Preface to the Second Edition

The field of topological materials has been developing very rapidly since the first publication of this book. The experimental observation of the quantum anomalous Hall effect in magnetically doped topological insulator thin films and the discovery of the topological semimetals are two outstanding examples. Measurement of Majorana fermions has been reported by several experimental groups. Besides topological band structures have gone beyond quantum materials and are found in materials such as the photonic crystals, metamaterials, and even mechanic systems. Thus, the topological quantum phenomena and related materials now have become an important and inalienable part in condensed matter physics and material sciences.

In this edition, Chap. 11 on topological semimetals and several sections on experimental observation of the quantum anomalous Hall effect, the quantum spin Hall effect, and Majorana fermions are added. Also the first and last chapters have been updated. Here I would like to thank Drs. Hai-Zhou Lu, Song-Bo Zhang, and Jianhui Zhou for their contributions and helpful discussions on Weyl semimetals.

Preface to the First Edition

Recent years, we have seen rapid emergence of topological insulators and super-conductors. The field is an important advance of the well-developed band theory in solids since its birth in 1920s. The band theory or Fermi liquid theory and Landau's theory of spontaneously broken symmetry are two themes for most collective phenomena in many-body systems, such as semiconductors and superconductors. Discovery of the integer and fractional quantum Hall effects in 1980s opens a new window to explore the mystery of condensed matters: Topological order has to be introduced to characterize a large class of quantum phenomena. Topological insulator is a triumph of topological order in condensed matter physics.

The book grew out of a series of lectures I delivered in an international school on "Topology in Quantum Matter" at Bangalore, India, in July 2011. The aim of this book is to provide an introduction for a large family of topological insulators and superconductors based on the solutions of the Dirac equation. I believe that the Dirac equation is a key to the door of topological insulators. It is a line that could thread all relevant topological phases from one to three dimensions, and from insulators to superconductors or superfluids. This idea actually defines the scope of this book on topological insulators. For this reason, a lot of topics in topological insulators are actually not covered in this book, for example, the interacting systems and topological field theory. Also I have no ambition to review rapid developments of the whole field and consequently no intention to introduce all topics in this introductory book.

Chapter 1
Introduction

Abstract The discovery of topological insulators and superconductors is an important advance in condensed matter physics. Topological phases reflect global properties of the quantum states in materials, and the boundary states are characteristic of the materials. Such phases constitute a new branch in condensed matter physics. Here a historic development is briefly introduced, and the known family of phases in condensed matter are summarized.

1.1 From the Hall Effect to the Quantum Spin Hall Effect

In 1879, Edwin H. Hall observed an effect that now bears his name; he measured the voltage that arises from the deflected motion of charged particles in solids under externally applied electric and magnetic fields [1]. Consider a two-dimensional sample subjected to a perpendicular magnetic field $\mathbf{B}$. Charged particles passing through the sample are deflected by the Lorentz force and accumulate near the boundary. As a result, the charge accumulation along the boundary produces an electric field $\mathbf{E}$. When electric and magnetic forces are balanced, the Lorentz force on a moving charged particle is zero,

$$\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}) = 0, \tag{1.1}$$

where $\mathbf{v}$ is the velocity of the particle and q is the charge of particle. The voltage difference between the two boundaries is $V_H = EW$ (W is the width of the sample) and the electric current through the sample is $I = q\rho_e v W$ (ρ_e is the density of the charge carriers). The ratio of the voltage to the electric current is known as the Hall resistance

$$R_H = \frac{V_H}{I} = \frac{B}{q\rho_e}, \tag{1.2}$$

which is linear in the magnetic field B. In practice, the Hall effect is used to measure the sign of charge carriers q, i.e., the particle-like or hole-like charge carrier, and the density of charge carriers ρ_e in solids. It can be also used to measure the magnetic field.

In the year following his discovery, Hall measured the resistances in ferromagnetic as well as paramagnetic metals under various magnetic fields, and observed that it could have an additional contribution other than the term linear in the magnetic field [2]. That contribution can depend on the magnetization M in a ferromagnetic metal, and hence the Hall effect can persist even in the absence of an external magnetic field. An empirical relation describes this effect:

$$R_H = R_O B + R_A M, \tag{1.3}$$

which has been applied to many materials over a broad range of values of the external field. The second term, representing the contribution from the magnetization of M, cannot be simply understood as a result of the Lorentz force on a charged particle. It has taken almost one century to explore the physical origin, probably because this effect involves the topology of the band structure in solids, which was not formulated until 1980s. In 1954, Karplus and Luttinger [3] proposed a microscopic theory and found that electrons acquired an additional group velocity when an external electric field is applied to a solid. The anomalous velocity is perpendicular to the electric field, and contributes to the Hall conductance. It is related to the change in the phase of the Bloch wave function when an electric field forces the wave function to evolve in momentum space of the crystal [4, 5].

Generally speaking, the anomalous Hall effect can have either an extrinsic origin arising from the disorder-related spin-dependent scattering of the charge carriers, or an intrinsic origin because of the spin-dependent band structure of the conduction electrons. The latter can be expressed in terms of the Berry phase in the momentum space [6]. This effect originates from the coupling of the electron's orbital motion to its spin, which is a relativistic quantum mechanical effect. A spin-orbit force or spin transverse force can be used to understand the spin-dependent scattering by either impurities or the band structure. When an electron moves in an external electric field, the electron experiences a transverse force, which is proportional to the spin current of the electron rather than the charge current as for the Lorentz force [7]. As a result, spin-up electrons are deflected to one direction while spin-down electrons are deflected in the opposite direction. In a ferromagnetic metal, the magnetization creates an imbalance in the population between spin-up and spin-down electrons that consequently leads to the anomalous Hall effect.

Although the Hall resistance vanishes in the absence of an external magnetic field and magnetization in a paramagnetic metal, the spin-dependent deflection of electrons in solids can still lead to an observable effect, i.e., the spin Hall effect. The spin version of the Hall effect was first proposed by Russian physicists Dyakonov and Perel in 1971 [8, 9]. It yields a spin accumulation on the lateral surfaces of a current-carrying sample, the spin directions being opposite along the two opposite boundaries. When the current is reversed, the spin orientation is also reversed.

Initially, theorists argued that the spin accumulation was caused through asymmetric scattering of the spin-up and spin-down electrons within the impurity potentials, hence termed the extrinsic spin Hall effect [10]. In 2003, two independent groups demonstrated that the spin-orbit coupling in the electron band structure can produce a transverse spin current even without impurity scattering, hence called the intrinsic spin Hall effect [11, 12]. In the quantum Hall regime, the competition between Zeeman splitting and spin-orbit coupling leads to the resonant spin Hall effect, in which a small current induces a finite spin current and spin polarization [13]. The spin Hall effect has been observed experimentally in a GaAs and InGaAs thin film [14] and in the spin light-emitting diode of a p-n junction [15].

The discovery of the integer quantum Hall effect opened a new phase in the study of the various forms of the Hall effect. In 1980, von Klitzing, Dorda, and Pepper discovered experimentally that, in a two-dimensional electron gas produced at a semiconductor hetero-junction subjected to a strong magnetic field, the longitudinal conductance vanishes while quantum plateaus appear in the Hall conductance at values $\nu e^2/h$ [16]. The prefactor is an integer ($\nu = 1, 2, \ldots$), known as the filling factor. The quantum Hall effect is a quantum mechanical version of the Hall effect in two dimensions. This effect is now very well understood, and can be simply explained in terms of the single-particle orbitals of an electron in a magnetic field [17]. It is known that the motion of a charged particle in a uniform magnetic field is equivalent to that of a simple harmonic oscillator in quantum mechanics, in which the energy levels are quantized with energy $(n+\frac{1}{2})\hbar\omega_c$, and $\omega_c = eB/m$ is the cyclotron frequency. The energy levels, called Landau levels, are highly degenerate. When one Landau level is fully filled, the filling factor is $\nu = 1$ and the corresponding Hall conductance is e^2/h. It is realized now that the integer ν is actually a topological invariant, i.e, Thouless-Kohmoto-Nightingale-Njis (TKNN) invariant, that is insensitive to the geometry of the system and the interaction of electrons [18].

For clarity, physicists like to use a semi-classical picture to explain the quantization of the Hall conductance. For a charged particle in a uniform magnetic field, the particle cycles rapidly around the magnetic flux because of the Lorentz force. The cyclotron radius is given by the magnetic field $R_n = \sqrt{\frac{\hbar}{eB}(2n+1)}$. When the particle is close to the boundary, the particle bounces off the rigid boundary, and thus skips forward along the boundary. As a result, it forms a conducting channel called edge state (see Fig. 1.1). The group velocity of the particle in the bulk is much slower than the cyclotron velocity, and hence the particles in the bulk are pinned or localized by impurities or disorders. However, the rapid-moving particles along the edge channel are not affected by the impurities or disorders and thus form a perfect one-dimensional conducting channel with a quantum conductance e^2/h. Because the Landau levels are discrete, each Landau level will generate one edge channel. Consequently, the number of filled Landau levels, i.e., the filling factor, determines the quantized Hall conductance. Thus the key feature of the quantum Hall effect is that all electrons in the bulk are localized, whereas the electrons near the edge form a series of edge conducting channels [19], which is characteristic of a topological phase.
Fig. 1.1 Schematic of the formation of the chiral edge channel in the quantum Hall effect under the Lorentz force on charge carriers. In the quantum anomalous and spin Hall effects, the driving force is replaced by the spin transverse force

In 1982, Tsui, Stormer, and Gosard observed that, in a sample with higher mobility, the quantum plateaus appear at filling factors ν with rational fractions ($\nu = \frac{1}{3}$, $\frac{2}{3}$, $\frac{1}{5}$, $\frac{2}{5}$, $\frac{3}{5}$, $\frac{12}{5}$, $\cdots$). Known as the fractional quantum Hall effect [20], this effect relies fundamentally on the electron–electron interaction as well as the Landau level quantization. Laughlin proposed that the $\nu = 1/3$ state is a new type of many-body condensate, which can be described by the Laughlin wave function [21]. The quasi-particles in the condensate carry the fractional charge $e/3$ because of their strong Coulomb interaction. The observed Hall conductance plateaus arise from the localization of the fractionally charged quasi-particles in the condensate. Thus, the fractional quantum Hall effect can be regarded as the integer quantum Hall effect of these quasi-particles. In 1988, Jainendra K. Jain proposed that the quasi-particles, called composite fermions, can be regarded a combination of an electron charge and quantum magnetic flux [22]. This picture is applicable to all the quantum plateaus observed in the fractional quantum Hall effect, which is now well-accepted in terms of a topological quantum phase of composite fermions that breaks time-reversal symmetry.

In 1988, Duncan Haldane proposed that the integer quantum Hall effect can be realized in a lattice system of spinless electrons in a periodic magnetic flux [23]. Although the total magnetic flux is zero, electrons are driven to form a conducting edge channel by the periodic magnetic flux. As there is no pure magnetic field, the quantum Hall conductance originates from the electron band structure for the lattice not from the discrete Landau levels with a strong magnetic field. Thus this is a version of the quantized anomalous Hall effect in the absence of an external field or Landau levels. Furthermore, it was found that the role of the periodic magnetic flux can be replaced by spin-orbit coupling. The quantized anomalous Hall effect can be realized in a ferromagnetic insulator with strong spin-orbit coupling. The anomalous Hall effect persists in an insulating regime. The anomalous Hall conductance can be expressed in terms of the integral of the Berry curvature over the momentum space or the Chern number for fully-filled bands [24]. The Haldane model produces a non-zero Chern numbers for an electron band without the presence of a magnetic field or Landau levels. According to the bulk-edge correspondence, the quantized Hall conductance originates from the dissipationless transport of topologically protected edge states. There have been extensive investigations on this topic [25–29]. One of the promising schemes is based on a magnetically doped topological insulator thin

film, where an interplay between the strong spin-orbit coupling in the surface states and magnetic exchange coupling gives rise to a band gap opening to form chiral edge states [27]. In 2013, the experimental observation of the quantum anomalous Hall effect was reported in Cr-doped $(Bi,Sb)_2Te_3$ ultra thin film by a group led by Xue in Beijing [30].

The quantum spin Hall effect is a quantum version of the spin Hall effect or a spin version of the quantum Hall effect, and can be regarded as a combination of the quantum anomalous Hall effects for spin-up and spin-down electrons with opposite chirality. Overall, it results in no charge Hall conductance, but a non-zero spin-Hall conductance. In 2005, Kane and Mele generalized the Haldane model to a graphene lattice of spin-$\frac{1}{2}$ electrons with spin-orbit coupling [31]. Strong spin-orbit coupling is introduced to replace the periodic magnetic flux in the Haldane model. This interaction looks like a spin-dependent magnetic field to electron spins. The different electron spins experience opposite spin transverse forces [7]. As a result, a bilayer spin-dependent Haldane model can be realized in a spin-$\frac{1}{2}$ electron system with spin-orbit coupling, which exhibits the quantum spin Hall effect. When spin-dependent edge states exist around the boundary of the system, electrons with different spins move in opposite directions, and form a pair of helical edge states. Time-reversal symmetry is still preserved, and the edge states are robust against impurities or disorders because the electron backscattering in the two edge channels is prohibited because of the symmetry. However, the spin-orbit coupling in graphene is minute. In 2006 Bernevig, Hughes and Zhang proposed that the quantum spin Hall effect can be realized in the CdTe/HgTe/CdTe sandwiched quantum well [32]. HgTe is a material with an inverted band structure, and CdTe has a normal band structure. Tuning the thickness of HgTe layer leads to band inversion in the quantum well, which exhibits a topological phase transition. This prediction was confirmed experimentally by Konig et al. 1 year later [33]. The stability of the quantum spin Hall effect was studied by several groups [34–37]. The other confirmed quantum spin Hall system is an inverted electron–hole bilayer engineered from indium arsenide–gallium antimonide (InAs/GaSb) semiconductors [38]. A quantized conductance associated with helical edge states was first measured for the quantum transport of helical edge states in a π shape device of an InAs/GaSb quantum well [39]. One of its key features is that the quantum conductance is accompanied with the opening of a mobility gap in the sample, strongly indicating that impurities localize the bulk electrons.

A system exhibiting the quantum spin Hall effect is also known as a two-dimensional topological insulator. A flow chart from the ordinary Hall effect to the quantum spin Hall effect is presented in Fig. 1.2.

Hall Effect $B \neq 0$ 1879	→	Anomalous Hall Effect $B = 0, M \neq 0$ 1880	→	Spin Hall Effect $B = 0, M = 0$ 2004-2006

1.2 Topological Insulators as a Generalization of the Quantum Spin Hall Systems

There is no Hall effect in three dimensions. However, the generalization of the quantum spin Hall effect to three dimensions is one of the milestones in the development of topological insulators [40–43]. It is not a simple generalization from two dimensions to three dimensions of the transverse transport of an electron charge or spin, or the Hall effect. Instead, bound states evolve near the system boundary based on the intrinsic band structure; the one-dimensional helical edge states in the two-dimensional quantum spin Hall system can evolve into two-dimensional surface states surrounding the three-dimensional topological insulator. A topological insulator is a material in a state of quantum matter that behaves as an insulator in its interior but as a metal on its boundary. In the bulk of a topological insulator, the electronic band structure resembles an ordinary insulator, with separated conduction and valence bands. Near the boundary, the surface states within the bulk energy gap allow electron conduction. Electron spins in these states are locked to their momenta. A topological insulator preserves the time-reversal symmetry. Because of the Kramers degeneracy, for a given energy, there always exists a pair of states that have opposite spins and momenta; the backscattering between these states is forbidden. These states are characterized by a topological index. Kane and Mele proposed a Z_2 index to classify materials with time-reversal invariance as strong and weak topological insulators [44]. For a weak topological insulator, the resultant surface states are not robust against disorder or impurities, although its physical properties are very similar to those of two-dimensional states. The relationship of a strong topological insulator with the quantum spin Hall system is more subtle. It is possible to classify conventional and topological insulators by time-reversal symmetry. The surface states in a strong topological insulator is protected by time-reversal symmetry.

$Bi_{1-x}Sb_x$ was the first candidate as a three-dimensional topological insulator predicted [45] and verified experimentally [46] by Fu and Kane. Zhang et al. [47] and Xia et al. [48] pointed out that Bi_2Te_3 and Bi_2Se_3 are topological insulators with

a single Dirac cone of surface states. Angle-resolved photoemission spectroscopy data showed clearly the existence of a single Dirac cone in Bi_2Se_3 [48] and Bi_2Te_3 [49]. Electrons in the surface states possess a quantum spin texture, and the electron momenta are strongly coupled with the electron spins. These can produce many exotic magneto-electric properties. Qi et al. [50] proposed an unconventional magneto-electric effect for the surface states, in which electric and magnetic fields are coupled together and are governed by the so-called axion equation instead of by Maxwell's equations. This is now regarded as one of the characteristic features of topological insulators [51, 52].

Reducing the system to one dimension brings some new insights with respect to topological properties. The boundary of one-dimensional system is simply an end point. A one-dimensional topological insulator is an insulator with two end states
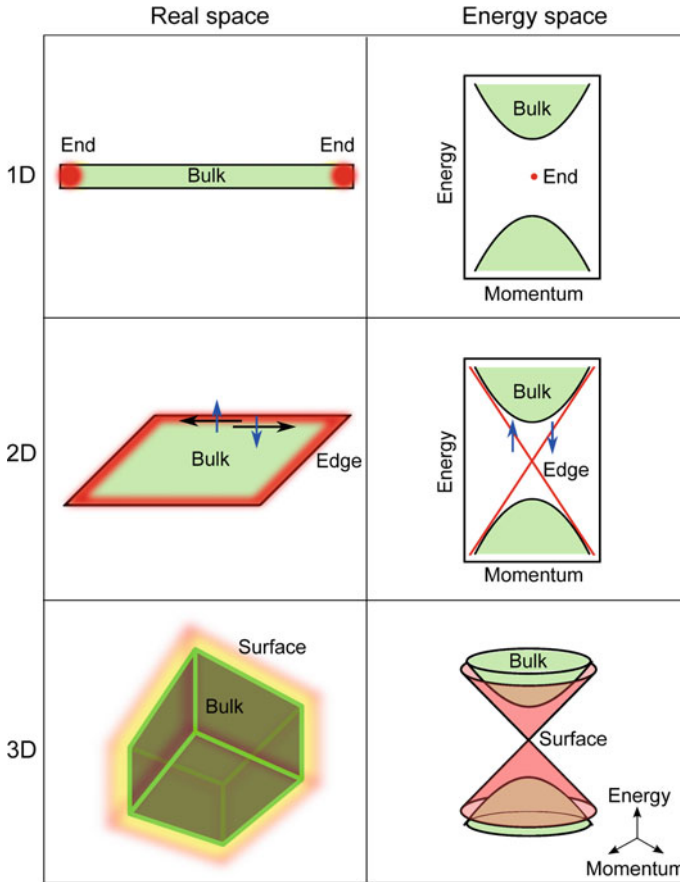

Fig. 1.3 The boundary states and their energy dispersions of topological materials. A d-dimensional material has a $(d-1)$-dimensional boundary

of zero energy. The end states in one dimension have been studied since the 1980s. Polyacetylene is a one-dimensional organic material with so-called A and B phases. The domain walls connecting the A and B phase induce rigid solitons with zero energy, and are the charge carriers for this organic conductor [53]. Although the soliton and anti-soliton are topological excitations in polyacetylene, the A and B phases are actually topologically distinct in an open boundary condition; one phase possesses two end states of zero energy while the other does not, although both phases open up an energy gap because of the Peierls instability or dimerization of the lattice. This is actually the simplest topological insulator protected by chiral symmetry, which is a combination of the time-reversal symmetry and particle-hole symmetry.

A d-dimensional topological insulator has $(d - 1)$-dimensional boundary states. For a summary, see Fig. 1.3.

1.3 Beyond Band Insulators: Disorder and Interaction

Topological phases exist in disordered and interacting systems. Generally a topological phase is robust against impurities or interactions that do not break time-reversal symmetry. The edge or surface states are protected by a band gap between the conduction and valence bands. It has even been demonstrated that the topological phase actually can be induced by either strong disorder or interaction.

For example, a topological Anderson insulator is a topological phase, in which impurities localize the bulk electrons but the edge or surface boundary remains conducting because of the presence of helical edge states occupied by surface electrons; this picture is very close to the picture of the quantum Hall effect. In the presence of disorder, there exists a metal-insulator transition in three-dimensional systems, or in two-dimensional systems with spin-orbit coupling. Electrons in low dimensional systems are always strongly localized. Li et al. discovered that, in the effective model for a HgTe/CdTe quantum well, impurities can generate the quantum spin Hall effect even starting from a normal band structure. They predicted such wells were a possible realization of the topological Anderson insulator [54]. This phase has been studied numerically and analytically [55, 56]. The phase was also generalized to three dimensions [57]. The edge or surface states in a topological Anderson insulator are protected by a mobility gap instead of a band gap for topological band insulators [58].

The electron–electron interaction provides another route to realize a topological phase. SmB_6 is a type of heavy fermion material that was first discovered 40 years ago [59]. In the material, the f-electrons from the outer shell of Sm are highly correlated because of their strong Coulomb interactions. The highly renormalized f-electrons hybridize with the conduction electrons to form an excitation gap in the millivolt range. Dzero et al. [60] pointed out that the position of the hybridized f-electrons at the bottom of the two bands determines a topologically nontrivial insulating phase that forms a topological Kondo insulator. The existence of surface states solved a

long-standing puzzle in SmB_6 in that it becomes conducting at very low temperatures. Several independent groups [61–63] reported experimental results that support the formation of the new phase.

A Mott insulator is a class of insulating materials with a strong electron correlation. Raghu et al. found that the strong Hubbard interaction can turn a semimetal into a quantum spin Hall phase in an extended Hubbard model at half filling. Such phases are called topological Mott insulators [64]. Usually the electron correlation and spin-orbit coupling are expected in compounds of 5d transition metals. Pesin and Balents further pointed out that, taking Ir-based pyrochlores as an example, the Mott correlation enhances the effect of spin-orbit coupling, which leads to the existence of a topological insulating phase. The phase can be regarded as a quantum spin liquid state, and neutral fermionic spin-1/2 spinons are deconfined [65]. It was also suggested that some Heusler compounds such as GdBiPt can be antiferromagnetic topological insulators [66].

1.4 Topological Phases in Superconductors and Superfluids

At low temperatures, liquid helium ^{3}He has two different superfluid phases, called the A and B phases. The ^{3}He atoms are neutrally charged fermions that can be described by the conventional Fermi liquid theory, just like electrons in a metal. Osheroff, Lee, and Richardson [67] studied the pressurization curve of a mixture of liquid and solid ^{3}He. They observed two reproducible anomalies, which indicate that the liquid phase existing between 2.0 and 2.6 mK is the A phase, and that below 2.0 mK is the B phase. The normal-to-A phase transition at $T_A \sim 2.6$ mK is of the second-order and the A-B phase transition at $T_B \sim 2.0$ mK is of the first-order. The theory of superconductivity for electrons in spin-triplet states was first developed by Balian and Werthamer in 1963 [68]. They observed that all Cooper pairs are in the p-wave pairing ($l = 1$) and spin-triplet states; this mechanism explains superfluidity in the B phase. The pairing symmetry determines the topology of the band structure of quasi-particles. The A phase is topologically different from the B phase; the pairs form only in the state of $S_z = 1$ and/or $S_z = -1$, i.e., the so-called equal spin pairing state or Anderson-Brinkman-Morel state. This conclusion was first drawn from an analysis of spatial profiles from the nuclear magnetic resonance experiment [69].

The insights gained from the study of superfluid phase of liquid ^{3}He have been widely applied in various fields from particle physics and cosmology to condensed matter physics [70]. In a spinless p-wave pairing superconductor, there are weak and strong coupling phases that are characterized by different topological invariants. The weak coupling phase is topologically non-trivial and can have chiral edge states around the boundary of the system, very similar to those occurring in the quantum Hall effect [71]. After the discovery of the fractional quantum Hall effect, the weak coupling state was found to have a pairing wave function that is asymptotically the same as in the Moore-Read quantum Hall state. Thus, topological order was introduced to characterize the superfluid phases. The topological aspects of these

two phases have been discussed in detail in a book by Volovik [70]. Some concepts and topological invariants can be applied explicitly to topological insulators in the framework of a single particle wave function in the band theory. For example, band inversion can accompany a topological quantum phase transition, as in the quantum spin Hall effect.

Now, we realize that the Bogoliubov-de Gennes equation for superconductors and superfluids has a mathematical structure very similar/identical to the Dirac equation for topological insulators. Like band gaps in insulators, the quasi-particle band structure in superconductors and superfluids can also have a non-zero gap. The symmetry classification of non-interacting Hamiltonians emerged in the context of random matrix theory long before the discovery of topological insulators. Schnyder et al. [72] systematically studied the topological phases of insulators and superconductors, and provided an exhaustive classification of topological insulators and superconductors for non-interacting systems of fermions. The Bogoliubov-de Gennes equation has particle-hole symmetry, and the Dirac equation has time-reversal symmetry. The similarity between the particle-hole symmetry and the time-reversal symmetry makes it possible to study topological insulators and superconductors in a single framework.

The discovery of the topological insulators stimulated a re-examination of the properties of spin-triplet superconductors, that are candidates for topological superconductors. Among several classes of spin triplet superconductors, Sr_2RuO_4 is thought to be a p-wave-pairing superconductor that is similar to the A phase in superfluid liquid ^{3}He [73, 74]. Initial data from tunneling spectroscopy measurements suggest the possible existence of chiral edge states in Sr_2RuO_4 [75]. The Cu-doped topological insulator $Cu_xBi_2Se_3$, which becomes superconducting below $T_c = 3.8$ K [76], might also be a topological superconductor [77].

Fu and Kane's proposal initiated a "gold rush" in Majorana fermion searches [78]; they found that, as a superconducting proximity effect, the interface of the surface states of topological insulators and an s-wave superconductor resembles a spinless p+ip superconductor. This actually indicates a way to achieve topological superconductivity in a conventional s-wave superconductor instead of p-wave superconductor as expected before. A feature of topological superconductors is that the quasi-particles of end states and edge states have a peculiar property: antiparticle and particle are identical, and hence are Majorana fermions. Mathematically, the particle's creation operator is equal to its annihilation operator, $\gamma^\dagger = \gamma$. There have been many schemes to engineer and detect Majorana fermions in quantum Hall systems and p-wave superconductors [79–81]. One promising scheme is a semiconductor with strong spin-orbit coupling connected to an s-wave superconductor [82, 83]. In a two-dimensional electron gas, Rashba spin-orbit coupling separates the parabolic bands for two spin-dependent projections, and the Zeeman field opens an energy gap near the crossing point. When the chemical potential falls within the gap, the penetrating Cooper pairs from the s-wave superconductor in this region behave like those of spinless p-wave superconductors. This picture persists in one-dimensional confined nanowires, which have become the experimental prototype in the hunt for Majorana fermions. While more and more experiments provide signatures of the

existence of Majorana fermions [84–87], it is still believed that the experimental data have not yet constituted a definitive proof, and "the race for the unambiguous detection of the particle continues" [88].

1.5 Topological Dirac and Weyl Semimetals

Topological phases of matter are not just limited to the systems with energy gaps. The discovery of topological Dirac and Weyl semimetals illustrates that the novel quantum phases of matter can exist even if band gaps are closed. In topological Dirac and Weyl semimetals the conduction and valence bands touch at a finite number of points, which are robust and protected by uniaxial rotation symmetries in crystal lattices. The energy dispersion of the quasiparticles near the points are linear, and can be described as massless relativistic particles as proposed by Hermann Weyl in 1929, who found that the massless Dirac equations can describe relativistic fermions with a definite handedness or chirality. Weyl's equation was intended to model elementary particles, but over 80 years no candidate of Weyl fermions have ever been observed in high-energy experiment. In 1937 Conyers Herring [89] proposed that the Weyl fermions can be realized in the electric band structure in solids. The energy bands can cross at points or nodes which are protected by a high crystal symmetry. The low-energy excitations near the points can be described by the Weyl equations. Weyl fermions have left or right-handedness or chirality. The chiral symmetry of Weyl fermions are broken in the presence of both electric field and magnetic field, i.e., chiral anomaly as a purely quantum mechanical effect. In 1983 Ninomiya and Nielsen [90] suggested that the chiral anomaly of Weyl fermions could be observable in solids as a magnetoresistivity in materials may reveal its signatures. After the discovery of topological insulators, initial proposals for Weyl semimetals included $Bi_{1-x}Sb_x$ at a critical point between the normal and topological insulators [91], pyrochlore iridates [92], and $HgCr_2Se_{13}$ [93], but there is no experimental evidence to support them yet. Cd_3As_2 [94] and Na_3Bi [95] were predicted to be Dirac semimetals, and confirmed to be so by photoemission and transport experiments [96, 97]. The Fermi arcs of the surface states which are characteristic of the topological phases of matter have been observed experimentally. TaAs [98, 99] is a stoichiometric and non-centrosymmetric material and confirmed to be a topological Weyl semimetal with the Fermi arcs on the surface [100, 101]. It is a representative of the transition metal monopnictide or TX family where T = Ta/Nb and X = As/P. There are twelves pairs of Weyl nodes near the Fermi surface. As a possible consequence of chiral anomaly of Weyl fermions, negative magnetoresistance has been extensively reported in a series of Dirac and Weyl semimetals at finite temperatures [102–105].

1.6 Dirac Equation and Topological Insulators

The Dirac equation is a relativistic quantum mechanical equation describing an elementary spin-$\frac{1}{2}$ particle [106, 107]. It enters the field of topological insulators for two ways. First, a large class of topological insulators is characterized by strong spin-orbit coupling, which arises in explicit form from the Dirac equation in the non-relativistic limit [108]. It enables spin, momentum, and the Coulomb or external electric fields to couple together. As a result, the band structures in some materials can become topologically non-trivial. This provides a physical source from which topological insulators form. Second, the minimal Hamiltonians for the quantum spin Hall effect and the three-dimensional topological insulators have a mathematical structure identical to the Dirac equation [109]

$$H = v_{eff}\mathbf{p} \cdot \alpha + \left(mv_{eff}^2 - Bp^2\right)\beta, \qquad (1.4)$$

where α and β are the Dirac matrices, v_{eff} is the effective velocity, and $2mv_{eff}^2$ the energy band gap. In these effective models, the equation is employed to describe the coupling between electrons in the conduction and valence bands in semiconductors, not the electrons and positions in Dirac's theory. The positive and negative energy spectra are the respective energies for the electrons and holes in the semiconductors, and not those in high energy physics. The conventional Dirac equation is time-reversal invariant. For a system with time-reversal symmetry, an effective Hamiltonian that describes electrons near the Fermi level can be derived from the theory of invariants or the $k \cdot p$ theory. As a consequence of the $k \cdot p$ expansion of the band structure, some effective continuous models have a mathematical structure identical to the Dirac equation. The equation can also be obtained from the effective model near the critical point of the transition for a topological quantum phase.

Generally speaking, each topological insulator or superconductor is governed by one Dirac equation. In this book, we start with the Dirac equation to provide a simple but unified description for a large family of topological insulators and superconductors. A series of solvable differential equations are presented to demonstrate the existence of the end, edge, and surface states in topological matters.

1.7 Topological Insulators and Landau Theory of Phase Transition

Topological insulators and superconductors go beyond the Landau theory of phase transitions, and constitute a new branch of condensed matter physics. There is no continuous order parameter to describe the topological quantum phase. Instead we have topological invariants, which characterize the phases [110]. Briefly speaking, a quantum system is an eigenvalue problem; the solutions of the problem are the eigenvalues and eigenvectors (also called eigenstates). The Landau theory actually

focuses on the eigenvalue problem; by introducing an order parameter for a quantum phase, Landau proposed that the free energy of a quantum system can be expanded in terms of the order parameter, and the variational principle is used to determine the general formalism of the free energy of quantum phase. A non-zero value for the order parameter represents the occurrence of the quantum phase transition. Usually the order parameter is related to the system symmetry. For example, there exists a SU(2) symmetry breaking in a phase transition from a paramagnetic phase to a ferromagnetic phase, and a U(1) symmetry breaking in a phase transition from a metallic phase to a superconducting phase.

The other aspect of the eigensystem is the eigenstates; the eigenstates themselves determine physical properties of the system, for example, the transport properties. Topological invariants of the band structure reflect bulk properties of the quantum system different from the order parameters in Landau theory of phase transitions. There is no symmetry breaking in topological quantum phase transition while the topological invariant changes. For example, the spin-orbit coupling can lead to a band inversion of the conduction and valence bands in a topological insulator. The Z_2 index changes from 0 to 1 while the time-reversal symmetry is not broken. The topological invariants are calculated from the eigenstates of the system, not from the free energy or the energy dispersion.

1.8   Summary

To summarize, there are several streams of research in the field.

1. The Hall effect: the integer and fractional quantum Hall effects (1980, 1982), the quantum anomalous Hall effect (2013), the quantum spin Hall effect (2007, 2011).
2. Topological insulators: one-dimensional polyacetylene (1980s); the two-dimensional HgTe/CdTe quantum well (2007) and the InAs/GaSb quantum well (2011); the three-dimensional $Bi_{1-x}Sb_x$ (2008), Bi_2Te_3 (2009), Bi_2Se_3 (2009), and Bi_2Te_2Se (2010).
3. Topological superconductors: superfluid A and B phases in liquid ^{3}He (1972), and semiconductor nanowires coupled to *s*-wave superconductors (2012), ...
4. Topological Dirac and/or Weyl semimetals: graphene as two-dimensional Dirac semimetal, Dirac semimetals Cd_2Sb_3, Weyl semimetals TaAs, ...
5. Beyond electronic materials: topological photonic crystals, metamaterials, ...

In 2016, Nobel prize in physics was divided, one half awarded to David J. Thouless, the other half jointly to F. Duncan M. Haldane and J. Michael Kosterlitz "for theoretical discoveries of topological phase transition and topological phases of matter". This is the third Nobel prize in physics related to the quantum Hall effect. It is believed that the prediction and discovery of topological insulators deserve one more Nobel prize in the future.

Chapter 2
Starting from the Dirac Equation

Abstract The Dirac equation is the key to understanding topological insulators and superconductors. A quadratic correction to the equation makes it topologically distinct. The solution of the bound states near the boundary reflects the topology of the system's band structure.

2.1 Dirac Equation

In 1928, Paul A.M. Dirac wrote an equation for a relativistic quantum mechanical wave function that describes an elementary spin-$\frac{1}{2}$ particle [1, 2],

$$H = c\mathbf{p} \cdot \alpha + mc^2\beta, \tag{2.1}$$

where m is the rest mass of a particle and c is the speed of light. α_i and β are known as the Dirac matrices that satisfy the relations

$$\alpha_i^2 = \beta^2 = 1, \tag{2.2}$$
$$\alpha_i \alpha_j = -\alpha_j \alpha_i, \tag{2.3}$$
$$\alpha_i \beta = -\beta \alpha_i. \tag{2.4}$$

Here a_i and β are not simple complex numbers. The anticommutation relation means that they can obey a Clifford algebra and must be expressed in a matrix form. In one- and two-dimensional spatial space, they are at least 2×2 matrices. The Pauli matrices σ_i $(i = x, y, z)$ satisfy all these relations,

$$\{\sigma_i, \sigma_j\} = 2\delta_{ij}, \tag{2.5}$$

where

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{2.6}$$

Thus, in one dimension, the two Dirac matrices α_x and β are any two of the three Pauli matrices, for example,

$$\alpha_x = \sigma_x, \beta = \sigma_z. \tag{2.7}$$

In two dimensions, the three Dirac matrices are the Pauli matrices,

$$\alpha_x = \sigma_x, \alpha_y = \sigma_y, \beta = \sigma_z. \tag{2.8}$$

In three dimensions, we cannot find more than three 2×2 matrices that satisfy the anticommutation relations. Thus, the four Dirac matrices are at least 4-dimensional, and can be expressed in terms of the Pauli matrices

$$\alpha_i = \begin{pmatrix} 0 & \sigma_i \\ \sigma_i & 0 \end{pmatrix} \equiv \sigma_x \otimes \sigma_i, \tag{2.9}$$

$$\beta = \begin{pmatrix} \sigma_0 & 0 \\ 0 & -\sigma_0 \end{pmatrix} \equiv \sigma_z \otimes \sigma_0, \tag{2.10}$$

where σ_0 is a 2×2 identity matrix.

From this equation, the relativistic energy-momentum relation will be automatically the solution of the following equation:

$$E^2 = m^2 c^4 + p^2 c^2. \tag{2.11}$$

In three dimensions, there are two solutions for positive energy E_+ and two solutions for negative energy E_-,

$$E_\pm = \pm\sqrt{m^2 c^4 + p^2 c^2}. \tag{2.12}$$

This equation can be used to describe the motion of an electron with spin: the two solutions of the positive energy correspond the two states of an electron, spin-up and down, and the two solutions of the negative energy correspond to the two states of an positron with spin-up and down. The energy gap between these two particles is $2mc^2 (\approx 1.0\,\text{MeV})$.

This equation requires the existence of an antiparticle, i.e., a particle with negative energy or mass, and predates the discovery of positrons, the antiparticles of an electron. It is one of the main achievements of modern theoretical physics. Dirac proposed that the negative energy states are fully filled, and the Pauli exclusion principle prevents a particle transiting into these occupied states. The normal state of the vacuum then consists of an infinite density of negative energy states. The state

of a single electron means that all the states of negative energies are filled, and only one state of positive energy is filled. It is assumed that any deviation from the norm produced by employing one or more of the negative energy states can be observed. The absence of a negative charged electron that has a negative mass and kinetic energy would then manifest itself as a positively charged particle that has an equal positive mass and positive energy. In this way, a hole or positron can be formulated. Unlike the Schrödinger equation for a single particle, the Dirac theory, in principle, is a many-body theory. This has been discussed in many textbooks on relativistic quantum mechanics [2].

Under the transformation of mass $m \to -m$, it is found that the equation remains invariant if we replace $\beta \to -\beta$, which satisfies all of the mutual anticommutation relations for α_i and β in (2.4). This reflects the symmetry between the positive and negative energy particles in the Dirac equation: there is no topological distinction between particles with positive and negative masses.

2.2 Solutions of Bound States

2.2.1 Jackiw-Rebbi Solution in One Dimension

A possible relation between the Dirac equation and the topological insulator is revealed by a solution of the bound state at the interface between the regions of positive and negative masses. We start with

$$h(x) = -iv\hbar\partial_x \sigma_x + m(x)v^2 \sigma_z \tag{2.13}$$

and

$$m(x) = \begin{cases} -m_1 & \text{if} \quad x < 0 \\ +m_2 & \text{otherwise} \end{cases} \tag{2.14}$$

(and m_1 and $m_2 > 0$). We use an effective velocity v to replace the speed of light c when the Dirac equation is applied to solids. The eigenvalue equation has the form

$$\begin{pmatrix} m(x)v^2 & -iv\hbar\partial_x \\ -iv\hbar\partial_x & -m(x)v^2 \end{pmatrix} \begin{pmatrix} \varphi_1(x) \\ \varphi_2(x) \end{pmatrix} = E \begin{pmatrix} \varphi_1(x) \\ \varphi_2(x) \end{pmatrix}. \tag{2.15}$$

For either $x < 0$ or $x > 0$, the equation is a second-order ordinary differential equation. We can solve the equation at $x < 0$ and $x > 0$ separately. The solution of the wave function should be continuous at $x = 0$. In order to have a solution of a bound state near the junction, we take the Dirichlet boundary condition that the wave function must vanish at $x = \pm\infty$. For $x > 0$, we set the trial wave function as

$$\begin{pmatrix} \varphi_1(x) \\ \varphi_2(x) \end{pmatrix} = \begin{pmatrix} \varphi_1^+ \\ \varphi_2^+ \end{pmatrix} e^{-\lambda_+ x}. \tag{2.16}$$

Then the secular equation gives

$$\det \begin{pmatrix} m_2 v^2 - E & i v \hbar \lambda_+ \\ i v \hbar \lambda_+ & -m_2 v^2 - E \end{pmatrix} = 0. \tag{2.17}$$

The solution to this equation is $\lambda_+ = \pm\sqrt{m_2^2 v^4 - E^2}/v\hbar$.

The solutions λ can be either real or purely imaginary. For $m_2^2 v^4 < E^2$ the solutions are purely imaginary, and the corresponding wave functions spread over the whole space. These are the extended states or the bulk states, which we are not interested in here. For $m_2^2 v^4 > E^2$ the solutions are real, and we choose a positive λ_+ to satisfy the boundary condition at $x \to +\infty$. The two components in the wave function satisfy

$$\varphi_1^+ = -\frac{i v \hbar \lambda_+}{m_2 v^2 - E} \varphi_2^+. \tag{2.18}$$

Similarly, for $x < 0$, we have

$$\begin{pmatrix} \varphi_1(x) \\ \varphi_2(x) \end{pmatrix} = \begin{pmatrix} \varphi_1^- \\ \varphi_2^- \end{pmatrix} e^{+\lambda_- x} \tag{2.19}$$

with $\lambda_- = \sqrt{m_1^2 v^4 - E^2}/v\hbar$, and

$$\varphi_1^- = -\frac{i v \hbar \lambda_-}{m_1 v^2 + E} \varphi_2^-. \tag{2.20}$$

At $x = 0$, the continuity condition for the wave function requires

$$\begin{pmatrix} \varphi_1^+ \\ \varphi_2^+ \end{pmatrix} = \begin{pmatrix} \varphi_1^- \\ \varphi_2^- \end{pmatrix}. \tag{2.21}$$

From this equation, it follows that

$$\frac{-\sqrt{m_2^2 v^4 - E^2}}{m_2 v^2 - E} = \frac{\sqrt{m_1^2 v^4 - E^2}}{-m_1 v^2 - E}. \tag{2.22}$$

Thus, there exists a solution of zero energy, $E = 0$, and the corresponding wave function is

$$\Psi(x) = \sqrt{\frac{v}{\hbar} \frac{m_1 m_2}{m_1 + m_2}} \begin{pmatrix} i \\ 1 \end{pmatrix} e^{-|m(x)|v x|/\hbar}. \tag{2.23}$$

Fig. 2.1 Probability density $|\Psi(x)|^2$ of the solution as a function of its position in (2.23)
The solution is dominantly distributed near the interface or domain wall at $x = 0$ and decays exponentially away from the point $x = 0$ as shown in Fig. 2.1. The solution of $m_1 = m_2$ was first obtained by Jackiw and Rebbi, and is the mathematical basis for the existence of topological excitations or solitons in one-dimensional systems [3]. The spatial distribution of the wave function are determined by the characteristic scales $\xi_{1,2} = \lambda_{\pm}^{-1} = \hbar/|m_{1,2}v|$. The solution exists even when $m_2 \rightarrow +\infty$. In this case, $\Psi(x) \rightarrow 0$ for $x > 0$. However, we have to point out that the wave function is not continuous at the interface, $x = 0$. If we regard the vacuum as a system with an infinite positive mass, a system with a negative mass with an open boundary condition possesses a bound state near the boundary if the continuity condition is relaxed to the wave function. This result leads to some popular impression of the formation of the edge and surface states in topological insulators.

With regards to the stability of the zero mode solution, we may find a general solution of zero energy for a distribution of mass $m(x)$ that changes from a negative to positive mass at two ends. Consider the solution of $E = 0$ for (2.13). The eigenvalue equation is reduced to

$$\left[-iv\hbar\partial_x\sigma_x + m(x)v^2\sigma_z\right]\varphi(x) = 0. \tag{2.24}$$

Multiplying σ_x from the left hand side, one obtains

$$\partial_x\varphi(x) = -\frac{m(x)v}{\hbar}\sigma_y\varphi(x). \tag{2.25}$$

Thus, the wave function should be the eigenstate of σ_y,

$$\sigma_y\varphi_\eta(x) = \eta\varphi_\eta(x) \tag{2.26}$$

with

$$\varphi_\pm = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ \pm i \end{pmatrix} \varphi(x).$$

The wave function has the form

$$\varphi_\eta(x) \propto \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ \eta i \end{pmatrix} \exp\left[-\int^x \eta \frac{m(x)v}{\hbar} dx' \right]. \tag{2.27}$$

For $x \to \pm\infty$, $\varphi(x) \propto \exp\left[-|m(\pm\infty)vx|/\hbar \right]$, and the sign η is determined by the signs of $m(\pm\infty)$. If $m(+\infty)$ and $m(-\infty)$ differ by a sign as a domain wall, there always exists a zero energy solution near a domain wall of the mass distribution $m(x)$. Therefore this solution is quite robust against the mass distribution $m(x)$.

2.2.2   Two Dimensions

In two dimensions (with $p_z = 0$), we consider a system with an interface at $x = 0$, $m(x) = -m_1$ for $x < 0$, and m_2 for $x > 0$. $p_y = \hbar k_y$ is a good quantum number. We have two solutions which the wave functions dominantly distribute around the interface: one solution has the form

$$\Psi_+(x, k_y) = \sqrt{\frac{v}{\hbar} \frac{m_1 m_2}{m_1 + m_2}} \begin{pmatrix} i \\ 0 \\ 0 \\ 1 \end{pmatrix} e^{-|m(x)vx|/\hbar + ik_y y} \tag{2.28}$$

with the dispersion $\epsilon_{k,+} = v\hbar k_y$ and the other has the form

$$\Psi_-(x, k_y) = \sqrt{\frac{v}{\hbar} \frac{m_1 m_2}{m_1 + m_2}} \begin{pmatrix} 0 \\ i \\ 1 \\ 0 \end{pmatrix} e^{-|m(x)vx|/\hbar + ik_y y} \tag{2.29}$$

with the dispersion $\epsilon_{k,-} = -v\hbar k_y$. We can check these two solutions in the following way. The Dirac equation can be divided into two parts,

$$H = [m(x)v^2 \beta + v p_x \alpha_x] + v p_y \alpha_y. \tag{2.30}$$

From the one-dimensional solution one has

$$(m(x)v^2 \beta + v p_x \alpha_x)\Psi_\pm = 0 \tag{2.31}$$

and

$$vp_y\alpha_y\Psi_\pm = \pm vp_y\Psi_\pm. \tag{2.32}$$

From the dispersions of the two states, the effective velocities of the electrons in the states are

$$v_\pm = \frac{\partial \epsilon_{k,\pm}}{\hbar\partial k} = \pm v. \tag{2.33}$$

Therefore, each state carries a current along the interface, but the electrons with different spins move in opposite directions. The current density decays exponentially away from the interface. As the system has the time reversal symmetry, the two states are time reversal counterpart of each other, constituting a pair of helical edge (or bound) states at the interface. Furthermore, the Dirac equation of $p_z = 0$ can be reduced to two independent sets of equations

$$h(x) = vp_x\sigma_x \pm vp_y\sigma_y + m(x)v^2\sigma_z \tag{2.34}$$

for different spins. Thus, it is clear why two bound states have opposite velocities.

2.2.3   Three and Higher Dimensions

In three and higher dimensions, bound states always exist at the interface of the system with positive and negative masses. Even when all other components of the momentum in the interface are good quantum numbers, there is always a solution for zero momentum, as in the one-dimensional case. We can use these solutions to derive the ones of non-zero momenta in higher dimensions.

2.3   Why not the Dirac Equation?

From the Dirac equation, we know there is a solution of bound states at the interface between two media with positive and negative masses or energy gaps. These solutions are quite robust against the roughness of the interface or other factors. If we assume that the vacuum is an insulator with an infinitely large and positive mass or energy gap, then the system with a negative mass should have bound states around the open boundary only if the contiuity condition of the wave function is relaxed. This is very close to the definition of topological insulators. However, because of the symmetry in the Dirac equation with positive and negative masses, there is no topological distinction between these two systems after a unitary transformation. We cannot determine which one is topologically trivial or non-trivial simply from the sign of the

mass or energy gap. If we use the Dirac equation to describe a topological insulating phase, we have to introduce or assign an additional "vacuum" as a benchmark. Thus, we think this additional condition is unnecessary as the existence of the bound state should be a physical and intrinsic consequence of the band structure in topological insulators. Therefore we conclude that the Dirac equation in (2.1) itself may not be a "suitable" candidate to describe the topology of quantum matters.

2.4 Quadratic Correction to the Dirac Equation

To explore a possible description of a the topological insulator, we introduce a quadratic correction $-Bp^2$ in momentum $\mathbf{p}$ to the band gap or rest-mass term in the Dirac equation [4],

$$H = v\mathbf{p} \cdot \alpha + \left(mv^2 - B\mathbf{p}^2\right)\beta, \tag{2.35}$$

where mv^2 is the band gap of the particle and m and v have dimensions of mass and speed, respectively. B^{-1} also has the dimension of mass. The quadratic term breaks the symmetry between the mass m and $-m$ in the Dirac equation, and makes this equation topologically distinct from the original Dirac equation in (2.1).

