount of line loss in dB. Divide the total line length by the *maximum* acceptable loss to calculate the *minimum* acceptable length of line with 1 dB of loss. From the table, select a cable type that has a length per 1 dB of loss that is greater than the minimum acceptable length.

**Example** — An installation requires 400 feet of feed line at 14 MHz with a maximum acceptable value of 3 dB of loss. This

## Using 75 $\Omega$ Hardline in 50 $\Omega$ Systems

Surplus CATV hardline is usually 75  $\Omega$  but can be used in 50  $\Omega$  systems without special impedance matching techniques. Make the 75  $\Omega$  line some integer multiple of  $\lambda/2$  at the operating frequency so that the impedance at the load end of the line is reproduced at the input to the line. This can also be done when feeding a 20/15/10 meter beam, for example, by making the 75  $\Omega$  line  $2\lambda$  on 20 meters so that it is  $3\lambda$  long on 15 and  $4\lambda$  long on 10 meters. If the load is 50  $\Omega$ , the SWR in the line will still be 75/50 = 1.5:1 but the simplicity often outweighs the minimal extra loss on the HF and lower VHF bands.

requires cable with a minimum of  $400/3 = 133$  feet per dB of loss. Find a cable in Table 20.1 that shows more than 133 feet for 1 dB of loss at 14.2 MHz. RG-213 has the highest acceptable loss at this frequency: 137 ft / dB of loss.

Don't forget that you can combine types of cable and accessories to lower the total system cost while still meeting performance requirements. For example, it is common to use a single low-loss cable from the shack to a distant tower with multiple antennas. At the tower, an antenna switch then selects short runs of less-expensive cable to the various antennas.

### 20.2.2 Practical Considerations

Either coaxial cable or open-wire transmission or feed line is used to connect the transmitter and antenna. There are pros and cons for each type of feed line. Coax is the common choice because it is readily available, its characteristic impedance is close to that of a center-fed dipole, and it may be easily routed through or along walls and among other cables. Where a very long feed line is required or the antenna is to be used at frequencies for which the feed point impedance is high, the increased RF loss and low working voltage (compared to that of open-wire line) make it a poor choice. Hardline is the preferred choice at VHF and higher frequencies when the line losses for flexible coax would be too high. It is often used for very long line lengths at HF, as well. Refer to the **Component Data and References** chapter for information that will help you evaluate the RF loss of coaxial cable at different lengths and SWR.

Note that most traditional RG-type designations are no longer MIL-spec and are only general references to the cable's construction and characteristics. For example, cable advertised as RG-213 is actually "RG-213 Type" and may have characteristics quite different from the original RG-213 specification. Use the manufacturer's part number to determine

the actual performance specifications.

## COAXIAL CABLE

Coaxial cable is mechanically much easier to use than open-wire line. Because of the excellent shielding afforded by its outer shield, coax can be installed along a metal tower leg or taped together with numerous other cables, with virtually no interaction or crosstalk. Coax can be used with a rotatable antenna without worrying about shorting or twisting the conductors, which might happen with an open-wire line.

Coaxial cable used in the amateur service is, for the most part, made with solid polyethylene (PE), extended or "foamed" polyethylene (FPE), and solid Teflon (TFE) center insulation. (Teflon dielectric coax is often used at VHF and UHF frequencies due to its low loss characteristics.)

Class 2 PVC (P2) noncontaminating outer jackets are designed for long-life outdoor installations. Class 1 PVC (P1) outer jackets are not recommended for outdoor installations. (See the table of coaxial cables in the **Component Data and References** chapter.) Coax and hardline can be buried underground, especially if run in plastic piping (with suitable drain holes) so that ground water and soil chemicals cannot easily deteriorate the cable. A cable with an outer jacket of polyethylene (PE) rather than polyvinyl chloride (PVC) is recommended for direct-bury installations.

Respect coax's power-handling ratings. Cables such as RG-58 and RG-59 are suitable for power levels up to 300 W with low SWR. RG-8X cable can handle higher power and there are a number of variations of this type of cable. For legal-limit power or moderate SWR, use the larger diameter cables that are 0.4 inches in diameter or larger. Subminiature cables, such as RG-174, are useful for very short lengths at low power levels, but the high RF losses associated with these cables make them unsuitable for most uses as antenna feed lines. In these applications, a PTFE (Teflon) insulated cable is a better choice.

### Bending Coax

Bending coax is acceptable as long as the radius of the bend is larger than the specified minimum bending radius. For example, a common minimum bending radius specification for RG-8 is 4 inches (8 times the cable diameter). Coax with more rigid shield materials will have a larger bending radius.

Bending the coax tighter than the minimum bending radius can cause impedance "bumps" in the line by distorting the geometry of the conductors. It can also cause the center conductor to migrate through the plastic insulation and eventually short to the outer shield. This is caused by several preventable conditions.

A major culprit for foam-insulation coax is bending the cable with a tight radius. Baluns are often made by wrapping several turns of

coax into a tight bundle with a tight radius, either as a coiled-coax choke or through ferrite cores. Coaxial cable stubs might be wrapped into a coil of small radius to keep them small overall and out of the way. Coax is sometimes coiled up just to use up extra length.

The forces pushing on the center conductor from coiling are aggravated by self-heating from cable loss — a direct function of the amount of power applied and SWR. RG-8X is not rated for 1500 W but lots of amateurs use it successfully at that power level. RG-8X gets warm to the touch at 1500 W. Increasing internal temperature softens the foam which facilitates center conductor migration. Tight radius bends taken together with heating are a recipe for an eventual short circuit. Tightly coiled baluns used outdoors receive solar heating in addition to self-heating and a tight bend radius. A balun made and used this way has a very high probability of shorting out over time — particularly when used at high power.

Avoiding center conductor migration is easy: don't use sharp bends, particularly at high power. Use solid dielectric coax to make tightly coiled coaxial baluns and if stubs must be coiled up, use solid dielectric coax for those too. Use up spare foam coax length by laying it flat on the floor and avoiding sharp radius turns or bends.

## Burying Coax

There are several reasons why you might choose to bury coax. One is that direct burial cable is virtually free from storm and UV damage, and usually has lower maintenance cost than cable that is out in the open. Another reason might be aesthetics; a buried cable will be acceptable in almost all communities. Also, being underground reduces common-mode feed line current on the outside of the shield, helping to reduce inter-station interference and RFI. Buried cable is also less susceptible to lightning.

Although any cable can be buried, a cable that is specifically designed for direct burial will have a longer life. The best cable to use is one that has a high-density polyethylene jacket because it is both nonporous and will take a relatively high amount of compressive loads. "Flooded" direct burial cables contain an additional moisture barrier of non-conductive grease under the jacket; this allows the material to leak out, thus "healing" small jacket penetrations. (These can be messy to work with when installing connectors.)

Here are some direct burial guidelines:

- 1) Because the outer jacket is the cable's first line of defense, any steps that can be taken to protect it will go a long way toward maintaining the internal quality of the cable.

- 2) Bury the cable in sand or finely pulverized dirt, without sharp stones, cinders, or rubble. If the soil in the trench does not meet these requirements, tamp four to six inches of sand into the trench, lay the cable

and tamp another six to eleven inches of sand above it. A pressure-treated board placed in the trench above the sand prior to backfilling will provide some protection against subsequent damage that could be caused by digging or driving stakes.

- 3) Lay the cable in the trench with some slack. A tightly stretched cable is more likely to be damaged as the fill material is tamped.

- 4) Examine the cable as it is being installed to be sure the jacket has not been damaged during storage or by being dragged across over sharp edges.

- 5) You may want to consider burying it in plastic pipe or conduit. Be careful to drill holes in the bottom of the pipe at all low spots so that any moisture can drain out. While PVC pipe or conduit provides a mechanical barrier, water incursion is practically guaranteed — you can't keep it out. It will leak in directly or condense from moisture in the air. Use the perforated type so that any water will just drain out harmlessly. Plastic drain pipe with drain holes also works well.

- 6) It is important that direct burial is below the frost line to avoid damage by the expansion and contraction of the earth during freezing and thawing of the soil and any water surrounding the buried cables.

## Connecting to and Weatherproofing Coax

Most manufacturers use some type of feed point system that accepts a PL-259 or N connector. Some antennas require you to split the coax and attach the shield and center conductor to machine screws attachment points on the driven element. The exposed end of the coax is very difficult to seal; indeed, it's nearly impossible. Water will wick down the outer shield and into your shack unless you take great pains to weatherproof it. Coating the entire pigtail and attachment terminals with Liquid Electrical Tape or some other conformal sealant is a good approach, although UV will degrade such coatings over time. Another approach for HF beams is to use a "Budwig HQ-1" style insulator with the integral SO-239 and wires for connecting to the terminals. As always, follow the manufacturer's directions.

With many beam antennas, the feed point is out of reach from the tower and should be connected to a jumper just long enough to reach from the feed point to the antenna mast. That way, the feed line connection and waterproofing can be done at the most convenient location. If you ever have to remove the antenna in the future you can just disconnect the jumper and lower the antenna.

The biggest mistake amateurs make with coaxial cable is improper weatherproofing. (See Weatherproofing Cable and Connectors in the **Safe Practices** chapter, showing one way to do it properly.) First, use high-quality electrical tape, such as 3M Scotch 33+ or

Scotch 88 (same as 33+ but 1.5 mil thicker). Avoid inexpensive utility tape. Before weatherproofing, tighten the connector (use pliers carefully to seat threaded connectors — hand-tight isn't good enough), and apply two wraps of tape around the joint.

When you're done making a tape wrap, sever the tape with a knife or tear it very carefully — do not stretch the tape until it breaks. This invariably leads to "flagging" in which the end of the tape loosens and blows around in the wind. Let the tape relax before applying the next layer and finishing the wrap.