To illustrate this, we plot the spin distribution of the ground state in momentum space as shown in Fig. 2.2. At $p = 0$, the spin orientation is determined by $mv^2\beta$ or the sign of mass m, but for a large p, it is determined dominantly by $-B\mathbf{p}^2\beta$ or the sign of B. If the dimensionless parameter $mB > 0$, when p increases along one direction, say the x-direction, the spin will rotate from the z-direction to the x-direction of $\mathbf{p}$ at $p_c^2 = mv^2/B$, and then eventually to the opposite z-direction for a larger $\mathbf{p}$. This consists of two so-called merons in momentum space, which is named
Fig. 2.2 Spin orientation in momentum space. *Left* ($mB < 0$) the spins at $p = 0$ and $p = +\infty$ are parallel, which is topologically trivial. *Left bottom* spin orientation along the p_x-axis. *Right* ($mB > 0$) the spins at $p = 0$ and $p = +\infty$ are anti-parallel, which is topologically non-trivial. *Right bottom* spin orientation along the p_x-axis

skymion. For $mB < 0$, when p increases, the spin will rotate from the z-direction to the direction of p, and then flips back to the initial z-direction. The question of whether the spin points in the same direction at $p = 0$ and $+\infty$ determines whether the equation is topologically distinct in the case of $mB > 0$ and $mB < 0$.

2.5 Bound State Solutions of the Modified Dirac Equation

2.5.1 One Dimension: End States

Let us start with a one-dimensional case. In this case, the 4×4 (2.35) can be decoupled into two independent sets of 2×2 equations,

$$h(x) = v p_x \sigma_x + \left(mv^2 - Bp_x^2\right) \sigma_z. \tag{2.36}$$

For a semi-infinite chain with $x \geq 0$, we consider an open boundary condition at $x = 0$. It is required that the wave function vanishes at the boundary, i.e., the Dirichlet boundary condition. Usually, we have a series of solutions of extended states, which wave functions spread throughout the whole space. In this section, we focus on the solution of the bound state near the boundary. To find the solution of zero energy, we have

$$\left[v p_x \sigma_x + \left(mv^2 - Bp_x^2\right) \sigma_z\right] \varphi(x) = 0. \tag{2.37}$$

Multiplying σ_x from the left hand side, one obtains

$$\partial_x \varphi(x) = -\frac{1}{v\hbar} \left(mv^2 + B\hbar^2 \partial_x^2\right) \sigma_y \varphi(x). \tag{2.38}$$

If $\varphi(x)$ is an eigen function of σ_y, take $\varphi(x) = \chi_\eta \phi(x)$ with $\sigma_y \chi_\eta = \eta \chi_\eta$ ($\eta = \pm 1$). Then, the differential equation is reduced to the second-order ordinary differential equation,

$$\partial_x \phi(x) = -\frac{\eta}{v\hbar} \left(mv^2 + B\hbar^2 \partial_x^2\right) \phi(x). \tag{2.39}$$

Taking the trial wave function $\phi(x) \propto e^{-\lambda x}$, one obtains the secular equation

$$B\hbar^2 \lambda^2 - \eta v \hbar \lambda + mv^2 = 0. \tag{2.40}$$

The two roots satisfy the relation $\lambda_+ + \lambda_- = \eta v \hbar / B$ and $\lambda_+ \lambda_- = mv^2 / B\hbar^2$. To have a bound state solution, it is required that the wave function vanishes at $x = 0$ and $x = +\infty$,

$$\varphi(x = 0) = \varphi(x = +\infty) = 0. \tag{2.41}$$

Fig. 2.3 Schematic of the probability density $|\Psi(x)|^2$ of the end state solution as a function of its position in (2.42)
The two roots should be positive and only one of χ_η satisfy the boundary condition for a bound state, $\eta = sgn(B)$ (without loss of generality, we assume that v is always positive). In the condition of $mB > 0$, there exists a solution of the bound state with zero energy

$$\varphi_\eta(x) = \frac{C}{\sqrt{2}} \begin{pmatrix} sgn(B) \\ i \end{pmatrix} (e^{-x/\xi_+} - e^{-x/\xi_-}), \tag{2.42}$$

where $\xi_\pm^{-1} = \frac{v}{2|B|\hbar} \left(1 \pm \sqrt{1 - 4mB}\right)$ and C is the normalization constant. The main feature of this solution is that the wave function distributes dominantly near the boundary, and decays exponentially away from one end as shown in Fig. 2.3. The two parameters ξ_+ and ξ_- decide the spatial distribution of the wave function. These are two important length scales, which characterize the end states. When $B \to 0$, $\xi_+ \to |B|\hbar/v$ and $\xi_- = \hbar/mv$, i.e., ξ_+ approaches to zero, and ξ_- becomes a finite constant that is determined by the energy gap mv^2. If we relax the constraint of the vanishing wave function at the boundary, the solution exists even if $B = 0$. In this way, we go back to the conventional Dirac equation. In this sense, the two equations reach the same conclusion. When $m \to 0$, $\xi_- = \hbar/mv \to +\infty$ and the state evolves into a bulk state. Thus, the end states disappear and a topological quantum phase transition occurs at $m = 0$.

In the four-component form to (2.35), two degenerate solutions have the form,

$$\Psi_1 = \frac{C}{\sqrt{2}} \begin{pmatrix} sgn(B) \\ 0 \\ 0 \\ i \end{pmatrix} (e^{-x/\xi_+} - e^{-x/\xi_-}) \tag{2.43}$$

and

$$\Psi_2 = \frac{C}{\sqrt{2}} \begin{pmatrix} 0 \\ sgn(B) \\ i \\ 0 \end{pmatrix} (e^{-x/\xi_+} - e^{-x/\xi_-}).$$

(2.44)

We shall see that these two solutions can be used to derive effective Hamiltonians for higher dimensional systems.

The role of this solution cannot be underestimated in the theory of topological insulators. We will see that all solutions of the edge or surface states, and topological excitations are closely related to this solution.

2.5.2 Two Dimensions: Helical Edge States

In two dimensions, the equation can also be decoupled into two independent equations

$$h_\pm = vp_x\sigma_x \pm vp_y\sigma_y + (mv^2 - Bp^2)\sigma_z.$$

(2.45)

These two equations break the "time" reversal symmetry under the transformation of $\sigma_i \to -\sigma_i$ and $p_i \to -p_i$, although the original four-component equation is time reversal invariant.

We consider a semi-infinite plane with the boundary at $x = 0$. $p_y = \hbar k_y$ is a good quantum number. At $k_y = 0$, the two-dimensional equation has the identical form as the one-dimensional equation. The x dependent part of the solution has the identical form as in the one dimension. Thus, we use the two one-dimensional solutions $\{\Psi_1, \Psi_2\}$ in (2.43) and (2.44) as the basis of the two-dimensional solutions. The y dependent part $\Delta H_{2D} = vp_y\alpha_y - Bp_y^2\beta$ is regarded as the perturbation to the one-dimensional Hamiltonian. In this way, we have a one-dimensional effective model for the helical edge states

$$H_{eff} = (\langle\Psi_1|, \langle\Psi_2|)\Delta H \begin{pmatrix} |\Psi_1\rangle \\ |\Psi_2\rangle \end{pmatrix} = vp_y sgn(B)\sigma_z.$$

(2.46)

The sign dependence of B in the effective model also reflects the fact that the helical edge states disappear if $B = 0$. The dispersion relations for the bound states at the boundary are

$$\epsilon_{p_y,\pm} = \pm vp_y.$$

(2.47)

Electrons have positive $(+v)$ and negative velocity $(-v)$ in their two different states, respectively, and form a pair of helical edge states.

The exact solutions of the edge states in this two-dimensional equation have the form similar to that in the one-dimensional equation [5],

$$\Psi_1 = \frac{C}{\sqrt{2}} \begin{pmatrix} sgn(B) \\ 0 \\ 0 \\ i \end{pmatrix} (e^{-x/\xi_+} - e^{-x/\xi_-})e^{+ip_y y/\hbar} \tag{2.48}$$

and

$$\Psi_2 = \frac{C}{\sqrt{2}} \begin{pmatrix} 0 \\ sgn(B) \\ i \\ 0 \end{pmatrix} (e^{-x/\xi_+} - e^{-x/\xi_-})e^{+ip_y y/\hbar}, \tag{2.49}$$

with the dispersion relations $\epsilon_{p_y,\pm} = \pm v p_y sgn(B)$. The characteristic lengths become p_y dependent,

$$\xi_\pm^{-1} = \frac{v}{2\,|B|\,\hbar} \left(1 \pm \sqrt{1 - 4mB + 4B^2 p_y^2/v^2}\right). \tag{2.50}$$

In two dimensions, the Chern number or Thouless-Kohmoto-Nightingale-Nijs (TKNN) integer can be used to characterize whether the system is topologically trivial or non-trivial [6]. For the two-band Hamiltonian in the form $H = \mathbf{d}(p) \cdot \sigma$, the Chern number is expressed as

$$n_c = -\frac{1}{4\pi} \int d\mathbf{p} \frac{\mathbf{d} \cdot (\partial_{p_x} \mathbf{d} \times \partial_{p_y} \mathbf{d})}{d^3}, \tag{2.51}$$

where $d^2 = \sum_{\alpha=x,y,z} d_\alpha^2$ (see Appendix A.2). The integral runs over the first Brillouin zone for a lattice system, in which the number n_c is always an integer (see Appendix A.1). In the continuous limit, the integral area becomes infinite, the integral can be fractional. For (2.45), the Chern number has the form [7, 8]

$$n_\pm = \pm\frac{1}{2}(sgn(m) + sgn(B)), \tag{2.52}$$

which is related to the Hall conductance $\sigma_\pm = n_\pm e^2/h$. When m and B have the same sign, $n_\pm = \pm 1$, and the system is topologically non-trivial. But if m and B have different signs, $n_\pm = 0$. The topologically non-trivial condition is in agreement with the existence condition of the edge state solution $mB > 0$. This reflects the bulk-edge relation of the integer quantum Hall effect [9].

2.5.3 Three Dimensions: Surface States

In three dimensions, we consider a y–z plane at $x = 0$. We can derive an effective model for the surface states by means of the one-dimensional solution of the bound state. As the momenta among the y–z plane are good quantum numbers, we use their eigenvalues to replace the momentum operators, p_y and p_z. Consider p_y and p_z dependent part as a perturbation to $H_{1D}(x)$,

$$\Delta H_{3D} = vp_y\alpha_y + vp_z\alpha_z - B(p_y^2 + p_z^2)\beta. \tag{2.53}$$

The solutions of the three-dimensional Dirac equation at $p_y = p_z = 0$ are identical to the two one-dimensional solutions, $|\Psi_1\rangle$ and $|\Psi_2\rangle$ in (2.43) and (2.44). For $p_y, p_z \neq 0$, we use the solutions

$$\Psi_1 = \frac{C}{\sqrt{2}} \begin{pmatrix} sgn(B) \\ 0 \\ 0 \\ i \end{pmatrix} (e^{-x/\xi_+} - e^{-x/\xi_-})e^{i(p_y y + p_z z)/\hbar} \tag{2.54}$$

and

$$\Psi_2 = \frac{C}{\sqrt{2}} \begin{pmatrix} 0 \\ sgn(B) \\ i \\ 0 \end{pmatrix} (e^{-x/\xi_+} - e^{-x/\xi_-})e^{i(p_y y + p_z z)/\hbar} \tag{2.55}$$

as the basis. A straightforward calculation as in the two-dimensional case gives

$$H_{eff} = (\langle\Psi_1|, \langle\Psi_2|)\Delta H_{3D} \begin{pmatrix} |\Psi_1\rangle \\ |\Psi_2\rangle \end{pmatrix} = vsgn(B)(p \times \sigma)_x. \tag{2.56}$$

Under a unitary transformation,

$$\Phi_1 = \frac{1}{\sqrt{2}}(|\Psi_1\rangle - i\,|\Psi_2\rangle) \tag{2.57}$$

and

$$\Phi_2 = \frac{-i}{\sqrt{2}}(|\Psi_1\rangle + i\,|\Psi_2\rangle), \tag{2.58}$$

one can have a gapless Dirac equation for the surface states

$$H_{eff} = \frac{1}{2}(\langle \Phi_1|, \langle \Phi_2|) \Delta H_{3D} \begin{pmatrix} |\Phi_1\rangle \\ |\Phi_2\rangle \end{pmatrix}$$

$$= v sgn(B)(p_y \sigma_y + p_z \sigma_z). \tag{2.59}$$

The dispersion relations become $\epsilon_{p,\pm} = \pm v p$ with $p = \sqrt{p_y^2 + p_z^2}$. In this way, we have an effective model for a single Dirac cone of the surface states as plotted in Fig. 2.4. Note that σ_i in the Hamiltonian is not a real spin, which is determined by two states at $p_y = p_z = 0$. In some systems $|\Psi_1\rangle$ and $|\Psi_2\rangle$ are almost polarized along the z-direction of the electron spin. In this sense, the Pauli matrices in (2.56) may be regarded as approximating a real spin.

The exact solutions of the surface states of this three-dimensional equation with a boundary are

$$\Psi_\pm = C \Psi_\pm^0 (e^{-x/\xi_+} - e^{-x/\xi_-}) \exp[+i(p_y y + p_z z)/\hbar], \tag{2.60}$$

Fig. 2.4 The Dirac cone of
the surface states in
momentum space
where

$$\Psi_+^0 = \begin{pmatrix} \cos\frac{\theta}{2} sgn(B) \\ -i \sin\frac{\theta}{2} sgn(B) \\ \sin\frac{\theta}{2} \\ i \cos\frac{\theta}{2} \end{pmatrix} \tag{2.61}$$

and

$$\Psi_-^0 = \begin{pmatrix} \sin\frac{\theta}{2} sgn(B) \\ i \cos\frac{\theta}{2} sgn(B) \\ -\cos\frac{\theta}{2} \\ i \sin\frac{\theta}{2} \end{pmatrix} \tag{2.62}$$

with the dispersion relation $\epsilon_{p,\pm} = \pm v p \mathrm{sgn}(B)$. $\tan\theta = p_y/p_z$. The penetration depth becomes p dependent,

$$\xi_\pm^{-1} = \frac{v}{2\,|B|\,\hbar} \left(1 \pm \sqrt{1 - 4mB + 4B^2 p^2/\hbar^2}\right). \tag{2.63}$$

2.5.4   Generalization to Higher-Dimensional Topological Insulators

The solution can be generalized to higher-dimensional system. We conclude that there is always a (d-1)-dimensional surface state in the d-dimensional modified Dirac equation when $mB > 0$.

2.6   Summary

From the solutions of the modified Dirac equation, we found the following conclusions under the condition of $mB > 0$,

- in one dimension, there exists a bound state of zero energy near the end;
- in two dimensions, there exists solution of a pair of helical edge states near the edge;
- in three dimensions, there exists solution of surface states near the surface; and
- in higher dimensions, there always exists a higher dimensional boundary states.

From the solutions of the bound states near the boundary and the calculation of the Z_2 index, we conclude that the modified Dirac equation can provide a description of a large class of topological insulators from one to higher dimensions.

Chapter 3
Minimal Lattice Model for Topological Insulators

Abstract A lattice model can be mapped into a continuous model near the critical point of a topological quantum phase transition. The topology of a lattice model remains unchanged if no energy gap in the band structure closes and reopens.

3.1 Tight Binding Approximation

The tight-binding model has been extensively used to describe the band structure of electrons in solids. The schematic in Fig. 3.1 depicts the formation of a tight binding lattice from the point of view of atomic physics. Consider an isolated atom, say hydrogen atom. In quantum mechanics, an electron rotates around the nuclei in the Coulomb interaction, and forms a series of discrete energy levels or orbits, $E_n = -e^2/(8\pi\epsilon_0 n^2 a_0)$, where the Bohr radius $a_0 = 4\pi\epsilon_0\hbar^2/(m_e e^2)$ and n is an integer. The ground state energy is $E_{n=1} = -13.6$ eV and the radius of the orbit is $a_0 = 0.529$ Å. The energy of the first excited state is $E_{n=2} = -3.4$ eV. The energy difference between the two states is about -10.2 eV, which is very large in a solid. Thus, it is a good approximation to consider only the ground state of an electron at low temperatures. When two atoms get close to each other, the orbits of two electrons from different atoms may overlap in space. As a result, the electron of one atom may jump into the orbit of another atom. Since the electron is mainly localized around the original nuclei, the probability of an electron tunneling from one atom to another is still quite tiny. The picture can be generalized to a lattice system consisting of atoms: the electrons move from one atom to another one, and form energy bands.

In the second quantization the tight binding Hamiltonian is written as

$$H = \sum_{i,\sigma=\uparrow,\downarrow} \epsilon_0 c_{i,\sigma}^\dagger c_{i,\sigma} - \sum_{\langle i,j\rangle,\sigma=\uparrow,\downarrow} t_{ij} c_{i,\sigma}^\dagger c_{j,\sigma}, \tag{3.1}$$

where the summation i runs over all the lattice sites, and $\sigma = \uparrow, \downarrow$ represent the electron spin up and down, respectively. $c_{i,\sigma}^\dagger$ and $c_{i,\sigma}$ are the creation and annihilation operators of an electron at site i with spin σ obeying the anticommutation relation,

Fig. 3.1 Schematic explaining the tight binding approximation. **a** A single atom with discrete orbits for its electron. **b** When atoms get together to form a *solid*, the wave functions of the two orbits (*black*) of adjunct atoms overlap in space. **c** If the overlap of the orbits is small, the electrons are still considered to be almost localized around the original orbits, but have a tiny probability tunneling into the adjunct orbits to form an energy band (color figure online)
$c_{i,\sigma}^{\dagger} c_{j,\sigma'} + c_{j,\sigma'} c_{i,\sigma}^{\dagger} = \delta_{\sigma\sigma'} \delta_{ij}$. It is required that $c_{i,\sigma} |0\rangle = 0$. t_{ij} describes the hopping amplitude of the electron from site i to site j.

For a ring of one-dimensional lattice with N lattice sites or a one-dimensional lattice with a periodic boundary condition, we take $c_{i,\sigma} = c_{i+N,\sigma}$. For simplicity, we suppose that the lattice is translationally invariant by taking $t_{ij} = t$ for a pair of nearest neighbor lattice sites. Performing the Fourier transformation, one obtains

$$c_{i,\sigma} = \frac{1}{\sqrt{Na}} \sum_{k_n} e^{ik_n R_i} c_{k_n,\sigma}, \tag{3.2}$$

$$c_{i,\sigma}^{\dagger} = \frac{1}{\sqrt{Na}} \sum_{k_n} e^{-ik_n R_i} c_{k_n,\sigma}^{\dagger}. \tag{3.3}$$

and the periodic boundary condition gives $e^{ik_n R_i} = e^{ik_n(R_i + Na)}$ with $k_n = 2n\pi/Na$ ($n = 0, 1, \ldots, N-1$). In this way the Hamiltonian can be diagonalized as

$$H = \sum_{k_n} \epsilon(k_n) c_{k_n,\sigma}^{\dagger} c_{k_n,\sigma} \tag{3.4}$$

with the dispersion $\epsilon(k_n) = \epsilon_0 - 2t \cos k_n a$. Notice that for $K = 2\pi/a$, $\epsilon(k_n + K) = \epsilon(k_n)$. For a very large N, $k_n a$ can be taken to be continuous number from 0 to 2π and K is called the reciprocal lattice vector.

The approach can be generalized to two and three dimensions. The reciprocal lattice vector can be defined for the purpose of the Fourier transformation from the real space to the momentum space. In a three-dimensional lattice with the lattice spaces **a**, **b**, and **c**, the reciprocal lattice vectors are given by

$$\mathbf{K}_a = 2\pi \frac{\mathbf{b} \times \mathbf{c}}{\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c})}, \tag{3.5}$$

$$\mathbf{K}_b = 2\pi \frac{\mathbf{c} \times \mathbf{a}}{\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c})}, \tag{3.6}$$

$$\mathbf{K}_c = 2\pi \frac{\mathbf{a} \times \mathbf{b}}{\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c})}, \tag{3.7}$$

and $K_\alpha R_\alpha = 2\pi$ for $\alpha = a, b, c$.

The Fourier transformation is a powerful tool to study the periodic problem. Usually it is a very good approximation for periodic lattices with a large lattice sites. It is noted that the energy dispersions obtained in this way only describe the bulk band structure. However, it may ignore solutions of possible states near system boundary as phsyical systems usually are in the open boundary conditions instead of the periodic boundary conditions.

3.2   Mapping from a Continuous Model to a Lattice Model

Usually a continuous model describes low energy physics in a long wave length limit. The topology of the band structure should reveal the properties of the whole band structure in the Brillouin zone. In practise, people like to use a lattice model instead of a continuous model to explore the topology of a system. A continuous model can be mapped into a lattice model in the tight binding approximation, in which the Brillouin zone is periodic and finite. In a d-dimensional hyper-cubic lattice, one makes the following replacements [1]:

$$k_i \rightarrow \frac{1}{a} \sin k_i a \tag{3.8}$$

and

$$k_i^2 \rightarrow \frac{4}{a^2} \sin^2 \frac{k_i a}{2} = \frac{2}{a^2}(1 - \cos k_i a), \tag{3.9}$$

which are equal only in a long wave length limit, i.e., $k_i a \rightarrow 0$ by using the relation $\sin x \approx x$ for a small x. We use $\sin^2 \frac{k_i a}{2}$ or $\cos k_i a$ instead of $\sin^2 k_i a$ for k_i^2 to avoid the next nearest neighbour hopping in the lattice Hamiltonian. In this way the hopping terms in the lattice model only exist between the nearest neighbor sites.

Usually, the fermion doubling problem exists in the lattice model for massless Dirac particles. The replacement of $k_i \rightarrow \frac{1}{a} \sin k_i a$ will cause an additional zero point for $\frac{1}{a} \sin k_i a$ at $k_i a = \pi$ as well as at $k_i a = 0$. Thus, there exist four Dirac cones in a square lattice at $k = (0, 0)$, $(0, \pi/a)$, $(\pi/a, 0)$, and $(\pi/a, \pi/a)$ for a gapless Dirac equation. A large B term removes the zero point at $(\pi/a, \pi/a)$ as $\frac{4B}{a^2} \sin^2 \frac{k_i a}{2} \rightarrow \frac{4B}{a^2}$. Thus, the lattice model is equivalent to the continuous model only in the condition of a large B. For a finite B, the band gap may not open at the Γ point in the lattice model because of the competition between the linear term and the quadratic term of k_i. This fact may lead to a topological transition from a large B to a small B. Imura et al. [2] analyzed the two-dimensional case in details and found that there is a topological transition at a finite value of B in two dimensions. A similar transition also exists in higher dimensions. Thus, it is necessary to be careful when a lattice model is constructed based on the continuous model. However the topology of the band structure never changes if the energy gap in the band structure does not close and reopen, whereas the model parameters vary continuously.

With this mapping, one obtains the following lattice model for topological insulator

$$H = \frac{\hbar v}{a} \sum_{i=x,y,z} \sin k_i a \, \alpha_i + \left(m v^2 - B \frac{4\hbar^2}{a^2} \sum_{i=x,y,z} \sin^2 \frac{k_i a}{2} \right) \beta. \qquad (3.10)$$

The energy dispersions for this system are

$$E_{k,\pm} = \pm \sqrt{\frac{\hbar^2 v^2}{a^2} \sum_{i=x,y,z} \sin^2 k_i a + \left(m v^2 - \frac{4B\hbar^2}{a^2} \sum_{i=x,y,z} \sin^2 \frac{k_i a}{2} \right)^2}. \qquad (3.11)$$

For $mB < 0$ there is always an energy gap between the two bands $2|m|v^2$. For $mB = 0$ ($B \neq 0$) the energy gap closes at the points $k_i a = 0$ as $E_{0,+} = E_{0,-}$. For $mB > 0$ there exists several gapless points at $mv^2 = 4B\hbar^2/a^2$ (in one, two, and three dimensions), $8B\hbar^2/a^2$ (in two and three dimensions) and $12B\hbar^2/a^2$ (in three dimensions). We shall show that these are the critical points for topologically quantum phase transitions. For simplicity, we take the lattice constant $a = \hbar = 1$.

We can perform the Fourier transform to transfer the effective Hamiltonian from momentum space into lattice space. In the tight binding approximation, the model Hamiltonian on a hyper-cubic lattice has the form

$$H = \sum_{i,n,m} \Delta c_{i,n}^\dagger \beta_{nm} c_{i,m} - t \sum_{\langle i,j \rangle,} c_{j,n}^\dagger \beta_{nm} c_{im}$$
$$+ i t' \sum_{i,\delta,n,m} \left[c_{i+a,n}^\dagger (\alpha_a)_{nm} c_{im} - c_{i,n}^\dagger (\alpha_a)_{nm} c_{i+a,m} \right]. \qquad (3.12)$$

Here $\langle i, j \rangle$ runs over the pairs of nearest neighbor sites. $a = x, y, z$ and $i + a$ represents the lattice site $R_i + R_a$. $n, m = 1, 2, \ldots, d$ where d is the dimension of the Dirac matrices. The relations of the model parameters are

$$t' = \frac{\hbar v}{2a} = v/2, \; \Delta - 2dt = mv^2, t = -B\hbar^2/a^2 = -B. \tag{3.13}$$

Denote $\left(c_{i,1}^\dagger, c_{i,2}^\dagger, \ldots, c_{i,d}^\dagger \right)$ by $c_i^\dagger$. In this way, the equation can be written in a compact form:

$$H = \sum_i \Delta c_i^\dagger \beta c_i - t \sum_{\langle i,j \rangle,} c_j^\dagger \beta c_i + it' \sum_{i,\delta} \left[c_{i+a}^\dagger \alpha_a c_i - c_i^v \alpha_a c_{i+a} \right]. \tag{3.14}$$

3.3 One-Dimensional Lattice Model

Consider a one-dimensional lattice model

$$H = \Delta \sum_{j=1}^{N} c_j^\dagger \sigma_z c_j - t \sum_{,j=1}^{N-1} \left(c_{j+1}^\dagger \sigma_z c_j + c_j^\dagger \sigma_z c_{j+1} \right) \tag{3.15}$$

$$+it' \sum_{j=1}^{N-1} \left(c_{j+1}^\dagger \sigma_x c_j - c_j^\dagger \sigma_x c_{j+1} \right), \tag{3.16}$$

where $c_j^\dagger = \left(c_{j,\uparrow}^\dagger, c_{j,\downarrow}^\dagger \right)$. To find the end state, we adapt the open boundary condition. We choose $\left(c_1^\dagger, c_2^\dagger, \ldots, c_N^\dagger \right)$ as the basis. The Hamiltonian can be written in the form of a matrix:

$$H = \begin{pmatrix} \Delta\sigma_z & T & 0 & 0 & \ldots & 0 \\ T^\dagger & \Delta\sigma_z & T & 0 & \ldots & 0 \\ 0 & T^\dagger & \Delta\sigma_z & T & \ldots & 0 \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & T^\dagger & \Delta\sigma_z & T \\ 0 & 0 & 0 & 0 & T^\dagger & \Delta\sigma_z \end{pmatrix}, \tag{3.17}$$

where $T = -t\sigma_z - it'\sigma_x$. As σ_x and σ_z are 2×2 matrices, the Hamiltonian is a $2N \times 2N$ square matrix.

Here we present a solution for $N = +\infty$, i.e., a semi-infinite chain with an end at $j = 1$. We take the eigenvector for H as $\Psi^\dagger = (\Psi_1^\dagger, \Psi_2^\dagger, \ldots, \Psi_N^\dagger)$. The eigenvalue equation of this problem becomes

$$\Delta\sigma_z\Psi_j + T\Psi_{j+1} + T^+\Psi_{j-1} = E\Psi_j \tag{3.18}$$

for $j = 1, 2, \ldots$ and $\Psi_0 = 0$. To solve this equation, we set a trial solution,

$$\Psi_{j+1} = \lambda\Psi_j = \lambda^{j+1}\Psi. \tag{3.19}$$

Then (3.18) becomes

$$\left(\Delta\sigma_z + \lambda T + \lambda^{-1}T^+\right)\Psi = P\Psi = E\Psi. \tag{3.20}$$

where the operator $P = \Delta\sigma_z + \lambda T + \lambda^{-1}T^+ \equiv \gamma \cdot \sigma$ with

$$\gamma_x = -it'(\lambda - \lambda^{-1}), \tag{3.21}$$
$$\gamma_y = 0, \tag{3.22}$$
$$\gamma_z = \Delta - \lambda t - t\lambda^{-1}. \tag{3.23}$$

In general, the matrix P is non-Hermitian, and one may have two complex eigenvalues for P. However, E must be real as it is the eigenvalue for a physical system. Thus, P should meet one of the conditions:

(1). all components of γ are real, and
(2). all non-zero complex components combine to give $E = 0$.

The first condition is met when $\gamma = e^{ik}$, which gives solution of the bulk band. These solutions are not what we are interested in here. The second condition defines the so-called annihilator. In the present case, if $\gamma_z = is\gamma_x$ ($s = \pm 1$),

$$P = \gamma_x(\sigma_x + is\sigma_z). \tag{3.24}$$

$\Psi = \frac{1}{\sqrt{2}}(1, -is)^T$ satisfies $P\Psi = 0$, which is also one of the eigenstates of σ_y with the eigenvalue $-s$.

Increasing and decreasing operators are defined by $\sigma_\pm = \sigma_x \pm i\sigma_y$, which satisfy

$$\sigma_+\begin{pmatrix}1\\0\end{pmatrix} = 0; \; \sigma_+\begin{pmatrix}0\\1\end{pmatrix} = 2\begin{pmatrix}1\\0\end{pmatrix} \tag{3.25}$$

and

$$\sigma_-\begin{pmatrix}0\\1\end{pmatrix} = 0; \; \sigma_-\begin{pmatrix}1\\0\end{pmatrix} = 2\begin{pmatrix}0\\1\end{pmatrix}. \tag{3.26}$$

To have a zero-energy mode of $E = 0$, one has

$$\Delta - \lambda t - t\lambda^{-1} = st'(\lambda - \lambda^{-1}). \tag{3.27}$$

This equation has two roots,

$$\lambda_{\pm}(s) = \frac{\Delta}{2(t + st')} \left[1 \pm \sqrt{1 - \frac{4(t^2 - t'^2)}{\Delta^2}} \right]. \tag{3.28}$$

The solutions for the end state require $|\lambda_{\pm}| < 1$ as $\Psi_j \to 0$ for a large j. Thus,

$$\lambda_+ \lambda_- = \frac{t - st'}{t + st'} < 1, \tag{3.29}$$

which requires $s = \mathrm{sgn}(t'/t)$.

Case I: $\lambda_{\pm}$ are complex for

$$4(t^2 - t'^2) > \Delta^2 \tag{3.30}$$

and

$$|\lambda_+^2| = \frac{t - st'}{t + st'} = \frac{1 - \left| \frac{t'}{t} \right|}{1 + \left| \frac{t'}{t} \right|}. \tag{3.31}$$

Case II: For

$$4(t^2 - t'^2) < \Delta^2, \tag{3.32}$$

one requires

$$|\lambda_{\pm}|^2 = \frac{\Delta^2}{4(t + st')^2} \left[2 - \frac{4(t^2 - t'^2)}{\Delta^2} \pm 2\sqrt{1 - \frac{4(t^2 - t'^2)}{\Delta^2}} \right] < 1. \tag{3.33}$$

It follows that

$$4(t^2 - t'^2) < \Delta^2 < 4t^2. \tag{3.34}$$

Thus, the boundary condition of $\Psi_0 = 0$ gives the solution

$$\Psi_j = (\lambda_+^j - \lambda_-^j)\Psi, \tag{3.35}$$

which does not vanish at the boundary at $j = 1$.

We now consider the special case of two exact solutions of this lattice model at $\Delta = 0$ and $t = t'$. In this case we have the solutions:

$$\Psi_L = \begin{pmatrix} \varphi_1 \\ 0 \\ \vdots \\ 0 \end{pmatrix} \tag{3.36}$$

and

$$\Psi_R = \begin{pmatrix} 0 \\ 0 \\ \vdots \\ \varphi_N \end{pmatrix}, \tag{3.37}$$

with

$$T^\dagger \varphi_1 = -t(\sigma_z - i\sigma_x)\varphi_1 = 0; \tag{3.38}$$
$$T \varphi_N = -t(\sigma_z + i\sigma_x)\varphi_N = 0, \tag{3.39}$$

and

$$\varphi_1 = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 \\ -i \end{pmatrix}, \varphi_N = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 \\ +i \end{pmatrix}. \tag{3.40}$$

These two solutions are located at two ends, and the energy eigenvalues are zero. As the two solutions are degenerate, the linear combination of these two solutions is also the solution for the lattice model.

3.4 Two-Dimensional Lattice Model

3.4.1 Integer Quantum Hall Effect

In two dimensions, the lattice model on a square lattice can be written as

$$H = \mathbf{d}(\mathbf{k}) \cdot \sigma, \tag{3.41}$$

where

$$d_x = A \sin k_x a; \tag{3.42}$$
$$d_y = A \sin k_y a; \tag{3.43}$$
$$d_z = \Delta - 4B \sin^2 \frac{k_x a}{2} - 4B \sin^2 \frac{k_y a}{2}. \tag{3.44}$$

One can regard this model as a quantum spin in an effective magnetic field, $\mathbf{d}(k)$. The dispersion relations are

$$E_{k,\pm} = \pm |\mathbf{d}(\mathbf{k})| . \tag{3.45}$$

The zero points of the dispersion are determined by a set of equations

$$\sin^2 k_x a = \sin^2 k_x a = 0 \tag{3.46}$$

and

$$\Delta = 4B \sin^2 \frac{k_x a}{2} + 4B \sin^2 \frac{k_y a}{2}. \tag{3.47}$$

There are three solutions: (1). $\Delta = 0$ with ($k_x a = 0$, $k_y a = 0$); (2). $\Delta = 4B$ with ($k_x a = 0$, $k_y a = \pi$) or ($k_x a = \pi$, $k_y a = 0$); (3). and $\Delta = 8B$ with ($k_x a = \pi$, $k_y a = \pi$). Thus, the energy gap closes and re-opens near these points. We shall see that topological quantum phase transition will occur at the points (1) $\Delta = 0$, (2) $\Delta = 4B$, and (3) $\Delta = 8B$.

To find a solution of an edge state, we may adopt the geometry of a ribbon. Along the x-direction, we adapt the periodic boundary condition such that k_x is a good quantum number. Along the y-direction, we adapt an open boundary condition. Performing the partial Fourier transformation only for the x-direction, the problem is reduced to a one-dimensional problem as k_x is regarded as a variable.

$$H(k_x) = \sum_{j=1}^{N} c_{k_x,j}^{\dagger} h_{j,j}(k_x) c_{k_x,j}$$

$$+ \sum_{j=1}^{N-1} \left[c_{k_x,j}^{\dagger} h_{j,j+1}(k_x) c_{k_x,j+1} + c_{k_x,j+1}^{\dagger} h_{j+1,j}(k_x) c_{k_x,j} \right], \quad (3.48)$$

where

$$h_{j,j}(k_x) = A \sin k_x \sigma_x + \left(\Delta - 2B - 4B \sin^2 \frac{k_x a}{2} \right) \sigma_z, \tag{3.49}$$

$$h_{j,j+1}(k_x) = B\sigma_z + \frac{i}{2} A\sigma_y, \tag{3.50}$$

$$h_{j+1,j}(k_x) = h_{j,j+1}^{\dagger}(k_x) = B\sigma_z - \frac{i}{2} A\sigma_y. \tag{3.51}$$

The problem of finding the solution of the edge state is reduced to a one-dimensional problem for a specific k_x. It can be solved following the method introduced in the preceding section. This model can also be solved numerically.

3.4.2 Quantum Spin Hall Effect

The combination of two 2×2 modified Dirac models can generate an effective model for the quantum spin Hall effect. Under the time reversal $\Theta = i\sigma_y K$,

$$k_i \longrightarrow -k_i, \sigma_i \longrightarrow -\sigma_i, \tag{3.52}$$

we have

$$\begin{aligned}
\Theta \mathbf{d}(\mathbf{k}) \cdot \sigma \Theta^{-1} &= -\mathbf{d}(-\mathbf{k}) \cdot \sigma \\
&= A\sigma_x \sin k_x a + A\sigma_y \sin k_y a \\
&\quad - \sigma_z \left(\Delta - 4B \sin^2 \frac{k_x a}{2} - 4B \sin^2 \frac{k_y a}{2} \right).
\end{aligned} \tag{3.53}$$

We set $\mathbf{d}(\mathbf{k}) \cdot \sigma$ for the "spin-up" sector and then $-\mathbf{d}(-\mathbf{k}) \cdot \sigma$ for the "spin-down" sector. In this way, we obtain an effective Hamiltonian,

$$\begin{aligned}
H_{QSHE} &= \begin{pmatrix} \mathbf{d}(\mathbf{k}) \cdot \sigma & 0 \\ 0 & -\mathbf{d}(-\mathbf{k}) \cdot \sigma \end{pmatrix} \\
&= A \sin k_x a s_0 \otimes \sigma_x + A \sin k_y a s_0 \otimes \sigma_y \\
&\quad + \left(\Delta - 4B \sin^2 \frac{k_x a}{2} - 4B \sin^2 \frac{k_y a}{2} \right) s_z \otimes \sigma_z,
\end{aligned} \tag{3.54}$$

where s_0 is a 2×2 identity matrix and s_z is the Pauli matrix for the spin index. More terms can be included, such as the spin-orbit coupling which appears as an off-diagonal term in the matrix to couple the spin-up and -down. In this way S_z is no longer conserved, but the edge states may persist. This can be checked numerically.

3.5 Three-Dimensional Lattice Model

The lattice model on a cubic lattice is

$$H = A \sum_{i=x,y,z} \alpha_i \sin k_i a + \beta \left(\Delta - 4B \sum_{i=x,y,z} \sin^2 \frac{k_i a}{2} \right). \tag{3.55}$$

Its dispersions are

$$E_{k,\pm} = \pm \sqrt{ A^2 \sum_{i=x,y,z} \sin^2 k_i a + \left(\Delta - 4B \sum_{i=x,y,z} \sin^2 \frac{k_i a}{2} \right)^2 }. \tag{3.56}$$

The zero points of the dispersion are determined by a set of equations:

$$\sin^2 k_x a = \sin^2 k_y a = \sin^2 k_z a = 0, \tag{3.57}$$

and

$$\Delta = 4B \sin^2 \frac{k_x a}{2} + 4B \sin^2 \frac{k_y a}{2} + 4B \sin^2 \frac{k_z a}{2}. \tag{3.58}$$

There are four solutions at $\Delta = 0$, $\Delta = 4B$, $\Delta = 8B$ and $\Delta = 12B$. The topological non-trivial regions are $0 < \Delta/B < 4$ and $8 < \Delta/B < 12$. Topological quantum phase transition occurs at the points of $\Delta = 0$, and $\Delta/B = 4$, 8 and 12.

To find the solution of the surface states, we consider a semi-infinite x–y plane. In this case, the k_x and k_y are still good quantum numbers. In this case, performing the partial Fourier transformation for the x- and y-axis,

$$c_{k_x,k_y,j_z} = \frac{1}{\sqrt{N_x N_y}} \sum_{j_x,j_y} c_{j_x,j_y,j_z} \exp[i(k_x j_x + k_y j_y)] \tag{3.59}$$

and

$$c_{j_x,j_y,j_z} = \frac{1}{\sqrt{N_x N_y}} \sum_{k_x,k_y} c_{k_x,k_y,j_z}, \exp[-i(k_x j_x + k_y j_y)], \tag{3.60}$$

we have a one-dimensional effective Hamiltonian along the z-axis:

$$H(k_x, k_y) = \sum_i c_{k_x,k_y,j_z}^\dagger \epsilon(k_x, k_y) c_{k_x,k_y,j_z}$$

$$+ \sum_i c_{k_x,k_y,j_z+1}^\dagger (i \frac{A}{2} \alpha_z - 2B\beta) c_{k_x,k_y,j_z} + h.c., \tag{3.61}$$

where

$$\epsilon(k_x, k_y) = (A \sin k_x \alpha_x + A \sin k_y \alpha_y) + \left(\Delta - 2B - 4B \sum_{i=x,y} \sin^2 \frac{k_i a}{2} \right) \beta. \tag{3.62}$$

Here c_{k_x,k_y,j_z} is a four-component spinor. One can find the surface states solution by means of exact diagonalization.

3.6   Parity at the Time Reversal Invariant Momenta

We have constructed a lattice model by mapping the continuous model onto a lattice. In the continuous model, the energy gap of the conduction bands and the valence bands opens near $k = 0$. In the mapping, k is replaced by $\frac{1}{a} \sin ka$. As $\sin ka$ has two zero points at $ka = 0$ and $ka = \pi$, this property may make the two models topologically distinct. The topology of a system should be determined by the band structure of the whole Brillouin zone, not simply by the asymptotic behavior near a single point. In this section, we calculate the parity of the eigenstates at time reversal invariant momenta, which may reveal whether the lattice model is topologically trivial or non-trivial. We find that the parity of the eigenstates will change when the energy gap between the two bands closes and re-opens, which accompanies a topological quantum phase transition. Readers can come back to this section after reading Chap. 4.

The parity operation π changes a right-handed system into a left-handed system,

$$\pi^{\dagger} \mathbf{x} \pi = -\mathbf{x} \tag{3.63}$$

and

$$\pi^{\dagger} \mathbf{p} \pi = -\mathbf{p}. \tag{3.64}$$

π is not only unitary, but also Hermitian

$$\pi^{\dagger} = \pi^{-1} = \pi \tag{3.65}$$

and $\pi^2 = 1$. Hence its eigenvalue is either $+1$ or -1. For a system with a parity symmetry, the energy eigenstates must be symmetric $(+1)$ or antisymmetric (-1),

$$\pi \phi(\mathbf{x}) = \phi(-\mathbf{x}) = \pm \phi(\mathbf{x}), \tag{3.66}$$

if they are nondegenerate. In the Dirac equation, the full parity operator P needs to be augmented with a unitary operator β [3],

$$P = \pi \beta, \tag{3.67}$$

such that

$$P \alpha_i P = -\alpha_i, \; P \beta P = \beta. \tag{3.68}$$

In this way the Dirac equation is invariant under parity P.

3.6.1 *One-Dimensional Lattice Model*

We begin with the one-dimensional lattice model:

$$H = A \sin k_x a \alpha_x + \left(\Delta - 4B \sin^2 \frac{k_x a}{2} \right) \beta. \tag{3.69}$$

The eigenvalues are doubly degenerate,

$$E_\pm = \pm \sqrt{A^2 \sin^2 k_x a + \left(\Delta - 4B \sin^2 \frac{k_x a}{2} \right)^2}. \tag{3.70}$$

Suppose the Fermi energy is zero. Then two occupied states has negative energy and are time reversal partners with each other,

$$\psi_1 = \begin{pmatrix} -\dfrac{A \sin k_x a}{\sqrt{2E_+ \left(E_+ + \Delta - 4B \sin^2 \frac{k_x a}{2} \right)}} \\ 0 \\ 0 \\ \dfrac{\Delta - 4B \sin^2 \frac{k_x a}{2} + E_+}{\sqrt{2E_+ \left(E_+ + \Delta - 4B \sin^2 \frac{k_x a}{2} \right)}} \end{pmatrix} \tag{3.71}$$

and

$$\psi_2 = \Theta \psi_1, \tag{3.72}$$

where Θ is the time reversal operator.

The system is invariant under parity P as

$$PH(k) = H(-k)P. \tag{3.73}$$

Noted that k is now a good quantum number, not an operator. From this relation, two time reversal invariant momenta can be defined,

$$PH(\Gamma_i) = H(\Gamma_i)P. \tag{3.74}$$

In one dimension, the first is $\Gamma_1 = 0$,

$$PH(\Gamma_1 = 0) = H(-\Gamma_1)P \tag{3.75}$$

and the second is $\Gamma_2 = \frac{1}{2}K = \frac{\pi}{a}$ (K is the reciprocal lattice vector),

$$PH(\Gamma_2) = H(-\Gamma_2 + K)P. \tag{3.76}$$

We calculate the eigenvalue of the parity of the state $|\psi_1\rangle$,

$$\delta|_{k=\Gamma_i} = \langle \psi_1|P|\psi_1\rangle = sgn\left(-\Delta + 4B\sin^2\frac{\Gamma_i a}{2}\right). \tag{3.77}$$

At the two time reversal invariant points, we have

$$\delta|_{ka=0} = sgn(-\Delta) \tag{3.78}$$

and

$$\delta|_{ka=\pi} = sgn(-\Delta + 4B). \tag{3.79}$$

We notice that the parity changes sign at the points of $\Delta = 0$ and $\Delta = 4B$, where the energy gap closes. The Z_2 index ν is determined by

$$(-1)^\nu = \delta|_{ka=0}\delta|_{ka=\pi} = sgn(\Delta)sgn(\Delta - 4B). \tag{3.80}$$

Thus, there are two distinct values of $(-1)^\nu$, $+1$ or -1. Correspondingly, $\nu = 0$ or 1. Therefore, for $0 < \Delta^2 < 4\Delta B$, the Z_2 index is

$$\nu = 1, \tag{3.81}$$

which shows that the system is topologically non-trivial.

3.6.2 Two-Dimensional Lattice Model

For a two-dimensional lattice model,

$$H = A\sum_{i=x,y}\sin k_i a\alpha_i + \left(\Delta - 4B\sum_{i=x,y}\sin^2\frac{k_i a}{2}\right)\beta. \tag{3.82}$$

The two energy eigenstates with the negative energy are

$$\psi_1 = \begin{pmatrix} \dfrac{-A(\sin k_x a - i \sin k_y a)}{\sqrt{2E_+ \left(E_+ + \Delta - 4B\left(\sin^2 \dfrac{k_x a}{2} + \sin^2 \dfrac{k_y a}{2}\right)\right)}} \\ 0 \\ 0 \\ \dfrac{\Delta - 4B\left(\sin^2 \dfrac{k_x a}{2} + \sin^2 \dfrac{k_y a}{2}\right) + E_+}{\sqrt{2E_+ \left(E_+ + \Delta - 4B\left(\sin^2 \dfrac{k_x a}{2} + \sin^2 \dfrac{k_y a}{2}\right)\right)}} \end{pmatrix} \tag{3.83}$$

and

$$\psi_2 = \Theta \psi_1. \tag{3.84}$$

The corresponding energy eigenvalue is

$$E_- = -\sqrt{A^2 \sum_{i=x,y} \sin^2 k_i a + \left(\Delta - 4B \sum_{i=x,y} \sin^2 \frac{k_i a}{2}\right)^2}. \tag{3.85}$$

The parity or the δ quantity at the time reversal invariant momenta is

$$\delta|_{k=\Gamma_i} = \langle \psi_1 | P | \psi_1 \rangle = sgn\left(-\Delta + 4B \sum_{i=x,y} \sin^2 \frac{\Gamma_i a}{2}\right). \tag{3.86}$$

In two dimensions there are four time reversal invariant momenta, $\Gamma_i a = (0, 0)$, $\Gamma_i a = (0, \pi)$, $\Gamma_i a = (\pi, 0)$, and $\Gamma_i a = (\pi, \pi)$. At these points the parity of the state ψ_1 is

$$\delta|_{\Gamma_i a=(0,0)} = -sgn(\Delta); \tag{3.87}$$
$$\delta|_{\Gamma_i a=(0,\pi)} = sgn(-\Delta + 4B); \tag{3.88}$$
$$\delta|_{\Gamma_i a=(\pi,0)} = sgn(-\Delta + 4B); \tag{3.89}$$
$$\delta|_{\Gamma_i a=(\pi,\pi)} = sgn(-\Delta + 8B). \tag{3.90}$$

As a result,

$$(-1)^\nu = sgn(\Delta) \left[sgn(-\Delta + 4B)\right]^2 sgn(\Delta - 8B). \tag{3.91}$$

Therefore, we have a non-trivial index

$$\nu = 1 \tag{3.92}$$

for $0 < \Delta^2 < 8\Delta B$.

However, it is noted that $\delta|_{ka=(0,\pi)} = \delta|_{ka=(\pi,0)}$ discontinues at $\Delta = 4B$. Although the index is equal to 1 near the point, there exists another topological quantum phase transition. Both phases are topologically non-trivial. Accompanying the transition, the spin current around the boundary will change its sign.

3.6.3 Three-Dimensional Lattice Model

For a three-dimensional lattice model,

$$H = A \sum_{\alpha=x,y,z} \sin k_\alpha a \alpha_\alpha + \left(\Delta - 4B \sum_{\alpha=x,y,z} \sin^2 \frac{k_\alpha a}{2} \right) \beta. \tag{3.93}$$

The two energy eigenstates are

$$\psi_1 = \begin{pmatrix} \dfrac{-A(\sin k_x a - i \sin k_y a)}{\sqrt{2E_+ \left(E_+ + \Delta - 4B \sum_{\alpha=x,y,z} \sin^2 \frac{k_\alpha a}{2} \right)}} \\[2em] \dfrac{A \sin k_z}{\sqrt{2E_+ \left(E_+ + \Delta - 4B \sum_{\alpha=x,y,z} \sin^2 \frac{k_\alpha a}{2} \right)}} \\[2em] 0 \\[1em] \dfrac{\Delta - 4B \sum_{\alpha=x,y,z} \sin^2 \frac{k_\alpha a}{2} + E_+}{\sqrt{2E_+ \left(E_+ + \Delta - 4B \sum_{\alpha=x,y,z} \sin^2 \frac{k_\alpha a}{2} \right)}} \end{pmatrix} \tag{3.94}$$

and

$$\psi_2 = \Theta \psi_1. \tag{3.95}$$

The corresponding negative energy is

$$E_- = -\sqrt{A^2 \sum_{\alpha=x,y,z} \sin^2 k_\alpha a + \left(\Delta - 4B \sum_{\alpha=x,y,z} \sin^2 \frac{k_\alpha a}{2} \right)^2}. \tag{3.96}$$

The parity at the time reversal invariant momenta is

$$\delta|_{k=\Gamma_i} = \langle \psi_1 | P | \psi_1 \rangle = sgn\left(-\Delta + \sum_{\alpha=x,y,z} 4B \sin^2 \frac{\Gamma_\alpha a}{2}\right). \tag{3.97}$$

At the time reversal invariant points

$$\delta|_{\Gamma_i a=(0,0,0)} = -sgn(\Delta), \tag{3.98}$$

$$\delta|_{\Gamma_i a=(0,0,\pi)} = \delta|_{\Gamma_i a=(0,\pi,0)} = \delta|_{\Gamma_i a=(\pi,0,0)} = sgn(-\Delta + 4B), \tag{3.99}$$

$$\delta|_{\Gamma_i a=(0,\pi,\pi)} = \delta|_{\Gamma_i a=(\pi,\pi,0)} = \delta|_{\Gamma_i a=(\pi,0,\pi)} = sgn(-\Delta + 8B), \tag{3.100}$$

$$\delta|_{\Gamma_i a=(\pi,\pi,\pi)} = sgn(-\Delta + 12B). \tag{3.101}$$

For $k_x = 0$,

$$(-1)^{\nu_1} = \delta|_{\Gamma_i a=(0,0,0)} \delta|_{\Gamma_i a=(0,0,\pi)} \delta|_{\Gamma_i a=(0,\pi,0)} \delta|_{\Gamma_i a=(0,\pi,\pi)}$$

$$= sgn(\Delta)sgn(\Delta - 8B). \tag{3.102}$$

For $k_y = 0$,

$$(-1)^{\nu_2} = \delta|_{\Gamma_i a=(0,0,0)} \delta|_{\Gamma_i a=(0,0,\pi)} \delta|_{\Gamma_i a=(\pi,0,0)} \delta|_{\Gamma_i a=(\pi,0,\pi)}$$

$$= sgn(\Delta)sgn(\Delta - 8B). \tag{3.103}$$

For $k_z = 0$,

$$(-1)^{\nu_3} = \delta|_{\Gamma_i a=(0,0,0)} \delta|_{\Gamma_i a=(0,\pi,0)} \delta|_{\Gamma_i a=(\pi,0,0)} \delta|_{\Gamma_i a=(\pi,\pi,0)}$$

$$= sgn(\Delta)sgn(\Delta - 8B). \tag{3.104}$$

For $k_x a = \pi$,

$$(-1)^{\nu_1'} = \delta|_{\Gamma_i a=(\pi,0,0)} \delta|_{\Gamma_i a=(0,0,\pi)} \delta|_{\Gamma_i a=(\pi,\pi,0)} \delta|_{\Gamma_i a=(\pi,\pi,\pi)}$$

$$= sgn(\Delta - 4B)sgn(\Delta - 12B). \tag{3.105}$$

The prime index ν_0 is determined by the product of the parities at the eight time reversal invariant points,

$$(-1)^{\nu_0} = \prod_i \delta_i = (-1)^{\nu_1 + \nu_1'}$$

$$= sgn(\Delta)sgn(\Delta - 4B)sgn(\Delta - 8B)sgn(\Delta - 12B). \tag{3.106}$$

Thus, for $B > 0$,

$$(\nu_0; \nu_1, \nu_2, \nu_3) = (0; 0, 0, 0), \text{ for } \Delta < 0, \tag{3.107}$$

$$(\nu_0; \nu_1, \nu_2, \nu_3) = (1; 1, 1, 1), \text{ for } 0 < \Delta < 4B, \tag{3.108}$$

$$(\nu_0; \nu_1, \nu_2, \nu_3) = (0; 1, 1, 1), \text{ for } 4B < \Delta < 8B, \tag{3.109}$$

$$(\nu_0; \nu_1, \nu_2, \nu_3) = (1; 0, 0, 0), \text{ for } 8B < \Delta < 12B, \tag{3.110}$$

$$(\nu_0; \nu_1, \nu_2, \nu_3) = (0; 0, 0, 0), \text{ for } \Delta > 12B, \tag{3.111}$$

The system is topologically non-trivial only if $0 < \Delta < 4B$ and $8B < \Delta < 12B$.

3.7 Summary

In summary, a minimal lattice model for a topological insulator is established in one, two and three dimensions. According to the parity of the eigenstates at the time reversal invariant momenta, we conclude that (supposing that B is positive),

1. In one dimension, it is topologically non-trivial for $0 < \Delta < 4B$.
2. In two dimensions, it is topologically non-trivial for $0 < \Delta < 4B$ and $4B < \Delta < 8B$.
3. In three dimensions, it is topologically non-trivial for $0 < \Delta < 4B$ and $8B < \Delta < 12B$.

Chapter 4
Topological Invariants

Abstract There are two classes of topological invariants for topological phases of matter. The first is characterized by the elements of the group Z, which consists of all integers. For example, the integer quantum Hall effect is characterized by the integer n, i.e., the filling factor of electrons. The second class is characterized by the elements of the group Z_2, which consists of 0 and 1, or 1 and -1 depending on convention. In a topological insulator with time reversal symmetry, 0 and 1 represent the existence of odd and even numbers of the surface states in three dimensions or even and odd numbered pairs of helical edge states in two dimensions, respectively.

4.1 Bloch's Theorem and Band Theory

A Bloch wave or a Bloch state, named after Felix Bloch, is the wave function of an electron in a periodic potential. Let us consider a Hamiltonian $\mathcal{H}(\mathbf{r}) = \mathcal{H}(\mathbf{r} + \mathbf{R})$ in a periodic potential. Bloch's theorem states that the eigenfunction for such a system must be in the form

$$|\psi_{n,\mathbf{k}}(\mathbf{r})\rangle = e^{i\mathbf{k}\cdot\mathbf{r}}|u_{n,\mathbf{k}}(\mathbf{r})\rangle, \tag{4.1}$$

where $u_{n,\mathbf{k}}(\mathbf{r})$ has the same period of the crystal lattice $\mathbf{R}$ with $u_{n,\mathbf{k}}(\mathbf{r}) = u_{n,\mathbf{k}}(\mathbf{r} + \mathbf{R})$. The corresponding energy eigenvalues satisfy $E_n(\mathbf{k}) = E_n(\mathbf{k} + \mathbf{K})$, periodic with the periodicity $\mathbf{K}$ of a reciprocal lattice vector. The energies associated with the index n vary continuously with the wave vector $\mathbf{k}$ and form an energy band identified by the band index n. The eigenvalues for a given n are periodic in $\mathbf{k}$; all distinct values of $E_n(\mathbf{k})$ are located within the first Brillouin zone of the reciprocal lattice. See [1].

According to the Pauli exclusion principle, each state can be occupied at most by one electron. Electrons will fill lower energy states first and consequently form the Fermi sea for a finite density of electrons. The highest energy of the occupied states is called the Fermi level or Fermi energy. Near the Fermi level, if a band is partially occupied, it is in a metallic state. In this case when an external field is applied to the system, the field will force electrons to shift away from the equilibrium position, and gain a non-zero total momentum to form a flow of electric current. If the band is

fully filled, and there exists an energy gap between the filled or valence band and the unfilled or conduction band, it is an insulating state. In this case a weak external field cannot force the electrons to move away from the occupied states to circulate a flow of electric current. This is the case for a band insulator. The size of the energy gap serves as a dividing line between semiconductors and insulators. If the energy gap is smaller than 4 eV (roughly), the electrons can be excited easily from the valence band to the conduction band at finite temperatures, although the fully filled band does not contribute to electrical conductivity at absolute zero. Thus, a semiconductor has a smaller energy gap than an insulator.

4.2 Berry Phase

The choice of $|u_{n,\mathbf{k}}\rangle$ is not unique. For example, there is always a $U(1)$, i.e., a phase uncertainty,

$$|u_{n,\mathbf{k}}\rangle \rightarrow e^{if(\mathbf{k})}|u_{n,\mathbf{k}}\rangle. \tag{4.2}$$

A definite set of phase choices in the Brillouin zone is called a definite gauge [2]. For a time reversal invariant system, there always exists a continuous gauge throughout the Brillouin zone. For a time reversal broken system with a nonzero Chern number, there is no such gauge so continuous gauges have to be defined in different patches of the Brillouin zone [2, 3]. However, any physical observable must be gauge independent.

Consider the system Hamiltonian that varies with time through a parameter $\mathbf{R} \rightarrow \mathbf{R}(t)$. We are interested in a cyclic evolution of the system from $t = 0$ to T such that $\mathbf{R}(t = 0) = \mathbf{R}(t = T)$. The parameter $\mathbf{R}(t)$ changes very slowly along a closed path C in the parameter space. To solve the problem, we first introduce an instantaneous orthogonal basis from the instantaneous eigenstates of $H(\mathbf{R}(t))$ at time t or each value of $\mathbf{R}(t)$,

$$H(\mathbf{R}(t)) |u_n(\mathbf{R}(t))\rangle = \varepsilon_n(\mathbf{R}(t)) |u_n(\mathbf{R}(t))\rangle . \tag{4.3}$$

This equation does not completely determine the basis function of $|u_n(\mathbf{R}(t))\rangle$ due to the phase uncertainty. However we can require that the functions are smooth and single valued along the closed path. The equation also does not describe correctly the time evolution of the quantum states. Instead, the quantum state should be governed by the time dependent Schrödinger equation,

$$i\hbar\partial_t |\Phi(t)\rangle = H(\mathbf{R}(t)) |\Phi(t)\rangle . \tag{4.4}$$

In the adiabatic approximation [4], the system will stay at one of the instantaneous eigenstates (usually we choose the lowest energy state or the ground state) if the

instantaneous state is clearly separated from the others and the time evolution is very slow. In this case, this wave function can be related to $|u_n(\mathbf{R}(t))\rangle$:

$$|\Phi(t)\rangle = e^{i\gamma_c(t)} \exp\left[-\frac{i}{\hbar}\int_0^t dt'\varepsilon_n\left(\mathbf{R}\left(t'\right)\right)\right]|u_n(\mathbf{R}(t))\rangle \tag{4.5}$$

and

$$\partial_t\gamma(t) = i\langle u_n(t)|\partial_t|u_n(t)\rangle. \tag{4.6}$$

Using the relation, $\partial_t = \partial_t\mathbf{R}\cdot\nabla_\mathbf{R}$ as the parameter $\mathbf{R}$ is a function of time t, the phase factor can be expressed as a path integral

$$\gamma_c = \int_C d\mathbf{R}\cdot\mathbf{A}_n(\mathbf{R}), \tag{4.7}$$

where $\mathbf{A}_n(\mathbf{R})$ is a vector

$$\mathbf{A}_n(\mathbf{R}) = i\langle u_n(\mathbf{R}(t))|\nabla_\mathbf{R}|u_n(\mathbf{R}(t))\rangle. \tag{4.8}$$

This vector is called the Berry connection or the Berry vector potential. In addition to the dynamic phase which is determined by integrating over $\varepsilon_n(\mathbf{R}(t'))$, the state $|\Phi(t)\rangle$ will acquire an additional phase γ_c during the adiabatic evolution.

As $\mathbf{A}_n(\mathbf{R})$ is gauge dependent, it becomes

$$\mathbf{A}_n(\mathbf{R}) \to \mathbf{A}_n(\mathbf{R}) - \nabla_\mathbf{R}\chi \tag{4.9}$$

if we make a gauge transformation

$$|u_n(\mathbf{R}(t))\rangle \to e^{i\chi(\mathbf{R})}|u_n(\mathbf{R}(t))\rangle. \tag{4.10}$$

Thus, the phase γ_c will be changed by $\chi(\mathbf{R}(t=T)) - \chi(\mathbf{R}(t=0))$ for the initial and final points. For a cyclic evolution of the system along a closed path C with $\mathbf{R}(0) = \mathbf{R}(T)$, the single-valued condition of the wave function requires

$$\chi(\mathbf{R}(T)) - \chi(\mathbf{R}(0)) = 2m\pi \tag{4.11}$$

with an integer m. Therefore for a closed path C, γ_c is independent of the gauge, and now is known as the Berry phase

$$\gamma_c = \oint_C d\mathbf{R}\cdot\mathbf{A}_n(\mathbf{R}). \tag{4.12}$$

By using the Stokes' theorem, γ_c can be expressed as an area integral

$$\gamma_c = \int_A d\mathbf{S} \cdot (\mathbf{R}), \tag{4.13}$$

where the Berry curvature from the Berry connection is defined as

$$\Omega^n(\mathbf{R}) = \nabla_{\mathbf{R}} \times \mathbf{A}_n(\mathbf{R}). \tag{4.14}$$

Its components are

$$\begin{aligned}\Omega^n_{\mu\nu}(\mathbf{R}) &= \partial_\mu \left(\mathbf{A}_n\right)_\nu - \partial_\nu \left(\mathbf{A}_n\right)_\mu \\ &= i \left(\langle \partial_\mu u_n(\mathbf{R}) | \partial_\nu u_n(\mathbf{R}) \rangle - \langle \partial_\nu u_n(\mathbf{R}) | \partial_\mu u_n(\mathbf{R}) \rangle \right),\end{aligned} \tag{4.15}$$

where we denote $\partial/\partial R_\mu$ by ∂_μ.

The Berry curvature Ω is analogous to the magnetic field in electrodynamics. Using the completeness relation for the basis,

$$\sum_n |u_n(\mathbf{R})\rangle \langle u_n(\mathbf{R})| = 1 \tag{4.16}$$

and the identity

$$\langle u_m(\mathbf{R})| \nabla_{\mathbf{R}} |u_n(\mathbf{R})\rangle = \frac{\langle u_m(\mathbf{R})| \nabla_{\mathbf{R}} H(\mathbf{R}) |u_n(\mathbf{R})\rangle}{E_n - E_m} \tag{4.17}$$

$(m \neq n)$, the Berry curvature has an alternative expression:

$$\Omega^n = \mathrm{Im} \sum_{m \neq n} \frac{\langle u_n(\mathbf{R})| \nabla_{\mathbf{R}} H(\mathbf{R}) |u_m(\mathbf{R})\rangle \times \langle u_m(\mathbf{R})| \nabla_{\mathbf{R}} H(\mathbf{R}) |u_n(\mathbf{R})\rangle}{(E_n - E_m)^2}. \tag{4.18}$$

It is noted that the Berry curvature in (4.15) is expressed in term of one state $u_n(\mathbf{R})$, but that in (4.18) is expressed as a summation over all possible states. It reflects that the Berry curvature describes the global properties of a system, NOT the property of a single band.

Consider a two-level system as an example. The general Hamiltonian describing a two-level problem has the form,

$$H = \frac{1}{2} \begin{pmatrix} Z & X - iY \\ X + iY & -Z \end{pmatrix} = \frac{1}{2}\mathbf{R} \cdot \sigma. \tag{4.19}$$

The energy eigenvalues are $E_\pm = \pm R = \pm\sqrt{X^2 + Y^2 + Z^2}$ and the two levels cross at the point of $R = 0$. The gradient of the Hamiltonian in the parameter space is

$$\nabla_{\mathbf{R}} H = \frac{1}{2}\sigma \tag{4.20}$$

and we find that the Berry curvature has its vector form

$$\Omega = \frac{1}{2}\frac{\mathbf{R}}{R^3}. \tag{4.21}$$

This curvature can be regarded as a field generated by a magnetic monopole at the origin $\mathbf{R} = 0$. Integrating the Berry curvature over a sphere surface containing the monopole, we have

$$\frac{1}{2\pi}\int_A d\mathbf{S}\cdot\Omega = 1. \tag{4.22}$$

The divergence of Ω has the property

$$\nabla_{\mathbf{R}} \cdot \Omega = 2\pi\delta(\mathbf{R}). \tag{4.23}$$

Thus, a point-like "magnetic monopole" is located at $R = 0$, which generates the Berry curvature.

In a Bloch band, the Berry curvature is defined as

$$\Omega^n(\mathbf{k}) = i \nabla_{\mathbf{k}} \times \langle u_n(\mathbf{k})| \nabla_{\mathbf{k}} |u_n(\mathbf{k})\rangle . \tag{4.24}$$

As the Brillouin zone has the periodic boundary condition in momentum space and the two points $\mathbf{k}$ and $\mathbf{k} + \mathbf{K}$ in the Brillouin zone can be identified as the same point, where $\mathbf{K}$ is the reciprocal lattice vector, a closed path can be realized when $\mathbf{k}$ sweeps the whole Brillouin zone. In this case the Berry phase across the Brillouin zone becomes [5]

$$\gamma_c = \int_{BZ} d\mathbf{k} \cdot [\nabla_{\mathbf{k}} \times \langle u_n(\mathbf{k})| i\nabla_{\mathbf{k}} |u_n(\mathbf{k})\rangle] . \tag{4.25}$$

4.3 Quantum Hall Conductance and the Chern Number

The Hall conductance in a two-dimensional band insulator can be expressed in terms of the Berry curvature,

$$\sigma_{xy} = \frac{e^2}{\hbar}\int_{BZ}\frac{d\mathbf{k}}{(2\pi)^2}\Omega_{k_x,k_y} = n\frac{e^2}{h}, \tag{4.26}$$

which is quantized for an integer n (including zero). Consider a crystal under perturbation of a weak electric field $\mathbf{E}$. Usually, the electrostatic potential $\phi(\mathbf{r})$, which produces an electric field $\mathbf{E} = -\nabla\phi$, varies linearly in space and breaks the translational

symmetry. If the electric field enters the Hamiltonian through the electrostatic potential $\phi(\mathbf{r})$, the wave vector is no longer a good quantum number and the Bloch's theorem fails to apply to the problem. To avoid this difficulty, recall the relation $\mathbf{E} = -\nabla\phi - \partial_t\mathbf{A}$. One can introduce a uniform vector potential $\mathbf{A}(t)$ that changes over time such that $\partial_t\mathbf{A}(t) = -\mathbf{E}$. The Hamiltonian is written as

$$H(t) = \frac{1}{2m}\left[\mathbf{p} + e\mathbf{A}(t)\right]^2 + V(r). \tag{4.27}$$

Here we take the elementary charge of electron $-e$ ($e > 0$). In this way the lattice translational symmetry is preserved, and the momentum $\mathbf{p}$ is still a good quantum number. In momentum space, $\mathbf{p} = \hbar\mathbf{q}$, we have

$$H(\mathbf{q}, t) = H\left[\mathbf{q} + \frac{e}{\hbar}\mathbf{A}(t)\right]. \tag{4.28}$$

Now we introduce the gauge-invariant crystal momentum,

$$\mathbf{k} = \mathbf{q} + \frac{e}{\hbar}\mathbf{A}(t). \tag{4.29}$$

As $\mathbf{q}$ is a good quantum number, i.e., $d\mathbf{q}/dt = 0$, it follows that

$$\frac{d\mathbf{k}}{dt} = -\frac{e}{\hbar}\mathbf{E}. \tag{4.30}$$

The velocity operator is defined by

$$\mathbf{v} = \frac{d\mathbf{r}}{dt} = \frac{i}{\hbar}[H, \mathbf{r}]. \tag{4.31}$$

In momentum space, it becomes

$$\mathbf{v}(\mathbf{q}) = \frac{1}{\hbar}\nabla_\mathbf{q}H(\mathbf{q}, t). \tag{4.32}$$

The presence of $\mathbf{A}(t)$ makes the problem time-dependent. The wave function for the quantum state $\psi(t)$ is governed by the time-dependent Schrödinger equation,

$$i\hbar\partial_t |\psi(t)\rangle = H(t) |\psi(t)\rangle. \tag{4.33}$$

Using the instantaneous eigenstates as the basis, we can expand the wave function $\psi(t)$ in terms of the instantaneous eigenstates $|u_n(t)\rangle$ and eigenvalues $E_n(t)$

$$|\psi(t)\rangle = \sum_n \exp\left(\frac{1}{i\hbar}\int_{t_0}^t dt' E_n(t')\right) a_n(t) |u_n(\mathbf{q}, t)\rangle. \tag{4.34}$$

Then the Schrödinger equation is reduced to

$$\frac{da_n(t)}{dt} = -\sum_m a_m(t) \langle u_n(t) | \partial_t u_m(t) \rangle \exp\left(-i \int_{t_0}^t dt' \omega_{mn}(t') \right), \qquad (4.35)$$

where $\omega_{mn}(t) = (E_m(t') - E_n(t'))/\hbar$. For our purpose we consider an adiabatic process in which the vector parameter $\mathbf{R}(t)$ varies with time very slowly, and

$$\langle u_n(\mathbf{q}, t) | \partial_t u_n(\mathbf{q}, t) \rangle = \partial_t \mathbf{R} \cdot \langle u_n(\mathbf{q}, \mathbf{R}) | \nabla_{\mathbf{R}} | u_n(\mathbf{q}, \mathbf{R}) \rangle \ll 1. \qquad (4.36)$$

In the limit of $\partial_t \mathbf{R} = 0$, we have

$$\partial_t a_n = 0. \qquad (4.37)$$

If the system is initially in the eigenstate $|u_n(\mathbf{q}, t = 0)\rangle$, it will stay in that state afterwards. This is the quantum adiabatic theorem [4].

Now we consider the case that $\partial_t \mathbf{R} \neq 0$ but is still very small. Suppose the initial state has $a_n(0) = 1$ and $a_m(0) = 0$ for all $m \neq n$. We apply the time-dependent perturbation theory to calculate the quantum correction to the states due to the perturbation of the electric field. The zero-order perturbation gives $a_m^{(0)} = \delta_{m,n}$. Thus, the first-order perturbation $a_m^{(1)}$ is given by

$$\frac{da_m^{(1)}(t)}{dt} = -\langle u_m(\mathbf{q}, t) | \partial_t u_n(\mathbf{q}, t) \rangle \exp\left(-i \int_{t_0}^t dt' \omega_{nm}(t') \right). \qquad (4.38)$$

For $m = n$, $\frac{da_m^{(1)}(t)}{dt} = 0$. Thus, we have

$$a_n^{(1)}(t) = 0. \qquad (4.39)$$

For $m \neq n$,

$$a_m^{(1)}(t) = -i\hbar \frac{\langle u_m(\mathbf{q}, t) | \partial_t u_n(\mathbf{q}, t) \rangle}{E_n - E_m} \exp\left(-i \int_{t_0}^t dt' \omega_{nm}(t') \right). \qquad (4.40)$$

Thus, the wave function up to the first-order perturbation is given by

$$|u_n(t)\rangle \rightarrow |u_n(\mathbf{q}, t)\rangle - i\hbar \sum_{m \neq n} |u_m(\mathbf{q}, t)\rangle \frac{\langle u_m(\mathbf{q}, t) | \partial_t u_n(\mathbf{q}, t) \rangle}{E_n - E_m}. \qquad (4.41)$$

The second term is caused by the external field. Using the velocity operator in (4.32), the average velocity in the state after the perturbation becomes

$$\mathbf{v}_n(\mathbf{q}) = -i \sum_{m \neq n} \left(\frac{\langle u_n(\mathbf{q}, t)| \nabla_{\mathbf{q}} H |u_m(\mathbf{q}, t)\rangle \langle u_m(\mathbf{q}, t)|\partial_t u_n(\mathbf{q}, t)\rangle}{E_n - E_m} - h.c \right)$$
$$+ \frac{1}{\hbar} \nabla_{\mathbf{q}} E_n(\mathbf{q}) \tag{4.42}$$

by ignoring the higher order terms. Furthermore using the identity

$$\langle u_n(\mathbf{q}, t)| \nabla_{\mathbf{q}} H |u_m(\mathbf{q}, t)\rangle = (E_n - E_m) \langle \nabla_{\mathbf{q}} u_n(\mathbf{q}, t)|u_m(\mathbf{q}, t)\rangle, \tag{4.43}$$

the expression can be simplified in a compact form,

$$\mathbf{v}_n(\mathbf{q}) = \frac{1}{\hbar} \nabla_{\mathbf{q}} E_n(\mathbf{q}) - \Omega^n_{\mathbf{q},t}, \tag{4.44}$$

where

$$\Omega^n_{\mathbf{q},t} = i \left(\langle \nabla_{\mathbf{q}} u_n|\partial_t u_n\rangle - \langle \partial_t u_n|\nabla_{\mathbf{q}} u_n\rangle \right). \tag{4.45}$$

Thus, in the presence of an electric field, an electron can acquire an anomalous transverse velocity proportional to the Berry curvature of the energy band [6, 7]. It is noted that the Berry curvature is defined in the space of $(t, \mathbf{q})$.

It follows from (4.29) and (4.30) that

$$\nabla_{\mathbf{q}} = \nabla_{\mathbf{k}} \tag{4.46}$$

and

$$\partial_t = \partial_t \mathbf{k} \cdot \nabla_{\mathbf{k}} = -\frac{e}{\hbar} \mathbf{E} \cdot \nabla_{\mathbf{k}}. \tag{4.47}$$

Thus, the velocity is reduced to

$$\mathbf{v}_n(\mathbf{q}) = \frac{1}{\hbar} \nabla_{\mathbf{k}} E_n(\mathbf{k}) - \frac{e}{\hbar} \mathbf{E} \times \Omega^n(\mathbf{k}), \tag{4.48}$$

where

$$\Omega^n(\mathbf{k}) = \nabla_{\mathbf{k}} \times \langle u_n(\mathbf{k})| i \nabla_{\mathbf{k}} |u_n(\mathbf{k})\rangle$$
$$= i \langle \nabla_{\mathbf{k}} u_n(\mathbf{k})| \times |\nabla_{\mathbf{k}} u_n(\mathbf{k})\rangle. \tag{4.49}$$

Thus, the external field produces a transverse velocity in an adiabatic process. The electric current in the presence of $\mathbf{E}$ is defined by

$$\mathbf{j} = -e \sum_n \int \frac{d\mathbf{k}}{(2\pi)^2} \mathbf{v}_n(\mathbf{k}) f(k), \tag{4.50}$$

where $f(k)$ is the Fermi-Dirac distribution function. Suppose all bands below the Fermi level are fully filled. The sum over the first term in the velocity in (4.48) becomes zero, and the second term gives a Hall current

$$j_\alpha = \sigma_H \epsilon_{\alpha\beta} E_\beta \tag{4.51}$$

with

$$\sigma_H = \frac{e^2}{h} \frac{1}{2\pi} \sum_n \int_{BZ} d\mathbf{k} \Omega^n_{k_x, k_y}. \tag{4.52}$$

The integral runs over the first Brillouin zone, and

$$\Omega^n_{k_x, k_y} = \Omega^n_{k_x+\pi, k_y} = \Omega^n_{k_x, k_y+\pi}. \tag{4.53}$$

Hence the first Brillouin zone forms a closed torus. In this expression, we assume that all bands are fully filled, and there exists an energy gap between the filled band or valence band and the unfilled band or conduction band. The integral over a closed torus gives an integer ν (including zero).

$$\sigma_H = \nu \frac{e^2}{h}. \tag{4.54}$$

The number is called Thouless–Kohmoto–Nightingale–den Nijs or TKNN number. This result can also be derived from the Kubo formula explicitly (see Appendix A.1).

4.4 Electric Polarization in a Cyclic Adiabatic Evolution

Electric polarization $\mathbf{P}$ is the electric dipole moment per volume in dielectric media, which is one of the essential concepts in electrodynamics. It is an intensive vector quantity that carries the meaning of the dipole moment per unit volume. For example, in a ferroelectric material, the electric polarization can present spontaneously. In the Maxwell's equation for the displacement $\mathbf{D}$,

$$\nabla \cdot \mathbf{D} = -\rho(t), \tag{4.55}$$

where $\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}$. Here $\mathbf{E}$ is the electric field, $\mathbf{P}$ is the polarization density and $\rho(t)$ is the charge density. Consider a solid in which there is no electric field. The continuity equation $\partial_t \rho = -\nabla \cdot \mathbf{j}$ leads to

$$\nabla \cdot (\partial_t \mathbf{P} - \mathbf{j}) = 0, \tag{4.56}$$

where $\mathbf{j}$ is the macroscopic current density. In an adiabatic evolution of a system, up to a divergence-free part, the change in the polarization density in a cyclic evolution is given by

$$\Delta P_\alpha = \int_0^T dt j_\alpha. \tag{4.57}$$

This equation is the basis for the modern theory of polarization. In the early 1990s, it was realized that the polarization difference has a topological meaning, and is actually related to the Berry phase [2, 8].

In an adiabatic process, it follows from (4.44) that

$$\Delta P_\alpha = e \sum_n \int_0^T dt \int_{BZ} \frac{d\mathbf{q}}{(2\pi)^d} \Omega^n_{q_\alpha,t}, \tag{4.58}$$

which is determined by the Berry curvature $\Omega^n_{q_\alpha,t}$ The summation runs over all the occupied bands. In general we suppose that the adiabatic transformation is parameterized by a scalar $\lambda(t)$, it follows that [9]

$$\Delta P_\alpha = e \sum_n \int_{\lambda(0)}^{\lambda(T)} d\lambda \int_{BZ} \frac{d\mathbf{q}}{(2\pi)^d} \Omega^n_{q_\alpha,\lambda}, \tag{4.59}$$

where

$$\Omega^n_{q_\alpha,\lambda} = \partial_{q_\alpha} \mathbf{A}^n_\lambda - \partial_\lambda \mathbf{A}^n_{q_\alpha}. \tag{4.60}$$

In the course of a cyclic evolution, $\lambda(T)$ and $\lambda(0)$ will represent the same state. Consider the periodicity of the $\mathbf{q}$ space. The $q_\alpha - \lambda$ plane forms a close torus. It should be pointed out that the polarization is determined up to an uncertainty quantum. As the integral does not track the history of λ, there is no information on how many cycles λ has gone through. For each cycle an integer number ν of electrons are transported across the sample [2],

$$\Delta P_\alpha = e\nu a, \tag{4.61}$$

where a is the lattice constant. Here the integer ν appears as a topological invariant for the adiabatic transport.

From the Bloch function we can define the Wannier function associated with the lattice vector,

$$|\mathbf{R}, n\rangle = \frac{1}{2\pi} \int d\mathbf{k} e^{-i\mathbf{k}\cdot(\mathbf{R}-\mathbf{r})} |u_{n,\mathbf{k}}\rangle. \tag{4.62}$$

King-Smith and Vanderbilt [9] showed that the polarization can be defined by the sum over all the bands of the center of the charge of the Wannier state associated with $\mathbf{R} = 0$,

$$\mathbf{P} = -e \sum_n \langle \mathbf{R} = 0, n | \mathbf{r} | \mathbf{R} = 0, n \rangle = -\frac{e}{2\pi} \int d\mathbf{k} \cdot \mathbf{A}(k), \qquad (4.63)$$

where $\mathbf{A}(\mathbf{k}) = i \sum_n \langle u_{n,\mathbf{k}} | \nabla_{\mathbf{k}} | u_{n,\mathbf{k}} \rangle$. Here we have used the relation, $\mathbf{r} = i\nabla_{\mathbf{k}}$.

4.5 Thouless Charge Pump

In the cyclic adiabatic evolution of a one-dimensional insulator,

$$H(k, t + T) = H(k, t), \qquad (4.64)$$

the charge pumped across the insulator is always an integer, which is defined as a topological invariant, i.e., the electric polarization

$$\Delta P = \frac{e}{2\pi} \oint [A(k, T) - A(k, 0)] \, dk = nea. \qquad (4.65)$$

Here we present an example to illustrate the process of the charge pump. The Rice–Mele model was introduced in the study of solitons in polyenes in the 1980's, and later used to study ferroelectricity [10]. It reads

$$H = +h_{st}(t) \sum_n (-1)^n c_n^\dagger c_n + \frac{1}{2} \sum_{n=1}^N \left[t_0 + \delta(t)(-1)^n \right] c_n^\dagger c_{n+1} + h.c., \qquad (4.66)$$

where

$$(\delta(t), h_{st}(t)) = \left(\delta_0 \cos \frac{2\pi t}{T}, h_0 \sin \frac{2\pi t}{T} \right) \qquad (4.67)$$

and N is an even number. This is a time-dependent model: $\delta(t)$ denotes the displacements of the nth and $(n + 1)$th electrons from their respective equilibrium positions in a staggered or dimerized form, and $\pm h_{st}(t)$ are the staggered on-site potentials. Both $\delta(t)$ and $h_{st}(t)$ are periodic function of time t with the same period T.

We consider a system with an even number $2N$ of lattice sites and take a periodic boundary condition. After performing the Fourier transformation,

$$a_k = \frac{1}{\sqrt{N}} \sum_{j \in 2n} c_j e^{-ikj} \qquad (4.68)$$

and

$$b_k = \frac{1}{\sqrt{N}} \sum_{j \in 2n+1} c_j e^{-ikj}, \tag{4.69}$$

the Hamiltonian is reduced to

$$H = \sum_k (a_k^\dagger, b_k^\dagger) \left[\mathbf{d}(k,t) \cdot \sigma \right] \begin{pmatrix} a_k \\ b_k \end{pmatrix}, \tag{4.70}$$

where

$$d_x(k,t) = \frac{1}{2}(t_0 + \delta(t)) + \frac{1}{2}(t_0 - \delta(t)) \cos k, \tag{4.71}$$

$$d_y(k,t) = -\frac{1}{2}(t_0 - \delta(t)) \sin k, \tag{4.72}$$

$$d_z(k,t) = h_{st}(t). \tag{4.73}$$

The instantaneous dispersions of the two bands at time t are

$$\varepsilon_\pm(k,t) = \pm |\mathbf{d}(k,t)|$$
$$= \pm \sqrt{h_0^2 \sin^2 \frac{2\pi t}{T} + \delta_0^2 \cos^2 \frac{2\pi t}{T} \sin^2 \frac{k}{2} + t_0^2 \cos^2 \frac{k}{2}}. \tag{4.74}$$

The degeneracy points are $h_0 = 0$, or $\delta_0 = 0$, or $t_0 = 0$. The energy gap between the two bands is $\Delta E = \min(2|t_0|, 2|h_0|, 2|\delta_0|)$. Therefore, the adiabatic condition requires that $T \gg \hbar / \min(2|t_0|, 2|h_0|, 2|\delta_0|)$. If the low band is fully filled, the charge pump in the cyclic adiabatic evolution is associated with the Chern number of the ground state $\Delta P = n_c e a$,

$$n_c = \int_0^T dt \int_{BZ} \frac{dk}{2\pi} \Omega_{k,t}^n$$
$$= -\frac{1}{4\pi} \int dk \int_0^T dt \frac{\mathbf{d}(k,t) \cdot [\partial_k \mathbf{d}(k,t) \times \partial_t \mathbf{d}(k,t)]}{|\mathbf{d}(k,t)|^3}$$
$$= -sgn(t_0 h_0 \delta_0), \tag{4.75}$$

because the $k - t$ plane forms a closed torus due the the periodicity of T. We find that the Chern number is $+1$ or -1 once $t_0 h_0 \delta_0 \neq 0$. A topological quantum phase transition occurs at the points of $h_0 = 0$, or $\delta_0 = 0$, or $t_0 = 0$, where the Chern number changes its sign whenever any one of the parameters changes its sign.

The charge pumping can be understood by examining the end states in an open chain. The Rice–Mele model is reduced to the Su–Schrieffer–Heeger model when $\delta(t) \neq 0$ and $h_{st}(t) = 0$. The solution of the end state in this model can be found in Sect. 5.1. At $t = 0$, $(\delta(t), h_{st}(t)) = (+\delta_0, 0)$. The hopping amplitudes along the chain starting from site $i = 1$ are $t_0 - \delta_0, t_0 + \delta_0, t_0 - \delta_0, t_0 + \delta_0, \cdots$. Assume $t_0 > \delta_0 > 0$. In this case, there are the two end states of zero energy at two ends of the chain, which are degenerate at $h_0 = 0$. At the half filling, which occurs when one particle occupies two sites on average, we suppose that the right end state is occupied, and the left end state is empty. With increasing time t, the on-site energy $h_{st}(t)$ lifts the end mode away from the zero energy to the valence band: one is pushed to the positive band and the other to the negative band At $t = T/2$, $(\delta(t), h_{st}(t)) = (-\delta_0, 0)$. The hopping amplitudes become $t_0 + \delta_0, t_0 - \delta_0, t_0 + \delta_0, t_0 - \delta_0, \cdots$. In this case, the two end states disappear, as they have already evolved into bulk states. When t continuously increases, the end states reappear. However, the left end state becomes the occupied state, and the right end state becomes empty. At $t = T$, $(\delta(t), h_{st}(t)) = (+\delta_0, 0)$. The hopping amplitudes go back to the case of $t = 0$. The Hamiltonian returns to the original at $t = 0$. Although the energy eigenstates remain unchanged, due to the double degeneracy of the ground state at half filling, the electron configuration has changed: the electron in the right end state at $t = 0$ has been transferred to the left end state at $t = T$. In this way one electron has been pumped from the left to the right side. The instantaneous spectra of the Rice–Mele mode in (4.66) are plotted in Fig. 4.1.

Fig. 4.1 Instantaneous energy spectra of the Rice–Mele model. The *solid line* stands for the end state near the *right side* and the *dashed line* stands for the state at the *left side*. It illustrates the evolution of the end state from one side to the other. Here we take $\delta_0 = 0.2t_0$ and $h_0 = 0.5t_0$
4.6 Fu–Kane Spin Pump

Fu and Kane proposed an electronic model with spin $\frac{1}{2}$ for the spin pump by generalizing the spinless Rice–Mele model [11],

$$H = h_{st}(t) \sum_{i,\sigma=\pm1} (-1)^i c^\dagger_{i,\sigma} \sigma^z_{\sigma\sigma'} c_{i,\sigma'} + \frac{1}{2} \sum_{i,\sigma=\pm1} \left[t_0 + (-1)^i \delta(t) \right] c^\dagger_{i,\sigma} c_{i+1,\sigma} + h.c.,$$

(4.76)

where

$$(\delta(t), h_{st}(t)) = \left(\delta_0 \cos \frac{2\pi t}{T}, h_0 \sin \frac{2\pi t}{T} \right).$$

(4.77)

A magnetic staggered field is introduced to replace the on-site potential. We choose the eigenstates of σ_z as a basis, and set $\phi^\dagger_{k,\uparrow} = (a^\dagger_{k,\uparrow}, b^\dagger_{k,\uparrow})$ and $\phi^\dagger_{k,\downarrow} = (a^\dagger_{k,\downarrow}, b^\dagger_{k,\downarrow})$. The model is diagonalized in block with spin up and down,

$$H = \sum_k (\phi^\dagger_{k,\uparrow}, \phi^\dagger_{k,\downarrow}) \begin{pmatrix} d_+ \cdot \sigma & 0 \\ 0 & d_- \cdot \sigma \end{pmatrix} \begin{pmatrix} \phi_{k,\uparrow} \\ \phi_{k,\downarrow} \end{pmatrix},$$

(4.78)

where

$$(\mathbf{d}_\pm)_x = \frac{1}{2}(t_0 + \delta(t)) + \frac{1}{2}(t_0 - \delta(t)) \cos k,$$

(4.79)

$$(\mathbf{d}_\pm)_y = -\frac{1}{2}(t_0 - \delta(t)) \sin k,$$

(4.80)

$$(\mathbf{d}_\pm)_z = \pm h_{st}(t).$$

(4.81)

Thus, electrons with spin up and down are decoupled. It is noted that $(\mathbf{d}_\pm)_z$ differ by a minus sign. The corresponding Berry curvatures for electrons with spin up and down will also differ by a minus sign. As t increases from 0 to T, if an electron with spin up moves from left to right, there must be another electron with spin down moving from right to left

$$\Delta P_\uparrow = +ea$$

(4.82)

and

$$\Delta P_\downarrow = -ea.$$

(4.83)

As a result, there is no charge pump in a cyclic evolution. Instead electron spins exchange at the ends as electrons with spin up and down move in opposite directions simultaneously. When S_z is conserved, this idea can be used to describe the a quantized spin pump.

Usually electron spin does not obey a fundamental conservation law. The concept of spin pump cannot be simply generalized to the case that S_z is non-conserved. However, Fu and Kane [11] proposed that similar events occur even when the spin degrees of freedom are non-conserved. Consider the inclusion of an additional term for spin-orbit coupling,

$$V_{so} = \sum_{i,\sigma,\sigma'} i\mathbf{e}_{so} \cdot (c_{i\sigma}^{\dagger} \sigma_{\sigma\sigma'} c_{i+1\sigma'} - c_{i+1\sigma}^{\dagger} \sigma_{\sigma\sigma'} c_{i\sigma'}), \tag{4.84}$$

into (4.76) where e_{so} is an arbitrary vector characterizing the spin-orbit interaction. In this way, the z-component spin σ^z is no longer a good quantum number

$$V_{so} = \sum_{i,\sigma,\sigma'} i\mathbf{e}_{so} \cdot \sigma_{\sigma\sigma'} \left[(1 - e^{ik}) a_{k,\sigma}^{\dagger} b_{k,\sigma'} - (1 - e^{-ik}) b_{k,\sigma}^{\dagger} a_{k,\sigma'} \right]. \tag{4.85}$$

In this case, there still exists an additional symmetry, i.e., time reversal symmetry, and the Hamiltonian satisfies the following relation

$$H(-t) = \Theta H(t) \Theta^{-1}. \tag{4.86}$$

For an adiabatic cyclic evolution, we have

$$H(t) = H(t + T). \tag{4.87}$$

There exist two distinct points, $t_1^* = 0$ and $t_2^* = T/2$ at which the Hamiltonian is time reversal invariant

$$H(t_i^*) = \Theta H(t_i^*) \Theta^{-1} \tag{4.88}$$

($i = 1, 2$). The existence of these two points plays a crucial role in the topological classification of the pump cycle.

In general, in the absence of a conservation law, there will be no level crossing, and the system will stay in the same state before and after cycling. In the case of charge pump, the level crossing is protected by the charge conservation. In this case it is the time reversal symmetry that protects the level crossing at t_1^* or t_2^*. At the two points, there exists a Kramers degeneracy: the two states, as time reversal counterparts, have the same energy. Fu and Kane proposed introducing the concept of time reversal polarization, which is quantized in the spin pump.

4.7 Integer Quantum Hall Effect: The Laughlin Argument

Laughlin showed that the quantization of the Hall conductance is a consequence of the gauge invariance and the existence of the mobility gap [12]. Consider a two-dimensional electron gas which is rolled as a cylinder along the y-direction, as shown in Fig. 4.2. A magnetic flux ϕ is threading through the cylinder and varies with time very slowly. Suppose the system has an energy gap and the Fermi energy is located in the gap. According to the Faraday law, the varying magnetic field induces an electric field E_y around the magnetic flux ϕ. The Hall current density J_x is given by

$$J_x = \sigma_{xy} E_y, \tag{4.89}$$

where the coefficient σ_{xy} is the Hall conductance. Then, from the continuity equation of charge, the charge Q flowing through the cylinder is

$$\frac{dQ}{dt} = -\oint dl \cdot J_x = -\sigma_{xy} \oint dl \cdot E_y. \tag{4.90}$$

Using the Stokes' theorem,

$$\oint dl \cdot E_y = \int d\mathbf{S} \cdot \nabla \times E_y. \tag{4.91}$$

Furthermore it follows from Faraday law, $\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}$, that

$$\frac{dQ}{dt} = \sigma_{xy} \int d\mathbf{S} \cdot \frac{\partial \mathbf{B}}{\partial t} = \sigma_{xy} \frac{d\phi}{dt} \tag{4.92}$$

or

$$\Delta Q = \sigma_{xy} \Delta\phi, \tag{4.93}$$
Fig. 4.2 Schematic of the setup for Laughlin's Gedanken experiment for the integer quantum Hall effect. A changing flux through the cylindrical device generates an electric field E_y in the y-direction, which induces a Hall current J_x in the surface along the x-direction. The change of one quantum flux will transfer an integer of elementary charges from one side to the other side

where $\phi = \int d\mathbf{S} \cdot \mathbf{B}$ is the magnetic flux. Taking the change of magnetic flux as $\Delta\phi = \phi_0 = h/e$, the Hall conductance becomes $\sigma_{xy} = \frac{e}{h}\Delta Q$. Thus, the Hall conductance is determined by the charge transfer ΔQ after changing the magnetic flux by one magnetic flux quantum $\Delta\phi = \phi_0$.

What's the value of ΔQ? In the present geometry, the presence of the magnetic flux in the cylinder will lead to a gauge transformation in the vector potential,

$$\mathbf{p} + e\mathbf{A} \rightarrow \mathbf{p} + e(\mathbf{A} + \delta\mathbf{A}). \tag{4.94}$$

We take $\delta\mathbf{A} = \frac{\hbar}{e}\nabla\lambda$. The wave function will be transformed as

$$\Psi(r) \rightarrow e^{i\lambda(r)}\Psi(r). \tag{4.95}$$

For a quantum flux $\oint \delta\mathbf{A} \cdot dl = \phi_0$, one has $\lambda(\mathbf{r}, \phi = \phi_0) - \lambda(\mathbf{r}, \phi = 0) = 2\pi$. Thus, the eigenstate before and after the variation of one quantum flux are identical, i.e.,

$$H(\phi = \phi_0) = H(\phi = 0). \tag{4.96}$$

However, for a many-body system, the occupancy of electrons may be different after the variation of one quantum flux,

$$\Delta Q = ne, \tag{4.97}$$

where n is an integer that is determined by the topology of the band structure of the system. Therefore we conclude that

$$\sigma_{xy} = n\frac{e^2}{h}. \tag{4.98}$$

This can be regarded as a generalization of the adiabatic charge pump in a two-dimensional system.

The Fu–Kane argument is a spin version of the Laughlin argument as a generalization from the integer quantum Hall effect to the quantum spin Hall effect, which is similar to a generalization from a charge pump to a spin pump. For a quantum spin system, time reversal symmetry will give a different topological invariant for the quantum spin Hall system. Consider a setup of the same geometry as in the previous subsection for the quantum Hall effect, as shown in Fig. 4.2. A magnetic flux ϕ threads a two-dimensional cylinder, which will cause an extra change of the phase factor before the physical states, $e^{i2\pi\phi/\phi_0}$. the magnetic flux plays the role of the edge crystal momentum k_x in the band theory. Increasing the magnetic flux with time t from $\phi = 0$ to ϕ_0 may form an adiabatic cyclic evolution. There exists a Kramers degeneracy at $\phi = 0$ and $\phi_0/2$,

$$H(0) = \Theta H(0)\Theta^{-1} \tag{4.99}$$

and

$$H(\phi_0/2) = \Theta H(\phi_0/2)\Theta^{-1}. \tag{4.100}$$

Thus, a variation by a half flux quantum will change the electron parity number at two ends.

4.8 Time Reversal Symmetry and the Z_2 Index

Time reversal symmetry implies that $[\mathcal{H}(\mathbf{r}), \Theta] = 0$, where the time reversal operator $\Theta = -i\sigma_y K$ and K is the complex conjugation. Note in the band theory time reversal symmetry means that,

$$H(-\mathbf{k}) = \Theta H(\mathbf{k})\Theta^{-1}, \tag{4.101}$$

as the good quantum number $\mathbf{k}$ has already replaced the momentum operator $\mathbf{p} = -i\hbar\nabla$ in the Hamiltonian, and the later changes a minus sign under time reversal Θ. In the Brillouin zone of a square lattice, there are four (eight for a cubic lattice in three dimensions) time reversal invariant points satisfying $-\Gamma_i = \Gamma_i + n_i\mathbf{G}$, where $\mathbf{G}$ is a reciprocal lattice vector and $n_i = 0$ or 1 [11, 13, 16]. At these points, $\Gamma_i = n_i\mathbf{G}/2$,

$$H(\Gamma_i) = \Theta H(\Gamma_i)\Theta^{-1} \tag{4.102}$$

always holds, therefore the eigenstates are always at least doubly degenerate due to the Kramers degeneracy. A pair of such energy bands $E_{2n-1}(k)$ and $E_{2n}(k)$ are called a Kramers pair, as illustrated in Fig. 4.3. These two bands (labeled as (n, I) and (n, II), respectively) are related with each other by a time reversal operation

Fig. 4.3 Schematic of band structures $E_n(k)$, along the direction of one reciprocal vector. The Kramers pairs cross at time reversal invariant points $k = 0, G_1/2$
accompanied by a phase factor [11]. Their crossings at time reversal invariant points are protected by time reversal symmetry. If a Kramers pair is isolated from other pairs by finite gaps, a topological invariant associated with this pair can be defined.