Begin by applying two wraps of electrical tape around the joint. Next put a layer of butyl rubber vapor wrap over the joint. (3M Butyl Mastic Tape 2212 is one such material. This butyl rubber tape is also usually available in the electrical section of hardware and home improvement stores.) Finally, add two more layers of regular tape over the vapor wrap, creating a professional-quality joint that will never leak. Finally, if the coax is vertical, be sure to wrap the final layer so that the tape is going up the cable. In that way, the layers will act like roofing shingles, shedding water off the connection. Wrapping it top to bottom will guide water between the layers of tape.

An alternative method suggested by K4ZA begins with a wrap of "military grade" Teflon tape — a thread wrapping tape thicker than what you'll find at your local hardware store. (McMaster-Carr #6802K44) Over that, install a layer of Scotch 130C (liner-less rubber sealing tape), using a 50% wrap (half the tape width is overlapped). Cover that with a layer of either Scotch 33+ or Scotch 88. Taken apart, 20-year-old joints have revealed connectors with like new appearance.

A recent product for coax joints is shrink-fit tubing impregnated with hot-melt glue along the inside. As you apply heat to the shrink-fit tubing, it shrinks while the glue melts and oozes inside between the fitting and the tubing. It not only keeps the tubing from slipping, but it also fills in the voids in the joint and provides an additional seal. It's an expensive alternative (approximately \$1 per inch) but is very simple to use and remove if necessary.

Do not use silicone sealant that gives off acetic acid (a vinegary smell) and absorbs water when curing. Acid and water will migrate into the connection causing problems later. Use only aquarium-type sealants or Dow-Corning 3145 for reliable connections. Be aware that once cured, silicone sealants are very hard to remove from connectors — practically impossible.

## OPEN-WIRE LINE

The most common open-wire transmission lines are *ladder line* (also known as *window line*) and *twin-lead*. Since the conductors are not shielded, two-wire lines are affected by their environment. Use standoffs and insulators to keep the line several inches from struc-

tures or other conductors. Ladder line has very low loss (twin-lead has a little more), and it can stand very high voltages (created by high SWR) as long as the insulators are clean. Twin-lead can be used at power levels up to 300 W and ladder line to the full legal power limit.

The characteristic impedance of open-wire line varies from 300 Ω for twin-lead to 450 to 600 Ω for most ladder and window line. The common 450 Ω window line with plastic insulation and 1" spacing has a characteristic impedance of approximately 360 to 405 Ω and velocity factor (VF) of approximately 91% depending on the manufacturer and materials used. The solid plastic insulation also means that rain, snow, or ice will affect the line's  $Z_0$  and VF, typically dropping both by about 3% when the line is wet, according to a paper by Wes Stewart, N7WS ([k6mhe.com/n7ws/Ladder\\_Line.pdf](http://k6mhe.com/n7ws/Ladder_Line.pdf)). This variability suggests that if precise characteristics are important,  $Z_0$  and VF should be measured for the line to be used.

When used with ½ λ dipoles, the resulting moderate to high SWR requires an impedance-matching unit at the transmitter. The low RF losses of open-wire lines make this an acceptable situation on the HF bands.

Ladder line is available with both solid cop-

perweld and stranded copper conductors. The solid conductor types tend to be less expensive but will break if flexed repeatedly, such as from being blown around in the wind. For that reason, stranded conductor ladder line is preferred, but if solid conductor ladder line is used, be sure to provide adequate mechanical support to provide stress relief and protection against flexing. To minimize movement due to wind, twist ribbon or open-wire/window line once every two or three feet. This also helps balance the effect of capacitance to nearby objects and surfaces.

### CONTROL CABLES

In addition to coaxial cables, most towers will have some sort of control cable for rotators, antenna switches, or other accessories. The manufacturer should provide the size that is necessary and again, you should follow their specifications.

Multi-conductor cables are not usually as waterproof as coaxial cable. The jacket is usually just a plastic sleeve around the inner wires. If the jacket is nicked or cut, water can easily get in and collect at the lowest point of the cable. If the water does not leak out, it will fill the cable jacket all the way into the

station where it will run out the unsealed end of the cable. For this reason, it is common to make a drip loop in the cable where it enters the station and make a small slice or hole in the jacket to allow any accumulated water to leak out.

In the case of rotator cables, some rotators are sensitive to voltage drop so bigger sizes should be used. For really long runs, some amateurs use THHN house wire or UF-Romex, (with the motor start capacitor installed at the rotator) from the local hardware store to get reasonably-priced bigger wire. Only the motor and solenoid (if used) conductors typically require the larger wire.

For medium-length runs of buried cable, multi-conductor irrigation system control cable can be used in place of standard light-duty rotator cable. If the cable has extra conductors, pairs of conductors can be doubled to provide for the higher-current brake connections. For example, four conductors in a 10-conductor irrigation cable with #18 conductors can be doubled up in pairs to create two heavy conductors for the brake solenoid circuits. Irrigation cables generally have solid wires, requiring different terminals and splicing techniques than for stranded wire.

## 20.3 The Transmission Line as Impedance Transformer

If the complex mechanics of reflections, SWR and line losses are put aside momentarily, a transmission line can very simply be considered as an impedance transformer. A certain value of load impedance, consisting of a resistance and reactance, at the end of the line is transformed into another value of impedance at the input of the line. The amount of transformation is determined by the electrical length of the line, its characteristic impedance, and by the losses inherent in the line. The input impedance of a real, lossy transmission line is computed using the following equation

$$Z_{in} = Z_0 \times \frac{Z_L \cosh(\eta \ell) + Z_0 \sinh(\eta \ell)}{Z_L \sinh(\eta \ell) + Z_0 \cosh(\eta \ell)} \quad (12)$$

where

- $Z_{in}$  = complex impedance at input of line =  $R_{in} \pm j X_{in}$
- $Z_L$  = complex load impedance at end of line =  $R_l \pm j X_l$
- $Z_0$  = characteristic impedance of line =  $R_0 \pm j X_0$
- $\eta$  = complex loss coefficient =  $\alpha + j \beta$
- $\alpha$  = matched line loss attenuation constant, in nepers/unit length (1 neper = 8.688 dB, so divide line loss in dB per unit length by 8.688)
- $\beta$  = phase constant of line in radians/unit length (multiply electrical

### Smith Chart Software

The standard way of visualizing transmission line and impedance matching mechanics is by using a Smith chart. (If you are unfamiliar with the Smith chart, recent editions of this book and the *ARRL Antenna Book* include a detailed tutorial on the Smith chart, either in print or with the downloadable supplemental information.) Yesterday's paper charts, however, have been replaced by interactive computer software such as the easy-to-use *jsSmith* (Windows only) by Jim Tonne, W4ENE, available with the online supplemental content and *SimSmith* ([www.ae6ty.com/Smith\\_Charts.html](http://www.ae6ty.com/Smith_Charts.html)) by Ward Harriman, AE6TY. *SimSmith* is written in Java and runs on a number of operating systems. Learning about the Smith chart will be a great aid in understanding the mechanics of transmission lines and impedance matching.

- length in degrees by  $2\pi$  radians/360 degrees)
- $\ell$  = electrical length of line in same units of length as used for  $\alpha$ .

This and other complex equations describing the electrical behavior of transmission lines were traditionally solved through the use of Smith charts. (Smith charts are discussed in the article "Smith Chart Supplement" with the downloadable supplemental content. Many

references to Smith charts and their use may be found on-line.) While the Smith chart is an extremely effective way of visualizing and understanding the transmission line, using it directly in design has been replaced by software. Programs such as those mentioned in the sidebar "Smith Chart Software" can perform the numerical calculations and display the results on a Smith chart. The software *TLW* provided with the *ARRL Antenna Book* also solves problems of this nature, although without Smith chart graphics.

### 20.3.1 Transmission Line Stubs

The impedance-transformation properties of a transmission line are useful in a number of applications. If the terminating resistance is zero (that is, a short) at the end of a low-loss transmission line which is less than ¼ λ long, the input impedance consists of a reactance, which is given by a simplification of equation 12.

$$X_{in} \cong Z_0 \tan \ell \quad (13)$$

If the line termination is an open circuit, the input reactance is given by

$$X_{in} \cong Z_0 \cot \ell \quad (14)$$

The input of a short (less than ¼ λ) length of line with a short circuit as a terminating load appears as an inductance, while an open-circuited line appears as a capacitance. This

## Where to Place Stubs Used as Harmonic Filters

A quarter-wave ( $\frac{1}{4} \lambda$ ) shorted stub makes an effective harmonic filter that is able to handle high power without expensive components. As described in this section, it is easy to build without special components or construction techniques. In order to get the best performance from the stub filter, however, it is important to install the stub at an appropriate location in the transmission line.

This type of stub works by presenting an open circuit at the fundamental frequency and a short circuit on the harmonics where it is a multiple of one-half wavelength ( $\frac{1}{2} \lambda$ ). For the short circuit to be most effective, the stub should be placed at a location in the transmission line where impedance is high at the harmonic frequency. The difference in performance can be dramatic. If the stub is connected at a low-impedance point, attenuation of the harmonic can be less than 10 dB. On the other hand, connected at a high-impedance point, attenuation can be well in excess of 30 dB. Without recognizing this dependence on impedance at the point of connection, applying stub filters will result in erratic results.

A complete discussion of how to determine the optimum location for a stub is beyond the scope of this chapter but two *National Contest Journal* articles on stub placement by George Cutsogeo, W2VJN, and Jim Brown, K9YC, have been added to the supplemental files supplied with the online supplemental content. (See the Table of Contents page at the beginning of this chapter.) A convenient rule of thumb that will result in good — if not optimum — filter performance is to first determine the output circuit of the amplifier or transmitter. In almost all tube amplifiers, the output circuit will either be a Pi or a Pi-L network. (See the chapter on RF Power Amplifiers.) Solid-state transmitters usually have a low-pass LC filter at the output. Determine whether the output component of the network or filter is a shunt (parallel) capacitor or a series inductor. (Ignore protective RF chokes or similar components.)