For simplicity, we consider a one-dimensional system and suppose that there is no additional degeneracy other than those required by the time reversal symmetry. Therefore the $2N$ eigenstates cab be divided into N pairs that satisfy

$$\left| u_n^I(-k) \right\rangle = -e^{i\chi_{k,n}} \Theta \left| u_n^{II}(k) \right\rangle. \tag{4.103}$$

Then,

$$\Theta \left| u_n^I(-k) \right\rangle = -\Theta e^{i\chi_{k,n}} \Theta \left| u_n^{II}(k) \right\rangle = e^{-i\chi_{k,n}} \left| u_n^{II}(k) \right\rangle, \tag{4.104}$$

as $\Theta^2 = -1$ for electrons with spin $\frac{1}{2}$. Thus, one has the relation,

$$\left| u_n^{II}(-k) \right\rangle = e^{i\chi_{-k,n}} \Theta \left| u_n^I(k) \right\rangle. \tag{4.105}$$

The partial polarization associated with either of the categories $s = I$ or II can be written as

$$P^s = \int_{BZ} \frac{dk}{2\pi} A_k^s. \tag{4.106}$$

with $A_k^s = i \sum_n \left\langle u_n^s(k) | \nabla_k | u_n^s(k) \right\rangle$. It is invariant (up to a lattice translation) under changes in the phases of $\left| u_n^I(k) \right\rangle$ and $\left| u_n^{II}(k) \right\rangle$. However, this appears to depend on the arbitrary choice of the label I and II being assigned to each band. To make this invariance explicit for P^s, we separate the integral into two parts

$$\begin{aligned} P^I &= \int_0^\pi \frac{dk}{2\pi} A_k^I + \int_{-\pi}^0 \frac{dk}{2\pi} A_k^I \\ &= \int_0^\pi \frac{dk}{2\pi} A_k^I + \int_0^\pi \frac{dk}{2\pi} A_{-k}^I. \end{aligned} \tag{4.107}$$

Using the time reversal constraint,

$$\left\langle \Theta u_n^{II}(k) | \partial_k | \Theta u_n^{II}(k) \right\rangle = -\left\langle u_n^{II}(k) | \partial_k | u_n^{II}(k) \right\rangle, \tag{4.108}$$

we have

$$A_{-k}^I = A_k^{II} - \sum_n \partial_k \chi_{k,n}. \tag{4.109}$$

It then follows that

$$P^I = \int_0^\pi \frac{dk}{2\pi} A_k - \frac{1}{2\pi} \sum_n (\chi_{\pi,n} - \chi_{0,n}), \tag{4.110}$$

where $A_k = A_k^I + A_k^{II}$. Introduce the $U(2N)$ matrix

$$w_{mn}(k) = \langle u_m(-k) | \Theta | u_n(k) \rangle . \tag{4.111}$$

Then, only non-zero terms are

$$\langle u_n^I(-k) | \Theta | u_n^{II}(k) \rangle = -e^{-i\chi_{k,n}} \tag{4.112}$$

and

$$\langle u_n^{II}(-k) | \Theta | u_n^I(k) \rangle = e^{-i\chi_{-k,n}} . \tag{4.113}$$

The matrix w is a direct product of 2×2 matrices with $-e^{-i\chi_{k,n}}$ and $e^{-i\chi_{-k,n}}$ on the off-diagonal. At $k = 0$ and π, w is antisymmetric. An antisymmetric matrix may be characterized by a Pfaffian, whose square is equal to the determinant. Then we have

$$\frac{Pf\left[w(\pi)\right]}{Pf\left[w(0)\right]} = \exp\left[i\sum_n (\chi_{\pi,n} - \chi_{0,n})\right] . \tag{4.114}$$

Thus,

$$P^I = \frac{1}{2\pi} \left[\int_0^\pi dk A_k + i \ln \frac{Pf\left[w(\pi)\right]}{Pf\left[w(0)\right]}\right] . \tag{4.115}$$

A similar formula can be obtain for P^{II}. It follows from the time reversal symmetry that $P^{II} = P^I$ modulo an integer, reflecting the Kramers pairing of the Wannier states. The charge polarization for one Kramers pair of states is

$$P_\rho = P^I + P^{II} \tag{4.116}$$

and the time reversal polarization is defined as

$$
\begin{aligned}
P_\theta &= P^I - P^{II} \\
&= \frac{1}{2\pi} \left[\int_0^\pi dk A_k - \int_{-\pi}^0 dk A_k + 2i \ln \frac{Pf\left[w(\pi)\right]}{Pf\left[w(0)\right]}\right] .
\end{aligned} \tag{4.117}
$$

In terms of the matrix w_{nm}, the formula can be written in a compact form,

$$P_\theta = \frac{1}{2\pi i} \left[\int_0^\pi dk Tr[w^\dagger \nabla_k w] - 2 \ln \frac{Pf\left[w(\pi)\right]}{Pf\left[w(0)\right]}\right] . \tag{4.118}$$

In the matrix w, only non-zero elements are off-diagonal,

$$Tr\left[w^\dagger \nabla_k w\right] = Tr\left[\begin{pmatrix} 0 & e^{-i\chi_{-k,n}} \\ -e^{i\chi_{k,n}} & 0 \end{pmatrix} \nabla_k \begin{pmatrix} 0 & -e^{-i\chi_{k,n}} \\ e^{i\chi_{-k,n}} & 0 \end{pmatrix}\right] . \tag{4.119}$$

Thus,

$$Tr\left[w^\dagger \nabla_k w\right] = i\nabla_k \chi_{-k,n} - i\nabla_k \chi_{k,n}. \tag{4.120}$$

Using the unitarity of w, we have

$$Tr\left[w^\dagger \nabla_k w\right] = Tr[\nabla_k \ln w(k)] = \nabla_k \ln \det[w(k)]. \tag{4.121}$$

Thus, P_θ can be expressed as,

$$P_\theta = \frac{1}{i2\pi}\left[\ln \frac{\det(w(\pi))}{\det(w(0))} - 2\ln \frac{Pf(w(\pi))}{Pf(w(0))}\right] \tag{4.122}$$

or

$$(-1)^{P_\theta} = \frac{\sqrt{\det(w(0))}}{Pf(w(0))} \frac{\sqrt{\det(w(\pi))}}{Pf(w(\pi))}. \tag{4.123}$$

In general, for a cyclic process of $H(t + T) = H(t)$, it follows that

$$H(t_1^* = 0) = \Theta H(0)\Theta^{-1} \tag{4.124}$$

and

$$H(t_1^* = T/2) = \Theta H(T/2)\Theta^{-1}. \tag{4.125}$$

The change of time reversal polarization is gauge invariant:

$$\nu = [P_\theta(T/2) - P_\theta(0)]\, mod\, 2. \tag{4.126}$$

Consider the mapping between the time reversal invariant momenta Γ_i and the time invariant point of time t_i^*, we conclude that the topological invariant can be written as

$$(-1)^\nu = \prod_i \frac{\sqrt{\det(w(\Gamma_i))}}{Pf(w(\Gamma_i))}. \tag{4.127}$$

As

$$\det(w(\Gamma_i)) = \left[Pf(w(\Gamma_i))\right]^2, \tag{4.128}$$

the right hand side of (4.127) is always $+1$ or -1. Correspondingly, ν is only an integer modulo 2, i.e., 0 or 1. Thus, the time reversal polarization defines two distinct polarization states, topologically trivial ($\nu = 0$) and non-trivial ($\nu = 1$). Fu and Kane proposed that the value of ν is related to the presence or the absence of a Kramers degenerate states at the end of a finite system [11].

If an insulator has the additional inversion symmetry, there is a simplified algorithm to calculate the Z_2 invariant. Suppose that the Hamiltonian H has an inversion symmetry,

$$H(-\mathbf{k}) = PH(\mathbf{k})P^{-1}, \tag{4.129}$$

where the parity operator is defined by

$$P\,|\mathbf{r}, s_z\rangle = P\,|-\mathbf{r}, s_z\rangle\,. \tag{4.130}$$

Here $\mathbf{r}$ is the coordinate and s_z is the spin, which is unchanged by the parity P because it is a pseudo vector. An explicit consequence of the combination of the time reversal symmetry and inversion symmetry is the fact that the Berry curvature must vanish,

$$F(\mathbf{k}) = \nabla_{\mathbf{k}} \times \mathbf{A}(\mathbf{k}) = 0. \tag{4.131}$$

It follows from the definition of the Berry curvature that it is odd under time reversal, $F(-\mathbf{k}) = -F(\mathbf{k})$, and even under inversion, $F(-\mathbf{k}) = F(\mathbf{k})$. Considering the mth pair of the occupied energy bands at the time reversal invariant momentum Γ_i, we define $P\,|u_{2m,i}\rangle = \xi_{2m}(\Gamma_i)\,|u_{2m,i}\rangle$, where the parity eigenvalues $\xi_{2m}(\Gamma_i) = +1$ or -1. The degenerate Kramers partners share the same eigenvalue $\xi_{2m} = \xi_{2m-1}$. In this case, there a simple formula to calculate δ [13]

$$(-1)^{\nu} = \prod_{i} \prod_{m=1}^{N} \xi_{2m}(\Gamma_i). \tag{4.132}$$

In Sect. 3.6, we have already used this result to classify the topological phases in the lattice model.

Note on Pfaffian: In mathematics, a skew-symmetric matrix is a square matrix A whose transpose is its negative, $A = -A^T$. The determinant of a skew-symmetric matrix A can always be written as the square of a polynomial in the matrix entries, which is called the Pfaffian of the matrix, denoted by $Pf(A)$, i.e.,

$$\det(A) = Pf(A)^2. \tag{4.133}$$

The term Pfaffian was introduced by Cayley [17] who named it after Johann Friedrich Pfaff. The Pfaffian is nonvanishing only for $2n \times 2n$ skew-symmetric matrices, in which case it is a polynomial of degree n.

For example,

$$Pf\begin{pmatrix} 0 & a \\ -a & 0 \end{pmatrix} = a \tag{4.134}$$

and

$$Pf \begin{pmatrix} 0 & a & b & c \\ -a & 0 & d & e \\ -b & -d & 0 & f \\ -c & -e & -f & 0 \end{pmatrix} = af - be + dc. \tag{4.135}$$

4.9 Generalization to Two and Three Dimensions

The generalization of the Z_2 invariant from two to three dimensions is a milestone in the development of topological insulators. The topological invariant characterizing a two-dimensional band structure may be constructed by rolling a two-dimensional system into a cylinder, as shown in Fig. 4.4a. Then the magnetic flux threading the cylinder plays the role of the circumferential crystal momentum k_x, with $\phi = 0$ and $\phi = \phi_0/2$ to two edge time reversal momenta $k_x = \Lambda_1 = 0$ and $k_x = \Lambda_2 = \pi/a$.
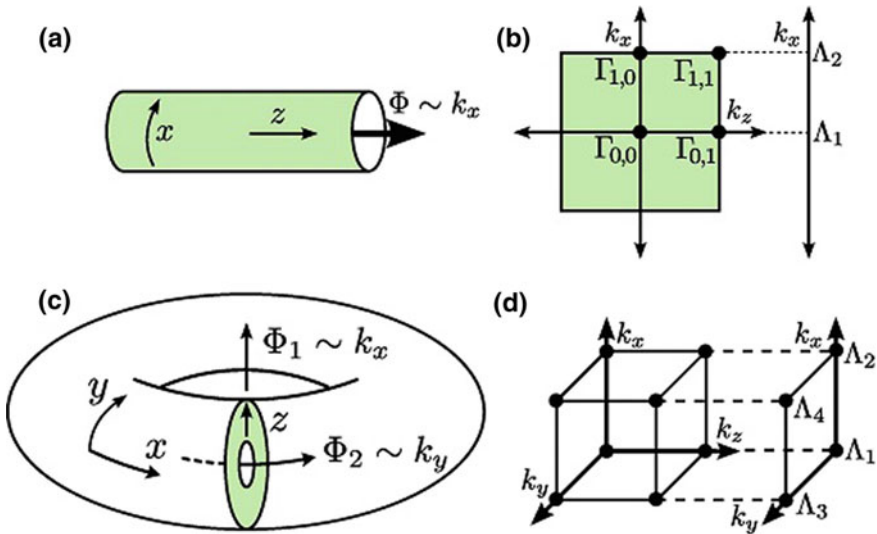

Fig. 4.4 **a** A two-dimensional cylinder threaded by magnetic flux Φ. When the cylinder has a circumference of a single lattice constant, Φ plays the role of the edge crystal momentum k_x in band theory. **b** The time-reversal invariant fluxes $\Phi = 0$ and $h/2e$ correspond to edge time-reversal invariant momenta $\Lambda_1 = 0$ and $\Lambda_2 = \pi/a$. Λ_a are projections of pairs of the four bulk time-reversal momenta $\Gamma_{i=(a\mu)}$, which reside in the two-dimensional Brillouin zone indicated by the *shaded region*. **c** In three dimensions, the generalized cylinder can be visualized as a Corbino donut, with two fluxes, which correspond to the two components of the surface crystal momentum. **d** The four time-reversal invariant fluxes Φ_1, $\Phi_2 = 0$, $h/2e$ correspond to the four two-dimensional surface momenta. Reprinted with permission from [13]. Copyright (2007) by the APS

The Z_2 invariant characterizes the change of the time reversal polarization in the Kramers degeneracy at the ends of the one-dimensional system between $k_x = \Lambda_1$ and $k_x = \Lambda_2$. The change is related to the bulk band structure of a two-dimensional system with the periodic boundary condition. For a square lattice, there are four time reversal invariant momenta in the first Brillouin zone,

$$\Gamma_{n_x,n_y} = \left(\frac{n_x}{2}\mathbf{G}_x, \frac{n_y}{2}\mathbf{G}_y\right) \tag{4.136}$$

with $n_x, n_y = 0, 1$. For an edge perpendicular to $\mathbf{G}_y$, the one-dimensional edge time reversal invariant momenta are $k_x = \Lambda_1$ and $k_x = \Lambda_2$, which satisfy $\Gamma_{1,n_y} - \Gamma_{0,n_y} = \frac{\mathbf{G}_x}{2}$. Thus, the time reversal polarization can be expressed as $\pi_x = \delta_{x1}\delta_{x2}$ where

$$\delta_{xi} = \frac{\sqrt{\det[w(\Gamma_{i,y})]}}{Pf[w(\Gamma_{i,y})]} = \pm 1. \tag{4.137}$$

However, π_x is a gauge invariant. A k-dependent gauge transformation can change the sign of any pair of δ_i. If we roll the system into a cylinder along another direction, we can calculate the time reversal polarization $\pi_y = \delta_{y1}\delta_{y2}$. The product $\pi_x\pi_y$ is gauge invariant,

$$(-1)^\nu = \prod_{n_x,n_y=0,1} \frac{\sqrt{\det[w(\Gamma_{n_x,n_y})]}}{Pf[w(\Gamma_{n_x,n_y})]}. \tag{4.138}$$

This ν can be equal to 0 or 1, and define a single Z_2 invariant in two dimensions.

The Z_2 invariant for three-dimensional crystals can be reduced to the problems in two dimensions [11, 14, 15]. The three-dimensional Brillouin zone can be rolled into a donus along the x- and y-directions as illustrated in Fig. 4.4c. There are 8 time reversal invariant momenta for three-dimensional systems,

$$\Gamma_{i=(n_1,n_2,n_3)} = \left(\frac{n_1}{2}\mathbf{G}_1, \frac{n_2}{2}\mathbf{G}_2, \frac{n_3}{2}\mathbf{G}_3\right) \tag{4.139}$$

with $n_j = 0, 1$. They can be viewed as vertexes of a parallelepiped. For a fixed n_1, for example, $n_1 = 1$, the point set

$$\left(\frac{n_1}{2}\mathbf{G}_1, \frac{a_2}{2}\mathbf{G}_2, \frac{a_3}{2}\mathbf{G}_3\right) \tag{4.140}$$

for all $a_2, a_3 \in [-\frac{1}{2}, \frac{1}{2})$ defines a two-dimensional Brillouin zone of a two-dimensional system respecting time reversal symmetry, for which a Z_2 invariant can be calculated using the method for the two-dimensional system, referred to as $\nu_{n_1=1}$. The other 5 invariants $\nu_{n_1=0}$, $\nu_{n_2=0,1}$ and $\nu_{n_3=0,1}$ can be defined in a similar way. These 6 invariants are associated with the six planes of the above parallelepiped. As they

belong to the same three-dimensional crystal, only four of them can be independent due to the constraints [11, 14]

$$\nu_{n_1=0} \cdot \nu_{n_1=1} = \nu_{n_2=0} \cdot \nu_{n_2=1} = \nu_{n_3=0} \cdot \nu_{n_3=1} \, mod2. \tag{4.141}$$

The 4 independent invariants can be chosen as, say, $\nu_0 = \nu_{n_1=0}\nu_{n_1=1}$, $\nu_1 = \nu_{n_1=1}$, $\nu_2 = \nu_{n_2=1}$ and $\nu_3 = \nu_{n_3=1}$. The indices $\nu_0; (\nu_1\nu_2\nu_3)$ reflects the topology of the surface states [13, 16]. ν_0 is given by

$$(-1)^{\nu_0} = \prod_{n_1,n_2,n_3=0,1} \frac{\sqrt{\det[w(\Gamma_{n_1,n_2,n_3})]}}{Pf[w(\Gamma_{n_1,n_2,n_3})]}. \tag{4.142}$$

If $\nu_0 = 1$, then the system is a strong topological insulator, with an odd number of Dirac cones on all surfaces of the crystal. If $\nu_0 = 0$, then the crystal is a weak topological insulator, with an even number (including 0) of Dirac cones on the surfaces. The case of $\nu_0 = 0$ is topologically equivalent to a two-dimensional insulator, and therefore is not robust against disorder. Let's take 0; (001) for an example [13]. The surface states corresponding to the two-dimensional Brillouin zone spanned by G_2 and G_3 (with index $\nu_1 = 0$) have two Dirac cones, as do the surface states in the Brillouin zone spanned by G_1 and G_3, with index $\nu_2 = 0$. However, there are no any surface states in the $G_2 - G_3$ plane with index $\nu_3 = 1$.

4.10 Phase Diagram of the Modified Dirac Equation

We now consider whether the modified Dirac equation is topologically trivial or non-trivial. The general solution of the wave functions for an infinite system or with the periodic boundary conditions can be expressed as

$$\Psi_\nu = u_\nu(\mathbf{p}) \exp[i(\mathbf{p} \cdot \mathbf{r} - E_{p,\nu}t)/\hbar], \tag{4.143}$$

in which the momentum is a good quantum number. The dispersion relations of four energy bands are

$$E_{p,\nu(=1,2)} = -E_{p,\nu(=3,4)} = \sqrt{v^2p^2 + (mv^2 - Bp^2)^2}. \tag{4.144}$$

The four-component spinors $u_\nu(\mathbf{p})$ can be expressed as $u_\nu(\mathbf{p}) = Su_\nu(\mathbf{p} = 0)$ with

$$
S = \sqrt{\frac{\epsilon_p}{2E_{p,1}}}
\begin{pmatrix}
1 & 0 & -\dfrac{p_z v}{\epsilon_p} & -\dfrac{p_- v}{\epsilon_p} \\[2mm]
0 & 1 & -\dfrac{p_+ v}{\epsilon_p} & \dfrac{p_z v}{\epsilon_p} \\[2mm]
\dfrac{p_z v}{\epsilon_p} & \dfrac{p_- v}{\epsilon_p} & 1 & 0 \\[2mm]
\dfrac{p_+ v}{\epsilon_p} & -\dfrac{p_z v}{\epsilon_p} & 0 & 1
\end{pmatrix},
\tag{4.145}
$$

where $p_\pm = p_x \pm ip_y$, $\epsilon_p = E_{p,1} + \left(mv^2 - Bp^2\right)$, and $u_\nu(0)$ is one of the four eigen states of β.

The topological properties of the modified Dirac equation can be gained from these solutions. The Dirac equation is invariant under the time reversal symmetry, and can be classified according to the Z_2 topological classification following Kane and Mele [18]. In the representation of the Dirac matrices in (2.9), the time reversal operator defined as $\Theta \equiv -i\alpha_x\alpha_z\mathcal{K}$ [19], where $\mathcal{K}$ is the complex conjugate operator that forms the complex conjugation of any coefficient that multiplies a ket or wave function (and stands on the right of $\mathcal{K}$). Under the time reversal operation, the modified Dirac equation remains invariant,

$$
\Theta H(\mathbf{p})\Theta^{-1} = H(-\mathbf{p})
\tag{4.146}
$$

(p is a good quantum number of the momentum). Furthermore we have the relations that $\Theta u_1(\mathbf{p}) = -iu_2(-\mathbf{p})$ and $\Theta u_2(\mathbf{p}) = +iu_1(-\mathbf{p})$, which satisfy the relation of $\Theta^2 = -1$. Similarly, $\Theta u_3(\mathbf{p}) = -iu_4(-\mathbf{p})$ and $\Theta u_4(\mathbf{p}) = +iu_3(-\mathbf{p})$. Thus, the solutions of $\{u_1(\mathbf{p}), u_2(-\mathbf{p})\}$ and $\{u_3(\mathbf{p}), u_4(-\mathbf{p})\}$ are two degenerate Kramers pairs of positive and negative energies, respectively. The matrix of overlap $\left\{\langle u_\mu(\mathbf{p})|\,\Theta\,|u_\nu(\mathbf{p})\rangle\right\}$ has the form:

$$
\begin{pmatrix}
0 & i\dfrac{mv^2 - Bp^2}{E_{p,1}} & -i\dfrac{p_- v}{E_{p,1}} & i\dfrac{p_z v}{E_{p,1}} \\[3mm]
-i\dfrac{mv^2 - Bp^2}{E_{p,1}} & 0 & i\dfrac{p_z v}{E_{p,1}} & i\dfrac{p_+ v}{E_{p,1}} \\[3mm]
i\dfrac{p_- v}{E_{p,1}} & -i\dfrac{p_z v}{E_{p,1}} & 0 & i\dfrac{mv^2 - Bp^2}{E_{p,1}} \\[3mm]
-i\dfrac{p_z v}{E_{p,1}} & -i\dfrac{p_+ v}{E_{p,1}} & -i\dfrac{mv^2 - Bp^2}{E_{p,1}} & 0
\end{pmatrix},
\tag{4.147}
$$

which is antisymmetric, $\langle u_\mu(\mathbf{p})|\,\Theta\,|u_\nu(\mathbf{p})\rangle = -\langle u_\nu(\mathbf{p})|\,\Theta\,|u_\mu(\mathbf{p})\rangle$. For the two negative energy bands $u_3(\mathbf{p})$ and $u_4(\mathbf{p})$ which are fully occupied for an insulator, the submatrix of the overlap can be expressed in terms of a single number as $\epsilon_{\mu\nu}P(\mathbf{p})$,

$$P(\mathbf{p}) = i\frac{mv^2 - Bp^2}{\sqrt{(mv^2 - Bp^2)^2 + v^2p^2}}, \tag{4.148}$$

which is the Pfaffian for the 2×2 matrix. According to Kane and Mele [18], the even or odd number of zeros in $P(\mathbf{p})$ defines the Z_2 topological invariant. Here we want to emphasize that the sign of a dimensionless parameter mB will determine the Z_2 invariant of the modified Dirac equation. As $P(\mathbf{p})$ is always non-zero for $mB \leq 0$ and there exists no zero in the Pfaffian, we conclude immediately that the modified Dirac Hamiltonian for $mB \leq 0$, including the conventional Dirac Hamiltonian ($B = 0$), is topologically trivial.

For $mB > 0$ the case is different. In this continuous model, the Brillouin zone becomes infinite. At $p = 0$ and $p = +\infty$, $P(0) = i\,\mathrm{sgn}(m)$ and $P(+\infty) = -i\,\mathrm{sgn}(B)$. In this case $P(\mathbf{p}) = 0$ at $p^2 = mv^2/B$. $\mathbf{p} = 0$ is always one of the time reversal invariant momenta. As a result of an isotropic model in the momentum space, we think all points of $p = +\infty$ shrink into one point if we regard the continuous model as a limit of the lattice model by taking the lattice space $a \to 0$ and the reciprocal lattice vector $G = 2\pi/a \to +\infty$. In this sense as a limit of a square lattice other three time reversal invariant momenta have $P(0, G/2) = P(G/2, 0) = P(G/2, G/2) = P(+\infty)$ which has an opposite sign of $P(0)$ if $mB > 0$. Similarly for a cubic lattice the $P(\mathbf{p})$ of the other seven time reversal invariant momenta have the opposite sign of $P(0)$. Following Fu et al. [13, 16], we conclude that *the modified Dirac Hamiltonian is topologically non-trivial only if $mB > 0$.*

In two dimensions, Z_2 index can be determined by evaluating the winding number of the phase of $P(p)$ around a loop of enclosing the half the Brillouin zone in the complex plane of $\mathbf{p} = p_x + ip_y$,

$$I = \frac{1}{2\pi i} \oint_C d\mathbf{p} \cdot \nabla_{\mathbf{p}}\log[P(\mathbf{p}) + i\delta]. \tag{4.149}$$

Because the model is isotropic, the integral is then reduced to only the path along p_x -axis and the half-circle integral vanishes for $\delta > 0$ and $|\mathbf{p}| \to +\infty$. Along the p_x axis one one of a pair of zeros in the ring is enclosed in the contour C when $mB > 0$, which gives a Z_2 index $\nu = 1$. This defines the non-trivial quantum spin Hall phase.

Volovik [20, 21] proposed that the Green function rather than the Hamiltonian is more suitable for classifying topological insulators. From the 3-dimensional Dirac equation, the Green function has the form

$$\begin{aligned} G(i\omega_n, \mathbf{p}) &= \frac{1}{i\omega_n - H} \\ &= -\frac{i\omega_n + v\mathbf{p} \cdot \alpha + (mv^2 - Bp^2)\beta}{\omega_n^2 + h^2(p)}, \end{aligned} \tag{4.150}$$

where $h^2(k) = H^2 = v^2p^2 + (mv^2 - Bp^2)^2$. The frequency $\omega_n = (2n + 1)\pi/\beta = (2n + 1)\pi k_B T$. ($k_B$ is the Boltzman constant and T is the temperature). The topological invariant is defined as

Fig. 4.5 Phase diagram of topological states of the modified Dirac equation as a function of the two model parameters *m* and *B*
$$\tilde{N} = \frac{1}{24\pi^2} \epsilon_{ijk} Tr[K \int_{i\omega_n=0} d\mathbf{p} G \partial_{p_i} G^{-1} G \partial_{p_j} G^{-1} G \partial_{p_k} G^{-1}], \qquad (4.151)$$

where $K = \sigma_y \otimes \sigma_0$ is the symmetry-related operator. After tedious algebra, it is found that

$$\tilde{N} = sgn(m) + sgn(B). \qquad (4.152)$$

When $mB > 0$, $\tilde{N} = \pm 2$, which defines the phase as topologically non-trivial. If B is set to be positive, there exist a quantum phase transition from a topologically trivial phase of $m < 0$ to a topologically non-trivial phase of $\mu > 0$. This is in a good agreement with the result of the Z_2 index in the preceding section [22].

As a summary, we present in Fig. 4.5 the phase diagram of the topological invariants.

Chapter 5
Topological Phases in One Dimension

Abstract Polyacetylene was studied extensively in the 1980s. A re-examination of the Su–Schrieffer–Heeger model for polyacetylene shows that it is actually a one-dimensional topological insulator with the end states. Topological phases also exist in other one-dimensional systems.

5.1   Su–Schrieffer–Heeger Model for Polyacetylene

The simplest "two-band" model is the Su–Schrieffer–Heeger model for polyacetylene [1], which is an insulator with chirality symmetry. Chiral symmetry is a combination of particle-hole symmetry and time reversal symmetry. Physically, Peierls' theorem states that a one-dimensional equally spaced chain with one electron per ion is unstable due to lattice distortion. The lattice distortion becomes energetically favourable to form a dimerized lattice when the new band gap outweighs the elastic energy cost of rearranging the ions. Consider a one-dimensional dimerized lattice,

$$H = \sum_{n=1}^{N}(t + \delta t)c_{A,n}^{\dagger}c_{B,n} + \sum_{n=1}^{N-1}(t - \delta t)c_{A,n+1}^{\dagger}c_{B,n} + h.c., \qquad (5.1)$$

where $c_{A(B),n}^{\dagger}$ and $c_{A(B),n}$ are the creation and annihilation operators of the electrons on the A (or B) sublattice site $(A(B), n)$, respectively. In this model, each unit cell consists of two sites, A and B, and the hopping term connects the two different sublattice sites. The hopping amplitude in the unit cell is $t + \delta t$ and that between the two unit cells is $t - \delta t$. There are two distinct phases, the A and B phases, which are plotted in Fig. 5.1. These two phases were believed to be degenerate. The interface of these two phases forms a domain wall, which may generate a soliton solution nearby. In this section, we demonstrate that these two phases are topologically distinct in an open boundary condition.
Fig. 5.1 Two distinct phases in the Su–Schrieffer–Heeger model. The *solid* and *dashed lines* stand for the long and short bonds of hopping, respectively. Note that the boundary conditions are distinct in the two phases

Performing the Fourier transformation,

$$a_k = \frac{1}{\sqrt{N}} \sum_n e^{-ik \cdot na} c_{A,n}, \tag{5.2}$$

$$b_k = \frac{1}{\sqrt{N}} \sum_n e^{-ik \cdot na} c_{B,n}, \tag{5.3}$$

where N is the number of the unit cells (the total number of lattice sites is $2N$), we obtain

$$H = (t + \delta t) \sum_{k \in (-\pi, \pi)} \left(a_k^\dagger b_k + b_k^\dagger a_k \right) + (t - \delta t) \sum_k \left(e^{ik} a_k^\dagger b_k + e^{-ik} b_k^\dagger a_k \right). \tag{5.4}$$

Introducing the spinor

$$\psi_k = \begin{pmatrix} a_k \\ b_k \end{pmatrix}, \tag{5.5}$$

we can write the Hamiltonian in a compact form,

$$H = \sum_k \psi_k^\dagger [((t + \delta t) + (t - \delta t) \cos k) \sigma_x + (t - \delta t) \sin k \sigma_y] \psi_k. \tag{5.6}$$

Under the unitary transformation, $\sigma_x \to \sigma_z$, $\sigma_y \to \sigma_x$ and $\sigma_z \to \sigma_y$ and $k \to k + \pi$, it is reduced to

$$H = \sum_k \psi_k^\dagger \left[-(t - \delta t) \sin k \sigma_x + \left(2\delta t + 2(t - \delta t) \sin^2 \frac{k}{2} \right) \sigma_z \right] \psi_k. \tag{5.7}$$

It is easy to check that

$$\sigma_y H \sigma_y = -H \tag{5.8}$$

which means the Hamiltonian possesses the chirality symmetry. Thus, a one-dimensional dimerized lattice is equivalent to the Dirac lattice model in Chap. 3.

In general, the dispersions of this two-band model are

$$E_\pm = \pm\sqrt{d_x^2 + d_z^2}, \tag{5.9}$$

where $d_x = -(t - \delta t)\sin k$ and $d_z = 2\delta t + 2(t - \delta t)\sin^2\frac{k}{2}$. The eigenstates for the negative dispersion are

$$|\varphi\rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} sgn(d_x)\sqrt{1 - \frac{d_z}{\sqrt{d_x^2 + d_z^2}}} \\ -\sqrt{1 + \frac{d_z}{\sqrt{d_x^2 + d_z^2}}} \end{pmatrix}. \tag{5.10}$$

They are fully filled for a half filling, i.e., an average of one electron at every two sites. An energy gap $\Delta E = 4\delta t$ opens for $\delta t \neq 0$.

Thus, the Berry phase for this state is defined as

$$\begin{aligned} \gamma &= \int_{-\pi}^{+\pi} dk \langle \varphi| i\partial_k |\varphi\rangle \\ &= \frac{1}{2}\int_{-\pi}^{+\pi} dk i\partial_k \ln sgn(d_x)\left(1 - \frac{d_z}{\sqrt{d_x^2 + d_z^2}}\right) \\ &= \frac{1}{2}\int_{-\delta}^{+\delta} dk i\partial_k \ln sgn(d_x)\,(1 - sgn(\delta t)) \\ &\quad + \frac{1}{2}\int_{\pi-\delta}^{\pi+\delta} dk i\partial_k \ln sgn(d_x)\,(1 - sgn(t + \delta t)) \\ &= \frac{1}{2}\pi\,[sgn(t + \delta t) - sgn(\delta t)] \end{aligned} \tag{5.11}$$

with a modulus 2π. For $\delta t > 0$, $\gamma = 0$, but for $\delta t < 0$, $\gamma = \pi$. This is consistent with the conclusion from the Dirac model. Alternatively, the winding index is given by

$$(-1)^\nu = sgn(\delta t)sgn(t + \delta t) = sgn(1 + t/\delta t). \tag{5.12}$$

A change in the Berry phase or the winding number accompanies a closing and re-opening of the energy gap between the two bands near $\delta t = 0$. It can be understood that the energy gap changes from positive to negative, as shown in Fig. 5.2. At $\delta t = 0$,
Fig. 5.2 Energy dispersions of $\delta t > 0$, $\delta t = 0$ and $\delta t < 0$. The closing and reopening of the energy gap near $\delta t = 0$ indicates the occurrence of a quantum phase transition

the spectrum is gapless and the two bands cross at $k = 0$. Near the point, using $\sin x \approx x$ for a small x, one obtains

$$H = \sum_k \psi_k^\dagger \left[-(t - \delta t)k\sigma_x + \left(2\delta t + \frac{1}{2}(t - \delta t)k^2 \right) \sigma_z \right] \psi_k. \qquad (5.13)$$

This is the continuous model of the Dirac equation. Thus, we can define the energy gap, $\Delta E = 4\delta t$, not $4|\delta t|$. The sign change of δt indicates a topological quantum phase transition.

Existence of the end states in an open boundary condition is characteristic of the topological phase when the Berry phase is π or the winding index $\nu = 1$. It should be noted that in the open boundary the chain is cut between two unit cells, not between two sites within a unit cell. Assume that $t > 0$. It is topologically non-trivial for $\delta t < 0$, but trivial for $\delta t > 0$. In other words, if the end bond is a long bond, $|t + \delta t| < |t - \delta t|$, it is topologically non-trivial. Otherwise it is topologically trivial.

A topological quantum transition occurs at $\delta t = 0$. In the long wave approximation, we can make use of the solution given in Sect. 2.5.1 when $\delta t < 0$. In this case, there exists a solution of zero energy near the end. The spatial distribution of the wave function is mainly determined by the scale length,

$$\xi_- = \frac{2|B|\hbar}{v}(1 - \sqrt{1 - 4mB})^{-1} \rightarrow \frac{\hbar}{|m|v} = \frac{t - \delta t}{2|\delta t|}. \qquad (5.14)$$

It becomes divergent when $\delta t \rightarrow 0$, because the end state evolves into a bulk state and the system becomes gapless. There is no end state when $\delta t > 0$. This demonstrates a topological quantum phase near $\delta t = 0$ [2].

We can also use a numerical method to calculate the energy eigenstates and eigenvalues by diagonalizing the Hamiltonian, which can be written in the form of square matrix:

$$
H = \begin{pmatrix}
0 & t + \delta t & 0 & 0 & 0 & 0 & 0 \\
t + \delta t & 0 & t - \delta t & 0 & 0 & 0 & 0 \\
0 & t - \delta t & 0 & t + \delta t & 0 & 0 & 0 \\
0 & 0 & t + \delta t & 0 & t - \delta t & 0 & 0 \\
0 & 0 & 0 & t - \delta t & 0 & \ddots & 0 \\
0 & 0 & 0 & 0 & \ddots & 0 & t + \delta t \\
0 & 0 & 0 & 0 & 0 & t + \delta t & 0
\end{pmatrix}. \tag{5.15}
$$

One can find the zero energy mode at the end by changing the sign of δt. The end state solutions at $\delta t = -0.1t$ and $-0.3t$ are plotted in Fig. 5.3. This figure demonstrates that the wave function has a wider distribution in the space for a smaller $|\delta t|$.

However, the most famous excitations in this model are soliton and anti-soliton, which are the charge and spin carriers in polyacetylene [3]. They are the domain walls of two distinct phases of π and 0. These solutions correspond to those of the Dirac equation at the interface between two regions of positive and negative masses, which is discussed in Chap. 2. The wave function of the in-gap bound state is distributed around the domain walls. Given the degeneracy of the electron spins, there are two bound states with different spins. The charge and spin states of the soliton follow from the solutions of the domain wall along with the localized chemical-bond representation. In total there are four possible states according to the electron number n in the two states: (a) two neutral spin-$\frac{1}{2}$ solitons with $S_z = \pm\frac{1}{2}$ for $n = 1$ and (b) two charge species $S^{\pm}$ for $n = 0$ and $n = 2$, in which the total

Fig. 5.3 Amplitudes of the wave function Ψ_i of the end states at the lattice site i for $\delta t = -0.1t$ and $-0.3t$. The smaller value of $|\delta t|$ corresponds to the wider distribution of the wave function in space
spin is zero and may be viewed as spinless "ions". However, the solitons can move freely unless they are pinned, in contrast to the chemical analogs. From the point of view of topological insulators, these states are the end states at the interface between a topologically trivial phase and a topologically non-trivial phase.

5.2 Topological Ferromagnet

In the Su–Schrieffer–Heeger model, the Hamiltonian is written as a 2×2 matrix on the basis of the A and B sublattices, $(a_k^\dagger, b_k^\dagger)$. A new type of topological phase in one dimension can be obtained if we replace the A and B sublattices with electrons with different spins, $(c_{k,\uparrow}^\dagger, c_{k,\downarrow}^\dagger)$. For a ferromagnet with spin–orbit coupling, the Hamiltonian becomes

$$H = \sum_k (c_{k,\uparrow}^\dagger, c_{k,\downarrow}^\dagger) \left[\lambda \sin k \sigma_x + \left(M - 4B \sin^2 \frac{k}{2} \right) \sigma_z \right] \begin{pmatrix} c_{k,\uparrow} \\ c_{k,\downarrow} \end{pmatrix}, \qquad (5.16)$$

where $c_{k,\sigma}^\dagger$ and $c_{k,\sigma}$ are the creation and annihilation operators for the electrons with spin $\sigma(=\uparrow, \downarrow)$. Here λ is the strength of spin–orbit coupling. In the absence of spin–orbit coupling, the two bands of electrons with spin-up and -down are well separated. If the lower band is fully filled, the ground state is fully saturated with a maximal spin, and the system is an insulating ferromagnet. In the presence of the spin–orbit coupling λ the total S_z is no longer conserved. However, the filled band is still ferromagnetic, as the expectation value of S_z is still non-zero. We find that this model has the identical mathematical structure as the Su–Schrieffer–Heeger model, although the bases for the two models are different. It describes a one-dimensional topological ferromagnet.

5.3 *p*-Wave Pairing Superconductor

The *p*-wave pairing spinless superconductor has two distinct phases, strong pairing and weak pairing, which correspond to the topologically trivial and non-trivial phase, respectively [4]. In the Bardeen-Cooper-Schrieffer theory for superconductivity, the effective model for the superconductor can be written as,

$$H = \sum_k \left(\frac{\hbar^2 k^2}{2m} - \mu \right) c_k^\dagger c_k + \Delta_k c_k c_{-k} + h.c., \qquad (5.17)$$

where μ is the chemical potential to determine the number of electrons. Introducing the Nanbu spinor $(c_k^\dagger, c_{-k})$, one obtains

$$H = \sum_k (c_k^\dagger, c_{-k}) \left[\Delta_k \sigma_x + \frac{1}{2} \left(\frac{\hbar^2 k^2}{2m} - \mu \right) \sigma_z \right] \begin{pmatrix} c_k \\ c_{-k}^\dagger \end{pmatrix}. \qquad (5.18)$$

Here a constant $\frac{1}{2} \sum_k (\frac{\hbar^2 k^2}{2m} - \mu)$ is omitted. For a *p*-wave pairing superconductor, the order parameter for Cooper pairing satisfies $\Delta_k = -\Delta_{-k}$. For simplicity here we take $\Delta_k = \Delta_0 k$. The Berry phase in the ground state is always π for $\mu > 0$ as m is assumed to be positive. In this system, if $\Delta = 0$,

$$H = \frac{1}{2} \sum_k (c_k^\dagger, c_{-k}) \left(\frac{\hbar^2 k^2}{2m} - \mu \right) \sigma_z \begin{pmatrix} c_k \\ c_{-k}^\dagger \end{pmatrix}$$
$$= \sum_k \left(\frac{\hbar^2 k^2}{2m} - \mu \right) c_k^\dagger c_k - \frac{1}{2} \sum_k \left(\frac{\hbar^2 k^2}{2m} - \mu \right), \qquad (5.19)$$

the two states with eigenvalues $\pm \frac{1}{2} (\frac{\hbar^2 k^2}{2m} - \mu)$ actually correspond to one state. This is because the basis in the term of the spinors is redundant. This so-called particle-hole symmetry persists even when $\Delta \neq 0$.

On a lattice, k and k^2 can be replaced by $\sin k$ and $4 \sin^2 \frac{k}{2}$. The effective model becomes

$$H = \sum_k (c_k^\dagger, c_{-k}) \left[\Delta_0 \sin k \sigma_x + \left(t + 4t' \sin^2 \frac{k}{2} \right) \sigma_z \right] \begin{pmatrix} c_k \\ c_{-k}^\dagger \end{pmatrix}. \qquad (5.20)$$

The energy eigenvalues of the quasi-particles always appear in pairs,

$$E_{\pm,k} = \pm \sqrt{\Delta_0^2 \sin^2 k + \left(t + 4t' \sin^2 \frac{k}{2} \right)^2}. \qquad (5.21)$$

Performing the Fourier transformation, one obtains a lattice model in real space, which is the one-dimensional Kitaev model for Majorana fermions.

When the system has an open boundary condition in a topologically non-trivial phase, there exists an energy zero mode near the boundary, which satisfies

$$\gamma^\dagger (E = 0) = \gamma (E = 0). \qquad (5.22)$$

Thus, the creation operator of the zero mode is equal to its annihilation operator. This particle is called a Majarona fermion. Due to the particle-hole symmetry, these two states actually correspond to one state after the particle-hole transformation. Thus, the ground states are doubly degenerate depending on whether the zero energy mode is occupied or not. As the Cooper pairing term in the effective Hamiltonian creates or annihilates the electrons in pairs, the number parity of electrons is always conserved. The occupancy of the zero mode changes the number parity of the system.

The p-wave pairing superconductor and the Su–Schrieffer–Heeger model are connected through a partial particle-hole transformation [5]. Performing a particle-hole transformation for electrons on the site B,

$$c_{B,n} \rightarrow c_{B,n}^{\dagger}, \tag{5.23}$$

the Su–Schrieffer–Heeger model in (5.1) is transformed into

$$H = \sum_{n=1}^{N}(t + \delta t)c_{A,n}^{\dagger}c_{B,n}^{\dagger} + \sum_{n=1}^{N-1}(t - \delta t)c_{A,n+1}^{\dagger}c_{B,n}^{\dagger} + h.c., \tag{5.24}$$

which is a model for the p-wave pairing superconductor on a lattice [6]. A solution for the end states of the lattice model in terms of Majorana fermions can be found in Sect. 10.2.2.

5.4   Ising Model in a Transverse Field

The one-dimensional Ising model with a transverse field is equivalent to a spinless p-wave pairing superconductor under the Jordan–Wigner transformation. The model is defined as

$$H = J \sum_{n=1}^{N-1} \sigma_{x,n}\sigma_{x,n+1} + h \sum_{n=1}^{N} \sigma_{z,n}, \tag{5.25}$$

where N is the number of lattice sites.

When $|J| >> |h|$, the ground state is determined by the first term. It is antiferromagnetic if $J > 0$, and ferromagnetic if $J < 0$. The magnetization is along the x-direction and the ground state is doubly degenerate. If $|h| >> |J|$ the ground state is ferromagnetic along the z-direction, and is non-degenerate. The doubly degeneracy and non-degeneracy of the ground state means two distinct states. Thus, a change in the degeneracy of the ground state reveals a quantum phase transition at $J = h$.

For a lattice with an even number of lattice sites, under the Jordan–Wigner transformation [7],

$$\sigma_n^+ = \sigma_{x,n} + i\sigma_{y,n} = \exp\left[-i\pi \sum_{k=1}^{n-1} f_k^{\dagger} f_k\right] f_n^{\dagger}, \tag{5.26}$$

$$\sigma_n^- = \sigma_{x,n} - i\sigma_{y,n} = \exp\left[+i\pi \sum_{k=1}^{n-1} f_k^{\dagger} f_k\right] f_n^{\dagger}, \tag{5.27}$$

$$\sigma_{z,n} = 2f_n^{\dagger} f_n - 1, \tag{5.28}$$

where $f_n^\dagger$ and f_n are the fermion operators and satisfy the anticommutation relation of $\{f_n^\dagger, f_{n'}\} = \delta_{n,n'}$. In this way, the model is reduced to a model for a p-wave pairing superconductor or the Kitaev's toy model for Majorana fermions,

$$H = J \sum_i (f_n^+ - f_n)(f_{n+1}^\dagger + f_{n+1}) + h \sum_i (2 f_n^\dagger f_n - 1). \tag{5.29}$$

The ground state is doubly degenerate due to the existence of the end states when $J < h$. However, it is noted that the Jordan–Wigner transformation is a non-local transformation. The ground states in the Ising model simply have different polarizations along the x-direction, not the end states.

5.5 One-Dimensional Maxwell's Equations in Media

A one-dimensional plane electromagnetic wave of the frequency ω in a nonconducting media can be described by the Maxwell's equations [8],

$$\partial_x E_y = -i\omega\mu(x)H_z \tag{5.30}$$

and

$$\partial_x H_z = -i\omega\epsilon(x)E_y. \tag{5.31}$$

E_y is the electric field and $H_z = \frac{1}{\mu_0}B_z - M_z$ is the magnetic field. ϵ is the electric permittivity and μ is the magnetic permeability, which are functions of position.

To derive a Dirac-like equation for the electromagnetic wave, we introduce dimensionless fields, $e = E_y/E_0$ and $h = H_z/H_0$, where E_0 and H_0 are the field units for the electric and magnetic fields, respectively, and can be determined by the incident wave, i.e, $E_0/H_0 = 1/c\epsilon_0 = c\mu_0$ in the vacuum. Equations (5.30) and (5.31) can be combined to form a matrix equation,

$$-i\sigma_x\partial_x \begin{pmatrix} e \\ h \end{pmatrix} = \left(-\frac{k}{2}(\tilde{\mu} + \tilde{\epsilon}) + \frac{k}{2}(\tilde{\mu} - \tilde{\epsilon})\sigma_z\right) \begin{pmatrix} e \\ h \end{pmatrix}, \tag{5.32}$$

where $k = \omega/c$, $\tilde{\epsilon}(x) = \epsilon(x)/\epsilon_0$, and $\tilde{\mu} = \mu(x)/\mu_0$. The dimensionless permittivity $\tilde{\epsilon}(x)$ and permeability $\tilde{\mu}(x)$ satisfy the relation $\tilde{\epsilon}\tilde{\mu} = n(x)$ where $n(x)$ is the index of refraction. In this way we obtain a Dirac-like equation for the electromagnetic wave

$$\left[-i\sigma_x\partial_x + m(x)\sigma_z + V(x)\right] \begin{pmatrix} e \\ h \end{pmatrix} = E \begin{pmatrix} e \\ h \end{pmatrix}. \tag{5.33}$$

Here the mass distribution $m(x) = \frac{k}{2}(\tilde{\epsilon} - \tilde{\mu})$, and the potential $V(x) - E = \frac{k}{2}(\tilde{\epsilon} + \tilde{\mu})$. This equation looks like the stationary Dirac equation with the eigenvalue E ($\hbar = c = 1$).

In a metamaterial with subwavelength resonant unit cells, both ϵ and μ can be tuned, and can even change their signs [9]. From this equation, it is possible to simulate the topological phase by performing the microwave experiment in meta-materials. For example, design a sample with an interface with $m(x) > 0$ if $x > 0$ and $m(x) < 0$ if $x < 0$. It is required that $E = V(x) = 0$. It follows from (5.33) that we may have a solution that is distributed around the interface as in the case of a domain wall, as shown in Fig. 2.1. Furthermore if we design a periodic structure for $m(x)$, it is possible to have a solution for the end states, as we plotted in Fig. 2.3. In this way, the topological phase can be observed in quasi-one-dimensional periodic metamaterial [10]. This provides a platform for observing topological excitations in one dimension.

5.6 Summary

The re-examination of the Su–Schrieffer–Heeger model demonstrates that polyacety-lene actually has two distinct topological phases. The domain wall of these two phases constitutes the topological excitations or charge and spin carriers in the system. Also the Dirac equation in different bases may be applied to describe topological phases in different physical systems such as a dimerized lattice model, a ferromagnet with spin–orbit coupling, and a superconductor.

Chapter 6
Quantum Anomalous Hall Effect and Quantum Spin Hall Effect

Abstract A quantum anomalous Hall system possesses chiral edge states around its boundary, giving rise to quantized Hall conductance even in the absence of external magnetic field. Quantum spin Hall effect is a spin version of quantum Hall effect. A quantum spin Hall system possesses a pair of helical edge states, in which an electric current can induce a transverse spin current or a spin accumulation near the system boundary. It is also called two-dimensional topological insulator.

6.1 Quantum Anomalous Hall Effect

6.1.1 Two-Dimensional Dirac Model and the Chern Number

In two dimensions, the Chern number or TKNN number is associated with the quantum Hall conductance in the band insulators. We first focus on the Chern number in the two-dimensional Dirac equation in (2.45), in which time reversal symmetry is broken. The Hamiltonian can be written in a compact form,

$$H = \mathbf{d}(\mathbf{p}) \cdot \sigma, \tag{6.1}$$

where $d_x = v p_x$, $d_y = v p_y$ and $d_z = m v^2 - B p^2$. Using the formula in (A.33), the Chern number is given by

$$n_c = -\frac{1}{2} \left(sgn(m) + sgn(B) \right). \tag{6.2}$$

From this formula, we have topological non-trivial phase with $n = \pm 1$ for $mB > 0$, and a topologically trivial phase with $n = 0$ for $mB < 0$. We also have two marginal phases with $n = \pm\frac{1}{2}$ for $m = 0$ or $B = 0$. The case of $B = 0$ is a marginal phase. At the junction of two systems with a positive mass and a negative mass, the topological invariant changes by $\delta n = 1$ or -1. Thus, there exists a boundary state at the junction.

For the gapless Dirac fermions $m = 0$ and $B \neq 0$, the system is also marginal. The topological invariant also changes by $\delta n = 1$ at the interface between a positive and a negative B.

In the lattice model in (3.41), using the formula for the Chern number in (A.33), one obtains

$$n_c = \begin{cases} 1 & if \ 0 < \Delta/B < 4 \\ -1 & if \ 4 < \Delta/B < 8 \end{cases}. \tag{6.3}$$

The number is always an integer, as the first Brillouin zone is finite and periodic for a lattice model. There exist three transition points: the first point is at $\Delta/B = 0$ for a transition from $n_c = 0$ to $n_c = 1$; the second point is at $\Delta/B = 4$ for a transition from $n_c = 1$ to $n_c = -1$; and the third point is at $\Delta/B = 8$ for a transition from $n_c = -1$ to $n_c = 0$. It is noted that the transition at $\Delta/B = 4$ is between two topological phases with $n_c = 1$ and -1.

A non-zero Chern number indicates the existence of quantum Hall conductance. Therefore, the two-dimensional Dirac equation is a good starting point for studying the quantum anomalous Hell effect in ferromagnetic insulator with spin-orbit coupling.

6.1.2 Haldane Model

In 1988 Haldane proposed a spinless fermion model for the integer quantum Hall effect without Landau levels, in which two independent effective Hamiltonians in the form as in the two-dimensional Dirac equation were obtained [1]. He proposed that the quantum Hall effect may result from the broken time reversal symmetry with no net magnetic flux through the unit cell of a periodic two-dimensional graphite or graphene model, as depicted in Fig. 6.1. The lattice is bipartite with A (black) and B (white) sublattice sites. A real hopping term t_1 between the nearest neighbor sites (solid line) and t_2 between the next nearest neighbor sites (dashed line) are considered. On-site energies of $+M$ on A sites and $-M$ on B sites are included to break the inversion symmetry on the A and B sublattices. In addition he added a periodic magnetic flux density $\mathbf{B}(r)$ normal to the plane with the full symmetry of the lattice and with no flux through the unit cell, that is, the flux ϕ_a in the region a and the flux ϕ_b in the region b have the relation $\phi_a = -\phi_b$. As the closed path of the nearest neighbor hops enclose a complete unit cell, but the net flux is zero, the hopping terms t_1 are not affected, but the hopping terms t_2 acquire a phase $\phi = 2\pi(2\phi_a + \phi_b)/\phi_0$ where the flux quantum $\phi_0 = h/e$. The hopping direction is indicated when the amplitudes are $t_2 \exp[i\phi]$.
Fig. 6.1 Haldane's honey-comb model. The *white* and *black dots* represents the two sublattice sites with different on-site energy. The areas a and b are threaded by the magnetic flux ϕ_a and $\phi_b = -\phi_a$, respectively. The area c has no flux

To diagonalize the Hamiltonian, a two-component spinor $\left(c_{k,A}^\dagger, c_{k,B}^\dagger\right)$ of Bloch states constructed on the two sublattices is applied. Let $(\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3)$ be the displacements from a B site to its three adjacent A sites. In this representation the model Hamiltonian can be expressed as

$$H = \epsilon(k) + \mathbf{d}(k) \cdot \sigma, \tag{6.4}$$

where

$$\epsilon(k) = 2t_2 \cos\phi \sum_{i=1,2,3} \cos(\mathbf{k} \cdot \mathbf{b}_i), \tag{6.5}$$

$$d_x(k) = +t_1 \sum_i \cos(\mathbf{k} \cdot \mathbf{a}_i), \tag{6.6}$$

$$d_y(k) = +t_1 \sum_i \sin(\mathbf{k} \cdot \mathbf{a}_i), \tag{6.7}$$

$$d_z(k) = M - 2t_2 \sin\phi \left(\sum_{i=1,2,3} \sin(\mathbf{k} \cdot \mathbf{b}_i) \right) \tag{6.8}$$

with $\mathbf{b}_1 = \mathbf{a}_2 - \mathbf{a}_3$, $\mathbf{b}_2 = \mathbf{a}_3 - \mathbf{a}_1$ and $\mathbf{b}_3 = \mathbf{a}_1 - \mathbf{a}_2$. The Brillouin zone is a hexagon rotated $\pi/2$ with respect to the Wigner-Seitz unit cell. At its six corners $(\mathbf{k} \cdot \mathbf{a}_1, \mathbf{k} \cdot \mathbf{a}_2, \mathbf{k} \cdot \mathbf{a}_3)$ is a permutation of $(0, 2\pi/3, 4\pi/3)$. Two distinct corners $\mathbf{k}_\alpha^0$ are defined such that $\mathbf{k}_\alpha^0 \cdot b_i = \alpha \frac{2\pi}{3}$ with $\alpha = \pm 1$. The energy spectra are easily obtained by diagonalizing the 2×2 matrix. There are two bands, which only touch if all three Pauli matrix terms have vanishing coefficients. This can only occur at

the zone corner $\mathbf{k}_\alpha^0$ and only if $M = \alpha 3\sqrt{3}t_2 \sin\phi$. Assume $|t_2/t_1| < 1/3$, which guarantees that the two bands never overlap, and are separated by a finite gap unless they touch. At the point $\mathbf{K}$, $(\mathbf{K} \cdot \mathbf{a}_1, \mathbf{K} \cdot \mathbf{a}_2, \mathbf{K} \cdot \mathbf{a}_3) = (0, 2\pi/3, -2\pi/3)$. Near the point, we expand the Hamiltonian up to the linear order in $\delta\mathbf{k} = \mathbf{k} - \mathbf{K}$. As a result,

$$H_+ = v(\delta k_x \sigma_x - \delta k_y \sigma_y) + m_+ v^2 \sigma_z, \tag{6.9}$$

where $v = \frac{3}{2}t_1 a/\hbar$ and $m_+ v^2 = M - 3\sqrt{3}t_2 \sin\phi$. At another point $\mathbf{K}'$, $(\mathbf{K}' \cdot \mathbf{a}_1, \mathbf{K}' \cdot \mathbf{a}_2, \mathbf{K}' \cdot \mathbf{a}_3) = (0, -2\pi/3, +2\pi/3)$,

$$H_- = v(-\delta k_x \sigma_x - \delta k_y \sigma_y) + m_- v^2 \sigma_z, \tag{6.10}$$

where $v = \frac{3}{2}t_1 a/\hbar$ and $m_- v^2 = M + 3\sqrt{3}t_2 \sin\phi$. The two Hamiltonians have different chirality when $m_\pm = 0$.

To compare H_+ and H_-, we make a transformation for σ in H_-,

$$(\sigma_x, \sigma_y, \sigma_z) \rightarrow (-\sigma_x, \sigma_y, -\sigma_z). \tag{6.11}$$

Thus, H_- can be written as

$$H_- = v(\delta k_x \sigma_x - \delta k_y \sigma_y) + \tilde{m}_- v^2 \sigma_z \tag{6.12}$$

with $\tilde{m}_- = -m_- = -M - 3\sqrt{3}t_2 \sin\phi$. Therefore the effective models near the two points have the form:

$$H_\alpha = v(\delta k_x \sigma_x - \delta k_y \sigma_y) + \tilde{m}_\alpha v^2 \sigma_z, \tag{6.13}$$

where $\tilde{m}_\alpha = \alpha M - 3\sqrt{3}t_2 \sin\phi$. Clearly, inclusion of M in the graphene lattice opens the opposite energy gaps M and $-M$ at $\mathbf{K}$ and $\mathbf{K}'$, respectively, while the magnetic flux opens the same energy gap at the two points. This demonstrates that the on-site energy $\pm M$ and a magnetic flux play different roles in opening the energy gap, and they generate different topological results.

The Chern number of the whole system is determined by

$$n_c = \frac{1}{2}\left[sgn(\tilde{m}_+) + sgn(\tilde{m}_-)\right]. \tag{6.14}$$

In the absence of magnetic flux, the Chern number is always zero, as the gaps at $\mathbf{K}$ and $\mathbf{K}'$ have opposite signs while it can be $+1$ or -1 in the presence of magnetic flux.

Of course, the topology of the system should be determined by the whole band structure. In his pioneering paper, Haldane used the Streda formula to calculate the Hall conductance [2],
Fig. 6.2 Phase diagram of the Haldane model for $|t_2/t_1| < 1/3$. The zero-field quantum Hall effect phases where $\sigma_{xy} = n_c e^2/h$ occur if $|M/t_2| < 3\sqrt{3}\,|\sin\phi|$

$$\sigma_H = \left.\frac{\partial\rho}{\partial B_z}\right|_\mu, \tag{6.15}$$

which shows the variation in the density of charge carriers ρ with respect to the external field B_z perpendicular to the plane for a fixed chemical potential μ. For a full and complete calculation, we can use the formula in (A.33) to calculate the Chern number, which gives $+1$, 0 or -1. The Hall conductance is expressed in terms of the Chern number $\sigma_{xy} = n_c \frac{e^2}{h}$, which depicts a phase diagram shown in Fig. 6.2.

6.1.3 Experimental Realization

In 2013, the quantum anomalous Hall effect was observed experimentally in a $Cr_{0.15}(Bi_{0.1}Sb_{0.9})_{1.85}Te_3$ ultrathin film by a group led by Xue in Beijing [3]. The measured Hall conductance exhibits a quantized plateau while the longitudinal conductance decreases drastically at lower temperatures. The effect was later confirmed in a series of independent experiments with high precisions. Theoretically, it was first predicted that quantum anomalous Hall effect could be realized in thin film of magnetically doped topological insulators such as Cr or Fe doped Bi_2Te_3 and Sb_2Te_3 [4].

An effective model for a ferromagnetic ultrathin film consists of two parts,

$$H = H_0 + \frac{m}{2}\tau_0 \otimes \sigma_z. \tag{6.16}$$

m is the exchange field from the magnetic dopants [4], which acts effectively like a Zeeman field. τ_0 is a 2×2 unit matrix, and H_0 is the effective model for topological insulator thin film [5, 6]

$$
H_0 = -Dk^2
$$
$$
+ \begin{pmatrix}
\frac{\Delta}{2} - Bk^2 & i\gamma k_- & V & 0 \\
-i\gamma k_+ & -\frac{\Delta}{2} + Bk^2 & 0 & V \\
V & 0 & -\frac{\Delta}{2} + Bk^2 & i\gamma k_- \\
0 & V & -i\gamma k_+ & \frac{\Delta}{2} - Bk^2
\end{pmatrix},
$$
(6.17)

where (k_x, k_y) is the wave vector, $k^2 = k_x^2 + k_y^2$. The D term breaks the particle-hole symmetry, and the band gap opening requires $|D| < |B|$. Δ is the hybridization of top and bottom surface states of the thin film, which becomes relevant for thin films, e.g., Bi_2Se_3 thinner than 5 nm. Both Δ and B are functions of the thickness of thin film, and approach zero simultaneously for a thicker film. $\gamma = v\hbar$, with v the effective velocity. V measures the structure inversion asymmetry between the top and bottom surfaces of the thin film, which is a natural starting point for a realistic thin film grown on a substrate, which always induces an electric field along the film growth direction. The derivation of H_0 can be found in Sect. 7.7.

It is noted that the four bands are coupled through the term V of the structural inversion asymmetry. This model is different from Haldane model. Under a unitary transformation, the Hamiltonian can be diagonalized into two 2×2 blocks [7]

$$
h_s = -Dk^2 + \sigma_z (\Gamma + s\Lambda) + s\gamma(k_x\sigma_y - k_y\sigma_x) \cos \Theta,
$$
(6.18)

where $s = \pm 1$ for the outer and inner blocks, respectively. The model parameters are

$$
\Gamma = \sqrt{(m/2)^2 + \gamma^2 k^2 \sin^2 \Theta},
$$
(6.19)

$$
\Lambda = \sqrt{(\Delta/2 - Bk^2)^2 + V^2},
$$
(6.20)

$$
\cos \Theta = (\Delta/2 - Bk^2)/\Lambda.
$$
(6.21)

For a small k, it reads

$$
h_s = \sigma_z \left(\frac{|m|}{2} + s\sqrt{\Delta^2 + V^2} \right) + \frac{s\gamma\Delta}{\sqrt{\Delta^2 + V^2}} (k_x\sigma_y - k_y\sigma_x),
$$
(6.22)

which is a massive Dirac equation. For $s = +1$, the energy gap between the bands is $|m| + \sqrt{\Delta^2 + 4V^2}$, which is always positive. For $s = -1$, the energy gap between the bands is $|m| - \sqrt{\Delta^2 + 4V^2}$. Without m, the inner bands and outer bands touch at
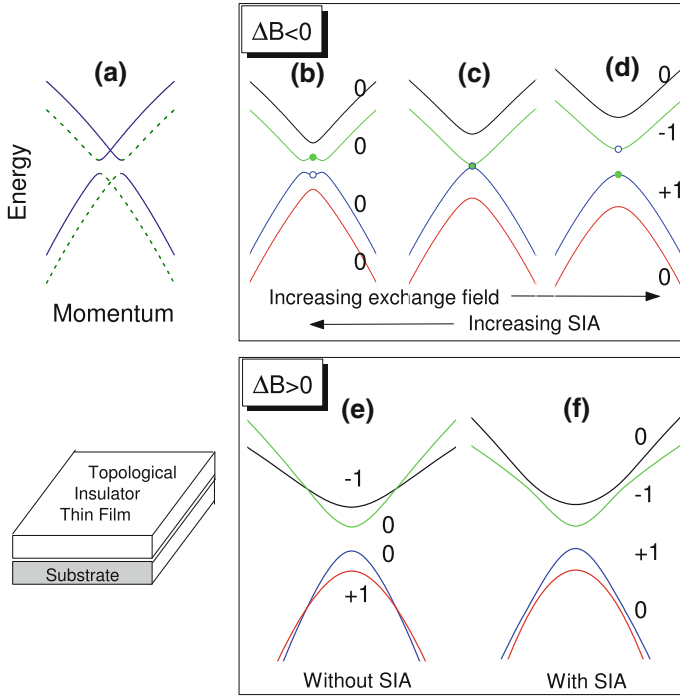

Fig. 6.3 a *Solid* and *dashed curves* depict the *top* and *bottom* surface states, respectively, of a thin film of topological insulator before magnetic doping. (**b–d**) The exchange field from magnetic dopants can lift the degeneracies at $k = 0$ and induce a band inversion, whereas structure inversion asymmetry is competing against the exchange field. **d** No band crossing if $\Delta B < 0$. **e** Band crossings are expected if the band inversion is achieved by doping a thin film with $\Delta B > 0$. **f** SIA can turn the band crossings to anti-crossings while exchange the topological properties between inner and outer bands. $0, \pm 1$ indicate the contribution to σ_{xy} (Chern number) of a band if the band is fully occupied (Adapted from [7])

$k = 0$ as shown in Fig. 6.3a. A finite m can lift the degeneracies at $k = 0$ as plotted in Fig. 6.3b. Increasing m then produces a band inversion when

$$|m| = \sqrt{\Delta^2 + 4V^2} \tag{6.23}$$

and change their topological properties from trivial to nontrivial or vice versa as shown in Fig. 6.3c, d. It is found that a large exchange field m always gives arise to a topological phase transition to quantum anomalous Hall effect once the gap closes and reopens.

The Hall conductance can be given by the integral of the Berry curvature over occupied states in momentum space, and the longitudinal conductivity can be given by the Einstein relation. The calculated Hall and longitudinal conductances are in good agreement with the experimental data as shown in Fig. 6.4.

Fig. 6.4 Calculated Hall (*square*) and longitudinal (*circle*) conductances. The energy-related parameters are up to a scaling compared to the experiment. *Inset* the Hall and longitudinal conductances measured in the experiment (Adapted from [7])
6.2 From the Haldane Model to the Kane-Mele Model

The Haldane model is for spinless fermions. One can generalize the Haldane model to an electron system with spin, which becomes doubly degenerate if there is no coupling between the electrons with spin up and spin down. The electrons in the edge channel are chiral, i.e., they flow around the boundary in a counterclockwise for $n_c = 1$ and in a clockwise direction for $n_c = -1$, which is characteristic of quantum Hall effect. This is a trivial generalization. In 2005 Kane and Mele [8] generalized the Haldane model to the graphene lattice model of electrons with spin $\frac{1}{2}$. They introduced the spin-orbit coupling between electron-spin and momentum to replace the periodic magnetic flux, and predicted a new quantum phenomenon— the quantum spin Hall effect. Simply speaking, the quantum spin Hall effect can be regarded as the combination of the two layers of the Haldane models for electrons with spin up and down. In a system with the time reversal symmetry, the electrons with spin up in the edge channel flow in one direction while electrons with spin down in the edge channel flow in the opposite direction, $I_\uparrow = -I_\downarrow$. The net charge current in the two edge channels must zero, $I_c \equiv I_\uparrow + I_\downarrow = 0$, as a net charge current breaks the time reversal symmetry. In constrast a pure spin current circulates around the boundary of the system, $I_s \equiv \frac{\hbar}{2e}(I_\uparrow - I_\downarrow)$. Unlike the quantum Hall effect in which the magnetic field breaks the time reversal symmetry, the spin-orbit coupling preserves the time reversal symmetry. The spin current itself does not break the symmetry, as the momentum $p \to -p$ and spin $\sigma \to -\sigma$ under the time reversal. However, it is noted that the spin-orbit coupling mixes the spin up and down, and the spin $\mathbf{S}_z$ is no longer a good quantum number. It is necessary to point out that generalization from quantum Hall effect to quantum spin Hall effect is revolutionary. It opens a new field to explore novel topological phases of matter.

The Kane-Mele model for the quantum spin Hall effect is a graphene model with the time reversal invariant spin-orbit coupling,

$$H = t \sum_{\langle i,j \rangle} c_i^\dagger c_j + i\lambda_{SO} \sum_{\langle\langle i,j \rangle\rangle} \nu_{ij} c_i^\dagger s_z c_j + i\lambda_R \sum_{\langle i,j \rangle} c_i^\dagger (\mathbf{s} \times \mathbf{d}_{ij}) c_j + \lambda_v \sum_i \xi_i c_i^\dagger c_i.$$

$$(6.24)$$

The first term is the nearest neighbor hopping term on a graphene lattice, where $c_i^\dagger = (c_{i,\uparrow}^\dagger, c_{i,\downarrow}^\dagger)$. The second term is a mirror symmetric spin-orbit interaction, which involves spin-dependent second neighbor hopping. Here $\nu_{ij} = \frac{2}{\sqrt{3}} (\mathbf{d}_i \times \mathbf{d}_j)_z = \pm 1$, where $\mathbf{d}_1$ and $\mathbf{d}_2$ are two unit vectors along the two bonds that the electron traverses going from site j to i. The Pauli matrices $\mathbf{s}_i$ describe the electron spin. The third term is the nearest neighbor Rashba term, which explicitly violates the $z \to -z$ mirror symmetry. The last term is a staggered sublattice potential with $\xi_i = \pm 1$. Inclusion of the Rashba term makes the system more complicate as s_z is no longer conserved and the electrons with spin up and down are coupled together. Thus, Kane-Mele model is not a simply addition of two layers of the Haldane model for electrons with spin up and down.

Following the method in the Haldane model, a four-band Hamiltonian can always be expressed in terms of the Dirac Gamma matrices:

$$H(k) = \sum_{a=1}^{5} d_a(k) \Gamma^a + \sum_{a<b=1}^{5} d_{ab}(k) \Gamma^{ab}. \qquad (6.25)$$

Here the 5 Dirac matrices are

$$\Gamma^a = (\sigma_x \otimes s_0, \sigma_z \otimes s_0, \sigma_y \otimes s_x, \sigma_y \otimes s_y, \sigma_y \otimes s_z) \qquad (6.26)$$

($a = 1, 2, 3, 4, 5$), where the Pauli matrices σ_i represent the sublattice indices and

$$\Gamma^{ab} = \frac{1}{2i} [\Gamma^a, \Gamma^b]. \qquad (6.27)$$

In this representation the time reversal operator is $\Theta = i(\sigma_0 \otimes s_y,)K$. The five Dirac matrices are even under time reversal,

$$\Theta \Gamma^a \Theta^{-1} = \Gamma^a \qquad (6.28)$$

while the 10 commutators are odd,

$$\Theta \Gamma^{ab} \Theta^{-1} = -\Gamma^{ab}. \qquad (6.29)$$

To have a time reversal invariant Hamiltonian, the coefficients should satisfy the relations,

$$d_\alpha(-k) = d_\alpha(k) \qquad (6.30)$$

and

$$d_{ab}(-k) = -d_{ab}(k). \tag{6.31}$$

Thus, the coefficients in the Kane-Mele model are

$$d_1 = t \left(1 + 2 \cos \frac{k_x}{2} \cos \frac{\sqrt{3}k_y}{2} \right); \tag{6.32}$$

$$d_2 = \lambda_v; \tag{6.33}$$

$$d_3 = \lambda_R \left(1 - \cos \frac{k_x}{2} \cos \frac{\sqrt{3}k_y}{2} \right); \tag{6.34}$$

$$d_4 = -\sqrt{3}\lambda_R \sin \frac{k_x}{2} \sin \frac{\sqrt{3}k_y}{2}; \tag{6.35}$$

$$d_{12} = -2t \cos \frac{k_x}{2} \sin \frac{\sqrt{3}k_y}{2}; \tag{6.36}$$

$$d_{15} = \lambda_{SO} \left(2 \sin k_x - 4 \sin \frac{k_x}{2} \cos \frac{\sqrt{3}k_y}{2} \right); \tag{6.37}$$

$$d_{23} = -\lambda_R \cos \frac{k_x}{2} \sin \frac{\sqrt{3}k_y}{2}; \tag{6.38}$$

$$d_{24} = \sqrt{3}\lambda_R \sin \frac{k_x}{2} \sin \frac{\sqrt{3}k_y}{2}. \tag{6.39}$$

This equation gives two pairs of doubly degenerated energy dispersions. When the two lower energy bands are fully occupied, the system becomes insulating if an energy gap exists between the two upper bands and two lower bands. As the whole system does not break the time reversal symmetry, the Chern number is always zero. For $\lambda_R = 0$, the Hamiltonian is split into two independent parts,

$$H = \sum_{s=\uparrow,\downarrow} H_s, \tag{6.40}$$

where

$$H_s = t \sum_{\langle i,j \rangle} c_{i,s}^\dagger c_{j,s} + is\lambda_{SO} \sum_{\langle\langle i,j \rangle\rangle} \nu_{ij} c_{i,s}^\dagger c_{j,s} + \lambda_v \sum_i \xi_i c_{i,s}^\dagger c_{i,s}. \tag{6.41}$$

In this case there is an energy gap with the magnitude $\left| 6\sqrt{3}\lambda_{SO} - 2\lambda_v \right|$. For $\lambda_v > 3\sqrt{3}\lambda_{SO}$ the gap is dominated by λ_v, while for $\lambda_v < 3\sqrt{3}\lambda_{SO}$ the gap is dominated by λ_{SO}. For each H_s, we can define a spin dependent Chern number. For $\lambda_v > 3\sqrt{3}\lambda_{SO}$ the corresponding Chern number is zero for both $H_\uparrow$ and $H_\downarrow$. However, for $\lambda_v < 3\sqrt{3}\lambda_{SO}$ the corresponding Chern number becomes nonzero,
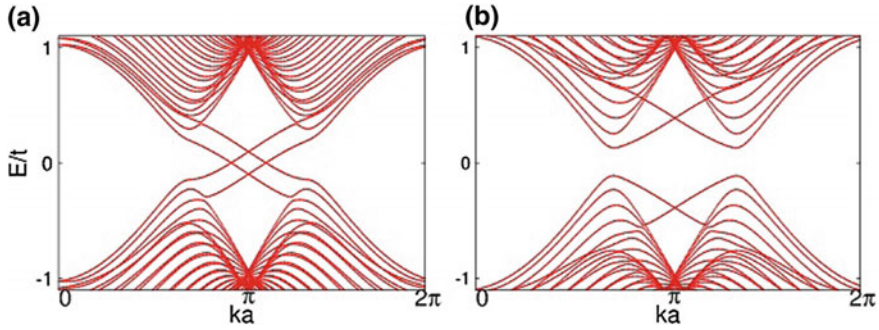

Fig. 6.5 Energy bands for a one-dimensional stripe with a zig-zag boundary condition. **a** Quantum spin Hall phases with $\lambda_v = 0.1t$. **b** Insulating phase with $\lambda_v = 0.4t$. In both cases $\lambda_{SO} - 0.06t$ and $\lambda_R = 0.05t$

$$n_s = sgn(s\lambda_{SO}). \tag{6.42}$$

Although the total Chern number $n_+ + n_- = 0$, their difference $n_+ - n_- = 2$ or -2. Thus, for $\lambda_v < 3\sqrt{3}\lambda_{SO}$ it is a combination of two independent quantum Hall phases with different chirality, *i.e.*, the quantum spin Hall system [9].

For $\lambda_R \neq 0$ the electrons with spin up and spin down will mix together, and we cannot separate the whole system into two independent parts as in the case of $\lambda_R = 0$. In other word, we couldn't introduce a spin-dependent Chern number to describe this new phase. Instead Kane and Mele introduced the Z_2 invariant to describe it.

For a strip sample we adopt the periodic boundary condition in the x-direction such that k_x is a good quantum number. Exact diagonalization gives the energy dispersion of the system as a function of $k_x a$. It is found that there are two distinct phases: (a) a pair of the bands connects the conduction and valence band; (b) no band connects the two bands, as plotted in Fig. 6.5. As the system is insulating and there is an energy gap in the bulk, the bands connecting the conduction and valence bands must be the edge states, which could be confirmed numerically. Thus, we conclude that in the topologically non-trivial phase, we have a pair of edge states between the bulk band gap at each boundary.

6.3 Transport of Edge States

The helical edge states are characteristic of a two-dimensional topological insulator. It can be detected through the transport measurement in a mesoscopic device. Before we discuss the transport properties of the edge states in the quantum spin Hall system, we briefly introduce the Landauer-Büttiker formula for electron transport.

6.3.1 Landauer-Büttiker Formalism

Consider a one-dimensional conductor. Suppose the left side (the source) is filled up to the energy level μ_s, slightly higher than that of the right-hand side (the drain) μ_d. Then in the range between μ_s and μ_d the conductor has fully occupied states poring from left to right. The current through the channel is defined as

$$I = -e v_{eff} \delta N, \tag{6.43}$$

where v_{eff} is the effective velocity of charge carriers along the channel near the Fermi energy and δN is the density of the charge carriers. Assume the voltage difference between two leads is quite small. Then

$$\delta N = D(E_f)(\mu_s - \mu_d), \tag{6.44}$$

where $D(E_f) = \partial N/\partial E|_{E_f}$ is the density of states at the Fermi level, and $D(E_f) \approx D(\mu_s) \approx D(\mu_d)$. In one dimension, the velocity v_{eff} is given by the variance of dispersion with respect to the wave vector $v_{eff} = \partial E(k)/\hbar \partial k$ and the density of states $D(E) = \frac{\partial k/2\pi}{\partial E} = \frac{1}{h v_{eff}}$ and $\mu_s - \mu_d = -e(V_s - V_d)$. As a result, the current through the channel is given by

$$I = \frac{e^2}{h}(V_s - V_d). \tag{6.45}$$

The conductance is

$$G = \frac{I}{V_s - V_d} = \frac{e^2}{h}, \tag{6.46}$$

which is quantized in an ideal one-dimensional conductor.

More generally, Landauer proposed that the conductance of a mesoscopic conductor is given by [10, 11],

$$G = \frac{2e^2}{h} MT, \tag{6.47}$$

where M stands for the number of transverse modes in the conductor, and T is the averaged probability that an electron injected from one end can transmit to the other. The factor 2 comes from the spin degeneracy of the electron. The conductance is then independent of the system's length or width. Assume a conductor is connected to two electron reservoirs through ballistic leads. Then at low temperatures the current flow is caused by motion of the electrons in the energy window $\mu_1 \sim \mu_2$. So the current transmitted from the left lead into the right lead is:

$$I = -\frac{2e}{h} MT(\mu_1 - \mu_2), \tag{6.48}$$

and thus, the conductance is given by the linear response formula $G = I/\delta V$ ($\mu_1 - \mu_2 = -e\delta V$), which is exactly the Landauer formula in (6.47).

It can be shown that the Landauer formula recovers the classic Ohm's law in the large conductor scale limit. For a wide conductor, its conducting mode number is proportional to the width W: $M \propto W$. Assuming the conductor is long, we can prove that its transmission probability is given by:

$$T(L) = \frac{L_0}{L + L_0},\qquad(6.49)$$

where L_0 is a characteristic length, and L is the conductor's length.

Büttiker developed an approach to systematically treat the voltage and current probes in a multiple terminal device [12, 13], which has helped in the interpretation of numerous mesoscopic experimental results since the 1980s. The approach was to extend the two-terminal Landauer formula and to sum over all of the probes. In a multi-terminal device, the current in the ith terminal is given by:

$$I_i = \frac{e}{h} \sum_{j \neq i} [T_{ji}\mu_i - T_{ij}\mu_j],\qquad(6.50)$$

where μ_i is the Fermi energy in the ith probe and is related with the voltage through $V_i = \mu_i/e$, and T_{ij} can be seen as the product of the number of modes and the transmission probability from the jth probe to the ith probe. The summation runs over all of the probes apart from probe i. The above formula can be written in terms of the inter-terminal transmission coefficient T_{ij} as:

$$I_i = \frac{e^2}{h} \sum_{j \neq i} [T_{ji}V_i - T_{ij}V_j].\qquad(6.51)$$

In the equilibrium condition, all the probes have equal voltage and zero current flow. And thus, from the above equation, we must have

$$\sum_{j \neq i} T_{ji} = \sum_{j \neq i} T_{ij},\qquad(6.52)$$

which enables us to rewrite the Büttiker formula in (6.51) in a more straight forward form:

$$I_i = \frac{e^2}{h} \sum_{j \neq i} T_{ij}[V_i - V_j].\qquad(6.53)$$

The Büttiker formula in (6.53) enables us to write the multi-terminal conductance and resistance in the compact forms of matrices. For example, without knowing the specific pattern of a three-terminal device, we know the current and voltage in the terminals are related with a set of equations:

$$\begin{pmatrix} I_1 \\ I_2 \\ I_3 \end{pmatrix} = \frac{e^2}{h} \begin{pmatrix} T_{12} + T_{13} & -T_{12} & -T_{13} \\ -T_{21} & T_{21} + T_{23} & -T_{23} \\ -T_{31} & -T_{32} & T_{31} + T_{32} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \\ V_3 \end{pmatrix}. \tag{6.54}$$

This matrix equation satisfies the law of charge conservation, *i.e.,* the total current flow is conserved, $I_1 + I_2 + I_3 = 0$. Also we know from the Landauer formula as well as the Büttiker formula that it is only the voltage difference between the probes that determines the magnitude of the current. Thus, we can set an arbitrary probe voltage to be 0. For instance, we can set $V_3 = 0$ and this enables us to reduce the matrix dimension by 1:

$$\begin{pmatrix} I_1 \\ I_2 \end{pmatrix} = \frac{e^2}{h} \begin{pmatrix} T_{12} + T_{13} & -T_{12} \\ -T_{21} & T_{21} + T_{23} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \end{pmatrix}. \tag{6.55}$$

The resistance is also in the matrix form, it is related with the conductance matrix through:

$$\begin{pmatrix} R_{11} & R_{12} \\ R_{21} & R_{22} \end{pmatrix} = \frac{h}{e^2} \begin{pmatrix} T_{12} + T_{13} & -T_{12} \\ -T_{21} & T_{21} + T_{23} \end{pmatrix}^{-1}. \tag{6.56}$$

The above approach has become a standard technique to calculating the conductance and resistance in a multi-terminal device.

6.3.2   Transport of Edge States

In the quantum spin Hall system, a pair of helical edge states consists two chiral states of electrons with spin up ($\sigma = \uparrow$) and down ($\sigma = \downarrow$). The transmission coefficient of the chiral state with spin up from one terminal to its neighbor terminal, say, in the clockwise direction is $T_{ij}^{\uparrow} = 1$, and the transmission coefficient from one terminal to its neighbor terminal in the counter-clockwise direction is $T_{ji}^{\uparrow} = 0$. Meanwhile the transmission coefficient of the chiral state with spin down from one terminal to its neighbor terminal in the clockwise direction is $T_{ij}^{\downarrow} = 0$, and the transmission coefficient from one terminal to its neighbor terminal in the counter-clockwise direction is $T_{ji}^{\downarrow} = 1$.

The charge current at terminal i is defined as the summation of the currents with spin up and down

$$I_i^c \equiv I_i^{\uparrow} + I_i^{\downarrow} = \frac{e^2}{h} \sum_{j \neq i, \sigma} (T_{ij}^{\sigma} V_j - T_{ji}^{\sigma} V_i). \tag{6.57}$$

The spin current at terminal i is defined as the difference between the currents with spin up and spin down

$$I_i^s \equiv \frac{\hbar/2}{e}\left(I_i^\uparrow - I_i^\downarrow\right) = \frac{e}{4\pi}\sum_{j\neq i,\sigma}\sigma(T_{ij}^\sigma V_j - T_{ji}^\sigma V_i), \tag{6.58}$$

where we convert the unit of the charge current into that of the spin current: change the unit of charge e into the unit of spin $\hbar/2$ by the ratio $\frac{\hbar/2}{e}$.

Two-terminal measurement: as the edge states are helical, there are two conducting channel to connect the two terminals. The transmission coefficients $T_{12}^\sigma = T_{21}^\sigma = 1$ for electrons with both spin up ($\sigma =\uparrow$) and down ($\sigma =\downarrow$). Take $V_1 = V/2$ and $V_2 = -V/2$. The spin-dependent current flowing out of the terminal 2 is

$$I_2^\uparrow = I_2^\downarrow = \frac{e^2}{h}(V_1 - V_2). \tag{6.59}$$

Thus, the charge conductance is

$$G = G_\uparrow + G_\downarrow = 2\frac{e^2}{h} \tag{6.60}$$

as there are two conducting channels from the left to right. This is equivalent to a quantum Hall conductance for $n = 2$ in a setup with two terminals.

Four-terminal measurement: In this case, the transmission coefficients for an electron with spin up, $T_{43}^\uparrow = T_{32}^\uparrow = T_{21}^\uparrow = T_{14}^\uparrow = 1$, and 0 otherwise, and the transmission coefficients for an electron with spin down, $T_{12}^\downarrow = T_{23}^\downarrow = T_{34}^\downarrow = T_{41}^\downarrow = 1$, and 0 otherwise. From the Landauer-Büttiker formula, we have

$$\begin{pmatrix} I_1^\uparrow \\ I_2^\uparrow \\ I_3^\uparrow \\ I_4^\uparrow \end{pmatrix} = \begin{pmatrix} -1 & 0 & 0 & 1 \\ 1 & -1 & 0 & 0 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 1 & -1 \end{pmatrix}\begin{pmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \end{pmatrix} \tag{6.61}$$

and

$$\begin{pmatrix} I_1^\downarrow \\ I_2^\downarrow \\ I_3^\downarrow \\ I_4^\downarrow \end{pmatrix} = \begin{pmatrix} -1 & 1 & 0 & 0 \\ 0 & -1 & 1 & 0 \\ 0 & 0 & -1 & 1 \\ 1 & 0 & 0 & -1 \end{pmatrix}\begin{pmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \end{pmatrix}. \tag{6.62}$$

The total charge current is the sum of the currents with spin up and down, $I_i = I_i^\uparrow + I_i^\downarrow$. Thus, the equation for the charge current,

$$\begin{pmatrix} I_1 \\ I_2 \\ I_3 \\ I_4 \end{pmatrix} = \frac{e^2}{h} \begin{pmatrix} -2 & 1 & 0 & 1 \\ 1 & -2 & 1 & 0 \\ 0 & 1 & -2 & 1 \\ 1 & 0 & 1 & -2 \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \end{pmatrix}. \tag{6.63}$$

The total spin current in each terminal is the difference between the currents with spin up and down, $I_i^s = \left(I_i^\uparrow - I_i^\downarrow \right) \times \frac{\hbar/2}{e}$,

$$\begin{pmatrix} I_1^s \\ I_2^s \\ I_3^s \\ I_4^s \end{pmatrix} = \frac{e}{4\pi} \begin{pmatrix} 0 & -1 & 0 & 1 \\ 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \\ -1 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \end{pmatrix}. \tag{6.64}$$

Set the voltages at terminal 1 and 3 as $V/2$ and $-V/2$ and as 0 for terminal 2 and 4:

$$\begin{pmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \end{pmatrix} = \begin{pmatrix} \frac{V}{2} \\ 0 \\ -\frac{V}{2} \\ 0 \end{pmatrix}. \tag{6.65}$$

The currents at terminal 2 are

$$I_2^\uparrow = \frac{e^2}{h} T_{21}^\uparrow V_1 = +\frac{e^2}{2h} V \tag{6.66}$$

and

$$I_2^\downarrow = \frac{e^2}{h} T_{23}^\downarrow V_3 = -\frac{e^2}{2h} V. \tag{6.67}$$

As a result, the total current is

$$I_2^c = I_2^\uparrow + I_2^\downarrow = 0. \tag{6.68}$$

However,

$$I_2^s = \left(I_2^\uparrow - I_2^\downarrow \right) \times \frac{\hbar/2}{e} = \frac{e}{4\pi} V. \tag{6.69}$$

Thus, the spin Hall conductance is $G_s = \frac{e}{4\pi}$. However it is noted that the Hall conductance for each sector is

$$G^\uparrow = \frac{I_2^\uparrow}{V_1 - V_3} = \frac{e^2}{2h} \tag{6.70}$$
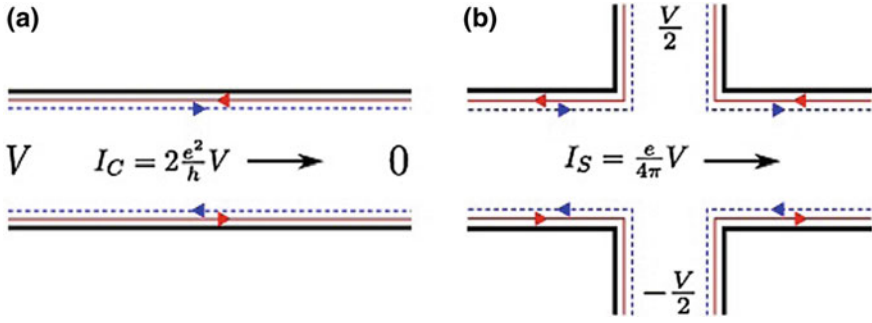

Fig. 6.6 Schematic diagram showing **a** two-terminal and **b** four-terminal measurement geometries. In (**a**) a charge current $I_C = (2e^2/h)V$ flows into the *right lead*. In (**b**) a spin current $I_S = \frac{e}{4\pi}V$ flows into the *right lead*

as we have set the voltages at the four terminals. In conclusion, the quantum spin Hall effect can be measured through the charge transport in a mesoscopic system as shown in Fig. 6.6 [8].

Strictly speaking, spin up and down here mean two different conducting channels of the edge state, NOT a real electron spin. Due to the spin-orbit coupling none of the spin components S_α ($\alpha = x, y, z$) are conserved. So the "real" spin Hall conductance is not quantized.

6.4 Stability of Edge States

Assume the impurity potential V is time reversal invariant. There does not exist backscattering between the two helical edge states. The time reversal operator $\Theta^2 = -1$. Thus, we set $|u_{-k,\downarrow}\rangle = \Theta |u_{k,\uparrow}\rangle$ and $|u_{k,\uparrow}\rangle = -\Theta |u_{-k,\downarrow}\rangle$. The operator Θ is anti-unitary and has the property,

$$\langle \Theta\alpha| V |\Theta\beta\rangle = \langle \beta| V |\alpha\rangle. \tag{6.71}$$

Using this relation it is easy to conclude,

$$\langle u_{k,\uparrow}| V |u_{-k,\downarrow}\rangle = 0. \tag{6.72}$$

Li and Shi proposed a general argument for the robustness of the helical edge state transport [14]. In essence, a two-dimensional quantum spin Hall insulator is a conductor with odd number of the Kramers pairs in the conducting channel. This is different from the ordinary one-dimensional conductor which always has an even number of Kramers pairs in the conducting channel. In general, the transmission

along the conductor can be characterized by a $2N \times 2N$ S matrix, which relates the in-coming (ψ_{in}) and out-coming (ψ_{out}) wave amplitude:

$$\psi_{out} = S\psi_{in}, \tag{6.73}$$

where

$$\psi_{in} = (a_1^+, a_2^+, \ldots, a_N^+; b_1^-, b_2^-, \ldots, b_N^-)^T \tag{6.74}$$

and

$$\psi_{out} = (a_1^-, a_2^-, \ldots, a_N^-; b_1^+, b_2^+, \ldots, b_N^+)^T. \tag{6.75}$$

$a_i^+ (b_i^+)$ and $a_i^- (b_i^-)$ denote the right-going and left-going wave amplitudes, respectively. $a_i^\pm$ or $b_i^\pm$ with the same index i are related by the time reversal and form a Kramers pair. N denotes the total number of Kramers pairs at each edge, and can be odd for the quantum spin Hall insulator or even for an ordinary insulator. In this notation, the time reversal symmetry imposes a constraint on the S matrix:

$$S^T = -S. \tag{6.76}$$

Moreover, the conservation of charge implies that the S matrix must be unitary: $S^\dagger S = 1$.

Under these constraints, the polar decomposition of the S matrix reads [15]

$$S = \begin{pmatrix} U^T & 0 \\ 0 & V^T \end{pmatrix} \begin{pmatrix} \Sigma & T \\ T & \Sigma \end{pmatrix} \begin{pmatrix} U & 0 \\ 0 & V \end{pmatrix}, \tag{6.77}$$

where U and V are the two $N \times N$ unitary matrix. For an even $N = 2n$, Σ is a block diagonal matrix

$$\Sigma = \sqrt{1 - T_1}\sigma_x \oplus \sqrt{1 - T_2}\sigma_x \oplus \cdots \oplus \sqrt{1 - T_n}\sigma_x \tag{6.78}$$

and

$$T = diag[\sqrt{T_1}\sigma_0, \sqrt{T_2}\sigma_0, \cdots, \sqrt{T_n}\sigma_0]. \tag{6.79}$$

For an odd $N = 2n + 1$, Σ is a block diagonal matrix

$$\Sigma = \sqrt{1 - T_1}\sigma_x \oplus \sqrt{1 - T_2}\sigma_x \oplus \cdots \oplus 0_{1 \times 1} \tag{6.80}$$

and

$$T = diag[\sqrt{T_1}\sigma_0, \sqrt{T_2}\sigma_0, \cdots, 1]. \tag{6.81}$$

T_i denotes the transmission coefficient in the ith conducting channel. One immediately sees that for odd N there is at least one conducting channel that has the perfect transmission $T_i = 1$, that is not being adversely affected by the disorder. This is the reason behind the robustness of helical edge states in the quantum spin Hall effect.

According to the Z_2 classification for the time reversal invariant insulating system, there always exist an odd number of Kramers pairs in the conducting edge states along each edge of a sample. However, in the geometry of a strip, there are two edges and the total number of Kramers pairs is still even in the system. The conductance is not really quantized if the interaction or finite size effect makes the channels at two edges coupling together [16].

6.5 Realization of the Quantum Spin Hall Effect in HgTe/CdTe Quantum Wells

In 2006, Bernevig et al. [17] predicted that the HgTe/CdTe quantum well may have an inverted band structure and may exhibit the quantum spin Hall effect. One year later, Konig et al. [18] verified this theoretical prediction experimentally.

6.5.1 Band Structure of HgTe/CdTe Quantum Wells

The band structures of HgTe and CdTe near the Γ point can be described very well by the 6-band bulk Kane model which incorporates the Γ_6 and Γ_8 bands but neglects the split-off Γ_7 band. CdTe has a so-called normal band structure, in which the band Γ_6 of the s-wave electron ($j = \frac{1}{2}$) has a higher energy, and the band Γ_8 ($j = \frac{3}{2}$) has a lower energy. However, HgTe has an inverted band structure, as shown in Fig. 6.7. In order to consider the coupling between the Γ_6 and Γ_8 bands we choose the 6-band basis set [19, 20]:

$$u_1(\mathbf{r}) = \left|\Gamma_6, +\frac{1}{2}\right\rangle_c = S \uparrow, \tag{6.82}$$

$$u_2(\mathbf{r}) = \left|\Gamma_6, -\frac{1}{2}\right\rangle_c = S \downarrow, \tag{6.83}$$

$$u_3(\mathbf{r}) = \left|\Gamma_8, +\frac{3}{2}\right\rangle_v = \frac{1}{\sqrt{2}}(X + iY) \uparrow, \tag{6.84}$$

$$u_4(\mathbf{r}) = \left|\Gamma_8, +\frac{1}{2}\right\rangle_v = \frac{1}{\sqrt{6}}[(X + iY) \downarrow -2Z \uparrow], \tag{6.85}$$

$$u_5(\mathbf{r}) = \left|\Gamma_8, -\frac{1}{2}\right\rangle_v = -\frac{1}{\sqrt{6}}[(X - iY) \uparrow +2Z \downarrow], \tag{6.86}$$
Fig. 6.7 Schematic illustration of the normal band structure and inverted band structure. The *left* is the normal band structure where the *blue curve* represents the light hole (LH) and the heavy hole (HH) of the Γ_8 valence bands, *the right* is the inverted band structure where the LH flips up and becomes the conduction band, the Γ_6 appears below the HH bands (Adapted from [20]) (color figure online)

$$u_6\left(\mathbf{r}\right) = \left|\Gamma_8, -\frac{3}{2}\right\rangle_v = -\frac{1}{\sqrt{2}}\left(X - iY\right)\downarrow. \tag{6.87}$$

For the chosen basis set, the Hamiltonian for a three-dimensional system with [001] growth direction takes the following form:

$$H = \begin{pmatrix} T & 0 & -\frac{1}{\sqrt{2}}Pk_+ & \sqrt{\frac{2}{3}}Pk_z & \frac{1}{\sqrt{6}}Pk_- & 0 \\ 0 & T & 0 & -\frac{1}{\sqrt{6}}Pk_+ & \sqrt{\frac{2}{3}}Pk_z & \frac{1}{\sqrt{2}}Pk_- \\ -\frac{1}{\sqrt{2}}Pk_- & 0 & U+V & -S_- & R & 0 \\ \sqrt{\frac{2}{3}}Pk_z & -\frac{1}{\sqrt{6}}Pk_- & -S_-^\dagger & U-V & 0 & R \\ \frac{1}{\sqrt{6}}Pk_+ & \sqrt{\frac{2}{3}}Pk_z & R^\dagger & 0 & U-V & S_+^\dagger \\ 0 & \frac{1}{\sqrt{2}}Pk_+ & 0 & R^\dagger & S_+ & U+V \end{pmatrix}, \tag{6.88}$$

where

$$k_\parallel^2 = k_x^2 + k_y^2, k_\pm = k_x \pm ik_y, \tag{6.89}$$

$$T = E_c\left(z\right) + \frac{\hbar^2}{2m_0}\left[\left(2F+1\right)k_\parallel^2 + k_z\left(2F+1\right)k_z\right], \tag{6.90}$$

$$U = E_v(z) - \frac{\hbar^2}{2m_0}\left(\gamma_1 k_\parallel^2 + k_z \gamma_1 k_z\right), \tag{6.91}$$

$$V = -\frac{\hbar^2}{2m_0}\left(\gamma_2 k_\parallel^2 - 2k_z \gamma_2 k_z\right), \tag{6.92}$$

$$R = -\frac{\hbar^2}{2m_0}\frac{\sqrt{3}}{2}\left[(\gamma_3 - \gamma_2)k_+^2 - (\gamma_3 + \gamma_2)k_-^2\right], \tag{6.93}$$

$$S_\pm = -\frac{\hbar^2}{2m_0}\sqrt{3}k_\pm\left(\gamma_3 k_z + k_z \gamma_3\right). \tag{6.94}$$

$P = -\frac{\hbar}{m_0}\langle s|\,p_x\,|X\rangle$ is the Kane matrix element between the s and p bands with m_0 the bare electron mass.