- If the output component is a series inductor, such as in a low-pass filter or a Pi-L network, the output impedance at the frequency of the harmonic to be attenuated will probably be higher than  $50 \Omega$ . The stub is attached at the equipment output.

- If the output component is a shunt capacitor, such as in a Pi network, the output impedance at the frequency of the harmonic to be attenuated will probably be lower than  $50 \Omega$ . The nearest high-impedance point, as a result, will be  $\frac{1}{4} \lambda$  from the output. Connect a  $\frac{1}{4} \lambda$  jumper to the output and connect the stub at the junction of the jumper and the main feed line.

This simple rule-of-thumb procedure is unlikely to result in the best performance but it is a good substitute if measuring the feed line impedance directly is not practical. Both of the referenced articles go into some detail about feed line impedance measurement and determining the optimum location for the stub taking into account the antenna impedance and length of the main feed line. These are important considerations for high-performance station design to manage interstation interference. (Also see the reference section entry for *Managing Interstation Interference* by George Cutsogeo, W2VJN.) In addition, the article by Jim Brown, K9YC, discusses placement of stub harmonic filters for receiving.

Figure 20.5 — Method of attaching a stub to a feed line.

is a useful property of a transmission line, since it can be used as a low-loss inductor or capacitor in matching networks. Such lines are often referred to as stubs.

A line that is electrically  $\frac{1}{4} \lambda$  long is a special kind of a stub. When a  $\frac{1}{4} \lambda$  line is short circuited at its load end, it presents an open circuit at its input. Conversely, a  $\frac{1}{4} \lambda$  line with an open circuit at its load end presents a short circuit at its input. Such a line inverts the impedance of a short or an open circuit at the frequency for which the line is  $\frac{1}{4} \lambda$

long. This is also true for frequencies that are odd multiples of the  $\frac{1}{4} \lambda$  frequency. However, for frequencies where the length of the line is  $\frac{1}{2} \lambda$ , or integer multiples thereof, the line will duplicate the termination at its end.

### 20.3.2 Transmission Line Stubs as Filters

The impedance transformation properties of stubs can be put to use as filters. For example, if a shorted line is cut to be  $\frac{1}{4} \lambda$  long at

## Commercial Triplexer Design Example

Provided with the online supplemental content, the article “Commercial Triplexer Design” by George Cutsogeo, W2VJN, discusses the issues encountered in adapting a popular *QST* article on a Field Day-style triplexer to become a commercial product. The referenced *QST* article by Gary Gordon, K6KV, is provided as well.

Figure 20.6 — Frequency response with a shorted stub.

7.1 MHz, the impedance looking into the input of the cable will be an open circuit. The line will have no effect if placed in parallel with a transmitter’s output terminals. However, at twice the fundamental frequency, 14.2 MHz, that same line is now  $\frac{1}{2} \lambda$ , and the line looks like a short circuit. The line, often dubbed a *quarter-wave stub* in this application, will act as a trap for not only the second harmonic, but also for higher even-order harmonics, such as the fourth or sixth harmonics.

This filtering action is extremely useful in multitransmitter situations, such as Field Day, emergency operations centers, portable communications facilities and multioperator contest stations. Transmission line stubs can operate at high power where lumped-constant filters would be expensive. Using stub filters reduces noise, harmonics and strong fundamental signals from the closely spaced antennas that cause overload and interference to receivers. (For information on determining isolation between radios and filter requirements, see the supplemental article “Measuring Receiver Isolation” by W2VJN with the downloadable supplemental content.)

Quarter-wave stubs made of good-quality coax, such as RG-213, offer a convenient way to lower transmitter harmonic levels. Despite the fact that the exact amount of harmonic attenuation depends on the impedance (often unknown) into which they are working at the harmonic frequency, a quarter-wave stub will typically yield 20 to 25 dB of attenuation of

the second harmonic when placed directly at the output of a transmitter feeding common amateur antennas.

This attenuation may be a bit higher when the output impedance of the plate tuning network in an amplifier increases with frequency, such as for a pi-L network. Attenuation may be a bit lower if the tuning network's output impedance decreases with frequency, such as for a pi network.

Because different manufacturing runs of coax will have slightly different velocity factors, a quarter-wave stub is usually cut a little longer than calculated, and then carefully pruned by snipping off short pieces, while using an antenna analyzer to monitor the response at the fundamental frequency. Because the end of the coax is an open circuit while pieces are being snipped away, the input of a  $\frac{1}{4} \lambda$  line will show a short circuit exactly at the fundamental frequency. Once the coax has been pruned to frequency, a short jumper is soldered across the end, and the response at the second harmonic frequency is measured. **Figure 20.5** shows how to connect a shorted stub to a transmission line and **Figure 20.6** shows a typical frequency response.

The shorted quarter-wave stub shows low loss at 7 MHz and at 21 MHz where it is  $\frac{3}{4} \lambda$  long. It nulls 14 and 28 MHz. This is useful for reducing the even harmonics of a 7 MHz transmitter. It can be used for a

**Figure 20.7** — Frequency response with an open stub.

**Table 20.2**

**Quarter-Wave Stub Lengths for the HF Contesting Bands**

Freq (MHz)	Length ( $L_e$ )*	Cut off per 100 kHz
1.8	90 ft, 10 in	57½ in
3.5	46 ft, 9 in	15½ in
7.0	23 ft, 4 in	4 in
14.0	11 ft, 8 in	1 in
21.0	7 ft, 9 in	¾ in
28.0	5 ft, 10 in	¼ in

\*Lengths shown are for RG-213 and any similar cable, assuming a 0.66 velocity factor ( $L_e = 163.5/f$ ). See text for other cables.

21 MHz transmitter as well, and will reduce any spurious emissions such as phase noise and wideband noise which might cause interference to receivers operating on 14 or 28 MHz.

The open-circuited quarter-wave stub has a low impedance at the fundamental frequency, so it must be used at two times the frequency for which it is cut. For example, a quarter-wave open stub cut for 3.5 MHz will present a high impedance at 7 MHz where it is  $\frac{1}{2} \lambda$  long. It will present a high impedance at those frequencies where it is a multiple of  $\frac{1}{2} \lambda$ , or 7, 14 and 28 MHz. It would be connected in the same manner as **Figure 20.5** shows, and the frequency plot is shown in **Figure 20.7**.

This open stub can protect a receiver operating on 7, 14, 21 or 28 MHz from interference by a 3.5 MHz transmitter. It also has nulls at 10.5, 17.5 and 24.5 MHz — the 3rd, 5th and 7th harmonics. The length of a quarter-wave stub may be calculated as follows:

$$L_e = \frac{VF \times 983.6}{4f} \quad (15)$$

where

- $L_e$  = length in ft
- VF = propagation constant for the coax in use
- f = frequency in MHz.

For the special case of RG-213 (and any similar cable with VF = 0.66), equation 15 can be simplified to:

$$L_e = \frac{163.5}{f} \quad (16)$$

where

- $L_e$  = length in ft
- f = frequency in MHz.

**Table 20.2** solves this equation for the major contesting bands where stubs are often used. The third column shows how much of the stub to cut off if the desired frequency is 100 kHz higher in frequency. For example: To cut a stub for 14.250 MHz, reduce the overall length shown by  $2.5 \times 1$  inches, or 2.5 inches. There is some variation in dielectric constant of coaxial cable from batch to batch or manufacturer to manufacturer, so it is always best to measure the stub's fundamental resonance before proceeding.

**CONNECTING STUBS**

Stubs are usually connected in the antenna feed line close to the transmitter. They may also be connected on the antenna side of a switch used to select different antennas. Some small differences in the null depth may occur for different positions.

To connect a stub to the transmission line it is necessary to insert a coaxial T (as shown in **Figure 20.5**). If a female-male-female T is used, the male can connect directly to the transmitter while the antenna line and the

stub connect to the two females. It should be noted that the T inserts a small additional length in series with the stub that lowers the resonant frequency. The additional length for an Amphenol UHF T is about  $\frac{3}{8}$  inch. This length is negligible at 1.8 and 3.5 MHz, but on the higher bands it should not be ignored.

**MEASURING STUBS WITH ONE-PORT METERS**

Many of the common measuring instruments used by amateurs are *one-port devices*, meaning they have one connector at which the measurement — typically VSWR — is made. Probably the most popular instrument for this type of work is the antenna analyzer, available from a number of manufacturers.

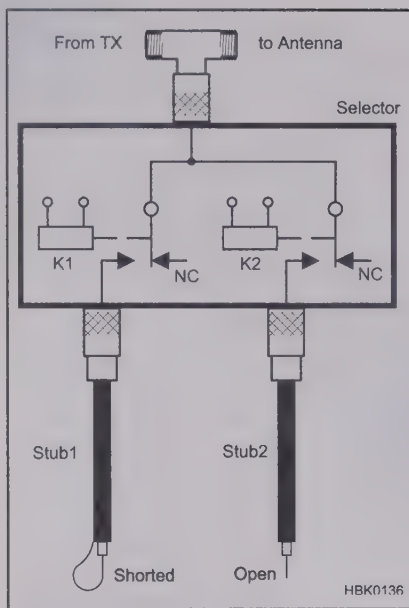

To test a stub using an antenna analyzer, connect the stub to the meter by itself and tune the meter for a minimum impedance value, ignoring the VSWR setting. It is almost impossible to get an accurate reading on the higher HF bands, particularly with open stubs. For example, when a quarter-wave open stub cut for 20 meters was nulled on an MFJ-259 SWR analyzer, the frequency measured 14.650 MHz, with a very broad null. A recheck with a professional-quality network analyzer measured 14.018 MHz. (Resolution on the network analyzer is about  $\pm 5$  kHz.) Running the same test on a quarter-wave shorted stub gave a measurement of 28.320 MHz on the MFJ-259 and 28.398 MHz on the network analyzer. (These inaccuracies are typical of amateur instrumentation and are meant to illustrate the difficulties of using inexpensive instruments for precise measurements.)