The quantum well growth direction is along z with $Hg_{1-x}Cd_xTe$ for $z < -d/2$, HgTe for $-d/2 < z < d/2$, and $Hg_{1-x}Cd_xTe$ for $z > d/2$. As the quantum well is confined along the z-direction, we make the Peierls substitution, $k_z = -i\frac{\partial}{\partial z}$. Now the problem reduces, in the presence of continuous boundary conditions, into the Hamiltonian (6.88) in each of the 3 regions of the quantum well.

The basic technique for deriving an effective Hamiltonian is to start with the Hamiltonian at $k_x = k_y = 0$ and to find the solutions of the wave function of the electrons in the confined quantum well. Then, using the solution of $k_x = k_y = 0$ as the basis, one can derive an effective Hamiltonian for $k_x, k_y \neq 0$ by means of the projected perturbation method.

For $k_x = k_y = 0$,

$$H(k_\parallel = 0) = \begin{pmatrix} T & 0 & 0 & \sqrt{\tfrac{2}{3}}Pk_z & 0 & 0 \\ 0 & T & 0 & 0 & \sqrt{\tfrac{2}{3}}Pk_z & 0 \\ 0 & 0 & U+V & 0 & 0 & 0 \\ \sqrt{\tfrac{2}{3}}Pk_z & 0 & 0 & U-V & 0 & 0 \\ 0 & \sqrt{\tfrac{2}{3}}Pk_z & 0 & 0 & U-V & 0 \\ 0 & 0 & 0 & 0 & 0 & U+V \end{pmatrix}, \tag{6.95}$$

which is reduced to a block diagonalized matrix after re-arranging the basis as $\{u_1, u_4, u_3, u_2, u_5, u_6\}$. On the subsector of $\{u_1, u_4\}$ for $j_z = \frac{1}{2}$,

$$H_{eff} = \begin{pmatrix} T & \sqrt{\tfrac{2}{3}}Pk_z \\ \sqrt{\tfrac{2}{3}}Pk_z & U-V \end{pmatrix}, \tag{6.96}$$

which is a one-dimensional modified Dirac equation. Consider a quantum well potential $V_{qw}(z)$. The model coefficients are different for CdTe at $|z| > d/2$ and HgTe at

$|z| < d/2$. Solving this one-dimensional problem, one obtains a bound state for the quantum well φ_1. Similarly, on the base $\{u_3\}$ of $j_z = \frac{3}{2}$, one obtains a solution for the quantum well φ_2. Use these two states, one can have an effective Hamiltonian near the point of $k \neq 0$,

$$h(k) = (\langle \varphi_1 |, \langle \varphi_2 |) H(k) \begin{pmatrix} |\varphi_1\rangle \\ |\varphi_2\rangle \end{pmatrix}. \tag{6.97}$$

Similarly, (u_2, u_5, u_6) gives two other states. In this way, Bernevig, Hughes and Zhang derived an effective model for a quantum well of HgTe/CdTe [17],

$$H_{BHZ} = \begin{pmatrix} h(k) & 0 \\ 0 & h^*(-k) \end{pmatrix}, \tag{6.98}$$

where $h(k) = \epsilon(k) + A(k_x \sigma_x + k_y \sigma_y) + (M - Bk^2)\sigma_z$.

The model is actually equivalent to the modified two-dimensional Dirac model as shown in (2.45) with the addition of the kinetic term $\epsilon(k)$,

$$h(k) = \epsilon(k) + h_+ \tag{6.99}$$

and

$$h^*(-k) = \epsilon(k) + U h_- U^{-1}, \tag{6.100}$$

where the unitary transformation matrix $U = \sigma_z$. All of the model parameters are functions of the thickness of the quantum well. The most striking property of this system is that the mass or gap parameter M changes sign when the thickness d of the quantum well is varied through a critical thickness d_c (=6.3 nm), associating with the transition of the electronic band structure from a normal to an "inverted" type [21].

If the inclusion of $\epsilon(k)$ does not close the energy gap caused by M for a non-zero B, the system should be insulating in the bulk. There exists a topological phase transition from a positive M to negative M. However, the sign of M alone cannot determine whether the system is topologically trivial or non-trivial. From the formula in (2.52), we know that the system is in a quantum spin Hall phase only for $MB > 0$, and there exists a pair of helical edge states at the boundary of the system.

6.5.2 Exact Solution of Edge States

In this subsection we present an exact solution of the edge state for the Bernevig-Hughes-Zhang model in (6.98), which was first solved by Zhou et al. [16]. Here we consider a semi-infinite plane with an open boundary condition at $y = 0$. In this case, k_x is a good quantum number, and k_y is replaced using the Peierls substitution $k_y = -i\partial_y$. The Hamiltonian is a block-diagonalized one,

$$\mathcal{H}\left(k_x, -i\partial_y\right) = \begin{pmatrix} h_\uparrow\left(k_x, -i\partial_y\right) & 0 \\ 0 & h_\downarrow\left(k_x, -i\partial_y\right) \end{pmatrix}, \tag{6.101}$$

where

$$h_\uparrow\left(k_x, -i\partial_y\right) = \begin{pmatrix} M - B_+\left(k_x^2 - \partial_y^2\right) & A(k_x - \partial_y) \\ A(k_x + \partial_y) & -M + B_-\left(k_x^2 - \partial_y^2\right) \end{pmatrix} \tag{6.102}$$

and

$$h_\downarrow\left(k_x, k_y\right) = \begin{pmatrix} M - B_+\left(k_x^2 - \partial_y^2\right) & -A(k_x + \partial_y) \\ -A(k_x - \partial_y) & -M + B_-\left(k_x^2 - \partial_y^2\right) \end{pmatrix}, \tag{6.103}$$

with $B_\pm = B \pm D$. The upper $h_\uparrow$ and lower $h_\downarrow$ blocks describe the states of spin up (strictly speaking, it is the sector of $j_z = \frac{1}{2}$ and $\frac{3}{2}$) and spin down (the sector of $j_z = -\frac{1}{2}$ and $-\frac{3}{2}$), respectively.

The eigenvalue problem of the upper and lower blocks can be solved separately. Here we focus on the solution for the upper block of this Hamiltonian,

$$h_\uparrow \Psi_\uparrow = E\Psi_\uparrow. \tag{6.104}$$

We take the trial wave function

$$\Psi_\uparrow = \begin{pmatrix} c \\ d \end{pmatrix} e^{\lambda y}, \tag{6.105}$$

and substitute it into (6.104). Then the characteristic equation gives

$$\det \begin{pmatrix} M - B_+\left(k_x^2 - \lambda^2\right) - E & A(k_x - \lambda) \\ A(k_x + \lambda) & -M + B_-\left(k_x^2 - \lambda^2\right) - E \end{pmatrix} = 0. \tag{6.106}$$

We obtain four real roots $\pm\lambda_1$ and $\pm\lambda_2$:

$$\lambda_{1,2}^2 = k_x^2 + F \pm \sqrt{F^2 - \frac{M^2 - E^2}{B_+ B_-}}, \tag{6.107}$$

where $F = [A^2 - 2(MB + ED)]/(2B_+ B_-)$. To find an edge state solution, the wave function must decay to zero when deviating far away from the boundary. We adopt the Dirichlet boundary condition $\Psi_\uparrow\left(k_x, y = 0\right) = \Psi_\uparrow\left(k_x, y = +\infty\right) = 0$. Thus, the solution has a general form,

$$\Psi_\uparrow = \begin{pmatrix} \tilde{c}(k_x) \\ \tilde{d}(k_x) \end{pmatrix} (e^{-\lambda_1 y} - e^{-\lambda_2 y}), \tag{6.108}$$

if λ_1 and λ_2 are positive or their real parts are positive. Substituting the solution into (6.104), we obtain

$$\frac{\tilde{c}}{\tilde{d}} = \frac{A(k_x + \lambda_1)}{E - M + B_+ k_x^2 - B_+ \lambda_1^2} = \frac{A(k_x + \lambda_2)}{E - M + B_+ k_x^2 - B_+ \lambda_2^2}. \tag{6.109}$$

Thus, it follows from this equation that

$$E = M - B_+ \lambda_1 \lambda_2 - B_+ (\lambda_1 + \lambda_2) k_x - B_+ k_x^2. \tag{6.110}$$

At $k_x = 0$,

$$E = M - B_+ \lambda_1 \lambda_2, \tag{6.111}$$

$$\lambda_1 = \sqrt{F + \sqrt{F^2 - (M^2 - E^2)/B_+ B_-}}, \tag{6.112}$$

$$\lambda_2 = \sqrt{F - \sqrt{F^2 - (M^2 - E^2)/B_+ B_-}}. \tag{6.113}$$

Thus, one obtains

$$E = \frac{B_- - B_+}{B_- + B_+} M = -\frac{D}{B} M, \tag{6.114}$$

$$\lambda_1 \lambda_2 = \frac{M - E}{B_+} = \frac{M}{B} > 0, \tag{6.115}$$

$$\lambda_1 + \lambda_2 = \sqrt{\frac{A^2}{B_+ B_-}} > 0. \tag{6.116}$$

Therefore the existing conditions of the edge state solution are,

$$\frac{A^2}{B_+ B_-} > 0, \quad \frac{M}{B} > 0. \tag{6.117}$$

Near $k_x = 0$, from the equations for λ_1, λ_2 and E, we calculate

$$\left. \frac{dE}{dk_x} \right|_{k_x=0} = -B_+ \left. \frac{d(\lambda_1 \lambda_2)}{dk_x} \right|_{k_x=0} - B_+ (\lambda_1 + \lambda_2)|_{k_x=0}$$

$$= sgn(B) A \sqrt{1 - \frac{D^2}{B^2}}. \tag{6.118}$$

It follows that the energy spectrum of the edge states near $k_x = 0$ reads

$$E_\uparrow (k_x) = -\frac{MD}{B} + sgn(B) A \sqrt{1 - \frac{D^2}{B^2}} k_x + O(k_x^2). \tag{6.119}$$

The effective velocity of this state is

$$v_\uparrow = +sgn(B)A\sqrt{1 - \frac{D^2}{B^2}}. \tag{6.120}$$

Similarly, we may have the energy dispersion of the edge states for the lower block $h_\downarrow$

$$E_\downarrow(k_x) = -\frac{MD}{B} - sgn(B)A\sqrt{1 - \frac{D^2}{B^2}}k_x + O(k_x^2) \tag{6.121}$$

and the effective velocity

$$v_\downarrow = -sgn(B)A\sqrt{1 - \frac{D^2}{B^2}}. \tag{6.122}$$

The results can be also obtained from the perturbation theory for a small k_x. Thus, the effective velocities in the two edge states are opposite, one is positive and the other is negative. These two edge states constitute a pair of helical edge states.

6.5.3 Experimental Measurement

The transition from the normal band to an inverted band structure coincides with the topological quantum phase transition from a trivial insulator to an quantum spin Hall insulator. The first experimental observation was made by a group in Wurzburg, Germany led by Molenkamp [18]. In order to cover the regime of normal and inverted band structures, a series of HgTe samples with quantum well widths from 4.5 to 12 nm were grown. Initial evidence for the quantum spin Hall state was revealed in studies of Hall bar of dimension $(L \times W) = (20.0 \times 13.3)\mu m^2$ with different thickness. For thinner samples with $d_{QW} < d_c$ the samples show an insulating behavior. But for thicker samples with $d_{QW} > d_c$ a finite value of resistance was measured, as shown in Fig. 6.8, which is anticipated as the theoretical prediction for the quantum spin Hall effect. The inset shows the resistances at two different temperatures. Surprisingly, the resistance at lower temperatures is larger than the resistance at higher temperatures, which usually is characteristic of an insulating phase rather than a conducting phase. We have to say that no quantized conductance has been measured experimentally in the quantum spin Hall effect, although the measured conductance is close to the predicted value at a specific temperature.

Further evidence in the helical edge states comes from the non-local transport measurement. which is performed in a multi-terminal setup. In conventional diffusive electronics, bulk transport satisfies Ohm's law. The resistance is proportional to the length and inversely proportional to the cross-sectional area, implying the existence of a local resistivity or conductivity tensor. However, the existence of the edge state necessarily leads to nonlocal transport, which invalidates Ohm's law. Such nonlocal
Fig. 6.8 Longitudinal four-terminal resistance, $R_{14,23}$, of various normal (d = 5.5nm) (I) and inverted (d = 7.3 nm) (II, III, and IV) quantum well structures as a function of the gate voltage measured for B = 0T at T = 30 mK. The device sizes are (20.0×13.3) μm^2 for devices I and II, (1.0×1.0) μm^2 for device III, and (1.0×0.5) μm^2 for device IV. The *inset* shows the $R_{14,23}(V_g)$ of two samples from the same wafer, that have the same device size (III) at 30 mK (*green*) and 1.8 K (*black*) on a linear scale (Adapted from [18] reprinted with permission from AAAS) (color figure online)

Fig. 6.9 H-shaped four-terminal device of the quantum spin Hall system. The spin-filtered edge channels are indicated by *red* (*spin up*) and *blue* (*spin down*) *arrowed lines* (color figure online)
transport was first observed in quantum Hall effect, and is well described by the quantum transport theory based on the Landauer-Büttiker formula.

In the device shown in Fig. 6.9, which is used in the non-local measurements to prove the existence of helical edge states, two terminals act as current probes and the other two act as voltage probes. The non-local resistance is defined as:

$$R_{ij,kl} = \frac{V_k - V_l}{I_{ij}}. \tag{6.123}$$

We can set $V_4 = 0$ and write down the Büttiker formula:

$$\begin{pmatrix} I_1 \\ I_2 \\ I_3 \end{pmatrix} = \frac{e^2}{h} \begin{pmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 2 \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \\ V_3 \end{pmatrix}. \tag{6.124}$$

If the current is driven through the terminal 1 and 4, and the terminal 2, 3 act as voltage probes, we have $I_1 = -I_4$ and $I_2 = I_3 = 0$. Then we obtain

$$R_{14,14} = \frac{V_1 - V_4}{I_1} = \frac{h}{e^2} \frac{3}{4} \tag{6.125}$$

and

$$R_{14,23} = \frac{V_2 - V_3}{I_1} = \frac{h}{e^2} \frac{1}{4}, \tag{6.126}$$

which are the predicted values if the helical edge states truly exist in the system. These predictions have been experimentally confirmed in HgTe/CdTe quantum wells [22].

However, so far the exact quantized plateau of the conductance has not yet been measured experimentally in HgTe/CdTe quantum wells.

6.6   Quantized Conductance in InAs/GaAs Bilayer Quantum Well

The double layer quantum wells InAs/GaSb, which is sandwiched between AlSb barriers, provides an alternative to observe the quantum spin Hall effect. In the system the conduction band of InAs layer and the valence band in GaSb layer are separated spatially in quantum wells and the overlap of the two bands is tunable by the gate voltages. Hybridization of the two bands may lead to a gap opening, which has been studied theoretically and experimentally for a long time. In 2008, a complete phase diagram was suggested to cover metallic, normal insulating, and topological quantum spin Hall insulating phase. In the quantum spin Hall regime a pair of helical edge states are expected to be protected topologically, and to be dominated the transport properties near the band crossing point [23]. The helical edge states in the hybridization gap were evidenced by low-temperature electronic transport measurement [24]. In 2015, Du et al. [25] reported the clear quantized conductance plateau of helical edge states in the sample of electron-hole bilayer of inverted InAs/GaSb by using dilute silicon impurity doping at the interference, and non-local transport measurement to support the helicity of edge states. Surprisingly it is observed that the quantized conductance plateau can survive even up to 12 Tesla in-plane magnetic

field, which goes beyond theoretical expectation asthe magnetic field will break time reversal symmetry and consequently the Zeeman coupling between electron with opposite spins destroys the helical edge states. It is anticipated that the robustness of the edge states may result from the electron-electron interaction effect in the system, such as the Luttinger liquid in the edge channel or the emergence of excitons in this special particle-hole bilayer quantum well structure. The edge current can be imaged in InAs/GaAs quantum well with long edge. An effective edge resistance can be determined to be larger than h/e^2, it is independent of temperature up to 30 K, which cannot be explained by existing scattering mechanism [26]. Besides, Ma et al. [27] demonstrates that HgTe/CdTe system also exhibits the robustness of edge states in the presence of strong magnetic field, which is very similar to the InAs/GaSb. Until now, the story behind these unconventional phenomena is still unclear theoretically.

6.7   Quantum Hall Effect and Quantum Spin Hall Effect: A Case Study

The difference between the quantum Hall effect and the quantum spin Hall effect can be illustrated with the conductance of a three-probe conductor with one contact playing the role of a voltage probe. At this contact the net charge current vanishes. Electrons that leave the contact is replaced by electrons from the contact reservoir. In the quantum Hall effect sample with $\nu = 2$, two edge states from the left source contact enter the voltage probe and two edge states leave the voltage probe for the right drain contact. The potential of the probe is equal to that of the source contact and the voltage probe has no effect on the overall conductance. However in the quantum spin Hall effect sample, the situation is different. Here, only one edge state is directed from the source contact to the voltage probe. Two other edge states lead away from the probe—one to the source contact and one to the sink contact. To maintain zero current, it is sufficient to tune the chemical potential at the probe halfway between the potentials of the source and sink contact. Now, half the current is directed back to the source contact. The voltage probe reduces the overall conductance by half a conductance quantum, i.e., $\sigma = \frac{3}{2}\frac{e^2}{h}$ not $2\frac{e^2}{h}$ as in the quantum Hall effect of $\nu = 2$ [28]. Such a probe maintains a zero net charge current into the contact. However, the spin current into the probe is nonzero with spin up in the case depicted. Simultaneously, a spin current is induced into both the source and drain electrodes.

6.7.1 Quantum Hall Effect ($\nu = 2$)

In this setup with three-terminal geometry, using the Landauer-Büttiker formula, the currents are

$$\begin{pmatrix} I_{left} \\ I_{probe} \\ I_{right} \end{pmatrix} = 2\frac{e^2}{h} \begin{pmatrix} -1 & 0 & 1 \\ 1 & -1 & 0 \\ 0 & 1 & -1 \end{pmatrix} \begin{pmatrix} \mu_{left} \\ \mu_{probe} \\ \mu_{right} \end{pmatrix}. \tag{6.127}$$

The probe potential is tuned such that the charge current at the voltage probe vanishes,

$$I_{probe} = 2\frac{e^2}{h}(\mu_{left} - \mu_{probe}) = 0. \tag{6.128}$$

Then,

$$\begin{aligned} I_{right} &= 2\frac{e^2}{h}(\mu_{probe} - \mu_{right}) \\ &= 2\frac{e^2}{h}(\mu_{left} - \mu_{right}). \end{aligned} \tag{6.129}$$

The conductance is

$$G_{QHE} = 2\frac{e^2}{h}. \tag{6.130}$$

6.7.2 Quantum Spin Hall Effect

Using the Landauer-Büttiker formula, the currents are

$$\begin{pmatrix} I_{left} \\ I_{probe} \\ I_{right} \end{pmatrix} = \frac{e^2}{h} \begin{pmatrix} -2 & 1 & 1 \\ 1 & -2 & 1 \\ 1 & 1 & -2 \end{pmatrix} \begin{pmatrix} \mu_{left} \\ \mu_{probe} \\ \mu_{right} \end{pmatrix}. \tag{6.131}$$

The probe potential is tuned such that the charge current at the probe vanishes,

$$I_{probe} = \frac{e^2}{h}(\mu_{left} + \mu_{right} - 2\mu_{probe}) = 0. \tag{6.132}$$

Then,

$$\begin{aligned} I_{right} &= \frac{e^2}{h}(\mu_{left} + \mu_{probe} - 2\mu_{right}) \\ &= \frac{3}{2}\frac{e^2}{h}(\mu_{left} - \mu_{right}). \end{aligned} \tag{6.133}$$

The charge conductance is

$$G_{QHE} = \frac{3}{2}\frac{e^2}{h}. \tag{6.134}$$

Fig. 6.10 Difference of quantum Hall effect and quantum spin Hall effect (*right*) in a setup with three probes. *Left* quantum Hall effect for $\nu = 2$ with two chiral edge chaneels. *Right* the quantum spin Hall effect with a pair of helical edge channels

In the quantum spin Hall effect, the spin currents are

$$
\begin{pmatrix} I^S_{left} \\ I^S_{probe} \\ I^S_{right} \end{pmatrix} = \frac{e}{4\pi} \begin{pmatrix} 0 & -1 & 1 \\ 1 & 0 & -1 \\ -1 & 1 & 0 \end{pmatrix} \begin{pmatrix} \mu_{left} \\ \mu_{probe} \\ \mu_{right} \end{pmatrix}. \tag{6.135}
$$

The spin current at the probe is

$$
I^S_{probe} = \frac{e}{4\pi} \left(\mu_{left} - \mu_{right} \right) \neq 0. \tag{6.136}
$$

Although the charge current vanishes at the probe, the spin current does not vanish. The results are summarized in Fig. 6.10.

6.8   Coherent Oscillation Due to the Edge States

We study here the device shown in Fig. 6.11, which consists of a two-dimensional strip of a topological insulator on which two quantum point contacts have been patterned in series through gates (shaded regions in Fig. 6.11). The quantum point contacts define a saddle shaped confining potential, whose height can be controlled by a gate voltage. An effective disk with the area $A = \pi R^2$ (R is the radius of the disk) is formed in the center. An Aharonov-Bohm effect in the device can be expected intuitively, because a topological insulator possesses a pair of independent gapless edge states of different spins moving in opposite directions, each forming an ideal one-dimensional loop around the disk. The two edge states are independent because no backscattering is allowed at a given sample edge even in the presence of weak time reversal invariant disorder. We note here that spin is not a good quantum number in topological insulators because of spin-orbit coupling. In the absence of a magnetic field, the actual edge states are eigenstates of the time reversal operator; their characterization as spin up and down is not precisely correct, and the word
Fig. 6.11 Schematic of the setup consisting of a disk connected to two reservoirs through two quantum point contacts. *Red* (*light gray*) and *blue* (*dark gray*) *lines* indicate the chiral edge channels of *spin up* and *down* electrons, with *arrows* indicating the direction of their motion (Adapted from [32]) (color figure online)

"spin" below is to be viewed more generally as the quantum number denoting the two states of a Kramers doublet.

Suppose a weak magnetic field $B_\perp$ exists normal to the plane. Following [29] we consider an electron with spin up (or spin down) travelling from the left hand side in Fig. 6.11. At the left hand side junction it splits into two partial waves: one is transmitted through the quantum point contact into the disk with amplitude t, and the other is transmitted across the quantum point contact with an amplitude r causing a backscattering. We denote the wave function amplitudes in the upper and lower edge, right after the left hand side junction, by u_1 and d_1, respectively. The corresponding amplitudes in the vicinity of the right hand side junction are $u_2 = u_1 \exp[i\theta/2]$ and $d_2 = d_1 \exp[-i\theta/2]$, where

$$\theta = 2\pi \frac{\phi}{\phi_0} + 2\pi k R_{\text{eff}}, \tag{6.137}$$

$\phi_0 = h/e$ is the magnetic flux quantum, $\phi = \pi R_{\text{eff}}^2 B_\perp$ is the magnetic flux threading the effective one-dimensional loop with an effective radius R_{eff}, and $2\pi k R_{\text{eff}}$ is the phase acquired by the wave function traveling along the loop. As the Fermi level of electrons in the edge states can be tuned by a gate voltage V_{gate} and the dispersion relation for the edge states is linear in k, the phase can be tuned by the gate voltage $\delta\theta = 2\pi R_{\text{eff}} \delta k \propto \delta V_{gate}$.

A partial wave goes through the right hand side slit with an amplitude t' and across the slit with an amplitude r'. Using the theory of multi-scattering processes [30], it follows that the total transmission for a spin-up electron through the slit A and B is given by

$$T^{\uparrow}(B_{\perp}) = \frac{\left|tt'\right|^2}{1 + |rr'|^2 - 2\,|rr'|\cos(\theta + \theta_0)}. \tag{6.138}$$

Here $\theta_0 = \arg(rr')$. For specificity, the following numerical calculations suppose two symmetric quantum point contacts with $|t| = \left|t'\right|$ and $|r| = \left|r'\right|$. Resonant tunneling, i.e. $T^{\uparrow}(B_{\perp}) = 1$, occurs for $\cos(\theta + \theta_0) = 1$.

The transmission coefficient for a spin down electron $T^{\downarrow}(B_{\perp})$, which is the time reversal counterpart of a spin-up electron at $-B_{\perp}$, is given by $T^{\downarrow}(B_{\perp}) = T^{\uparrow}(-B_{\perp})$. According to the Landauer-Büttiker formula [11, 31], the total conductance is

$$G(B) = \frac{e^2}{h}[T^{\uparrow}(B_{\perp}) + T^{\downarrow}(B_{\perp})]. \tag{6.139}$$

This coherence oscillations in the conductance G as a function of the magnetic flux ϕ through the disk are therefore expected to be symmetric with respect to the direction of the magnetic field.

Chapter 7
Three-Dimensional Topological Insulators

Abstract Three-dimensional topological insulators are characterized by surrounding surface states in which electrons are well described as two-dimensional Dirac fermions. A series of materials have been identified as topological insulators after being theoretically predicted.

7.1 Family Members of Three-Dimensional Topological Insulators

7.1.1 Weak Topological Insulators: $Pb_x Sn_{1-x} Te$

The first known inverted band material was SnTe, which was discovered more than 50 years ago [1]. The valence- and conduction-band edges in PbTe and SnTe occur at the L points in the Brillouin zone. The valence band of PbTe is an L_6^+ state and its conduction band is an L_6^- state, and the valence band of SbTe is an L_6^- state and its conduction band is an L_6^+ state, as shown in Fig. 7.1. In a $Pb_x Sn_{1-x} Te$ alloy sample, as the Sn composition increases, the energy gap initially decreases as the L_6^+ and L_6^- states approach each other, then closes at an intermediate composition where the two states become degenerate, and finally re-opens, with the L_6^+ state now forming the conduction band and the L_6^- state forming the valence band [2]. The band structures of PbTe and SnTe were calculated in the early sixties of the last century [3, 4]. It was realized that the change in the energy gap corresponding to different compositions of the $Pb_x Sn_{1-x} Te$ alloy series can be understood qualitatively in terms of the difference between the relativistic effects in Pb and Sn, and relativistic correction are extremely important in determining the positions of the energy bands. Nowadays we call the relativistic correction as the spin-orbit coupling in semiconductors.

The band inversion in $Pb_x Sn_{1-x} Te$ occurs at four equivalent valleys. The number of the surface states is even. Thus, it is a trivial or weak topological insulator according to the topological classification of time reversal symmetry [5].

energy evolution of
$Bi_{1-x}Sb_x$ as a function of x.
Replotted from [9]
7.1.2   Strong Topological Insulators: $Bi_{1-x}Sb_x$

The first strong topological insulator to be discovered was the bismuth antimony alloy
$Bi_{1-x}Sb_x$ [6, 7]. Semiconducting $Bi_{1-x}Sb_x$ alloys have been studied experimentally
because their thermoelectric properties make them desirable for thermocoupling. The
evolution of the band structure of the alloy $Bi_{1-x}Sb_x$ as a function of Sb composition
x has been well studied and is summarized in Fig. 7.2 [8, 9]. As the Sb concentration
increases, two things happen. First, the gap between the L_s and L_a bands decreases.
At $x = 4\%$, the band gap closes and then reopens with the inverted ordering. Second,
the top of the valence band at T comes down in energy and crosses the bottom of the
conduction band at $x = 7\%$. At this point, the indirect gap becomes positive, and the
alloy is a semiconductor. At $x = 9\%$ the T valence band crosses the L_s valence band,
and the alloy is a direct-gap semiconductor at the L points. As x increases further, the
gap increases and reaches its maximum value of about 30 meV at $x = 18\%$. At that
point, the valence band H crosses the L_s valence band. For $x > 22\%$, the H band

crosses the L_a conduction band, and the alloy is again a semimetal. As the inversion transition between the L_s and L_a bands occurs in the semimetal phase adjacent to pure bismuth, it is clear that the semiconducting $Bi_{1-x}Sb_x$ alloy inherits its topological class from pure antimony and is, thus, a strong topological insulator [6].

Direct observation of Dirac gapless surface states in $Bi_{1-x}Sb_x$ was first reported by a group led by Hasan [7]. High-momentum-resolution angle-resolved photoemission spectroscopy performed with varying incident photon energy allows for the measurement of electronic band dispersion along various momentum space (k-space) trajectories in the three-dimensional bulk Brillouin zone. The surface band-dispersion image along the $\Gamma - M$ direction shows five Fermi level crossings, which demonstrates that the materials are topologically non-trivial.

7.1.3 Topological Insulators with a Single Dirac Cone: Bi_2Se_3 and Bi_2Te_3

Soon after the discovery of $Bi_{0.9}Sb_{0.1}$, a new family of stoichiometric crystals, Bi_2Se_3, Bi_2Te_3, and Sb_2Te_3, was identified as a family of three-dimensional topological insulators [10–12]. Among them, Bi_2Se_3 (Bismuth selenide) is expected to be the most promising for applications. It has a large bulk band gap up to 0.3 eV, equivalent to 3000 K, which is much higher than room temperature. Its band inversion happens at the $\bar{\Gamma}$ point, leading to a simple band structure of the topological surface states with only a single Dirac cone. The high-resoluation ARPES measurement shows clearly the surface band dispersion on Bi_2Se_3, as shown in Fig. 7.3, which provides explicit and unambiguous evidence of the surface states of topological insulators. It also reveals a single ring around the $\bar{\Gamma}$ point formed by the pure surface states, and the band structure of the Dirac cone. The single Dirac cone of the surface states is now considered characteristic of topological insulators.

7.1.4 Strained HgTe

Three-dimensional crystal HgTe is a semimetal with a neutral charge when the Fermi level is at the touching point between the light-hole and heavy-hole Γ_8 bands. A unique property of the band structure of HgTe is the inversion of the Γ_6 and Γ_8 band ordering. The effective masses of light- and heavy-holes have opposite signs (see Fig. 6.7). The appearance of the heavy-hole band between the light-hole and Γ_6 bands makes the material metallic instead of insulating, as there is no energy gap in the band structure. Because of the band inversion, three-dimensional HgTe is also expected to have Dirac-like surface states, however, the surface states always mix with bulk states. Once the system opens an energy gap, it will evolve into a topological insulator. Usually, there are two ways to open an energy gap in the band structure. One
Fig. 7.3 High-resolution ARPES data of surface electronic band dispersion on Bi$_2$Se$_3$(111) measured with an incident photon energy of 22 eV near the Γ-point along the $\bar{\Gamma} - \bar{M}$ and $\bar{\Gamma} - \bar{K}$ momentum-space cuts. Fig. 7.4 **a** Surface local density of states of 3D HgTe without strain. The *bright line* in the direct gap between LH and HH bands indicates the first type surface state; the bright regimes in the valence band indicates the second type surface state. **b** An insulating band gap is opened and the first and second-type surface states becomes connected. **c** The surface states when the Γ_6 and the HH band are inverted

way is to fabricate a thin film or a quantum well. The finite size effect opens a gap, which is the origin of the quantum spin Hall effect in two-dimensional HgTe/CdTe quantum wells. The other way is the strain effect. A strained three-dimensional HgTe is expected to be a topological insulator (See Fig. 7.4). The quantum Hall effect of the surface states in a strained bulk HgTe was observed experimentally [13].

Based on the adiabatic continuity of their band structure to HgTe, a series of chalcopyrite semiconductors are predicted to be topological insulators [15].

7.2 Electronic Model for Bi$_2$Se$_3$

Bi$_2$Se$_3$ and Bi$_2$Te$_3$ are three-dimensional topological insulators with robust and simple surface states constituting a single Dirac cone at the Γ point [11]. Bi$_2$Se$_3$ and Bi$_2$Te$_3$ share the same rhombohedral crystal structure with the space group D$_{3d}^5$ (R$\bar{3}$m) with five atoms in one unit cell. We take Bi$_2$Se$_3$ as an example and show its crystal structure in Fig. 7.5; it is a layered structure with a triangle lattice within one layer. It has a trigonal axis (three-fold rotation symmetry), defined as the z-axis; a binary axis (two-fold rotation symmetry), defined as the x-axis; and a bisectrix axis (in the reflection plane), defined as the y-axis. The material consists of five-atom layers arranged along the z-direction, known as quintuple layers. Each quintuple layer consists of five atoms with two equivalent Se atoms (denoted as Se1 and Se1'),

**Fig. 7.5** *Top* Crystal structure of Bi$_2$Se$_3$ with three primitive vectors denoted as t$_{1,2,3}$. The Se1 (Bi1) layer can be related to the Se1' (Bi1') layer by an inversion operation in which the Se2 atoms have the role of inversion centres. *Bottom* Schematic diagram of the p_z orbitals of electrons, and the band inversion of the p_z^+ orbitals of Bi and the p_z^- orbitals of Se due to the spin-orbit coupling

two equivalent Bi atoms (denoted as Bi1 and Bi1') and a third Se atom (denoted as Se2). The coupling is strong between two atomic layers within one quintuple layer but much weaker, predominantly of the van der Waals type, between two quintuple layers. The primitive lattice vectors $t_{1;2;3}$ and the rhombohedral unit cells are shown in Fig. 7.5. The Se2 site has the role of an inversion center and under an inversion operation, Bi1 is changed to Bi1' and Se1 is changed to Se1'. The existence of inversion symmetry enables us to construct eigenstates with definite parity for this system.

To get a better understanding of the inversion of the band structure and the parity exchange in Fig. 7.5, we start from the atomic energy levels and consider the effect of crystal-field splitting and spin-orbit coupling on the energy eigenvalues at the Γ point. The states near the Fermi surface mainly come from p orbitals of Bi ($6s^2 6p^3$) and Se ($4s^2 4p^4$). The crystal-field removes the degeneracy of the p orbitals and only the p_z orbitals become relevant in the present problem. Furthermore due to the inversion symmetry of the crystal lattice, the p_z orbitals of the electrons from Bi and Se atoms near the Fermi surface have opposite parities. The band gap between these two orbitals is controlled by the spin-orbit coupling: increasing the spin-orbit coupling may cause a band inversion, as analyzed in [11].

The three-dimensional Dirac equation can be applied to describe a large family of three-dimensional topological insulators. $Bi_2 Te_3$, $Bi_2 Se_3$ and $Sb_2 Te_3$ have been confirmed to be topological insulators with a single Dirac cone of surface states. For example, in $Bi_2 Te_3$, the electrons near the Fermi surfaces mainly come from the p orbitals of Bi and Te atoms. According to the point group symmetry of the crystal lattice, a p_z orbital splits from $p_{x,y}$ orbitals. Near the Fermi surface the energy levels turn out to be the p_z orbital, $|P1_z^+, \uparrow\rangle$, $|P1_z^+, \downarrow\rangle$, $|P2_z^-, \uparrow\rangle$, and $|P2_z^-, \downarrow\rangle$, where $\pm$ stand for the parity of the corresponding states and $\uparrow, \downarrow$ for the electron spin. Four low-lying states at the Γ point can be used as a basis to construct the low-energy effective Hamiltonian [11]. On the basis of ($|P1_z^+, \uparrow\rangle, |P1_z^+, \downarrow\rangle, |P2_z^-, \uparrow\rangle, |P2_z^+, \downarrow\rangle$), we keep the terms up to the quadratic order in p, and obtain

$$H = \epsilon(p) + \sum_{i=x,y,z} v_i p_i \alpha_i + \left(M - \sum_{i=x,y,z} B_i p_i^2 \right) \beta \qquad (7.1)$$

with $v_x = v_y = v_\parallel$ and $v_z = v_\perp$, and $B_x = B_y = B_\parallel$ and $B_z = B_\perp$. The first term, $\epsilon(p) = C - D_\parallel(p_x^2 + p_y^2) - D_\perp p_z^2$, breaks the particle-hole symmetry of the system. The linear term in p_i is determined by the change in the parity of the different basis. Anisotropy of the crystal reveals that $B_\parallel \neq B_\perp$ and $v_\parallel \neq v_\perp$. This will modify the effective velocity of the surface states.

This model can be understood as a result of the $k \cdot p$ theory. Under the time reversal, $\alpha_i \rightarrow -\alpha_i$ and $\beta \rightarrow \beta$. Suppose the system is time reversal invariant. Expand the Hamiltonian near $p = 0$. The zero-order term is $M\beta$, where M represents the energy gap at the point, the first order term is $\sum_{i=x,y,z} v_i p_i \alpha_i$ since $p_i \rightarrow -p_i$, and the second order term is $\sum_{i=x,y,z} B_i p_i^2 \beta$, as $p_i^2 \rightarrow p_i^2$ under the time reversal. $\epsilon(p)$ is the dispersion independent of inter-band coupling.

7.3 Effective Model for Surface States

The effective Hamiltonian for the surface states can be derived from the electronic model for the bulk states. Consider an x-y plane at $z = 0$. Both p_x and p_y are good quantum numbers, and p_z is replaced by $-i\hbar\partial_z$ in (7.1) To derive an effective Hamiltonian for the surface states, we first find the solution of the surface states at $p_x = p_y = 0$ in (7.1):

$$H(z)\,|\Psi\rangle = E\,|\Psi\rangle, \tag{7.2}$$

where

$$H(z) = C + D_\perp \hbar^2 \partial_z^2 - iv_\perp \hbar \partial_z \alpha_z + (M + B_\perp \hbar^2 \partial_z^2)\beta. \tag{7.3}$$

We have derived an effective model for surface states for the modified Dirac equation in Chap. 2. Here the presence of $\epsilon(p)$ makes it a little bit more complicate to find the solution at $p_x = p_y = 0$. The term $\epsilon(p)$ breaks the particle-hole symmetry between the conduction band and the valence band. If $D_\perp^2 > B_\perp^2$, the band gap closes and the system is no longer an insulator. To have a surface state solution, we focus on the case of $D_\perp^2 < B_\perp^2$. In this matrix equation, the first and third rows are decoupled from the second and fourth rows. For this reason, we can adopt two trial wave functions:

$$|\Psi_1\rangle = \begin{pmatrix} a_1 \\ 0 \\ b_1 \\ 0 \end{pmatrix} e^{\lambda z} \tag{7.4}$$

and

$$\Psi_2 = \begin{pmatrix} 0 \\ a_2 \\ 0 \\ b_2 \end{pmatrix} e^{\lambda z}, \tag{7.5}$$

respectively. The equation is reduced into two independent sets of equations

$$\begin{pmatrix} M + B_+\lambda^2 & -iv_\perp\lambda \\ -iv_\perp\lambda & -M + B_-\lambda^2 \end{pmatrix} \begin{pmatrix} a_1 \\ b_1 \end{pmatrix} = E \begin{pmatrix} a_1 \\ b_1 \end{pmatrix} \tag{7.6}$$

and

$$\begin{pmatrix} M + B_+\lambda^2 & +iv_\perp\lambda \\ +iv_\perp\lambda & -M + B_-\lambda^2 \end{pmatrix} \begin{pmatrix} a_2 \\ b_2 \end{pmatrix} = E \begin{pmatrix} a_2 \\ b_2 \end{pmatrix}, \tag{7.7}$$

where $B_\pm = B_\perp \pm D_\perp$. These two equations are equivalent to those for the edge states in the quantum spin Hall effect at $k_x = 0$. We first focus on the solution of a_1

and b_1. To have a non-trivial solution, the characteristic equation is

$$\det \begin{pmatrix} M + B_+\lambda^2 - E & -iv_\perp\lambda \\ -iv_\perp\lambda & -M + B_-\lambda^2 - E \end{pmatrix} = 0. \qquad (7.8)$$

From this equation, we find four roots for λ: $\pm\lambda_1$ and $\pm\lambda_2$. We adopt the Dirichlet boundary conditions, which require that the wave function for the surface states must vanish at $z = 0$ and $z \to -\infty$. For $MB_\perp > 0$, we obtain

$$|\Psi_1\rangle = \begin{pmatrix} a_1 \\ 0 \\ b_1 \\ 0 \end{pmatrix} \left(e^{\lambda_1 z} - e^{\lambda_2 z} \right) \qquad (7.9)$$

with

$$\lambda_1 = \frac{1}{2}\sqrt{\frac{v_\perp^2}{B_+ B_-} + \sqrt{\frac{1}{4}\frac{v_\perp^2}{B_+ B_-} - \frac{M}{B_\perp}}} \qquad (7.10)$$

and

$$\lambda_2 = \frac{1}{2}\sqrt{\frac{v_\perp^2}{B_+ B_-} - \sqrt{\frac{1}{4}\frac{v_\perp^2}{B_+ B_-} - \frac{M}{B_\perp}}}, \qquad (7.11)$$

which requires that

$$\frac{a_1}{b_1} = \frac{iA\lambda_1}{B_+(\lambda_1^2 + \frac{M}{B_\perp})} = \frac{iA\lambda_2}{B_+(\lambda_2^2 + \frac{M}{B_\perp})}. \qquad (7.12)$$

The normalization of the wave function requires

$$|a_1|^2 + |b_1|^2 = \left(\frac{\lambda_1 + \lambda_2}{2\lambda_1\lambda_2} - \frac{2}{\lambda_1 + \lambda_2} \right)^{-1}. \qquad (7.13)$$

Similarly, we find the solution to $|\Psi_2\rangle$ by setting $a_2 = -a_1$ and $b_2 = b_1$,

$$|\Psi_2\rangle = \begin{pmatrix} 0 \\ -a_1 \\ 0 \\ b_1 \end{pmatrix} \left(e^{\lambda_1 z} - e^{\lambda_2 z} \right). \qquad (7.14)$$

The energy eigenvalue for both states is $E = -D_\perp M/B_\perp$.

To find the solution of $p_x, p_y \neq 0$ we may use the projection and perturbation method by utilizing the two solutions at $p_x = p_y = 0$ as the basis to project the

Hamiltonian. On the new basis, the effective Hamiltonian is projected out

$$H_{eff} = \begin{pmatrix} \langle \Psi_1| H |\Psi_1\rangle & \langle \Psi_1| H |\Psi_2\rangle \\ \langle \Psi_2| H |\Psi_1\rangle & \langle \Psi_2| H |\Psi_2\rangle \end{pmatrix}. \tag{7.15}$$

In this way, we obtain an effective Hamiltonian in the x-y plane [16],

$$H_{eff} = \epsilon_0(p) + v_{eff}(p \times \sigma)_z, \tag{7.16}$$

where $v_{eff} = \text{sgn}(B_\perp)\sqrt{1 - D_\perp^2/B_\perp^2}\, v_\parallel$. We note that the inclusion of $\epsilon(p)$ will revise the effective velocity of the surface states. A quadratic term appears up to p^2, $\epsilon_0(p) = E_0 - D_\parallel(p_x^2 + p_y^2)$. Note that the effective Hamiltonian is only valid for a small p.

A key feature of this effective model is the lock-in relation between the momentum and spin. In the polar coordinate, we set $p = \sqrt{p_x^2 + p_y^2}$ and $\phi_p = \arctan p_y/p_x$. The dispersions for the surface states are $E_\pm(p) = \epsilon_0(k) \pm v_{eff} p$ and the corresponding energy states are

$$|\Psi_\pm\rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} \pm e^{-i\phi_p} \\ 1 \end{pmatrix}. \tag{7.17}$$

The Berry phase, which is acquired by a state upon being transported around a loop in the k space, can be evaluated exactly,

$$\gamma_\pm = \oint d\phi_p \langle \Psi_\pm| i \frac{\partial}{\partial \phi_p} |\Psi_\pm\rangle = \mp\pi. \tag{7.18}$$

The Berry phase will play an essential role in the transport properties of the surface states, such as weak antilocalization. An ideal Dirac fermion gas is a super-metal, in which none of the states can be localized by disorders or impurities.

Hexagonal warping effect [17]: Bi$_2$Te$_3$ has a rhombohedral crystal structure with the space group R3m̄. In the presence of a [111] surface, the crystal symmetry is reduced to C$_{3v}$, which consists of a three-fold rotation of C$_3$ around the trigonal z-axis and a mirror operation M: $x \rightarrow -x$, where x is in the $\Gamma - K$ direction. Under the operations of C$_3$ and M, the momentum and spin transform as follows:

$$C_3 : p_\pm \rightarrow e^{\pm i2\pi/3} p_\pm, \sigma_\pm \rightarrow e^{\pm i2\pi/3}\sigma_\pm, \sigma_z \rightarrow \sigma_z \tag{7.19}$$

and

$$M : p_+ \rightarrow -p_-, \sigma_x \rightarrow \sigma_x, \sigma_{y,z} \rightarrow -\sigma_{y,z}. \tag{7.20}$$

In addition, the time reversal symmetry gives the constraint

$$H(\mathbf{p}) = \Theta H(-\mathbf{p})\Theta^{-1}. \tag{7.21}$$

Keeping the higher order term up to p^3, the effective Hamiltonian for the surface states has the form

$$H_{eff} = \epsilon_0(p) + v_{eff}(p_x\sigma_y - p_y\sigma_x) + \frac{\lambda}{2}(p_+^3 + p_-^3)\sigma_z, \qquad (7.22)$$

where $\epsilon_0 = p^2/2m^*$. The cubic term does not breaks the time reversal symmetry.

7.4 Physical Properties of Topological Insulators

7.4.1 Absence of Backscattering

The absence of backscattering in the topological surface states can be demonstrated as follows: a pair of the Kramers' states $|k, \uparrow\rangle$ and $|-k, \downarrow\rangle$ are related through the time reversal transformation, $|-k, \downarrow\rangle = \Theta |k, \uparrow\rangle$. As the operator Θ is anti-unitary, it is straightforward that

$$\langle -k, \downarrow| U |k, \uparrow\rangle = -\langle -k, \downarrow| \Theta U \Theta |k, \uparrow\rangle \qquad (7.23)$$

$$= -\langle k, \uparrow| U |-k, \downarrow\rangle^* = -\langle -k, \downarrow| U |k, \uparrow\rangle, \qquad (7.24)$$

where U is a time reversal invariant operator. Thus, for a potential of a nonmagnetic impurity V, $\langle -k, \downarrow| V |k, \uparrow\rangle = 0$.

The absence of backscattering of the surface states was studied in the alloy $Bi_{1-x}Sb_x$ [18], and in the single crystal Bi_2Te_3 [19]. Bi_2Te_3 has only a single Dirac cone and therefore the picture is clearer. The constant energy contour at the Fermi energy of the conduction band of Bi_2Te_3 is shown in Fig. 7.6. Due to the strong warping effect in (7.22), the constant energy contour of the surface band of Bi_2Te_3 is not a perfect ring, but looks like a hexagram. In the scanning tunneling microscopy (STM) measurement on the surface of Bi_2Te_3, non-magnetic Ag atom trimers are deposited, which can scatter the surface states. The electron wave functions before and after scattering will interfere with each other and form a standing wave pattern. The fast Fourier transformation from the real-space standing wave pattern to the momentum space can reveal the momentum difference before and after the scattering. On the hexagram, the density of states is not uniform. At some momenta, the density of states is relatively large, as depicted by the darker area on the hexagram in Fig. 7.6. The scattering between these high-density momenta is more obvious in some than in others. The momentum difference between two momenta with totally opposite momenta, i.e., backscattering is $\mathbf{q} = \mathbf{k}_f - \mathbf{k}_i = 2\bar{K}$. If the backscattering is present, there will be a high-value signal along $\mathbf{q}$ direction in the fast Fourier transformation spectra, more specifically, along the $\bar{K}$ direction of the surface Brillouin zone. However, there are apparent gaps along the $\bar{K}$ direction in the STM measurement [19].

Fig. 7.6 Constant energy contour of H_{eff} in (7.22). The dominant scattering wave vectors connect two points in $\overline{\Gamma} - \overline{K}$ directions on the constant energy contour. $\mathbf{k}_i$ and $\mathbf{k}_f$ denote the wave vectors of incident and scattered states
This provides a direct evidence of the absence of backscattering of Dirac fermions on the surface of topological insulator.

7.4.2 Weak Antilocalization

Weak antilocalization is a characteristic feature of transport experiments that demonstrates the presence of the Dirac fermions in topological insulators. It appears in the form of low-field negative magnetoconductivity, i.e., negative conductivity change as a function of an applied magnetic field [20–24]. A series of experimental measurements have been reported. So far, all of the reported samples in the transport experiments have low mobility and a short mean free path, indicating that diffusion dominates the electronic transport. Like many semiconductors, the phase coherence length in topological insulators can be as long as several hundred nanometers to more than one micrometer at low temperatures (below the liquid helium temperature). When the sample size is comparable to the phase coherence length, the quantum interference becomes an important correction to the diffusion transport. In materials without or with ignorable spin-orbit coupling, the constructive quantum interference will enhance the backscattering between two time-reversed scattering loops (Fig. 7.7), and suppress the resistivity. This suppression of resistivity by the quantum interference leads to the weak localization. It can be destroyed by applying a magnetic field that breaks the constructive quantum interference. On the other hand, people have known for a long time that strong spin-orbit scattering in some solids could also make the quantum interference change from constructive to destructive. As a result, the conductivity is enhanced and weak antilocalization happens.
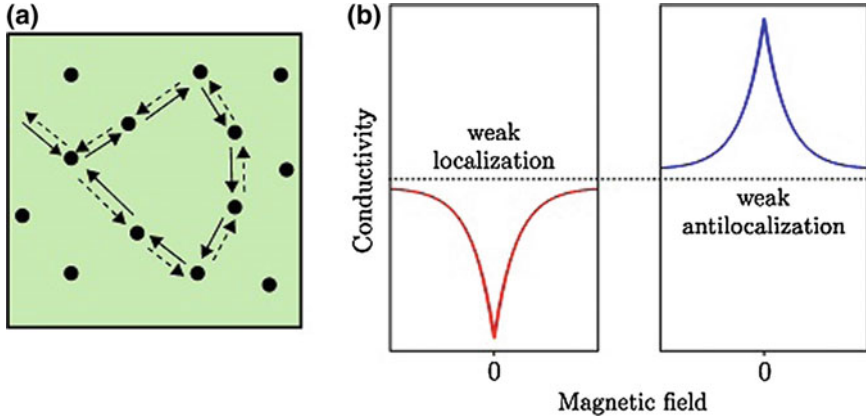

Fig. 7.7 a The back scattering between two time-reversed scattering loops. **b** The exhibition of weak localization and weak antilocalization in magnetoconductivity. The *horizontal dashed line* marks the classical conductivity

In addition to the spin-orbit scattering, the energy band structure with spin-orbit coupling can also lead to weak antilocalization, and this case can be understood in terms of the Berry phase argument. Due to the strong spin-orbit coupling, the surface states of topological insulators have a two-component spinor wave function, which describes a momentum-spin lock-in relation in the surface states. After an electron circles around the Dirac point, its spin orientation rotates by 2π, and the wave function accumulates only a π Berry phase [25, 26]. The π Berry phase changes the interference of the time-reversed scattering loops from constructive to destructive. The destructive interference will enhance the conductivity, which can be destroyed by applying a magnetic field, leading to a negative magnetoconductivity with the cusp.

7.4.3 Shubnikov-de Haas Oscillation

All of the early in-plane transport measurements reveal the dominance of three-dimensional bulk conductivity [20, 21, 27]. One way to determine the dimension of the carriers and to distinguish the two-dimensional surface states from the three-dimensional bulk states is the Shubnikov-de Haas oscillation. In the presence of a strong perpendicular magnetic field, an electron gas splits into discrete Landau levels, the separation between the Landau levels increases with the increasing magnetic field. As the magnetic field increases, the Landau levels cut through the Fermi surface one by one. When the Fermi level is (not) aligned with a Landau level, the resistivity drops (increases). As a result, the in-plane measurement will measure an oscillating resistivity, known as the Shubnikov-de Haas oscillation. Because the Shubnikov-de Haas

oscillation only responds to a perpendicular magnetic field, a two-dimensional electron gas has no Shubnikov-de Haas oscillation for in-plane magnetic fields, whereas a three-dimensional electron gas can have a Shubnikov-de Haas oscillation for a magnetic field applied along any directions. This angle-dependence of the Shubnikov-de Haas oscillation is a convenience tool to identify the dimension of carriers. The Shubnikov-de Haas oscillation revealed the coexistence of three-dimensional bulk carriers with the two-dimensional surface states in the transport for $Bi_{1-x}Sb_x$ [27, 28] and Bi_2Se_3 [29–31]. The Shubnikov-de Haas oscillation measured in a Bi_2Se_3 crystal shows that the bulk states dominate the transport, because it can be measured for an arbitrary magnetic field direction. The Shubnikov-de Haas oscillation also reveals the Berry phase information. The oscillating longitudinal resistivity ρ_{xx} can be formulated as

$$\rho_{xx} \sim \cos\left[2\pi\left(\frac{F}{B} - \gamma\right)\right], \tag{7.25}$$

where F is the oscillation frequency, γ is the phase of the oscillation. The Berry phase can be found as [32] $2\pi(\gamma - \frac{1}{2})$. One has zero Berry phase for $\gamma = \frac{1}{2}$, and π Berry phase for $\gamma = 0$. The Berry phase is about 0.4, giving another signature that the bulk states dominate the transport of as-grown topological insulator Bi_2Se_3.

7.5 Surface Quantum Hall Effect

When the surface states are subjected to a Zeeman field, the massless Dirac fermions gain a mass and open an energy gap:

$$H = v(p \times \sigma)_z + \Delta\sigma_z = d \cdot \sigma \tag{7.26}$$

with $d_x = -vp_y$, $d_y = vp_x$, and $d_z = \Delta$. From the Kubo formula, the Hall conductance can be expressed as

$$\sigma_{xy} = \frac{e^2}{2\hbar} \int \frac{dk_x dk_y}{(2\pi)^2} \frac{(f_{k,+} - f_{k,-})\, \mathbf{d}(k) \cdot \partial_{k_x}\mathbf{d}(k) \times \partial_{k_y}\mathbf{d}(k)}{|\mathbf{d}(k)|^3}, \tag{7.27}$$

where $f_{k,\pm} = \{1 + \exp[(\pm(\mathbf{d}(k) - \mu)/k_B T]\}^{-1}$ (for details see Sect. A.2). When the Fermi energy level is located in the gap, $i.e.$, $\mu = 0$, the Hall conductance is half quantized at zero temperature,

$$\sigma_{xy} = -\frac{sgn(\Delta)}{2} \frac{e^2}{h}. \tag{7.28}$$

It is noted that the Hall conductance is usually related to the Chern number, which is always an integer if the Brillouin zone is finite, as we prove in Sect. A.1. However,

here the integral range is infinite, which makes it possible that the conductance is not an integer.

This is regarded as one of the key features of the surface states in topological insulators. It has many applications in the field of topological insulators. For example, it plays a decisive role in the development of topological field theory [33].

Although we have a half quantized Hall conductance from the Kubo formula, it is still not clear whether or not the half quantization of the Hall conductance can be directly observed in transport measurement. In the integer quantum Hall system, the current-carrying chiral edge states are responsible for the quantized conductance measured in transport experiments [34, 35]. It is not immediately clear whether or not the similar chiral edge state will form on the closed surface of a topological insulator, and how the quantized nature of the edge states can be reconciled with the prediction of the half quantization of the Hall conductance [33, 36, 37]. To get a definite answer to these questions, we investigate the multi-terminal transport properties of a three-dimensional topological insulator in the presence of a uniform spin-splitting Zeeman field.

To illustrate the basic physics, we consider a three-dimensional topological insulator with a cubic shape. A Zeeman field is applied along the z-direction, as shown in Fig. 7.8a. As the bulk of the system is insulating, it is effectively a closed two-dimensional surface with six facets. The effective Hamiltonian of the Dirac fermions for the surface states can be written as [16, 38]:

$$H_{\text{eff}}(\mathbf{k}) = v\,(\mathbf{k} \times \sigma) \cdot \mathbf{n} - g_{\parallel}\mu_B h_{\parallel}\sigma_{\parallel} - g_{\perp}\mu_B \mathbf{h}_{\perp} \cdot \sigma_{\perp}, \qquad (7.29)$$

**Fig. 7.8 a** Schematic of a three-dimensional topological insulator in a weak Zeeman field, and the formation of the chiral current on the *top* and *bottom* surface boundaries. **b** Chiral edge state around the domain wall between the two-dimensional Dirac fermions with the positive and negative masses. **c** Edge mode splits into two halves separating by a metallic area

where **n** denotes the normal vector of the surface, $\sigma \equiv \{\sigma_x, \sigma_y, \sigma_z\}$ are the Pauli matrices, $h_\parallel$ ($\sigma_\parallel$) and $h_\perp$ ($\sigma_\perp$) are the Zeeman field (Pauli matrix) components parallel and perpendicular to the normal vector, respectively, and $g_\parallel$ and $g_\perp$ are the corresponding spin g-factors. Note that the surface states have anisotropic spin g-factors due to the strong spin-orbit coupling of the bulk band: $g_\parallel$ is the same as that of the bulk material, and $g_\perp$ is renormalized by the bulk band parameters and is usually strongly suppressed [16, 38]. Different facets of the surface have different effective Hamiltonians respective to different normal vectors **n**. For the top and the bottom facets, the effective Hamiltonian can be written as

$$H_{\text{eff}} = \pm v(k_x \sigma_y - k_y \sigma_x) + \Delta_z \sigma_z, \tag{7.30}$$

where $+$ and $-$ are for the top and bottom surfaces, respectively, and $\Delta_z \equiv -g_\parallel \mu_B h$. The spectrum will open a gap on these facets, and the Dirac fermions gain a mass $\pm \Delta_z$. On the other hand, the effective Hamiltonians for the side facets can be written as

$$H_{\text{eff}} = v[(k_x + \Delta_h)\sigma_z - k_z \sigma_x], \tag{7.31}$$

where $\Delta_h \equiv g_\perp \mu_B h$. In this case, the Zeeman field simply shifts the Dirac point from ($k_x = 0, k_y = 0$) to ($-\Delta_h, 0$). When the fermi level is located in the gap of the top and bottom surface, the system becomes effectively two insulating domains separated by a conducting belt with massless Dirac fermions.

A chiral edge state will form and is concentrated around the boundaries between the insulating domains and the metallic belt, as illustrated in Fig. 7.8b, c. Effectively, the chiral edge state is split into two halves, each of which is circulating around the boundary of one of the domains and carrying one half of the conductance quantum e^2/h. This reconciles the apparent conflict between the half quantization and the index theorem. After establishing the existence of the chiral surface-edge states, we can calculate the Hall conductance numerically using the Landauer-Büttiker formalism [39–41]. The setup of the device is illustrated in Fig. 7.9 four identical two-dimensional metallic leads ($\mu = 1, 2, 3, 4$) are attached to the top square surface of a semi-infinite three-dimensional topological insulator, acting as the measurement

Fig. 7.9 Schematic illustration of the three-dimensional (3D) device with two-dimensional (2D) semi-infinite metallic leads
electrodes. The Zeeman field is normal to the top surface, and the Fermi level is located in the gap. The multi-terminal conductance can be deduced from the transmission coefficient T_{pq} from the terminal p to terminal q,

$$T_{pq} = Tr[\Gamma_p G^r \Gamma_q G^a], \tag{7.32}$$

where Γ_p is determined by the self energy at the terminal p [40]. The advanced and retarded Green's functions are given by

$$G^{R,A}(E) = \frac{1}{E - H_c - \sum_{p=1}^{4} \Pi_p^{R,A}}, \tag{7.33}$$

where E is the electron energy and H_c is the model Hamiltonian for three-dimensional system. The retarded and advanced self-energy terms are introduced for the semi-infinite lead p [41].

In this way The transmission coefficients, as a function of the thickness of the sample, can be calculated numerically. When the sample is thick enough it was found that the transmission coefficients between the two neighboring terminals p and q has the relation [42]

$$T_{pq} - T_{qp} = \frac{1}{2}. \tag{7.34}$$

A straightforward way to measure the "half quantized" Hall conductance in the four-terminal setup is to apply a voltage between terminals 1 and 3 (V_{13}), and measure the current between terminal 2 and 4 (I_{24}). It is easy to show that the cross-conductance $\sigma_{24,13} \equiv I_{24}/V_{13} = (e^2/2h)(T_{12} - T_{21})$, yielding $e^2/4h$ for the half quantization. The measurement using the usual six-terminal Hall bar configuration could be more tricky due to the presence of the metallic side facets, which give rise to the finite longitudinal conductance σ_L. In the limit of a thick sample with $\sigma_L \gg e^2/h$, the Hall conductance σ_H approaches $(4e^2/h)(T_{pq} - T_{qp})$ (if we assume $T_{pq} - T_{qp}$ is the same between all neighboring leads), which yields $2e^2/h$ for the half quantization. It can be compared with the case of quantum Hall effect, where σ_L vanishes when σ_H is quantized [42].

7.6 Surface States in a Strong Magnetic Field

We now consider the surface states subjected to a uniform magnetic field. We first consider the geometry of a strip with width L_y and thickness H, which are much larger than the magnetic length l_B and the spatial distribution ξ of the surface states. suppose the magnetic field B (along the z-axis) is perpendicular to the slab. We focus on the top plane. The periodic boundary condition is adapted along the x-axis, and the open boundary condition along the y-axis. In this way the wave number k_x is still

a good quantum number, and k_y is substituted by $-i\partial_y$. We take the Landau gauge for the vector potential, $A_x = -By$ and $A_y = 0$. In this way, the effective model (7.26) in a B field can be expressed in

$$H_{eff} = v_F \left[(\hbar k_x - eBy)\sigma_y + i\hbar\partial_y\sigma_x \right] + \Delta\sigma_z. \tag{7.35}$$

To solve the problem, it is convenient to define

$$a(y_0) = i \frac{l_B}{\sqrt{2}} [\partial_y + l_B^{-2}(y - y_0)], \tag{7.36}$$

where the magnetic length $l_B = \sqrt{\hbar/eB}$ and $y_0 = l_B^2 k_x$ assuming $eB > 0$. The defined operators a and $a^\dagger$ satisfy the commutation relation,

$$[a(y_0), a^\dagger(y_0)] = 1. \tag{7.37}$$

For simplicity, we introduce a dimensionless parameters $m_0 = \frac{\Delta}{\sqrt{2}\hbar v_F/l_B}$. In this way, we obtain a dimensionless Schrödinger equation,

$$\begin{pmatrix} m_0 & a \\ a^\dagger & -m_0 \end{pmatrix} \begin{pmatrix} \varphi_1 \\ \varphi_2 \end{pmatrix} = \frac{E}{v_F\sqrt{2e\hbar/B}} \begin{pmatrix} \varphi_1 \\ \varphi_2 \end{pmatrix}. \tag{7.38}$$

The allowed values for y_0 are separated by $\delta y_0 = 2\pi l_B^2/L_x$ for a periodic boundary condition with length L_x and are limited within $0 < y_0 < L_y$. The solution is a function of the good quantum number k_x or $y_0 = l_B^2 k_x$. When y_0 is far away from two edges of $y = 0$ and $y = L$, the two components φ_1 and φ_2 will vanish at the two boundaries. Let $|0\rangle$ be the lowest energy state for a simple harmonic oscillator such that $a(y_0)|0\rangle = 0$. $|n\rangle = \frac{1}{(n!)^{1/2}}(a^\dagger(y_0))^n|0\rangle$ is the eigenstates of $N(y_0) = a^\dagger(y_0)a(y_0)$ with eigenvalue n (an integer). In this case, the energy eigenstates in (7.38) are

$$|n, \alpha\rangle = \begin{pmatrix} \sin\theta_{n,\alpha}|n-1\rangle \\ \cos\theta_{n,\alpha}|n\rangle \end{pmatrix}, \tag{7.39}$$

where $\tan\theta_{n,\alpha} = \frac{\sqrt{n}}{\alpha\sqrt{n+m_0^2}-m_0}$ and $\alpha = \pm 1$ [43]. The Landau energy is given by

$$E_{n,\alpha} = \alpha v_F\sqrt{2e\hbar B\left(n + m_0^2\right)}, \tag{7.40}$$

which are highly degenerate for different values of y_0. The number of the allowed values of y_0, $N_L = L_y/\delta y_0 = 2\pi L_x L_y/l_B^2$, is called the degeneracy of the Landau levels.

It should be emphasized that the zero mode $E_0 = -v_F\sqrt{2e\hbar B}\,|m_0|$ for $n = 0$ and the eigenstate is fully saturated, $|0,0\rangle = \begin{pmatrix} 0 \\ |0\rangle \end{pmatrix}$. The energy expressions yield an energy gap $\Delta E = |E_{n=\pm 1}| - E_0$ between the zero mode and the states of $n = \pm 1$. For $m_0 = 0$ the energy gap is about $\Delta E \approx 800$ K for Bi_2Se_3 at $B = 10$ T, which makes it possible to measure the quantum Hall effect even at room temperature, just as in single layer graphene [44].

Unlike the conversional two-dimensional electron gas where the landau levels are evenly spaced, $E_n = \hbar\omega_c(n+\frac{1}{2})$, and the lowest Landau level of the conventional two-dimensional electron gas has a nonzero energy $\hbar\omega_c/2$ (ω_c is the cyclotron frequency), the Landau-level energies of massless Dirac fermions have a square-root dependence on a magnetic field B and the level index n, given by

$$E_n = \mathrm{sgn}(n)v_F\sqrt{2eB\hbar|n|}, \tag{7.41}$$

where the level index $n = 0, \pm 1, \pm 2, ...$ Moreover, Dirac fermions can have the zero Landau level index, $n = 0$, or even negative level indices, $n < 0$. This square-root dependence has been observed in the measurement of scanning tunneling spectroscopy [45, 46]. Despite the observation of the Landau levels in the STM measurement, an in-plane measurement with a Hall-bar setup still poses an experimental challenge, so the quantum Hall conductance has not yet been observed for the surface states of topological insulators.

7.7   Topological Insulator Thin Film

Thin film of three-dimensional topological insulators may provide an alternative way to realize the quantum spin Hall effect. It presents the opportunity to reduce a three-dimension topological insulator to a two-dimensional topological insulator. The surface states have spatial distribution, which can be characterized by a length scale ξ_s. When this length scale is comparable to the thickness of the thin film, the wave functions of the two surface states from the top and bottom surfaces will overlap in space. Consequently, the two surface states open gaps. Thus, the surface states of the thin film can be described by a two-dimensional massive Dirac model [16, 38].

7.7.1   Effective Model for Thin Film

Consider an extra-thin film in the x-y plane such that k_x and k_y are good quantum numbers, and the thickness of the thin film along the z-direction is denoted as L. To establish an effective model for an ultra-thin film, we still start with the electronic model in (7.1) and follow the approach to derive an effective model for the surface states where only one surface is considered, as discusssed in Sect. 7.3. The boundary

condition in the present problem is different as two surfaces are considered simultaneously. If the thin film is so thick that the surface states at the top and bottom layers are well separated, *i.e.*, $L \gg \lambda_1^{-1}, \lambda_2^{-1}$ which are the characteristic scales of the surface states defined in (7.3), then the thin film consists of two independent massless Dirac cones when the Fermi level is located in the bulk gap. However, if the thickness L is comparable with λ_1^{-1} and λ_2^{-1}, the two surface states at the top and bottom layers will be coupled together and will open an energy gap at the Dirac point. Thus, the massless Dirac electrons will gain a mass and evolve into massive Dirac electrons.

At $k_x = k_y = 0$, we have four roots for λ in (7.8): $\pm\lambda_1$ and $\pm\lambda_2$ as function of energy E. Thus, the final solution for the wave function should be a linear superposition of these solutions; for example

$$|\Psi_1\rangle = \sum_{i=1}^{4} c_i \begin{pmatrix} a_i \\ 0 \\ b_i \\ 0 \end{pmatrix} e^{\lambda_i z}. \tag{7.42}$$

We take the Dirichlet boundary condition for the wave functions at $z = \pm L/2$, i.e., $\Psi(z = \pm\frac{L}{2}) = 0$. Then, we can obtain a set of transcendental equations to determine the values of E, λ_1 and λ_2 as function of thickness L,

$$\frac{\alpha_1^2 \lambda_2^2 + \alpha_2^2 \lambda_1^2}{\alpha_1 \alpha_2 \lambda_1 \lambda_2} = \frac{\tanh \frac{\lambda_1 L}{2}}{\tanh \frac{\lambda_2 L}{2}} + \frac{\tanh \frac{\lambda_2 L}{2}}{\tanh \frac{\lambda_1 L}{2}}, \tag{7.43}$$

where $\alpha_{1,2} = E - C - M - (D_1 + B_1)\lambda_{1,2}^2$. In (7.43), λ_α define the behavior of the wave functions along the z-axis, and are functions of the energy E

$$\lambda_\alpha(E) = \sqrt{\frac{-F + (-1)^{\alpha-1}\sqrt{R}}{2(D_1^2 - B_1^2)}}, \tag{7.44}$$

where for convenience we have defined $F = A_\perp^2 + 2D_\perp(E - C) - 2B_\perp M$ and $R = F^2 - 4(D_\perp^2 - B_\perp^2)[(E - C)^2 - M^2]$. The two equations in (7.43) can be found numerically, and give two energies at the Γ point, *i.e.*, E_+ and E_-, which define an energy gap

$$\Delta \equiv E_+ - E_-. \tag{7.45}$$

We can find two solutions of $|\Psi_1\rangle$: φ^1 for E_+ and χ^1 for E_- and other two solutions for $|\Psi_2\rangle$: φ^2 for E_+ and χ^2 for E_-. For details readers may refer to the reference [16, 38]. By using these four solutions as basis states and rearranging their sequence following (note that each basis state is a four component vector) $(\varphi^1, \chi^2, \chi^1, \varphi^2)$, we can map the original Hamiltonian to the Hilbert space spanned by these four states, and reach a new low-energy effective Hamiltonian for the ultra-thin film:

$$H_{\text{eff}} = \begin{bmatrix} h_+(k) & 0 \\ 0 & h_-(k) \end{bmatrix}, \tag{7.46}$$

in which

$$h_{\tau_z}(k) = E_0 - Dk^2 - \hbar v_F(k_x\sigma_y - k_y\sigma_x) + \tau_z\left(\frac{\Delta}{2} - Bk^2\right)\sigma_z. \tag{7.47}$$

Note that here the basis states of Pauli matrices stand for spin-up and spin-down states of real spin. In (7.47), we have introduced a hyperbola index $\tau_z = \pm1$ (or $\pm$). Unlike the momentum correspondence in graphene, therev is a σ_z to $-\sigma_z$ correspondence in the present case. Therefore, the dispersions of $h_\pm$ are actually doubly degenerate, which is secured by time reversal symmetry. Here, $\tau_z = \pm$ are used to distinguish the two degenerate hyperbolas; $h_+(k)$ and $h_-(k)$ describe two sets of Dirac fermions, each show a pair of conduction and valence bands with the following dispersions

$$\varepsilon_\pm(\mathbf{k}) = E_0 - Dk^2 \pm \sqrt{\left(\frac{\Delta}{2} - Bk^2\right)^2 + (\hbar v_F)^2 k^2}, \tag{7.48}$$

where $+$ and $-$ correspond to the conduction and valence bands, respectively. The eigen states for $\varepsilon_\pm$ are

$$u_\pm(\mathbf{k}) = \frac{1}{\|u_\pm\|}\begin{bmatrix} \left(\frac{\Delta}{2} - Bk^2\right)\tau_z \pm \sqrt{\left(\frac{\Delta}{2} - Bk^2\right)^2 + (\hbar v_F)^2 k^2} \\ -i\hbar v_F k_+ \end{bmatrix} \tag{7.49}$$

with

$$\|u_\pm\| = \sqrt{\left[\left(\frac{\Delta}{2} - Bk^2\right)\tau_z \pm \sqrt{\left(\frac{\Delta}{2} - Bk^2\right)^2 + (\hbar v_F)^2 k^2}\right]^2 + (\hbar v_F)^2 k^2}. \tag{7.50}$$

The energy gap Δ and other model parameters are functions of thickness L and can be calculated numerically. The numerical results of Δ, v_F, D, and B are presented in Fig. 7.10. It is noted that $|D|$ must be less than $|B|$, otherwise the energy gap will disappear, and all of the following discussions will not be valid. The Δ terms play a role in the mass term in 2+1 Dirac equations.

In the large L limit,

$$v_F = \frac{A_\parallel}{\hbar}\sqrt{1 - \frac{D_\perp^2}{B_\perp^2}}. \tag{7.51}$$
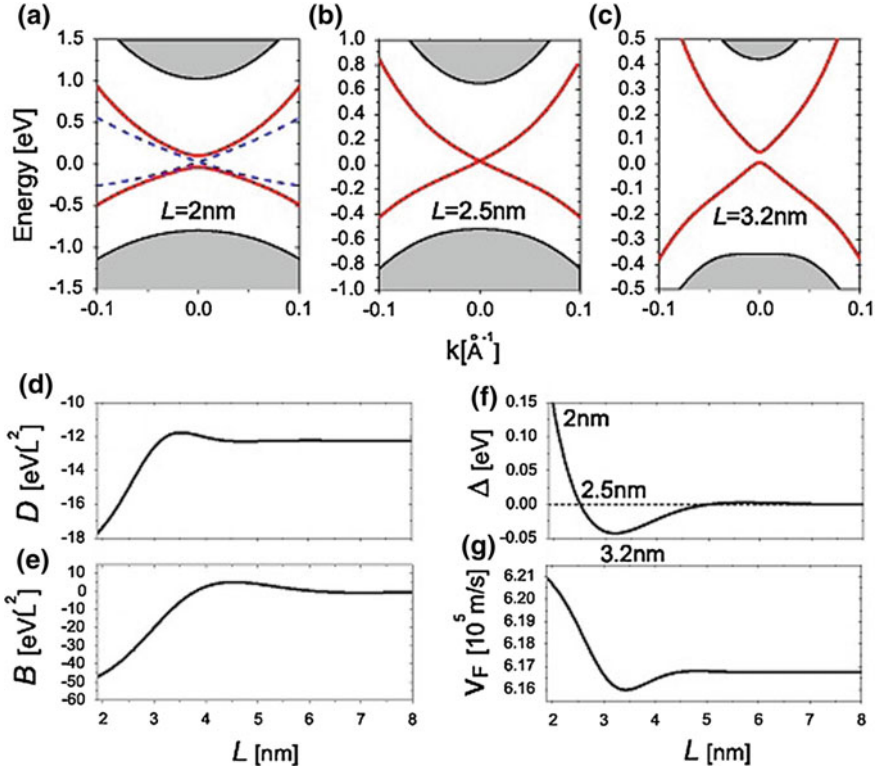

Fig. 7.10 a–c Two fold degenerate ($\tau_z = \pm 1$) energy spectra of surface states for thicknesses $L = 20, 25, 32$ (*solid lines*), and $L \rightarrow +\infty$ (*dash lines*). The *gray area* corresponds to the bulk states. The parameters are $M = 0.28\,\mathrm{eV}$, $A_1 = 2.2\,\mathrm{eV}$, $A_2 = 4.1\,\mathrm{eV}$, $B_1 = 10\,\mathrm{eV^2}$, $B_2 = 56.6\,\mathrm{eV^2}$, $C = -0.0068\,\mathrm{eV}$, $D_1 = 1.3\,\mathrm{eV^2}$, and $D_2 = 19.6\,\mathrm{eV^2}$. **d–g** The calculated parameters for the new effective model H_{eff} as a function of thickness L (Adapted from [38]) (color figure online)

The dispersion relation is given by

$$\varepsilon_{c/v}(k) = \pm v_F \hbar k \tag{7.52}$$

for small k. As a result, the energy gap closes at $k = 0$. The two massless Dirac cones are located near the top and bottom surfaces, respectively, as expected in a three-dimensional topological insulator.

In a small L limit,

$$v_F = \frac{A_\parallel}{\hbar}, \tag{7.53}$$

and

$$\Delta = \frac{2B_\perp \pi^2}{L^2}. \tag{7.54}$$

The ratio of the two velocities in the limits is

$$\eta = \frac{1}{\sqrt{1 - \frac{D_\perp^2}{B_\perp^2}}}. \tag{7.55}$$

It is noted that the velocity and energy gap for an ultra-thin film are enhanced for a thinner film.

7.7.2 Structural Inversion Asymmetry

Recent experiments [47, 48] revealed that the substrate on which the film is grown dramatically influences electronic structure inside the film. Because the top surface of the film is usually exposed to the vacuum and the bottom surface is attached to a substrate, the inversion symmetry does not hold along the z-direction, leading to the Rashba-like energy spectra for the gapped surface states. In this case, an extra term that describes the structure inversion asymmetry needs to be taken into account in the effective model.

Without loss of generality, we add a potential energy $V(z)$ into the Hamiltonian. Generally speaking, $V(z)$ can be expressed as $V(z) = V_s(z) + V_a(z)$, in which $V_s(z) = [V(z) + V(-z)]/2 = V_s(-z)$ and $V_a(z) = [V(z) - V(-z)]/2 = -V_a(-z)$. The symmetric term V_s could contribute to the mass term Δ in the effective model, which may lead to an energy splitting of the Dirac cone at the Γ point. Here we focus on the case of the antisymmetric term, $V(z) = V_a(z)$, which breaks the top-bottom inversion symmetry in the Hamiltonian. A detailed analysis gives the effective Hamiltonian for structure inversion asymmetry

$$V_{\text{eff}}^{\text{SIA}} = \begin{bmatrix} 0 & 0 & \tilde{V} & 0 \\ 0 & 0 & 0 & \tilde{V}^* \\ \tilde{V}^* & 0 & 0 & 0 \\ 0 & \tilde{V} & 0 & 0 \end{bmatrix}, \tag{7.56}$$

where

$$\tilde{V} = \int_{-L/2}^{L/2} dz \langle \varphi^1 | V_a(z) | \chi^1 \rangle. \tag{7.57}$$

When the term of the structure inversion asymmetry is included, the Hamiltonian in (7.46) with V_{eff}^{SIA} (7.56) gives

$$E_{1,\pm} = E_0 - Dk^2 \pm \sqrt{\left(\frac{\Delta}{2} - Bk^2\right)^2 + (|\tilde{V}| + \hbar v_F k)^2}, \qquad (7.58)$$

$$E_{2,\pm} = E_0 - Dk^2 \pm \sqrt{\left(\frac{\Delta}{2} - Bk^2\right)^2 + (|\tilde{V}| - \hbar v_F k)^2}, \qquad (7.59)$$

where the extra index 1 (2) stands for the inner (outer) branches of the conduction or valence bands. Consequently, both the conduction and valence bands show Rashba-like splitting in the presence of structure inversion asymmetry. An intuitive understanding of the energy spectra can be developed with the help of Fig. 7.11. On the left is a thicker freestanding symmetric topological insulator film with a single gapless Dirac cone on each of its two surfaces, with the solid and dash lines for the top and bottom surface, respectively. The two Dirac cones are degenerate. The top of Fig. 7.11 indicates that the inter-surface coupling across an ultrathin film will turn the Dirac cones into gapped Dirac hyperbolas. On the bottom of Fig. 7.11, the structure inversion asymmetry lifts the Dirac cone at the top surface, while lowering the Dirac cone at the bottom surface. The potential difference at the top and bottom surfaces removes the degeneracy of the Dirac cones. On the right of Fig. 7.11, the coexistence of both the inter-surface coupling and structure inversion asymmetry leads to two gapped Dirac hyperbolas that also split in the k-direction.

Fig. 7.11 Evolution of the doubly degenerate gapless Dirac cones for the 2D surface states, in the presence of both inter-surface coupling and structure inversion asymmetry (SIA), into gapped hyperbolas that also split in the k-direction. The *blue solid* and *green dashed lines* correspond to the states residing near the *top* and *bottom* surfaces, respectively (color figure online)

7.7.3 Experimental Data of ARPES

Several groups have investigated the thickness-dependent band structure of molecular beam epitaxy-grown ultrathin film Bi_2Se_3 using angle-resolved photoemission spectroscopy [47, 48]. The energy gap due to the interlayer coupling has been observed experimentally in the surface states of ultrathin film Bi_2Se_3 below the thickness of 6QL. The spectrum splitting caused by structure inversion asymmetry was also confirmed. The observed experimental data can be fitted by the dispersion in (7.59) very well as shown in Fig. 7.12.

The gap in the surface states is caused by the spatial confinement of thin film, which does not break the time reversal symmetry. This is different from the gap opening in the surface states in a Zeeman field or magnetic impurity doping.

7.8 HgTe Thin Film

HgTe is a semimetal with an inverted band structure. Usually a strain will induce an energy gap and force the HgTe to evolve into a topological insulator. However, it is technically difficult to apply a strong strain to a sample to make a semimetal insulating

in experimental conditions. The finite size effect provides a practical way to open an energy gap in the bulk state when the dimensionality of the sample is reduced from three dimensions to two dimensions, as in the case of a quantum well [14].

When the film is thin enough, the band gap caused by the finite size effect becomes obvious. In this case the finite confinement induced sub-bands are far away from the low-energy regime. We can then use the quantum well approximation $\langle k_z \rangle = 0$, $\langle k_z^2 \rangle \simeq (\pi/L)^2$. Using the relations in the Hamiltonian in (6.88), and choosing the basis set in the sequence $(|\psi_1\rangle, |\psi_3\rangle, |\psi_5\rangle, |\psi_2\rangle, |\psi_6\rangle, |\psi_4\rangle)$, we can obtain a two-dimensional 6-band Kane model

$$H(\mathbf{k}) = \begin{pmatrix} h(\mathbf{k}) & 0 \\ 0 & h^*(-\mathbf{k}) \end{pmatrix}, \tag{7.60}$$

where

$$h(\mathbf{k}) = \begin{pmatrix} h_{11} & -\frac{1}{\sqrt{2}}Pk_+ & \frac{1}{\sqrt{6}}Pk_- \\ -\frac{1}{\sqrt{2}}Pk_- & h_{22} & \sqrt{3}\overline{\gamma}Bk_-^2 \\ \frac{1}{\sqrt{6}}Pk_+ & \sqrt{3}\overline{\gamma}Bk_+^2 & h_{33} \end{pmatrix} \tag{7.61}$$

with

$$h_{11} = E_g + B(2F+1)(k_\parallel^2 + \langle k_z^2 \rangle), \tag{7.62}$$

$$h_{22} = -(\gamma_1 + \overline{\gamma})Bk_\parallel^2 - (\gamma_1 - 2\overline{\gamma})B\langle k_z^2 \rangle, \tag{7.63}$$

and

$$h_{33} = -(\gamma_1 - \overline{\gamma})Bk_\parallel^2 - (\gamma_1 + 2\overline{\gamma})B\langle k_z^2 \rangle. \tag{7.64}$$

The system retains the time reversal symmetry, and the representation of the symmetry operation in the new set of basis is given by $T = \mathcal{K} \cdot i\sigma^y \otimes I_{3\times3}$, where $\mathcal{K}$ is the complex conjugation operator, σ^y and I denote the Pauli matrix and identity matrix, respectively.

We can study the two blocks separately as they are time reversal counterparts of each other. Here we focus on the upper block first. At $k_x = 0$, the boundaries of Γ_6, light hole (LH) and heavy hole (HH) are at $E = E_g + B(2F+1)\langle k_z^2 \rangle$, $E = -(\gamma_1 - 2\overline{\gamma})B\langle k_z^2 \rangle$, and $E = -(\gamma_1 + 2\overline{\gamma})B\langle k_z^2 \rangle$, respectively, which are controllable by choosing film thickness L. Down to $L \approx 30$ Å, Γ_6 band flips up and exchanges position with HH, and the system is still non-trivial. Further down to $L \approx 20$ Å, Γ_6 flips up and exchanges with the conduction band. The band structure becomes trivial. Using the tight binding approximation, we can transform $h(\mathbf{k})$ into a tight binding model on a two-dimensional lattice. In Fig. 7.13 we show the local density of states on the edge of a semi-infinite film for $h(\mathbf{k})$. When $L > 20$ Å the edge states are found connecting the valence and conduction bands. After the system becomes trivial when $L < 20$ Å, the edge states do not cross the band gap anymore,
Fig. 7.13 Local density of states at the edge of thin films at different thickness using the Hamiltonian in (7.60) with 2D lattice model in the tight-binding approximation. **a** L = 28A; **b** L = 25A; **c** L = 20A; **d** L = 16A (Adapted from [14])

instead, they only attach to the valence band. At the critical point $L = 20\,\text{Å}$, the valence band and conduction band touch and form a linear Dirac cone at the low energy regime. This shows that by controlling the film thickness, it is possible to obtain a single-valley Dirac cone for each spin block without using the topological surface states [49]. Notice that in Fig. 7.13 we can also see the edge states submerging in the valence bands.

Chapter 8
Impurities and Defects in Topological Insulators

Abstract Impurities and defects in topological insulators can be regarded as system boundaries. Bound states may form around these impurities or defects for the same reason that the edge or surface states form.

Topological insulators are distinguished from conventional band insulators by the Z_2 invariant classification of the band insulators that respect time reversal symmetry. Variation in the Z_2 invariants at their boundaries will lead to topologically protected edge or surface states with a gapless Dirac energy spectrum. Impurities or defects are inevitably present in topological insulators. They may change the geometry or topology of the systems, and induce the bound states as those near the boundary. Given that a boundary state is a manifestation of the topological nature of bulk bands, one should examine the host bulk to understand how impurities or defects affect the electronic structure. It is known that a single impurity or defect can induce bound states in many systems, such as in the Yu-Shiba state in s-wave superconductors [1, 2] and in d-wave superconductors [3]. In this chapter, we study the formation of bound states around a single vacancy or defect in the bulk energy gap of topological insulators.

8.1 One Dimension

When a δ potential $V(x) = V_0\delta(x)$ is present in an infinite one-dimensional topological insulator, the equation for the wave function reads,

$$\left[vp_x\sigma_x + \left(mv^2 - Bp_x^2\right)\sigma_z + V_0\delta(x)\right]\Psi(x) = E\Psi(x), \qquad (8.1)$$

where $\Psi(x)$ is a two-component spinor. The continuity of the wave function at $x = 0$ requires

$$\lim_{\epsilon\to 0^+}\Psi(\epsilon) = \Psi(-\epsilon). \qquad (8.2)$$

In addition, the integral of (8.1) around the δ potential leads to

$$\lim_{\epsilon \to 0^+} \left[\partial_x \Psi|_{x=\epsilon} - \partial_x \Psi|_{x=-\epsilon} \right] = -\frac{V_0}{B\hbar^2} \sigma_z \Psi(0), \tag{8.3}$$

i.e., the derivative of the wave function is not continuous at $x = 0$. To find a bound state near $x = 0$, the electron wave function should vanish when $x \to \pm\infty$.

For $x > 0$,

$$\Psi(x > 0) = c_1^+ e^{-x/\xi_1} + c_2^+ e^{-x/\xi_2}, \tag{8.4}$$

and for $x < 0$,

$$\Psi(x < 0) = c_1^- e^{+x/\xi_1} + c_2^- e^{+x/\xi_2}, \tag{8.5}$$

with $\xi_{1,2}^{-1} = \frac{|v|}{2|B|\hbar}(1 \pm \sqrt{1 - 4mB})$.

Substituting the wave function into (8.2) and (8.3) at $x = 0$, one obtains two transcendental equations for the bound state energy,

$$\sqrt{1 - 2mB + 2|mB|\sqrt{1 - \frac{E^2}{m^2v^4}}} = \frac{V_0}{2\hbar v} \left[\frac{\pm mv^2 - E}{\sqrt{m^2v^4 - E^2}} \mp \text{sgn}(B) \right], \tag{8.6}$$

where up to two solutions can be found. When $V_0 = 0$ and the δ potential vanishes there is no solution to the equation that satisfies the boundary condition.

The bound states essentially have the same origin as the boundary states in topological insulators as shown in Fig. 8.1. Consider an infinite one-dimensional topological insulator, in which the energy gap separates the positive and negative spectra. If we

Fig. 8.1 In-gap bound states in a one-dimensional topological insulator. **a** The presence of end states with zero energy at the open boundaries of a broken one-dimensional topological insulator. **b** The zero-energy end states evolve into in-gap bound states when the two open boundaries are connected by an impurity

cut the chain at one point, say at $x = 0$, then we produce two open boundaries at the two sides of $x > 0$ and $x < 0$. There exists a pair of states (end states) at the boundaries with the following energy:

$$\Psi(\pm) = \frac{C}{\sqrt{2}} \begin{pmatrix} \pm \text{sgn}(B) \\ i \end{pmatrix} (e^{\mp x/\xi_1} - e^{\mp x/\xi_2}), \tag{8.7}$$

with $C = \sqrt{2(\xi_1 + \xi_2)}/|\xi_1 - \xi_2|$. $\pm$ indicates that the semi-infinite chain lies in the region $x > 0$ or < 0. The energies of these states lie inside the bulk gap, and are equal to zero. Now we paste the two ends together again with some kind of "glue potential", it is possible that these end states can be trapped or mixed around the connecting point and will evolve into in-gap bound states. The shapes of the possibility density of the wave function of our solutions for a $\delta-$potential supports this intuitive picture of the formation of the in-gap bound states. An impurity located at $x = 0$, unlike the open boundary, allows tunneling between the two ends of the chain, and will affect the behavior of the wave function near the point $x = 0$. For a $\delta-$potential, the bound states induced by it are always there, regardless its strength [4].

For comparison, consider an ordinary insulator of $mB < 0$. A pair of bound states induced by a $\delta-$potential is also possible when $0 < |V_0| < 2\hbar|v|/\sqrt{1 - 2mB}$, but vanishes after $|V_0|$ exceeds $2\hbar|v|/\sqrt{1 - 2mB}$, indicating a distinct origin from those induced when $mB > 0$.

8.2 Integral Equation for Bound State Energies

The bound states can be formally obtained by solving an integral equation. Although in most cases the integral equation cannot be solved analytically, it does provide rich information about the existence of bound states under certain impurity potentials in various dimensions. The modified Dirac equation with a potential $V(\mathbf{r})$ can be written as

$$[E - H_0(\mathbf{r})]\Psi(\mathbf{r}) = V(\mathbf{r})\Psi(\mathbf{r}). \tag{8.8}$$

The wave function $\Psi(\mathbf{r})$ can be expanded by its Fourier transformation components into

$$\Psi(\mathbf{r}) = \sum_{\mathbf{p}'} u_{\mathbf{p}'} e^{i\mathbf{p}' \cdot \mathbf{r}/\hbar}. \tag{8.9}$$

Thus, one obtains,

$$[E - H_0(\mathbf{p})]u_{\mathbf{p}} = \sum_{\mathbf{p}'} V_{\mathbf{p}\mathbf{p}'} u_{\mathbf{p}'}, \tag{8.10}$$

where $V_{\mathbf{p}\mathbf{p}'} = \int d\mathbf{r} V(\mathbf{r}) e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{r}/\hbar}$. Although this equation cannot be solved analytically in general, one can find the solution if $V_{\mathbf{p}\mathbf{p}'}$ is taken to be a factorizable

potential [5]:

$$V_{\mathbf{pp'}} = V_0 \xi^*(p)\xi(p'). \tag{8.11}$$

In this case,

$$u_{\mathbf{p}} = \frac{V_0 \xi^*(p)}{E - H_0(\mathbf{p})} \sum_{\mathbf{p'}} \xi(p')u_{\mathbf{p'}}. \tag{8.12}$$

Multiplying $\xi(p)$ in (8.12) and summarizing over p, it follows that

$$\left[\sum_p \frac{V_0 \xi^*(p)\xi(p)}{E - H_0(\mathbf{p})} - 1 \right] \sum_{\mathbf{p'}} \xi(p')u_{\mathbf{p'}} = 0. \tag{8.13}$$

Thus, one obtains

$$\det \left[\sum_p \frac{V_0 \xi^*(p)\xi(p)}{E - H_0(\mathbf{p})} - 1 \right] = 0. \tag{8.14}$$

For a magnetic impurity, it is more complicated.

More generally, the solution can be determined if the system is isotropic and $V_{\mathbf{pp'}}$ can be expanded into its partial wave components,

$$V_{\mathbf{pp'}} = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} V(|\mathbf{p}|,|\mathbf{p'}|)Y_l^m(\Omega_p)Y_l^{-m}(\Omega_{p'}), \tag{8.15}$$

with a factorizable $V(|\mathbf{p}|,|\mathbf{p'}|) = \lambda_l w_p^l(w_{p'}^l)^*$, where $Y_l^m(\Omega_p)$ is the spherical harmonic Bessel function.

8.2.1 δ−Potential

For a delta potential $V(\mathbf{r}) = V_0\delta(\mathbf{r})$, $V_{\mathbf{pp'}} \equiv V_0$. A nontrivial solution requires

$$\det \left[\sum_{\mathbf{p}} \frac{V_0}{E - H_0(\mathbf{p})} - 1 \right] = 0, \tag{8.16}$$

or

$$\det \left[\int \frac{d^d\mathbf{p}}{(2\pi\hbar)^d} \frac{V_0}{E - H_0(\mathbf{p})} - 1 \right] = 0, \tag{8.17}$$

where d is the dimensionality.

For the one-dimensional case, the modified Dirac Hamiltonian can be easily inverted. After some algebra we have,

$$\int_0^{+\infty} \frac{dk_x}{\pi} \frac{[E_{A/B} \pm (mv^2 - B\hbar^2 k_x^2)]V_0}{E_{A/B}^2 - (mv^2 - B\hbar^2 k_x^2)^2 - v^2\hbar^2 k_x^2} = 1, \tag{8.18}$$

where E_A and E_B denote the energy solution for $+$ and $-$, respectively. From this equation we can recover the result given in Sect. 8.1.

For the two-dimensional case, one can obtain a similar integral equation for the two-dimensional bound state energies,

$$\int_0^{+\infty} \frac{kdk}{2\pi} \frac{[E_{A/B} \pm (mv^2 - B\hbar^2 k^2)]V_0}{E_{A/B}^2 - (mv^2 - B\hbar^2 k^2)^2 - v^2\hbar^2 k^2} = 1, \tag{8.19}$$

where $k^2 = k_x^2 + k_y^2$. However the integral in (8.19) will logarithmically diverge when $|k| \to +\infty$. This means that in the two-dimensional case, an impurity with δ-potential cannot trap any bound states. Similarly, in three dimensions, although the integration equation is more complicated, divergence also exists in the k-integration, which excludes the possibility of three-dimensional bound states under δ-potential.

As the Brillouin zone of lattice crystal is always finite, it is possible to form bound states under δ−potential by introducing a reasonable cut-off of k.

8.3   Bound States in Two Dimensions

The formation of the in-gap bound states can be readily illustrated by reviewing the edge states in two-dimensional topological insulators. As the Z_2 index varies across the boundary, the edge states arise in the gap with the gapless Dirac dispersion. Unlike the quantum Hall effect in a magnetic field, spin-orbit coupling respects the time reversal symmetry, so the resulting edge states appear in pairs, of which one state is the time reversal counterpart of the other, propagating in opposite directions and with opposite spins (Fig. 8.2b). Now imagine that the system edge is bent into a hole or punch a large hole in the system; the edge states will then circulate around the hole, as the periodic boundary conditions along the propagating direction remain unchanged (Fig. 8.2d). The dispersion of these edge state is proportional to $(n + \frac{1}{2})\hbar/R$ ($n\hbar$ is for orbital angular momentum). As the radius of the hole shrinks, most of the edge states will be expelled into the bulk bands as the energy separation between the states becomes larger and larger for a smaller R. It is found that at least two degenerate pairs of the states will be trapped to form bound states in the gap as the hole shrinks into a point defect. This mechanism forming the bound states can be realized in a topological insulator in all dimensions.