Other one-port instruments that measure phase can be used to get a more accurate reading. The additional length added by the required T adapter must be accounted for. If the measurement is made without the T and then with the T, the average value will be close to correct.

**MEASURING STUBS WITH TWO-PORT INSTRUMENTS**

A two-port measurement is made with a signal generator and a separate detector. A T connector is attached to the generator with the stub connected to one side. The other side is connected to a cable of any length that goes to the detector. The detector should present a 50  $\Omega$  load to the cable. This is how a network analyzer is configured, and it is similar to how the stub is connected in actual use. If the generator is calibrated accurately, the measurement can be very good. There are a number of ways to do this without buying an expensive piece of lab equipment.

An antenna analyzer can be used as the signal generator. Measurements will be quite accurate if the detector has 30 to 40 dB dynamic range. Two setups were tested for accuracy. The first used a digital voltmeter with a diode detector. (A germanium diode

**Figure 20.8** — Schematic of the Field Day stub switching relay control box. Table 20.3 shows which relays should be closed for the desired operating band.

(1N34A or equivalent) must be used for the best dynamic range.) Tests on open and shorted stubs at 14 MHz returned readings within 20 kHz of the network analyzer. Another test was run using an oscilloscope as the detector with a 50 Ω load on the input. This test produced results that were essentially the same as the network analyzer.

A noise generator can be used in combination with a receiver as the detector. (An inexpensive noise generator kit is available from Elecraft, [www.elecraft.com](http://www.elecraft.com).) Set the receiver for 2-3 kHz bandwidth and turn off the AGC. An ac voltmeter connected to the audio output of the receiver will serve as a null detector. The noise level into the receiver without the stub connected should be just at or below the limiting level. With the stub connected, the noise level in the null should drop by 25 or 30 dB. Connect the UHF T to the

**Table 20.3**

**Stub Selector Operation**

See Figure 20.8 for circuit details.

Relay K1 Position	Relay K2 Position	Bands Passed (meters)	Bands Nulled (meters)
Open	Open	All	None
Energized	Energized	80	40, 20, 15, 10
Energized	Open	40, 15	20, 10
Open	Energized	20, 10	40, 15

noise generator using any necessary adapters. Connect the stub to one side of the T and connect the receiver to the other side with a short cable. Tune the receiver around the expected null frequency. After locating the null, snip off pieces of cable until the null moves to the desired frequency. Accuracy with this method is within 20 or 30 kHz of the network analyzer readings on 14 MHz stubs.

A vector network analyzer or VNA is another type of two-port device. VNAs can perform both reflection measurements as a one-port device and transmission measurements through a device or system at two locations. Once only available as expensive lab instruments, a number of inexpensive VNA designs that use a PC to perform display and calculations are now available to amateurs. The use of VNAs is discussed in the **Test Equipment and Measurements** chapter of this book.

**STUB COMBINATIONS**

A single stub will give 20 to 30 dB attenuation in the null. If more attenuation is needed, two or more similar stubs can be combined. Best results will be obtained if a short coupling cable is used to connect the two stubs rather than connecting them directly in parallel. The stubs may be cut to the same frequency for maximum attenuation, or to two slightly different frequencies such as the CW and SSB frequencies in one band. Open and shorted stubs can be combined together to attenuate higher harmonics as well as lower

frequency bands.

An interesting combination is the parallel connection of two  $\frac{1}{8} \lambda$  stubs, one open and the other shorted. The shorted stub will act as an inductor and the open stub as a capacitor. Their reactance will be equal and opposite, forming

a resonant circuit. The null depth with this arrangement will be a bit better than a single quarter-wave shorted stub. This presents some possibilities when combinations of stubs are used in a band switching system.

**20.3.3 Project: A Field Day Stub Assembly**

Figure 20.8 shows a simple stub arrangement that can be useful in a multi-transmitter Field Day station. The stubs reduce out-of-band noise produced by the transmitters that would cause interference to the other stations — a common Field Day problem where the stations are quite close together. This noise cannot be filtered out at the receiver and must be removed at the transmitter. One stub assembly would be connected to each transmitter output and manually switched for the appropriate band.

Two stubs are connected as shown. The two-relay selector box can be switched in four ways. Stub 1 is a shorted quarter-wave 40 meter stub. Stub 2 is an open quarter-wave 40 meter stub. Operation is as shown in Table 20.3.

The stubs must be cut and tuned while connected to the selector relays. RG-213 may be used for any amateur power level and will provide 25 to 30 dB reduction in the nulls. For power levels under 500 W or so, RG-8X may be used. It will provide a few dB less reduction in the nulls because of its slightly higher loss than RG-213.

**20.4 Matching Impedances in the Antenna System**

Only in a few special cases is the antenna impedance the exact value needed to match a practical transmission line. In all other cases, it is necessary either to operate with a mismatch and accept the SWR that results, or else to bring about a match between the line and the antenna.

When transmission lines are used with a transmitter, the most common load is an antenna. When a transmission line is connected between an antenna and a receiver, the receiver input circuit is the load, not the antenna, because the power taken from a pass-

ing wave is delivered to the receiver.

Whatever the application, the conditions existing at the load, and *only* the load, determine the reflection coefficient, and hence the SWR, on the line. If the load is purely resistive and equal to the characteristic impedance of the line, there will be no standing waves. If the load is not purely resistive, or is not equal to the line  $Z_0$ , there will be standing waves. No adjustments can be made at the input end of the line to change the SWR at the load. Neither is the SWR affected by changing the line length, except as previously described

when the SWR at the input of a lossy line is masked by the attenuation of the line.

**20.4.1 Conjugate Matching**

Technical literature sometimes uses the term *conjugate match* to describe the condition where the impedance seen looking toward the load from any point on the line is the complex conjugate of the impedance seen looking toward the source. This means that the resistive and reactive magnitudes of the impedances are the same, but that the reac-

tances have opposite signs. For example, the complex conjugate of  $20 + j 75$  is  $20 - j 75$ . The complex conjugate of a purely resistive impedance, such as  $50 + j 0 \Omega$ , is the same impedance,  $50 + j 0 \Omega$ . A conjugate match is necessary to achieve the maximum power gain possible from most signal sources.

For example, if 50 feet of RG-213 is terminated in a  $72 - j 34 \Omega$  antenna impedance, the transmission line transforms the impedance to  $35.9 - j 21.9 \Omega$  at its input. (The *TLW* program is used to calculate the impedance at the line input.) To create a conjugate match at the line input, a matching network would have to present an impedance of

$35.9 + j 21.9 \Omega$ . The system would then become resonant, since the  $\pm j 21.9 \Omega$  reactances would cancel, leaving  $35.9 + j 0 \Omega$ . A conjugate match is not the same as transforming one impedance to another, such as from  $35.9 - j 0 \Omega$  to  $50 + j 0 \Omega$ . An additional impedance transformation network would be required for that step.

Conjugate matching is often used for small-signal amplifiers, such as preamps at VHF and above, to obtain the best power gain. The situation with high-power amplifiers is complex and there is considerable discussion as to whether conjugate matching delivers the highest efficiency, gain and power output. Nevertheless, conjugate matching is the model most often applied to impedance matching in antenna systems.

The concept of conjugate impedance matching is explored in more detail by Lou Ernst, WA2GKH, in an online tutorial on this book's web page. The PDF presentation and *Excel* spreadsheet tool are available in the Software section of the web page at [arrrl.org/arrrl-handbook-reference](http://arrrl.org/arrrl-handbook-reference).

### 20.4.2 Impedance Matching Networks

When all of the components of an antenna system — the transmitter, feed line, and antenna — have the same impedance, all of the power generated by the transmitter is transferred to the antenna and SWR is 1:1. This is rarely the case, however, as antenna feed-point impedances vary widely with frequency and design. This requires some method of *impedance matching* between the various antenna system components.

Many amateurs use an *impedance-matching unit* or “antenna tuner” between their transmitter and the transmission line feeding the antenna. (This is described in a following section.) The antenna tuner's function is to transform the impedance, whatever it is, at the transmitter end of the transmission line into the  $50 \Omega$  required by the transmitter. Remember that the use of an antenna tuner at the transmitter does *not tune the antenna*, reduce SWR on the feed line or reduce feed line losses!

Some matching networks are built directly into the antenna (for example, the gamma and beta matches) and these are discussed in

the chapter on **Antennas** and in *The ARRL Antenna Book*. Impedance matching networks made of fixed or adjustable components can also be used at the antenna and are particularly useful for antennas that operate on a single band.

Remember, however, that impedance can be transformed anywhere in the antenna system to match any other desired impedance. A variety of techniques can be used as described in the following sections, depending on the circumstances.

An electronic circuit designed to convert impedance values is called an *impedance matching network*. The most common impedance matching network circuits for use in systems that use coax cable are:

- 1) The low-pass L network.
- 2) The high-pass L network.
- 3) The low-pass pi network.
- 4) The high-pass T network.

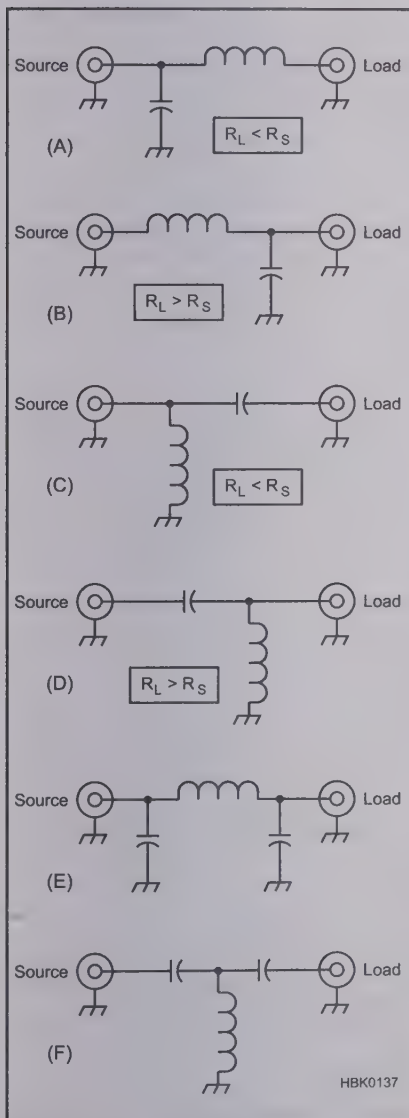

Basic schematics for each of the circuits are shown in **Figure 20.9**. Properties of the circuits are shown in **Table 20.4**. As shown in Table 20.4, the L networks can be reversed if matching does not occur in one direction. L networks are the most common for single-band antenna matching. The component in parallel is the *shunt* component, so the L networks with the shunt capacitor or inductor at the input (Figs 20.9A and 20.9C) are *shunt-input* networks and the others are *series-input* networks.

Impedance matching circuits can use fixed-value components for just one band when a particular antenna has an impedance that is too high or low, or they can be made to be adjustable when matching is needed on several bands, such as for matching a dipole antenna fed with open-wire line.

Additional material by Bill Sabin, WØIYH, on matching networks can be found with the downloadable supplemental content along with his program *MATCH*. The supplemental article “Using *TLW* to Design Impedance Matching Networks” by W2VJN is also with the downloadable supplemental content.

### DESIGNING AN L NETWORK

The L network, shown in Figure 20.9A through 20.9D, only requires two components and is a particularly good choice of matching network for single-band antennas. The L network is easy to construct so that

**Figure 20.9** — Matching network variations. A through D show L networks. E is a pi network, equivalent to a pair of L networks sharing a common series inductor. F is a T network, equivalent to a pair of L networks sharing a common parallel inductor.

**Table 20.4**

#### Network Performance

Figure 20.9 Section	Circuit Type	Match Higher or Lower?	Harmonic Attenuation?
(A)	Low-pass L network	Lower	Fair to good
(B)	Reverse Low-pass L network	Higher	Fair to good
(C)	High-pass L network	Lower	No
(D)	Reverse high-pass L network	Higher	No
(E)	Low-pass Pi network	Lower and Higher	Good
(F)	High-pass T network	Lower and higher	No

it can be mounted at or near the feed point of the antenna, resulting in 1:1 SWR on the transmission line to the shack. (Note that L networks as well as pi and T networks can easily be designed with the *TLW* software.)

To design an L network, both the source and load impedances must be known. Let us assume that the source impedance,  $R_S$ , will be  $50\ \Omega$ , representing the transmission line to the transmitter, and that the load is an arbitrary value,  $R_L$ .

First, determine the circuit  $Q$ .

$$Q^2 + 1 = \frac{R_L}{50} \quad (17A)$$

or

$$Q = \sqrt{\frac{R_L}{50} - 1} \quad (17B)$$

Next, select the type of L network you want from Figure 20.9. Note that the parallel component is always connected to the higher of the two impedances, source or load. Your choice should take into account whether either the source or load require a dc ground (parallel or shunt-L) and whether it is necessary to have a dc path through the network, such as to power a remote antenna switch or other such device (parallel- or shunt-C). Once you have selected a network, calculate the values of  $X_L$  and  $X_C$ :

$$X_L = Q R_S \quad (18)$$

and

$$X_C = \frac{R_L}{Q} \quad (19)$$

As an example, we will design an L network to match a  $300\ \Omega$  antenna ( $R_L$ ) to a

$50\ \Omega$  transmission line ( $R_S$ ).  $R_L > R_S$  so we can select either Figure 20.9B or Figure 20.9D. The network in B is a low-pass network and will attenuate harmonics, so that is the usual choice.

$$Q = \sqrt{\frac{300}{50} - 1} = 2.236$$

$$X_L = 50 \times 2.236 = 112\ \Omega$$

$$X_C = \frac{300}{2.236} = 134\ \Omega$$

If the network is being designed to operate at 7 MHz, the actual component values are:

$$L = \frac{X_L}{2\pi f} = 2.54\ \mu\text{H}$$

$$C = \frac{1}{2\pi f X_C} = 170\ \text{pF}$$

The components could be fixed-value or adjustable. By running the *TLW* software, additional information is obtained: At 1500 W there will be 942 V peak across the capacitor and 5.5 A flowing in the inductor.

The larger the ratio of the impedances to be transformed, the higher  $Q$  becomes. High values of  $Q$  (10 or more) may result in impractically high or low component values. In this case, it may be easier to design the matching network as a pair of L networks back-to-back that accomplish the match in two steps. Select an intermediate value of impedance,  $R_{INT}$ , the

geometric mean between  $R_L$  and the source impedance:

$$R_{INT} = \sqrt{R_L R_S}$$

Construct one L network that transforms  $R_L$  to  $R_{INT}$  and a second L network that transforms  $R_{INT}$  to  $R_S$ .

### 20.4.3 Matching Antenna Impedance at the Antenna

This section describes methods by which a network can be installed at or near the antenna feed point to provide matching to a transmission line. Having the matching system at the antenna rather than down in the shack at the end of a long transmission line does seem intuitively desirable, but it is not always very practical, especially in multiband antennas as discussed below.

#### RESONATING THE ANTENNA

If a highly reactive antenna can be tuned to resonance, even without special efforts to make the resistive portion equal to the line's characteristic impedance, the resulting SWR is often low enough to minimize additional line loss due to SWR. For example, the multiband 100 ft long flat-top antenna in **Figure 20.10** has a feed point impedance of  $4.18 - j1590\ \Omega$  at 1.8 MHz. Assume that the antenna reactance is tuned out with a network consisting of two symmetrical inductors whose reactance is  $+j1590/2 = j795\ \Omega$  each, with a  $Q$  of 200. These inductors are  $70.29\ \mu\text{H}$  coils in series with inherent loss resistances of  $795/200 = 3.98\ \Omega$ . The total series resistance is thus  $4.18 + 2 \times (3.98) = 12.1\ \Omega$ . If placed in series with each leg of the antenna reactance and inductor reactance cancel out, leaving a purely resistive impedance at the antenna feed point.

If this tuned system is fed with  $50\ \Omega$  coaxial cable, the SWR is  $50/12.1 = 4.13:1$ , and the loss in 100 ft of RG-213 cable would be 0.48 dB. The antenna's radiation efficiency is the ratio of the antenna's radiation resistance ( $4.18\ \Omega$ ) to the total feed point resistance including the matching coils ( $12.1\ \Omega$ ), so efficiency is  $4.18/12.1 = 34.6\%$  which is equivalent to 4.6 dB of loss compared to a 100% efficient antenna. Adding the 0.48 dB of loss in the line yields an overall system loss of 5.1 dB. Compare this to the loss of 26 dB if the RG-213 coax is used to feed the antenna directly, without any matching at the antenna. The use of moderately high- $Q$  resonating inductors has yielded almost 21 dB of "gain" (that is, less loss) compared to the case without the inductors. The drawback of course is that the antenna is now resonant on only one frequency, but it certainly is a lot more efficient on that one frequency!

**Figure 20.10** — The efficiency of a short dipole can be improved at 1.8 MHz with a pair of inductors inserted symmetrically at the feed point. Each inductor is assumed to have a  $Q$  of 200. By resonating the dipole in this fashion the system efficiency, when fed with RG-213 coax, is about 21 dB better than using this same antenna without the resonator. The disadvantage is that the formerly multiband antenna can only be used on a single band.

**Figure 20.11** — Array of two stacked Yagis, illustrating use of  $\frac{1}{4} \lambda$  matching sections. At the junction of the two equal lengths of 50  $\Omega$  feed line the impedance is 25  $\Omega$ . This is transformed back to 50  $\Omega$  by the two paralleled 75  $\Omega$ ,  $\frac{1}{4} \lambda$  lines, which together make a net characteristic impedance of 37.5  $\Omega$ . This is close to the 35.4  $\Omega$  value computed by the formula.

### THE QUARTER-WAVE TRANSFORMER OR “Q” SECTION

The range of impedances presented to the transmission line is usually relatively small on a typical amateur antenna, such as a dipole or a Yagi when it is operated close to resonance. In such antenna systems, the impedance-transforming properties of a  $\frac{1}{4} \lambda$  section of transmission line are often utilized to match the transmission line at the antenna.

If the antenna impedance and the characteristic impedance of a feed line to be matched are known, the characteristic impedance needed for a quarter-wave matching section of low-loss cable is expressed by another simplification of equation 12.

$$Z = \sqrt{Z_1 Z_0} \quad (20)$$

where

$Z$  = characteristic impedance needed for matching section

$Z_1$  = antenna impedance

$Z_0$  = characteristic impedance of the line to which it is to be matched.

**Figure 20.12** — A two-section twelfth-wave transformer can be used to match two different feed line impedances. This is a common technique for using surplus 75  $\Omega$  hardline in 50  $\Omega$  systems.

Such a matching section is called a *synchronous quarter-wave transformer* or a *quarter-wave transformer*. The term synchronous is used because the match is achieved only at the length at which the matching section is exactly  $\frac{1}{4} \lambda$  long. This limits the use of  $\frac{1}{4} \lambda$  transformers to a single band. Different  $\frac{1}{4} \lambda$  lengths of line are required on different bands.

**Figure 20.11** shows one example of this technique to feed an array of stacked Yagis on a single tower. Each antenna is resonant and is fed in parallel with the other Yagis, using equal lengths of coax to each antenna called *phasing lines*. A stacked array is used to produce not only gain, but also a wide vertical elevation pattern, suitable for coverage of a broad geographic area. (See *The ARRL Antenna Book* for details about Yagi stacking.)

The feed point impedance of two 50  $\Omega$  Yagis fed with equal lengths of feed line connected in parallel is 25  $\Omega$  (50/2  $\Omega$ ); three in parallel yield 16.7  $\Omega$ ; four in parallel yield 12.5  $\Omega$ . The nominal SWR for a stack of four Yagis is 4:1 (50/12.5). This level of SWR does not cause excessive line loss, provided that low-loss coax feed line is used. However, many station designers want to be able to select, using relays, any individual antenna in the array, without having the load seen by the transmitter change. (Perhaps they might wish to turn one antenna in the stack in a different direction and use it by itself.) If the load changes, the amplifier must be retuned, an inconvenience at best.

Example: To match a 50  $\Omega$  line to a Yagi stack consisting of two antennas fed in parallel to produce a 25  $\Omega$  load, the quarter-wave matching section would require a characteristic impedance of

$$Z = \sqrt{50 \times 25} = 35.4 \Omega$$

RG-83 is a 35- $\Omega$  cable suitable for this application. A transmission line with a characteristic impedance of 35  $\Omega$  could be closely approximated by connecting two equal  $\frac{1}{4} \lambda$  sections of 75  $\Omega$  cable (such as RG-11A) in parallel to yield the equivalent of a 37.5  $\Omega$  cable. Three Yagis fed in parallel would require a  $\frac{1}{4} \lambda$  transformer made using a cable having a characteristic impedance of

$$Z = \sqrt{16.7 \times 25} = 28.9 \Omega$$

This is approximated by using a  $\frac{1}{4} \lambda$  section of 50  $\Omega$  cable in parallel with a  $\frac{1}{4} \lambda$  section of 75  $\Omega$  cable, yielding a net impedance of 30  $\Omega$ , quite close enough to the desired 28.9  $\Omega$ . Four Yagis fed in parallel would require a  $\frac{1}{4} \lambda$  transformer made up using cable with a characteristic impedance of 25  $\Omega$ , easily created by using two 50  $\Omega$  cables in parallel.

The 100 foot flat-top example in the previous section with the two resonating coils has an impedance of 12  $\Omega$  at the feed point. Two RG-58A cables, each  $\frac{1}{4} \lambda$  long at 1.8 MHz (90 ft) can be connected in parallel to feed this antenna. An additional 10 ft length of RG-213 can make up the required 100 ft. The match will be almost perfect. The disadvantage of this system is that it limits the operation to one band, but the overall efficiency will be quite good.

Another use of  $\frac{1}{4} \lambda$  transformers is in matching the impedance of full-wave loop antennas to 50  $\Omega$  coax. For example, the driven element of a quad antenna or a full-wave 40 meter loop has an impedance of 100 to 150  $\Omega$ . Using a  $\frac{1}{4} \lambda$  transformer made from 62, 75 or 93  $\Omega$  coaxial cable would lower the line SWR to a level where losses were insignificant.

### TWELFTH-WAVE TRANSFORMERS

The Q-section is really a special case of series-section impedance matching. (See the *ARRL Antenna Book* for an extended discussion of the technique.) A particularly handy two-section variation shown in **Figure 20.12** can be used to match two different impedances of transmission line, such as 50  $\Omega$  coax and 75  $\Omega$  hardline. Sections with special impedances are not required, only sections of the two feed lines to be matched. (Also see the sidebar “Using 75  $\Omega$  Hardline in 50  $\Omega$  Systems” in the section on Choosing a Transmission Line.)

This configuration is referred to as a *twelfth-wave transformer* because when the ratio of impedances to be matched is 1.5:1 (as is the case with 50 and 75  $\Omega$  cables) the electrical length of the two matching sections between the lines to be matched is 0.0815  $\lambda$  (29.3°), quite close to  $\lambda/12$

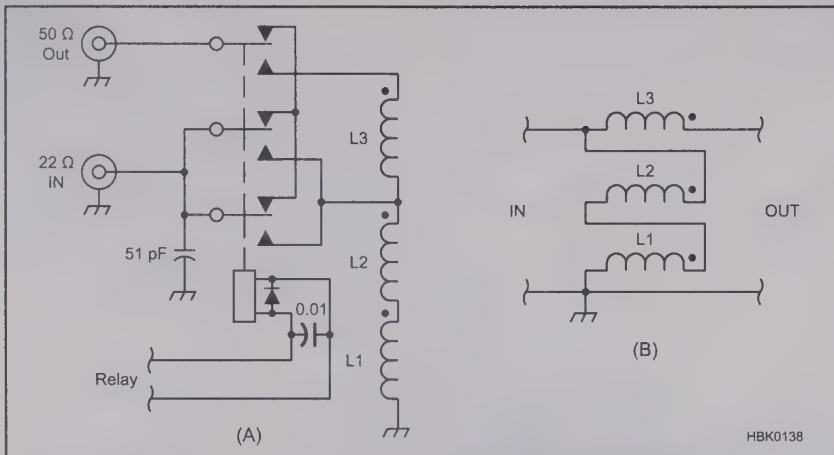

## 20.4.4 Matching the Line to the Transmitter

So far we have been concerned mainly with the measures needed to achieve acceptable amounts of loss and a low SWR for feed lines connected to antennas. Not only is feed line loss minimized when the SWR is kept within reasonable bounds, but also the transmitter is able to perform as specified when connected to the load resistance it was designed to drive.

Most modern amateur transmitters have solid-state final amplifiers designed to work into a 50  $\Omega$  load with broadband, non-adjustable impedance matching networks. While the adjustable pi networks used in vacuum-tube amplifiers can accommodate a wide range of impedances, typical solid-state transmitters utilize built-in protection circuitry that automatically reduces output power if the SWR rises to more than about 2:1.

Besides the rather limited option of using only inherently low-SWR antennas to ensure that the transmitter sees the load for which it was designed, an *impedance-matching unit* or *antenna tuner* ("tuner" for short) can be used. The function of an antenna tuner is to transform the impedance at the input end of the transmission line, whatever that may be, to the 50  $\Omega$  value required by the transmitter for best performance.

Some solid-state transmitters incorporate (usually at extra cost) automatic antenna tuners so that they too can cope with practical antennas and transmission lines. The range of impedances that can be matched by the built-in tuners is typically rather limited, however,

**Figure 20.13** — Schematic for the impedance matching transformer described in the text. The complete schematic is shown at A. The physical positioning of the windings is shown at B.

( $0.0833 \lambda$  or  $30^\circ$ ). As with all synchronous transformers, the matching function works on only one band.

### MATCHING TRANSFORMERS

Another matching technique uses wide-band toroidal transformers. Transformers can be made that operate over very wide frequency ranges and that will match various impedances.

A very simple matching transformer consists of three windings connected in series as shown in **Figure 20.13A**. The physical arrangement of the three windings is shown in **Figure 20.13B**. This arrangement gives the best bandwidth. **Figure 20.14** shows a picture of this type of transformer. An IN/OUT relay is included with the transformer. One relay pole switches the 50  $\Omega$  input port while two poles in parallel switch the 22  $\Omega$  port. Three 14 inch lengths of #14 AWG wire are taped together so they lie flat on the core. A #61 mix toroid core 2.4 inch in diameter will handle full legal power.

Use magnet wire rated for high-voltage use, such as TEMCo GP/MR-200 or Superior Essex ALLEX wire which is rated for use to 200  $^\circ\text{C}$  with 5.7 kV rating of the insulation. Motor repair shops may sell small quantities for single projects. Before winding on an uncoated toroid core, particularly ferrite which is abrasive, wrap the core with one or two layers of high-quality electrical tape such as Scotch 88 to avoid damaging the wire coating. When winding the toroid, it is not necessary for the wire to be pulled tight against the core, which can cause additional stresses to the insulation.

The impedance ratio of this design is 1:2.25 or 22.22-to-50  $\Omega$ . This ratio turns out to work well for two or three 50  $\Omega$  antennas in parallel. Two in parallel will give an SWR of 25/22.22 or 1.125:1. Three in parallel give an SWR of 22.22/16.67 or 1.33. The unit shown in **Figure**

**20.14** has an SWR bandwidth of 1.5 MHz to more than 30 MHz. The 51 pF capacitor is connected to ground (shunt) at the low-impedance input to cancel unwanted stray inductive reactance.

This is a good way to stack two or three triband antennas. If they have the same length feed lines and they all point the same way, their patterns will add and some gain will result. However, they don't even need to be on the same tower or pointed in the same direction or fed with the same length lines to have some benefit. Even dissimilar antennas can sometimes show a benefit when connected together in this fashion.

**Figure 20.14** — The completed impedance matching transformer assembly for the schematic shown in **Figure 20.13**.

especially at lower frequencies. Most built-in tuners specify a maximum SWR of 3:1 that can be transformed to 1:1.

Do not forget that a tuner does *not* alter the SWR on the transmission line between the tuner and the antenna; it only adjusts the impedance at the transmitter end of the feed line to the value for which the transmitter was designed. Other names for antenna tuners include *transmatch*, *impedance matcher*, *matchbox* or *antenna coupler*. Since the SWR on the transmission line between the antenna and the output of the antenna tuner is rarely 1:1, some loss in the feed line due to the mismatch is unavoidable, even though the SWR on the short length of line between the tuner and the transmitter is 1:1.

If separate feed lines are used for different bands, the tuner can be inserted in one feed line, tuned for best VSWR, and left at that setting. If a particular antenna has a minimum VSWR in the CW portion of a band and operation in the SSB end is desired, the tuner can be used for matching and switched out when not needed. Multiband operation generally requires retuning for each band in use.

Antenna tuners for use with balanced or open-wire feed lines include a balun or link-coupling circuit as seen in **Figure 20.15**. This allows a transmitter's unbalanced coaxial output to be connected to the balanced feed line. A fully-balanced tuner has a symmetrical internal circuit with a tuner circuit for each side of the feed line and the balun at the input to the tuner where the impedance is close to 50 Ω. Most antenna tuners are unbalanced, however, with a balun located at the output of the impedance matching network, connected directly to the balanced feed line. At very high or very low impedances, the balun's power rating may be exceeded at high transmitted power levels.

Automatic antenna tuners use a micro-processor to adjust the value of the internal components. Some models sense high values of SWR and retune automatically, while others require the operator to initiate a tuning operation. Automatic tuners are available for low- and high-power operation and generally handle the same values of impedance as their manually-adjusted counterparts.

## THE T NETWORK

Over the years, radio amateurs have derived a number of circuits for use as tuners. The most common form of antenna tuner in recent years is some variation of a T network, as shown in **Figure 20.16A**. Note that the choke or current balun can be used at the input or output of the tuner to match balanced feed lines.

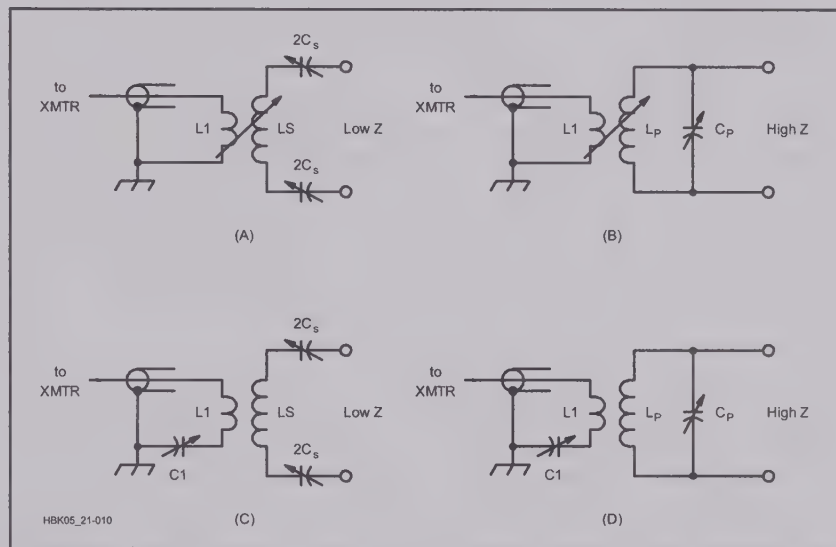

The T network can be visualized as being two L networks back to front, where the common element has been conceptually broken down into two inductors in parallel (see **Figure 20.16B**). The L network connected to the load transforms the output impedance

$R_a \pm j X_a$  into its parallel equivalent by means of the series output capacitor C2. The first L network then transforms the parallel equivalent back into the series equivalent and resonates the reactance with the input series capacitor C1.

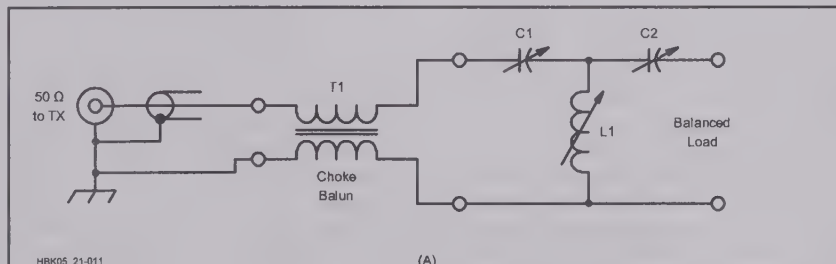

Note that the equivalent parallel resistance  $R_p$  across the shunt inductor can be a very large value for highly reactive loads, meaning that the voltage developed at this point can be very high. For example, assume that the load impedance at 3.8 MHz presented to the antenna tuner is  $Z_a = 20 - j 1000$ . If C2 is 300 pF,

then the equivalent parallel resistance across L1 is 66,326 Ω. If 1500 W appears across this parallel resistance, a peak voltage of 14,106 V is produced, a very substantial level indeed. Highly reactive loads can produce very high voltages across components in a tuner.

The ARRL computer program *TLW* calculates and shows graphically the antenna-tuner values for operator-selected antenna impedances transformed through lengths of various types of practical transmission lines. (See the supplemental article "Using *TLW* to

**Figure 20.15** — Simple antenna tuners for coupling a transmitter to a balanced line presenting a load different from the transmitter's design load impedance, usually 50 Ω. A and B, respectively, are series and parallel tuned circuits using variable inductive coupling between coils. C and D are similar but use fixed inductive coupling and a variable series capacitor, C1. A series tuned circuit works well with a low-impedance load; the parallel circuit is better with high impedance loads (several hundred ohms or more).

**Figure 20.16** — Antenna tuner network in T configuration. This network has become popular because it has the capability of matching a wide range of impedances. At A, the balun transformer at the input of the antenna tuner preserves balance when feeding a balanced transmission line. The balun can be placed at the input or output of the tuner. At B, the T configuration is shown as two L networks back to back. (In the L network version, the two ½-value inductors replacing L1 are assumed to be adjustable with identical values).

Design Impedance Matching Networks” with the downloadable supplemental content.) The **Station Accessories** chapter includes antenna tuner projects, and *The ARRL Antenna Book* contains detailed information on tuner design and construction.

### ANTENNA TUNER LOCATION

The tuner is usually located near the transmitter in order to adjust it for different bands or antennas. If a tuner is in use for one particular band and does not need to be adjusted once set up for minimum VSWR, it can be placed in a weatherproof enclosure near the antenna. Some automatic tuners are designed to be installed at the antenna, for example. For some situations, placing the tuner at the base of a tower can be particularly effective and eliminates having to climb the tower to perform maintenance on the tuner.

It is useful to consider the performance of the entire antenna system when deciding where to install the antenna tuner and what types of feed line to use in order to minimize system losses. Here is an example, using the program *TLW*. Let’s once again assume a flat-top antenna 50 ft high and 100 ft long and not resonant on any amateur band. As extreme examples, we will use 3.8 and 28.4 MHz with 200 ft of transmission line. There are many ways to configure this system, but three examples are shown in **Figure 20.17**.

Example 1 in **Figure 20.17A** shows a 200 ft run of RG-213 going to a 1:1 balun that feeds the antenna. A tuner in the shack reduces the VSWR for proper matching in the transmitter. Example 2 shows a similar arrangement using 300  $\Omega$  transmitting twin lead. Example 3 shows a 50 ft run of 300  $\Omega$  line dropping straight down to a tuner near the ground and 150 ft of RG-213 going to the shack. **Table 20.5** summarizes the losses and the tuner values required.

Some interesting conclusions can be drawn. First, direct feeding this antenna with coax through a balun is very lossy — a poor solution. If the flat-top were  $\frac{1}{2} \lambda$  long — a resonant half-wavelength dipole — direct coax feed would be a good method. In the second example, direct feed with 300  $\Omega$  low-loss line does not always give the lowest loss. The combination method in Example 3

provides the best solution.

There are other considerations as well. Supporting a balun at the antenna feed point adds stress to the wires or requires an additional support. Example 3 has some additional advantages. It feeds the antenna in a symmetrical arrangement which is best to reduce noise pickup on the shield of the feed line. The shorter feed line will not weigh down the antenna as much. The coax back to the shack can be buried or laid on the ground and it is perfectly matched. Burial of the cable will also prevent any currents from being induced on the coax shield. Once in the shack, the tuner is adjusted for minimum SWR per the manufacturer’s instructions.

### 20.4.5 Adjusting Antenna Tuners

The process of adjusting an antenna tuner is described here and results in minimum SWR to the transmitter and also minimizes power losses in the tuner circuitry. If you have a commercial tuner and have the user’s manual, the manufacturer will likely provide a method of adjustment that you should follow, including initial settings.

If you do not have a user’s manual, first open the tuner and determine the circuit for the tuner. The most common circuit for commercial tuners is the high-pass T network shown in **Figure 20.9F**. To adjust this type of tuner:

- 1) Set the series capacitors to maximum value. This may not correspond to the highest number on the control scale — verify that the capacitor’s plates are fully meshed.
- 2) Set the inductor to maximum value. This corresponds to placing a switch tap or roller inductor contact so that it is electrically closest to circuit ground.
- 3) If you have an antenna analyzer, connect it to the TRANSMITTER connector of the tuner. Otherwise, connect the transceiver and tune it to the desired frequency, but do not transmit.

In the following step, it is important to verify that you hear a peak in received noise before transmitting significant power through the tuner. Tuners can sometimes be adjusted to present a low SWR to the transmitter while coupling little energy to the output. Transmitting into a tuner in this configuration

can damage the tuner’s components.

4) Adjust the inductor throughout its range, watching the antenna analyzer for a dip in the SWR or listen for a peak in the received noise. Return the inductor to the setting for lowest SWR or highest received noise.

- 4a) If no SWR minimum or noise peak is detected, reduce the value of the capacitor closest to the transmitter in steps of about 20% and repeat.
- 4b) If still no SWR minimum or noise peak is detected, return the input capacitor to maximum value and reduce the output capacitor value in steps of about 20%.
- 4c) If still no SWR minimum or noise peak is detected, return the output capacitor to maximum value and reduce both input and output capacitors in 20% steps.
- 5) Once a combination of settings is found with a definite SWR minimum or noise peak:
  - 5a) If you are using an antenna analyzer, make small adjustments to find the combination of settings that produce minimum SWR with the maximum value of input and output capacitance.
  - 5b) If you do not have an antenna analyzer, set the transmitter output power to about 10 W, ensure that you won’t cause interference, identify with your call sign, and transmit a steady carrier by making the same adjustments as in step 5a.
  - 5c) For certain impedances, the tuner may not be able to reduce the SWR to an acceptable value. In this case, try adding feed line at the output of the tuner from  $\frac{1}{8}$  to  $\frac{1}{2} \lambda$  electrical wavelengths long. This will not change the feed line SWR, but it may transform the impedance to a value more suitable for the tuner components.

In general, for any type of tuner, begin with the maximum reactance to ground (maximum inductance or minimum capacitance) and the minimum series reactance between the source and load (minimum inductance or maximum capacitance). The configuration that produces the minimum SWR with maximum reactance to ground and minimum series reactance will generally have the highest efficiency and broadest tuning bandwidth.

To reduce on-the-air tune-up time, record the settings of the tuner for each antenna and band of operation. If the tuner requires readjustment across the band, record the settings of the tuner at several frequencies across the band. Print out the results and keep it near the tuner — this will allow you to adjust the tuner quickly with only a short transmission to check or fine tune the settings. This also serves as a diagnostic, since changes in the setting indicate a change in the antenna system.

### 20.4.6 Myths About SWR

This is a good point to stop and mention that there are some enduring and quite misleading myths in Amateur Radio concerning SWR.

**Table 20.5**

#### Tuner Settings and Performance

Example (Figure 20.17)	Frequency (MHz)	Tuner Type	L ( $\mu$ H)	C (pF)	Total Loss (dB)
A	3.8	Rev L	1.46	2308	8.53
	28.4	Rev L	0.13	180.9	12.3
B	3.8	L	14.7	46	2.74
	28.4	L	0.36	15.6	3.52
C	3.8	L	11.37	332	1.81
	28.4	L	0.54	94.0	2.95

Figure 20.17 — Variations of an antenna system with different losses. The examples are discussed in the text.

- Despite some claims to the contrary, a high SWR does not by itself cause RFI, or TVI or telephone interference. While it is true that an antenna located close to such devices can cause overload and interference, the SWR on the feed line to that antenna has nothing to do with it, providing of course that the tuner, feed line or connectors are not arcing. The antenna is merely doing its job, which is to radiate. The transmission line is doing its job, which is to convey power from the transmitter to the radiator.

- A second myth, often stated in the same breath as the first one above, is that a high SWR will cause excessive radiation from a transmission line. SWR has nothing to do with excessive radiation from a line. Imbalances in feed lines cause radiation, but such imbalances are not related to SWR. An asymmetric arrangement of a transmission line and antenna can result in current being induced on the transmission line — on the shield of coax or as an imbalance of currents in an open-wire line. This current will radiate just as if it was on an antenna. A choke balun is used on coaxial feed lines to reduce these currents as described in the section on baluns later in this chapter.

- A third and perhaps even more prevalent myth is that you can't "get out" if the SWR on your transmission line is higher than 1.5:1, or 2:1 or some other such arbitrary figure. On the HF bands, if you use reasonable lengths of good coaxial cable (or even better yet, open-wire line), the truth is that you need not be overly concerned if the SWR at the load is kept below about 6:1. This sounds pretty radical to some amateurs who have heard horror story after horror story about SWR. The fact is that if you can load up your transmitter without any arcing inside, or if you use a tuner to make sure your transmitter is operating into its rated load resistance, you can enjoy a very effective station, using antennas with feed lines having high values of SWR on them. For example, a 450-ohm open-wire line connected to the multiband dipole in the previous sections would have a 19:1 SWR on it at 3.8 MHz. Yet time and again this antenna has proven to be a great performer at many installations.

Fortunately or unfortunately, SWR is one of the few antenna and transmission-line parameters easily measured by the average radio amateur. Ease of measurement does not mean that a low SWR should become an end in itself! The hours spent pruning an antenna so that the SWR is reduced from 1.5:1 down to 1.3:1 could be used in far more rewarding ways — making contacts, for example, or studying transmission line theory.

## 20.5 Baluns and Transmission Line Transformers

A center-fed dipole or a loop in free space is *balanced*, meaning electrically and physically symmetrical with respect to the feed point. In practice, very few such antennas are balanced due to the effects of ground, nearby conductive objects and surfaces, and coupling to the feed line, whether coax or open-wire line. The last can result in *common-mode* current flowing on the feed line, which affects the antenna system impedance and can radiate in unwanted directions or pick up noise. In order to minimize these effects, the feed line can be detuned or *decoupled* from the antenna.

Many amateurs use center-fed dipoles or Yagis, fed with unbalanced coaxial line. Some method should be used for connecting the line to the antenna without upsetting the symmetry of the antenna itself. This requires a circuit that will isolate the balanced load from the unbalanced line, while still providing efficient power transfer. Devices for doing this are called *baluns* (a contraction for “balanced to unbalanced”). A balanced antenna fed with balanced line, such as two-wire ladder line, will maintain its inherent balance, so long as external causes of unbalance are avoided. However, even they will require some sort of balun at the transmitter, since modern transmitters have unbalanced (coaxial) outputs.

If a balanced antenna is fed at the center by a coaxial feed line without a balun, as indicated in Figure 20.18A, the inherent symmetry and balance is upset because one side of the  $\frac{1}{2}\lambda$

**Figure 20.18 — Quarter-wavelength baluns. Radiator with coaxial feed (A) and methods of preventing unbalanced currents from flowing on the outside of the transmission line (B and C). The  $\frac{1}{2}\lambda$  phasing section shown at D is used for coupling to an unbalanced circuit when a 4:1 impedance ratio is desired or can be accepted.**

**Figure 20.19 — At A, computer-generated azimuthal responses for two  $\lambda/2$  dipoles placed  $0.71\lambda$  high over typical ground. The solid line is for a dipole with no feed line. The dashed line is for an antenna with its feed line slanted  $45^\circ$  down to ground. Current induced on the outer braid of the  $1\lambda$  long coax by its asymmetry with respect to the antenna causes the pattern distortion. At B, azimuthal response for two 5 element 20 meter Yagis placed  $0.71\lambda$  over average ground. Again, the solid line is for a Yagi without a feed line and the dashed line is for an antenna with a  $45^\circ$  slanted,  $1\lambda$  long feed line. The distortion in the radiated pattern is now clearly more serious than for a simple dipole. A balun is needed at the feed point, and most likely point, preferably  $\frac{1}{4}\lambda$  from the feed point, to suppress the common-mode currents and restore the pattern.**

radiator is connected to the shield while the other is connected to the inner conductor. On the side connected to the shield, current can be diverted from flowing into the antenna, and instead can flow away from the antenna on the outside of the coaxial shield. The field thus set up cannot be canceled by the field from the inner conductor because the fields inside the cable cannot escape through the shielding of the outer conductor. Hence currents flowing on the outside of the line will be responsible for some radiation from the line, just as if they were flowing on an antenna.

This is a good point at which to say that striving for perfect balance in a line and antenna system is not always absolutely mandatory. For example, if a nonresonant, center-fed dipole is fed with open-wire line and a tuner for multiband operation, the most desirable radiation pattern for general-purpose communication is actually an omnidirectional pattern. A certain amount of feed-line radiation might actually help fill in otherwise undesirable nulls in the azimuthal pattern of the antenna itself. Furthermore, the radiation pattern of a coaxial-fed dipole that is only a few tenths of a wavelength off the ground (50 feet high on the 80 meter band, for example) is not very directional anyway, because of its severe interaction with the ground.

Purists may cry out in dismay, but there are many thousands of coaxial-fed dipoles in daily use worldwide that perform very effectively without the benefit of a balun. See **Figure 20.19A** for a worst-case comparison between a dipole with and without a balun at its feed point. This is with a  $1\lambda$  feed line slanted downward  $45^\circ$  under one side of the antenna. *Common-mode currents* are conducted and induced onto the outside of the shield of the feed line, which in turn radiates. The amount of pattern distortion is not particularly severe for a dipole. It is debatable whether the bother and expense of installing a balun for such an antenna is worthwhile.

Some form of balun should be used to preserve the pattern of an antenna that is purposely designed to be highly directional, such as a Yagi or a quad. **Figure 20.19B** shows the distortion that can result from common-mode currents conducted and radiated back onto the feed line for a 5 element Yagi. This antenna has purposely been designed for an excellent pattern but the common-mode currents seriously distort the rearward pattern and reduce the forward gain as well. A balun is highly desirable in this case.

Choke or current baluns force equal and opposite currents to flow in the load (the antenna) by creating a high common-mode impedance to currents that are equal in both conductors or that flow on the outside of coaxial cable shields, such as those induced by the antenna's radiated field. The result of using a current balun is that currents coupled back onto the

transmission line from the antenna are effectively reduced, or "choked off," even if the antenna is not perfectly balanced. Choke baluns are particularly useful for feeding asymmetrical antennas with unbalanced coax line. The common-mode impedance of the choke balun varies with frequency, but the line's differential-mode impedance is unaffected.

Reducing common-mode current on a feed line also reduces:

- Radiation from the feed line that can distort an antenna's radiation pattern
- Radiation from the feed line that can cause RFI to nearby devices
- RF current in the shack and on power-line wiring
- Coupling of noise currents on the feed line to receivers and receiving antennas
- Coupling between different antennas via their feed lines