In two dimensions, the modified Dirac model can be reduced into two independent 2×2 Hamiltonians:

$$h_{\pm} = (mv^2 - B\mathbf{p}^2)\sigma_z + v(\mathbf{p}_x\sigma_x \pm \mathbf{p}_y\sigma_y), \tag{8.20}$$

Fig. 8.2 Schematic description of the formation of vacancy-induced in-gap bound states in two-dimensional topological insulators. **a** and **b** A pair of helical edge states traveling along the edge of a two-dimensional topological insulator with the gapless Dirac dispersion. **c** and **d** When the edge is bent into a hole, the helical edge states evolve to circulate around the hole. **e** and **f** The circulating edge states may develop into bound states as the hole shrinks into a point or is replaced by a vacancy (Adapted from [6])

with h_- the time reversal counterpart of h_+ [7–9]. It is convenient to adopt the polar coordinates $(x, y) = r(\cos\varphi, \sin\varphi)$ in two dimensions. In the coordinate

$$p_\pm = -i\hbar e^{\pm i\theta}\left(\partial_r \pm \frac{i\partial_\theta}{r}\right) \tag{8.21}$$

and

$$\mathbf{p}^2 = -\hbar^2\left(\partial_r^2 + \frac{1}{r}\partial_r + \frac{1}{r^2}\partial_\theta^2\right). \tag{8.22}$$

Here these equations are solved under the Dirichlet boundary conditions (Fig. 8.2a), i.e., the center of the two-dimensional topological insulator is punched with a hole of radius R, thus, the wave function is required to vanish at $r = R$ and $r = +\infty$. Due to the rotational symmetry of h_+, it is found that the z-component of the total angular momentum $J_z = -i\hbar\partial_\theta + (\hbar/2)\sigma_z$ satisfies

$$[h_+, J_z] = 0 \tag{8.23}$$

and provides a good quantum number. The wave function has a general form

$$\varphi_l(r, \theta) = \begin{pmatrix} f_l(r)e^{il\theta} \\ g_l(r)e^{i(l+1)\theta} \end{pmatrix} \tag{8.24}$$

with an integer l, satisfying that $J_z \varphi_l(r, \theta) = j\hbar\varphi_l(r, \theta)$ with $j = l + \frac{1}{2}$. Thus, the equation is reduced so that for the radial part of the wave function,

$$h_{eff} \begin{pmatrix} f_l(r) \\ g_l(r) \end{pmatrix} = E \begin{pmatrix} f_l(r) \\ g_l(r) \end{pmatrix}, \tag{8.25}$$

where

$$h_{eff} = \begin{pmatrix} mv^2 + \hbar^2 B(\partial_r^2 + \frac{\partial_r}{r} - \frac{l^2}{r^2}) & -i\hbar v(\partial_r + \frac{l+1}{r}) \\ -i\hbar v(\partial_r - \frac{l}{r}) & -mv^2 - \hbar^2 B(\partial_r^2 + \frac{\partial_r}{r} - \frac{(l+1)^2}{r^2}) \end{pmatrix}. \tag{8.26}$$

We take the trial wave function

$$f_l(r) = c_l K_l(\lambda r) \tag{8.27}$$

and

$$g_l(r) = d_l K_{l+1}(\lambda r), \tag{8.28}$$

where $K_n(x)$ is the modified Bessel function of the second kind. The secular equations give four roots of $\lambda_n (= \pm\lambda_1, \pm\lambda_2)$ as functions of E,

$$\lambda_{1,2}^2 = \frac{v^2}{2B^2\hbar^2} \left[1 - 2mB \pm \sqrt{1 - 4mB + \frac{4B^2E^2}{v^4}} \right]. \tag{8.29}$$

Using the Dirichlet boundary conditions at $r = R$ and $r = +\infty$ we arrive at the transcendental equation for the bound-state energies:

$$\frac{\lambda_1^2 + \frac{mv^2 - E}{B\hbar^2}}{\lambda_1} \frac{K_{l+1}(\lambda_1 R)}{K_l(\lambda_1 R)} = \frac{\lambda_2^2 + \frac{mv^2 - E}{B\hbar^2}}{\lambda_2} \frac{K_{l+1}(\lambda_2 R)}{K_l(\lambda_2 R)}. \tag{8.30}$$

As there is more than one value of λ, the wave function should be the linear combination of the modified Bessel functions; for example, $f_l(r) = c_1 K_l(\lambda_1 r) + c_2 K_l(\lambda_2 r)$. With the boundary condition at $r = R$, the wave function $\varphi_l(r, \theta)$ for h_+ turns out to have the form

$$\begin{bmatrix} \frac{K_l(\lambda_1 R)}{K_{l+1}(\lambda_1 R)} f_l(r)e^{il\theta} \\ i\frac{\lambda_1^2 + \frac{mv^2 - E}{B\hbar^2}}{(\lambda_1 v/B\hbar)} f_{l+1}(r)e^{i(l+1)\theta} \end{bmatrix} \tag{8.31}$$

with

$$f_l(r) = \frac{K_l(\lambda_1 r)}{K_l(\lambda_1 R)} - \frac{K_l(\lambda_2 r)}{K_l(\lambda_2 R)}. \tag{8.32}$$

The solution for h_- can be derived following the same procedure.

In Fig. 8.2c, d, we show the bound-state energies as functions of R for an ideal case (Fig. 8.2b, $mB = 1$), for the HgTe quantum well (Fig. 8.2c, $mB = 0.05$), and for a two-quintuple-layer of Bi_2Se_3 thin film (Fig. 8.2d, $mB = 0.32$). For a macroscopically large R, we find an approximated solution for the energy spectrum

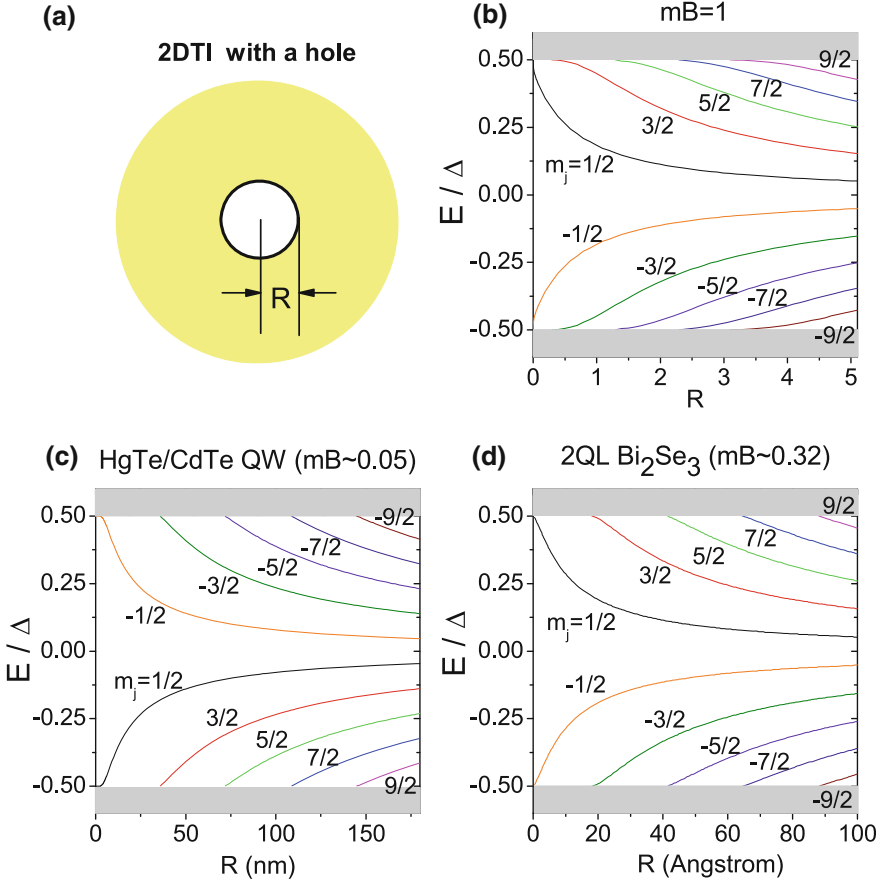

Fig. 8.3 Two-dimensional in-gap bound states. **a** A two-dimensional topological insulator with a hole of radius R at the center. **b**–**d** Energies (E in units of the band gap Δ) of in-gap bound states circulating around the hole as functions of the hole radius. m_j is the quantum number for the z-component of the total angular momentum of the circulating bound states. In **b**, $m = v = B = \hbar = 1$; in **c**, $mv^2 = -10$ meV, $B\hbar^2 = -686$ meV nm^2, and $\hbar v = 364.5$ meV nm (Adopted from Ref. [7]); in d, $mv^2 = 0.126$ eV, $B\hbar^2 = 21.8$ eV^2, $\hbar v = 2.94$ eV (Adopted from Ref. [11]). $\Delta = 2mv^2$ for $0 < mB < 1/2$, and $\Delta = (v^2/|B|)\sqrt{4mB - 1}$ for $mB > 1/2$. The *grey areas line* mark the bulk bands (Adopted from[6])

of h_+ as $E = (l + \frac{1}{2})\hbar v \text{sgn}(B)/R$. As the time reversal copy of h_+, h_- has an approximated spectrum $E = -(l + \frac{1}{2})\hbar v \text{sgn}(B)/R$. They form a series of paired helical edge states, in good agreement with the edge-state solutions in the two-dimensional quantum spin Hall system [10] if we take $k = (l + \frac{1}{2})/R$ for a large R. As R shrinks, the energy separation of these edge state $\Delta E = \hbar v R$ increases with the smaller R, and the edge states with a higher l will be pushed out of the energy gap gradually. However, we observe that for $mB > 0$ the state with $l = 0$ always stays in the energy gap, and as $R \to 0$ their energies approach $E = \pm(v^2/2|B|)\sqrt{4mB - 1}$ for $mB > \frac{1}{2}$ or $\pm mv^2$ for $0 < mB < \frac{1}{2}$. When comparing the details of Fig. 8.2c with d, we find that the two pairs of states for $l = 0$ have quite different asymptotic behaviors in the spectrum when R decreases to zero. This can be explained by noting that there is no in-gap bound state when $mB < 0$, suggesting that $mB = 0$ is the critical point for the topological phase transition. The bound state with a smaller mB is closer to the transition point, and thus, tends to enter the bulk more easily.

The solutions verify the formation of the in-gap bound states as shown in Fig. 8.3. Therefore considering the symmetry between h_+ and h_- we conclude that in the presence of vacancy or defect there always exist *at least* two pairs of bound states in the energy gap in the two-dimensional quantum spin Hall system.

8.4   Topological Defects

There are several types of topological defects, such as magnetic monopoles, vortex lines, or domain walls. In Sect. 2.2, we have already solved the problem of domain walls with a kink of mass distribution. The solution of zero energy is quite robust against the distribution of domain walls. The solution has many applications in polymers. The charge and spin carriers in one-dimensional polyacetylene are topological excitations generated by domain walls. Here we present a solution of a zero energy mode for a quantum vortex in the quantum Hall system, and its application to three-dimensional systems.

8.4.1   Magnetic Flux and Zero Energy Mode

When a magnetic flux is threading the hole, the energy levels of the in-gap bound states can be continuously manipulated. Consider a magnetic flux ϕ that threads through a hole with a radius R. We perform the Peierls substitution $\mathbf{p} \to \mathbf{p} + e\mathbf{A}$ in h_+ in (8.20) by taking the gauge $\mathbf{A} = (\Phi/2\pi r)\mathbf{e}_\theta$, which still keeps m_j as a good quantum number. Therefore the eigenfunctions of this new Hamiltonian can be readily expressed as $\exp(-i\nu\theta)\varphi_l(r, \theta)$ after a gauge transformation, with $\nu = \phi/\phi_0$ and the flux quantum $\phi_0 = h/e$. In this case, the allowed value for the total angular momentum becomes $j = l + \frac{1}{2} + \nu$. The energies of in-gap bound states vary with
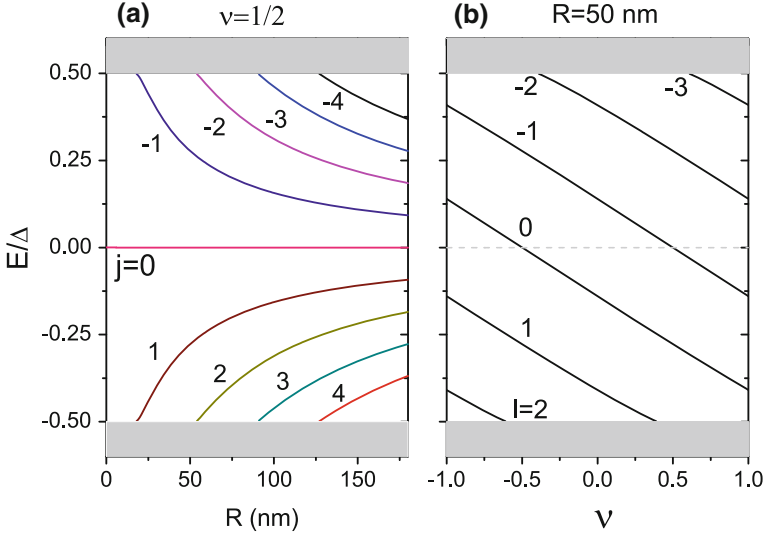

Fig. 8.4 Effect of magnetic flux on in-gap bound states. Energies (E in units of the band gap Δ) of in-gap bound states circulating around the hole as functions of **a** the hole radius R when half-quantum flux $\nu = 1/2$ is applied and **b** the magnetic flux ν (in unit of flux quantum $\Phi_0 = h/e$) for a fixed radius $R = 50$ nm. m_+ (m_-) is the quantum number for the z-component of the total angular momentum j_{z+} (j_{z-}) of the circulating bound states. $m_j = m_+ + \nu$. In **b**, *black* (*light gray*) lines belong to the h_+ (h_-) block. In **a** and **b**, $mv^2 = -10$ meV, $B\hbar^2 = -686$ meV nm^2, and $\hbar v = 364.5$ meV nm (adopted from Ref. [7]. $\Delta = 2mv^2$). The *grey areas mark* the bulk bands

the radius of the hole and the magnetic flux as shown in Fig. 8.4. When $\nu = \frac{1}{2}$ or $-\frac{1}{2}$, there always exists one solution of $j = 0$. In this case, the solution has a general form of

$$\varphi_{j=0}(r, \theta) = \begin{pmatrix} f_{\frac{1}{2}}(r)e^{-i\frac{\theta}{2}} \\ g_{\frac{1}{2}}(r)e^{+i\frac{\theta}{2}} \end{pmatrix}. \tag{8.33}$$

Equivalently, we replace l in (8.26) by $-\frac{1}{2}$,

$$\left[E + i\hbar v(\partial_r + \frac{1}{2r})\sigma_x - \left[mv^2 + \hbar^2 B\left(\partial_r^2 + \frac{\partial_r}{r} - \frac{1}{4r^2}\right)\right]\sigma_z\right]\begin{pmatrix} f \\ g \end{pmatrix} = 0. \tag{8.34}$$

Under a transformation,

$$\begin{pmatrix} f_{\frac{1}{2}}(r) \\ g_{\frac{1}{2}}(r) \end{pmatrix} = \frac{1}{\sqrt{r}}\phi(r), \tag{8.35}$$

the equation for the radial part of the wave function is reduced into a one-dimensional modified Dirac equation.

$$\left[-i\hbar v\partial_r\sigma_x + \left(mv^2 + \hbar^2 B\partial_r^2\right)\sigma_z\right]\phi(r) = E\phi(r). \tag{8.36}$$

There exists one bound state solution with zero energy near the boundary given in Sect. 2.5.1. As a result it is found that

$$\varphi_{j=0}(r,\theta) = C\left[\begin{array}{c} e^{-i\frac{\theta}{2}} \\ isgn(B)e^{+i\frac{\theta}{2}} \end{array}\right]\left(\frac{K_{\frac{1}{2}}(\lambda_1 r)}{K_{\frac{1}{2}}(\lambda_1 R)} - \frac{K_{\frac{1}{2}}(\lambda_2 r)}{K_{\frac{1}{2}}(\lambda_2 R)}\right) \tag{8.37}$$

with $E = 0$. The modified Bessel function $K_{1/2}(x) = \sqrt{\frac{\pi}{2x}}e^{-x}$, and C is a normalized constant. Thus, when $\nu = \frac{1}{2}$ or $-\frac{1}{2}$, there always exists a stable solution of $j = 0$ with the energy eigenvalue exactly zero for an arbitrary R. As the energy eigenvalue is independent of the radius R, the half quantum flux here is also called a topological defect. The existence of the zero energy mode is valid even for an irregular hole that can be deformed continuously into a point-like defect.

8.4.2 Wormhole Effect

This solution can be generalized to three dimensions. Consider a topological insulator with a cylindrical hole (say along the z-direction) of radius R thread by a magnetic flux $\nu = \frac{1}{2}$. We take the periodic boundary condition along the z-direction. Thus, k_z is a good quantum number. The three-dimensional effective Hamiltonian can be separated into two parts,

$$H_{3D}(k_z) = H_{2D} + V(k_z), \tag{8.38}$$

where

$$H_{2D}(x,y) = vp_x\alpha_x + vp_y\alpha_y + \left[mv^2 - B(p_x^2 + p_y^2)\right]\beta \tag{8.39}$$

and

$$V(k_z) = v\hbar k_z\alpha_z - Bk_z^2\beta. \tag{8.40}$$

At $k_z = 0$, $V(k_z = 0) = 0$. In this case, H_{3D} are equivalent to two separated two-dimensional Dirac equations in a hole threading a magnetic flux. Using the solutions in the last paragraph for the two-dimensional case, one obtains two solutions of zero energy

$$\varphi_1 = C\begin{pmatrix} e^{-i\frac{\theta}{2}} \\ 0 \\ 0 \\ isgn(B)e^{+i\frac{\theta}{2}} \end{pmatrix}\left(\frac{K_{\frac{1}{2}}(\lambda_1 r)}{K_{\frac{1}{2}}(\lambda_1 R)} - \frac{K_{\frac{1}{2}}(\lambda_2 r)}{K_{\frac{1}{2}}(\lambda_2 R)}\right) \tag{8.41}$$

and

$$\varphi_2 = C \begin{pmatrix} 0 \\ e^{+i\frac{\theta}{2}} \\ isgn(B)e^{-i\frac{\theta}{2}} \\ 0 \end{pmatrix} \left(\frac{K_{\frac{1}{2}}(\lambda_1 r)}{K_{\frac{1}{2}}(\lambda_1 R)} - \frac{K_{\frac{1}{2}}(\lambda_2 r)}{K_{\frac{1}{2}}(\lambda_2 R)} \right). \tag{8.42}$$

The order of the base has been re-organized. Note that the two separated equations are counter-partners of time reversal, and the prefactors of θ in φ_2 change signs. Use these two solutions as the basis, one obtains an effective Hamiltonian for a non-zero k_z,

$$H_{eff} = sgn(B)v\hbar k_z \sigma_y. \tag{8.43}$$

Thus, there exists a pair of gapless helical electron states along the hole or magnetic flux, which is independent of the radius R. This is the so-called wormhole effect [12].

Dislocations are line defects of the three-dimensional crystalline order, characterized by a lattice vector $\mathbf{B}$ (the Burgers vector). This is rather like the quantized vorticity of a superfluid vortex, and must remain constant over its entire length. Dislocations in the three-dimensional crystal of a topological insulator is equivalent to a hole threading a magnetic flux of $\nu = \frac{1}{2}$. Ran et al. found that each dislocation induces a pair of one-dimensional modes bound to it, which propagate in opposite directions and traverse the bulk band gap [13].

8.4.3 Witten Effect

The Witten effect is a fundamental property of the axion media [14]. The idea of the axion was first introduced as a means to solve what is known as the strong charge-parity problem in the physics of strong interactions. After the discovery of topological insulators, Qi, Hughes, and Zhang proposed that the electromagnetic response in topological insulators is characterized by an axion term, $\Delta L_{axion} = \theta \frac{e^2}{2\pi h} \mathbf{B} \cdot \mathbf{E}$ with $\theta = \pi$ [15]. The Witten effect means that a unit magnetic monopole $\phi_0 = h/e$ placed in a topological insulator will bind a fractional charge $Q = -e\left(n + \frac{1}{2}\right)$ with n integer. This effect has been already used to identify whether a system is topologically trivial or non-trivial by means of numerical calculation [16].

The axion term revises the Gauss' law and Ampere's law by adding extra source terms

$$\nabla \cdot \mathbf{D} = \rho - \frac{\alpha}{\pi \mu_0 c} \nabla \theta \cdot \mathbf{B} \tag{8.44}$$

and

$$\nabla \times \mathbf{H} = \partial_t \mathbf{D} + j + \frac{\alpha}{\pi \mu_0 c} \left(\nabla \theta \times \mathbf{E} + \partial_t \theta \mathbf{B} \right), \tag{8.45}$$

where $\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}$ and $\mathbf{H} = \frac{1}{\mu_0} \mathbf{B} - \mathbf{M}$. The fine structure constant $\alpha = \frac{e^2}{2\epsilon_0 hc}$. Suppose there is a point-like magnetic monopole situated at the origin of the strength ϕ_0. The static magnetic field is given by $\mathbf{B} = \frac{\phi_0}{r^2} \mathbf{r}$ or $\nabla \cdot \mathbf{B} = \phi_0 \delta(\mathbf{r})$. Suppose $\theta = 0$ initially and then increases to $\theta = \pi$. θ is uniform in space and there is no current in a vacuum. We take the divergence of the revised Ampere's law,

$$\nabla \cdot \partial_t \mathbf{E} = -\frac{\alpha c}{\pi} \partial_t \theta \nabla \cdot \mathbf{B}. \tag{8.46}$$

Thus, when θ increases from 0 to π, integrating the equation yields

$$\nabla \cdot [\mathbf{E}(\theta = \pi) - \mathbf{E}(\theta = 0)] = -\frac{1}{\epsilon_0} \frac{e^2}{2h} \nabla \cdot \mathbf{B} = -\frac{1}{\epsilon_0} \frac{e}{2} \delta(\mathbf{r}). \tag{8.47}$$

This demonstrates that a magnetic monopole ϕ_0 can bind an extra fractional charge $-e/2$.

To understand the Witten effect, we consider a sphere with radius R of an isotropic topological insulator with a magnetic monopole $2q\phi_0$ situated at the origin,

$$H = v\boldsymbol{\Pi} \cdot \alpha + \left[mv^2 - B\boldsymbol{\Pi}^2 \right] \beta, \tag{8.48}$$

where $\boldsymbol{\Pi} = \mathbf{p} + e\mathbf{A}$ and $\nabla \times \mathbf{A} = \frac{2q\phi_0}{r^2} \mathbf{r}$. It is well known that the magnetic field of a magnetic monopole cannot be derived from a single expression of vector potential valid everywhere. We can construct a pair of the vector potentials,

$$\mathbf{A}^I = +\frac{2q\phi_0}{r} \frac{1 - \cos \theta}{\sin \theta} \hat{\phi}, \textit{ for } \theta < \pi - \varepsilon \tag{8.49}$$

and

$$\mathbf{A}^{II} = -\frac{2q\phi_0}{r} \frac{1 + \cos \theta}{\sin \theta} \hat{\phi}, \textit{ for } \theta > \varepsilon, \tag{8.50}$$

such that there are no singularities in the two potentials in the defined range. In the overlapping region $\varepsilon < \theta < \pi - \varepsilon$, the two potentials are related by a gauge transformation,

$$\mathbf{A}^I - \mathbf{A}^{II} = \frac{4q\phi_0}{r \sin \theta} \hat{\phi}. \tag{8.51}$$

In the overlapping region we can use either $\mathbf{A}^I$ or $\mathbf{A}^{II}$; the corresponding wave functions are related by a phase factor $\exp[i4q\pi]$. Thus, the single value condition for the wave function for either $\mathbf{A}^I$ or $\mathbf{A}^{II}$ implies $2q = integer$, which is the quantization condition for a magnetic charge [17].

Following Kazama et al. [18], we can define

$$\mathbf{L} = \mathbf{r} \times \boldsymbol{\Pi} - q\hbar \frac{\mathbf{r}}{r}, \tag{8.52}$$

which satisfies the commutation relation of the orbital angular momentum, $[L_\alpha, L_\beta] = i\hbar\epsilon_{\alpha\beta\gamma}L_\gamma$. Denote Y_{q,l,l_z} as the eigenfunction of L^2 and L_z with the eigenvalues $l(l+1)\hbar^2$ and $l_z\hbar$ ($l_z = -l, -l_z + 1, \cdots,$ and l). The total angular momentum $\mathbf{J}$ is defined as $\mathbf{J} = \mathbf{L} + \mathbf{S}$, where the spin $\mathbf{S} = \frac{1}{2}\hbar\sigma$. The eigenstates of $\mathbf{J}^2$ and $\mathbf{J}_z$ can be constructed by adding $\mathbf{L}$ and $\mathbf{S}$:

$$\phi_{j,j_z}^{(1)} = \begin{pmatrix} \sqrt{\frac{j+m}{2j}} Y_{q,l=j-1/2,j_z-1/2} \\ \sqrt{\frac{j-m}{2j}} Y_{q,l=j-1/2,j_z+1/2} \end{pmatrix} \tag{8.53}$$

and

$$\phi_{j,j_z}^{(2)} = \begin{pmatrix} -\sqrt{\frac{j-m+1}{2j}} Y_{q,l=j+1/2,j_z-1/2} \\ \sqrt{\frac{j+m+1}{2j}} Y_{q,l=j+1/2,j_z+1/2} \end{pmatrix}, \tag{8.54}$$

which are for $j = l + 1/2$ and $j = l - 1/2$, respectively. The coefficients in the expressions are the Clebsch-Gordan coefficients. For simplicity, we here focus on the zero energy solution. We construct an ansatz for the trivial wave function for $j = |q| - \frac{1}{2}$ and $l = j + \frac{1}{2} = |q|$;

$$\Psi = \begin{pmatrix} F(r)\phi_{j,j_z}^{(2)} \\ G(r)\phi_{j,j_z}^{(2)} \end{pmatrix}. \tag{8.55}$$

Substituting the trial wave function into the stationary equation of H in (8.48), and using the relation

$$\sigma \cdot \Pi \phi_{j,j_z}^{(2)}(\theta, \phi) = -i\,sgn(q)\hbar(\partial_r + r^{-1})\phi_{j,j_z}^{(2)}(\theta, \phi), \tag{8.56}$$

the equation for the radial part of the wave function is reduced to

$$\left[-i\,sgn(q)v\hbar\partial_r\sigma_x + \left[mv^2 + B\hbar^2(\partial_r^2 - \frac{|q|}{r^2}) \right]\sigma_z \right] \begin{pmatrix} rF(r) \\ rG(r) \end{pmatrix} = E \begin{pmatrix} rF(r) \\ rG(r) \end{pmatrix}. \tag{8.57}$$

For our purpose, we consider a sphere with a large radius R enough by ignoring the finite size effect between the surface states and the bound states near the center.

When $r \gg 1$, $\frac{|q|}{r^2} \to 0$. In this case, (8.57) is approximately reduced to the one-dimensional Dirac equation,

$$\left[-i\,sgn(q)v\hbar\partial_r\sigma_x + \left(mv^2 + B\hbar^2\partial_r^2 \right)\sigma_z \right] \begin{pmatrix} rF(r) \\ rG(r) \end{pmatrix} = E \begin{pmatrix} rF(r) \\ rG(r) \end{pmatrix}, \tag{8.58}$$

as in (2.36) and (8.36), in which there always exists an end state solution of zero energy near $r = R$ when $mB > 0$. The solution has the form:

$$\begin{pmatrix} F(r) \\ G(r) \end{pmatrix} = \frac{C}{r} \left(\frac{e^{\lambda_1 r}}{e^{\lambda_1 R}} - \frac{e^{\lambda_2 r}}{e^{\lambda_2 R}} \right) \begin{pmatrix} 1 \\ i\eta \end{pmatrix} \tag{8.59}$$

with $\eta = -\text{sgn}(q B v)$, and $\lambda_{1,2} = \left| \frac{v}{2B\hbar} \right| \pm \sqrt{\frac{v^2}{4B^2\hbar^2} - \frac{mv^2}{B\hbar^2}}$. These solutions are valid even for complex $\lambda_{1,2}$.

Near the center of the sphere $r = 0$, we can find another solution

$$\begin{pmatrix} F(r) \\ G(r) \end{pmatrix} = C' \frac{e^{-\zeta\rho/2}}{\sqrt{\rho}} J_{\sqrt{|q|+1/4}} \left(\sqrt{1 - \zeta^2/4} \rho \right) \begin{pmatrix} 1 \\ -i\eta \end{pmatrix}, \tag{8.60}$$

where $\rho = \sqrt{m^* v^2 / B\hbar^2} r$, $\zeta = 1/\sqrt{mB}$, and $J_\alpha(x)$ is the first Bessel function. C and C' are the normalization constants. From the asymptotic behavior of the first Bessel function, $J_\alpha(x) \to x^{|\alpha|}$, it concludes that the solution is convergent at $\rho \to 0$ when $q \neq 0$. For $\zeta^2 > 4$, $J_\alpha(x)$ is replaced by the modified Bessel function $K_{\sqrt{|q|+1/4}} \left(\sqrt{\zeta^2/4 - 1} \rho \right)$.

As the final result is independent of the eigenvalue j_z, there is a $2|q| (= 2j + 1)$-fold degeneracy of the zero energy states as well as the double degeneracy of the states near the center and the surface. For each j_z, the double degeneracy of the bound states can be lifted when the radius R is finite, and the two states at the center and the surface will be coupled to form two new states, in which one has a positive energy and the other has a negative energy. The energy gap decays exponentially in the radius R. In this case, each bound state is split into two halves: one half is distributed around the surface of the system while the other surrounds the magnetic monopole. For a topological insulator, the system is half filled, and only the $2|q|$ zero energy states are occupied; all of the other negative energy states are filled. The charge around the magnetic monopole from these $2|q|$ bound states of zero energy is $-|q|e$. Therefore the magnetic monopole can bind extra charge

$$\Delta Q = -(n + |q|)e,$$

where n is an integer which is contributed by the states of non-zero energy around it. In this sense, the extra half charge in the Witten effect is actually related to a bound state induced by a topological defect in the topological insulator, just as the one induced by the half vortex in two-dimensional topological insulator. When $mB > 0$, the system is topologically non-trivial while when $mB < 0$, the system is topologically trivial. This means that the axion parameter θ is π when $mB > 0$ and 0 when $mB < 0$. To interpret (8.47), we may consider the variation of the parameter B with time t from negative to positive (assume m is positive). In this way the axion parameter θ changes from 0 to π. For a conventional insulator, the magnetic monopole can induce some bound states around it, in which each state traps only one charge $-e$. Therefore the extra half charge in (8.47) must be induced by the monopole in the topological insulator.

However, the double degeneracy of the zero energy bound states for $q = 1/2$ and a large R makes it possible that the bound state near the center is fully occupied and that near the surface is empty. The charge binding around the center is not determined. Therefore, further study is needed to determined whether the electromagnetic response in topological insulators is really characterized by an axion term.

8.5 Disorder Effect on Transport

We now discuss the effect of the in-gap bound states on transport in topological insulators. The wave function of the in-gap bound state is localized around the vacancy or defect. Away from the center the wave function decays exponentially, i.e., $\propto e^{-r/\xi}$. The characteristic length ξ reflects the spatial distribution of the wave function. When two vacancies are close, that is within a distance comparable to the characteristic length ξ, the overlapping of the wave functions in space becomes possible. Consequently electrons in one bound state may jump to another bound states.

Fig. 8.5 Schematic of the melting of the quantum spin Hall effect due to holes or defects. The helical edge states at different boundaries can be scattered via the in-gap bound states induced by these holes or defects
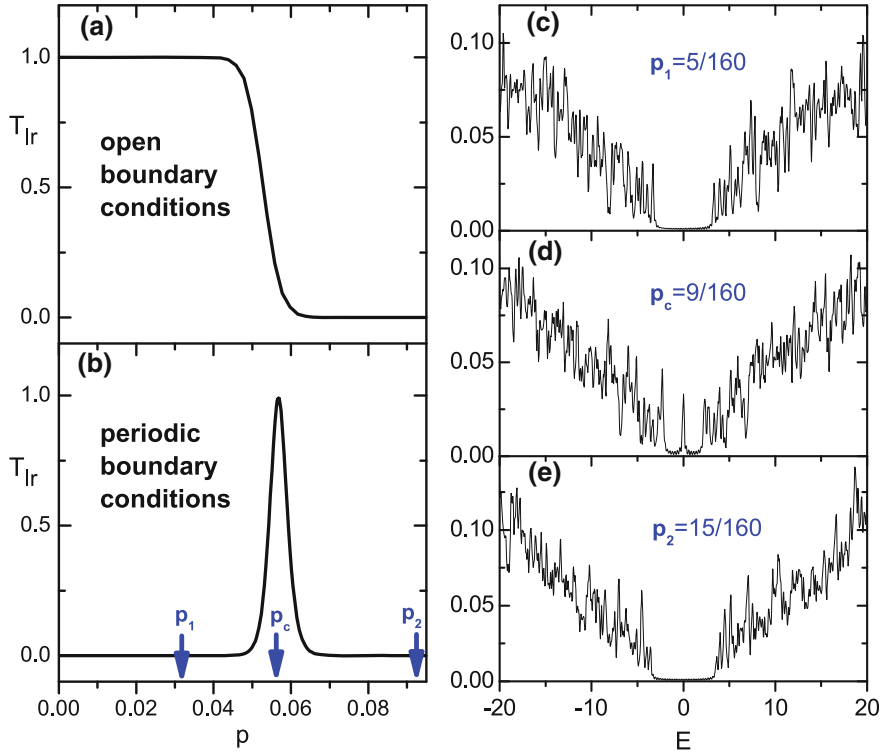

Fig. 8.6 Quantum percolation of electrons through in-gap bound states induced by randomly distributed vacancies or holes of size 1×1. The sample is $W \times L = 160 \times 160$ in size. **a** and **b** show the transmission coefficients T_{tr} versus the concentration of vacancies p under the open boundary condition and periodic or closed boundary condition. **c–e** are the density of states at the concentraion $p_1 = 5/160$, $p_c = 9/160$ and $p_2 = 15/160$, respectively

For a single vacancy close to the boundary of the quantum spin Hall system, the edge states will be scattered by the in-gap bound state of the vacancy. However, if there are no other defects or disorders in the bulk, the electrons in the edge state will not be further scattered away from the edge, as happens in the quantum Hall effect [19], which also indicates the robustness of the edge states against the defects or disorders. The situation will change if the concentration of vacancies is dense enough. The bound states could form an impurity band in the gap of bulk bands. When the wave functions of the bound states overlap in space as shown in Fig. 8.5 it becomes possible for the electrons in the edge state on one side to be scattered to the other side via a multiple scattering procedures. In this case, the backscattering of electrons on two sides occurs, and the quantum transport of the edge states will break down. Thus, there exist a critical point where the quantum percolation occurs due to the in-gap bound states of the vacancies.

This can be demonstrated explicitly by calculating the conductance in a two-terminal setup of the quantum spin Hall system as a function of a concentration of vacancies [20]. We use the open boundary condition with two edges and the periodic boundary condition or a cylinder without the edge states. In an open boundary condition, the calculated conductance is quantized to be $2e^2/h$. Although it is immune to the low density of vacancies, the conductance quickly decreases with the density of vacancies, and the quantum spin Hall effect is destroyed completely. See Fig. 8.6a. In a cylinder or periodic boundary condition, the conductance is zero in a pure quantum spin Hall state, as there is no edge state in the geometry. A non-zero conductance appears and increases with the concentration of vacancies, and reaches at a maximal for a specific value of the concentration. Then it decreases as the concentration of vacancies increases. See Fig. 8.6b. Figure 8.6c–e show the density of states at different concentrations. A non-zero peak appears at $E = 0$ near the critical concentration, which demonstrates the occurrence of quantum percolation and the appearance of a metallic phase. The calculated conductance reveals a quantum phase transition from a quantum spin Hall state (Z_2: $\nu = 1$) to a conventional insulator (Z_2: $\nu = 0$).

Chapter 9
Topological Superconductors and Superfluids

Abstract Quasiparticles in a superconductor or superfluid may have an energy gap as that for a band insulator. The quasiparticle bands can be topologically trivial or non-trivial. Topological superconductors and superfluids have topological nontrivial bands, and possess the edge states or surface states just like topological insulators. Superfluid phases in liquid helium 3 are topological ones. Spin-triplet superconductors are potential candidates for topological superconductors.

The study of topological phases in superconductors and superfluids had a long history even before the identification of topological insulators. ^{3}He-B and -A phases are topological superfluid liquids and can be characterized by topological invariants [1]. A complex $p + ip$ wave pairing superconductor is also known to process two topologically distinct phases [2]. Soon after the discovery of topological insulators, it was realized that there is an explicit analogy between topological insulators and superconductors because the particle-hole symmetry in the Bogoliubov-de Gennes (BdG) Hamiltonian for quasi-particles in superconductors is analogous to the time reversal symmetry in the Hamiltonian for a band insulator. The BdG Hamiltonians for a $p+ip$ wave superconductor and ^{3}He-B superfluids are identical to the modified Dirac equation that we discussed for topological insulators, although the bases of these equations are completely different.

Superconductivity is a quantum phenomenon; the resistivity in certain materials disappears below a characteristic temperature, which was discovered by Onnes in 1911 in Leiden [3]. A superconductor is characterized by zero resistance, The Meissner effect (or perfect diamagnetization), and magnetic flux quantization, though some physical properties vary from material to material, such as heat capacity, transition temperatures and critical fields. The existence of universal properties in superconductors implies that superconductivity is a quantum phase with distinguishing properties that are largely independent of microscopic details. The theory of superconductivity was formulated by Bardeen, Cooper and Schrieffer in 1957, and is named the BCS theory [4]. This theory has successfully described a large class of superconducting properties, such as aluminum, in which the electron-phonon interaction is weak.

The basic idea of the BCS theory is that electrons in metal form bound pairs. Cooper pointed out that the ground state of a normal metal is unstable at zero

temperature if the interaction between the electrons near the Fermi surface is attractive. For an ideal metal, electrons at zero temperature form a Fermi sphere in the momentum space, which has a sharp step in energy. If there exists an weak attractive interaction between the electrons near the Fermi surface, Cooper found that two electrons with equal and opposite spins and momentum can forget the mutual scattering and form a bound state, which always has a lower energy than that of two free electrons. In some metals, the electron-phonon interaction can provide this kind of attractive interaction near the Fermi surface. Most electrons in the Fermi sphere do not form bound states, only those within the Debye energy. The bound states of electrons pairs or Cooper pairs behave like bosons, and can condensate at low temperatures, which is known as Bose-Einstein condensation. The condensation of the Cooper pairs exhibits superconductivity, which requires a many-body description.

To explore topological phases in superconductor, we start with p-wave superconductivity.

9.1 Complex $(p + ip)$-Wave Superconductor for Spinless or Spin Polarized Fermions

A complex p-wave spinless superconductor has two topologically distinct phases, one is the strong pairing phase and the other is the weak pairing phase [1, 2]. The weak pairing phase is identical to the Moore-Read quantum Hall state [2]. The system can be described by the modified Dirac model. In the BCS theory, the effective Hamiltonian for the quasiparticles is

$$H_{eff} = \sum_k \left[\xi_k c_k^\dagger c_k + \frac{1}{2} \left(\Delta_k^* c_{-k} c_k + \Delta_k c_k^\dagger c_{-k}^\dagger \right) \right]. \tag{9.1}$$

It is noted that the electrons with k and $-k$ are coupled together to form a Cooper pair. Although the number of electrons is not conserved in this effective Hamiltonian, the number parity, i.e., the even or odd number of electrons, is conserved. For a small k, we take $\xi_k = \frac{k^2}{2m^*} - \mu$, where m^* is the effective mass, and $-\mu$ is a constant of $\xi_{k=0}$.

For the complex p-wave pairing, we take Δ_k to be an eigen function of rotations in k with angular momentum l. For $l = +1$ and small k, it generically takes the form

$$\Delta_k = \Delta(k_x + ik_y). \tag{9.2}$$

For $l = -1$, $\Delta_k = \Delta(k_x - ik_y)$. The states of $\Delta_k = \Delta(k_x \pm ik_y)$ are degenerate. Consider the anticommutation relation of fermions, $c_k^\dagger c_k = 1 - c_k c_k^\dagger$. Let $\psi_k^\dagger = (c_k^\dagger, c_{-k})$, and then the effective Hamiltonian can be written in a compact form,

$$H_{eff} = \frac{1}{2} \sum_k \psi_k^\dagger h_{eff} \psi_k \tag{9.3}$$

by ignoring a constant. Here H_{eff} has the identical form of the Dirac equation

$$h_{eff} = \Delta \left(k_x \sigma_x \mp k_y \sigma_y \right) + \left(\frac{k^2}{2m} - \mu \right) \sigma_z \tag{9.4}$$

for $\Delta_k = \Delta(k_x \pm ik_y)$.

The normalized ground state has the form

$$|\Omega\rangle = \prod_k (u_k + v_k c_k^\dagger c_{-k}^\dagger) |0\rangle , \tag{9.5}$$

where $|0\rangle$ is the vacuum state and the product runs over the distinct pairs of k and $-k$. The functions of u_k and v_k are complex and satisfy $|u_k|^2 + |v_k|^2 = 1$. We introduce the Bogoliubov transformation

$$\begin{pmatrix} \alpha_k \\ \alpha_{-k}^\dagger \end{pmatrix} = \begin{pmatrix} u_k & -v_k \\ -v_{-k}^* & u_{-k}^* \end{pmatrix} \begin{pmatrix} c_k \\ c_{-k}^\dagger \end{pmatrix} , \tag{9.6}$$

where $\left\{ \alpha_k, \alpha_{k'}^\dagger \right\} = \delta_{k,k'}$ and $\alpha_k |\Omega\rangle = 0$. The resulting Hamiltonian becomes

$$K_{eff} = \frac{1}{2} \sum_k \left(\alpha_k^\dagger, \alpha_{-k} \right) \begin{pmatrix} \varepsilon_k & 0 \\ 0 & -\varepsilon_k \end{pmatrix} \begin{pmatrix} \alpha_k \\ \alpha_{-k}^\dagger \end{pmatrix} \tag{9.7}$$

$$= \frac{1}{2} \sum_k \left(\varepsilon_k \alpha_k^\dagger \alpha_k - \varepsilon_k \alpha_{-k} \alpha_{-k}^\dagger \right) . \tag{9.8}$$

with $\varepsilon_k = \sqrt{\xi_k^2 + |\Delta_k|^2} > 0$. The first term represents the particle excitation with a positive energy and the second term represents the hole excitations with a negative energy. Performing the particle-hole transformation, or making using of $\alpha_{-k} \alpha_{-k}^\dagger = 1 - \alpha_{-k}^\dagger \alpha_{-k}$, we have

$$K_{eff} = \sum_k \frac{1}{2} \varepsilon_k \left(\alpha_k^\dagger \alpha_k - 1 + \alpha_{-k}^\dagger \alpha_{-k} \right) \tag{9.9}$$

$$= \sum_k \varepsilon_k \alpha_k^\dagger \alpha_k - \sum_k \frac{1}{2} \varepsilon_k \tag{9.10}$$

as $\varepsilon_k = \varepsilon_{-k}$.

From the eigenstate equation,

$$[K_{eff}, \alpha_k] = \varepsilon_k \alpha_k, \tag{9.11}$$

one obtains

$$\begin{pmatrix} \xi_k & -\Delta_k^* \\ -\Delta_k & -\xi_k \end{pmatrix} \begin{pmatrix} u_k \\ v_k \end{pmatrix} = \varepsilon_k \begin{pmatrix} u_k \\ v_k \end{pmatrix}. \tag{9.12}$$

The solutions are

$$u_k = \sqrt{\frac{1}{2}\left(1 + \frac{\xi_k}{\varepsilon_k}\right)} \tag{9.13}$$

and

$$v_k = -\frac{\Delta_k}{|\Delta_k|}\sqrt{\frac{1}{2}\left(1 - \frac{\xi_k}{\varepsilon_k}\right)}. \tag{9.14}$$

Here we choose a gauge that u_k is real and positive.

The Bogoliubov-de Gennes equation for u_k and v_k becomes

$$i\hbar\frac{\partial}{\partial t}\begin{pmatrix} u_k \\ v_k \end{pmatrix} = K_{eff}\begin{pmatrix} u_k \\ v_k \end{pmatrix}, \tag{9.15}$$

where

$$K_{eff} = \begin{pmatrix} \xi_k & -\Delta_k^* \\ -\Delta_k & -\xi_k \end{pmatrix} = -\Delta(k_x\sigma_x \pm k_y\sigma_y) + \xi_k\sigma_z. \tag{9.16}$$

In this way the Bogoliubov-de Gennes equation has the exact form of two-dimensional modified Dirac equation

$$K_{eff} = -\Delta\left(k_x\sigma_x \pm k_y\sigma_y\right) + \left(\frac{k^2}{2m} - \mu\right)\sigma_z. \tag{9.17}$$

It is noted that this effective Hamiltonian is distinct from that in an effective Hamiltonian for electrons.

If we treat the Bogoliubov-de Gennes equation as the same as a conventional Hamiltonian for a band insulator, we can introduce the topological invariant for K_{eff}, in which the Chern number is

$$n_c = \pm\left[sgn(\mu) + sgn\left(\frac{1}{m}\right)\right]/2. \tag{9.18}$$

As we take the mass of the spinless particles m positive, we conclude that for a positive $\mu(>0)$ the Chern number is $+1$ (or -1) and for a negative μ the Chern number is 0. For $\mu = 0$, the Chern number is equal to one half, which is similar to

the case of $m \to +\infty$ and a finite μ. If the quadratic term in ξ_k is neglected, we see that the topological property will change completely.

In general, from the solution of u_k and v_k, we have three possibilities of behavior at small k, $\varepsilon_k - \xi_k \to 0$.

(1). $\xi_k > 0$, in which $u_k \to 1$ and $v_k \to 0$. The BCS state is close to the vacuum, $|\Omega\rangle \to |0\rangle$.
(2). $\xi_k < 0$, in which $u_k \to 0$ and $|v_k| \to 1$. $|\Omega\rangle \to \prod_{k'} v_k c_k^\dagger c_{-k}^\dagger |0\rangle$ in which all the states with negative energy are occupied as free fermions.
(3). $\xi_k \to 0$, in which both u_k and v_k are both non-zero.

Usually for a positive μ, the system is in a weak pairing phase, and for a negative μ it is a strong coupling phase. Including the quadratic term in ξ_k we conclude that the weak pairing phase for a positive μ is a typical topological insulator. Read and Green [2] argued that a bound state solution exists at a straight domain wall parallel to the y-axis, with $\mu(r) = \mu(x)$ being small and positive for $x > 0$, and negative for $x < 0$. There is only one solution for each k_y and so we have chiral Majorana fermions on the domain wall. From the two-dimensional solution, the system in a weak pairing phase should have a topologically protected and chiral edge state of Majorana fermions.

If we make the Peirls substitution in K_{eff}: $k_x \to -i\partial_x$ and $k_y \to -i\partial_y$, the BdG equation in (9.15) has the same form as the two-dimensional Dirac equation. When we find a solution for the edge state within the band gap, we emphasize that the solution for u_k and v_k should satisfy the relation $|u_k^2| + |v_k^2| = 1$. For the vacuum, $u_k = 1$ and $v_k = 0$. The particle-hole spectra and the chiral edge spectra are presented in Fig. 9.1.

A p-wave superconductor is a thermal insulating phase as there exist an energy gap for the quasiparticles. The existence of edge states allows the heat conducting in

Fig. 9.1 **a** Particle-hole spectrum and edge state spectrum of a non-trivial Bogoliubov-de-Gennes equation for a weak pairing phase, or a topologically non-trivial phase. **b** After the particle-hole transformation, the hole spectrum is merged into the particle spectrum. The zero energy mode is a Majorana fermion, $\gamma(E = 0) = \gamma^\dagger(E = 0)$

the interior of the system, and produces the thermal analogue of the quantum Hall effect. Thus, the Chern number in a p-wave superconductor is associated with the thermal Hall conductance as that in quantum Hall effect. The quantum Hall effect in a two-dimensional electron gas is associated both with a quanitized Hall conductance $n \frac{e^2}{h}$ and a quantized thermal Hall conductance $n \frac{e^2}{h} \mathcal{L} T$ with T the temperature and $\mathcal{L} = \frac{1}{3} \left(\frac{\pi k_B}{e^2} \right)^2$ the Lorentz number. In a p-wave superconductor the thermal Hall conductance is also quantized, but the value of the thermal Hall conductance is only one half of that in quantum Hall effect, $\frac{n}{2} \frac{e^2}{h} \mathcal{L} T$. This exact half-quantization is caused by the structure of the Nambu spinor and the particle-hole symmetry in its Bogoliubov-de Gennes Hamiltonian. In the picture of the Majorana fermions in the edge states, it is attributed to the fact that the wave functions of the Majorana fermions are real rather than complex, which reduces the thermal conductance by two [5].

9.2   Spin Triplet Pairing Superfluidity: ^{3}He-A and -B Phases

Helium has two isotopes, ^{3}He and ^{4}He. ^{4}He atoms are bosons. At low temperatures, liquid ^{4}He shows a phase transition to a superfluid state that is similar to the Bose-Einstein condensation, although a strong inter-particle interaction should be taken into account. ^{3}He atoms are fermions. Liquid ^{3}He also shows a phase transition to a superfluid state, which is similar to the superconducting transition in a metal [6]. As ^{3}He atoms are neutral, there are no Meissner effect, but atoms form pairs like the Cooper pairs of electrons. Atoms also avoid the singlet pairing as in metals, and tend to pair in the form of a spin triplet, in which the spins align parallel [7]. A schematic of the phase diagram of ^{3}He as a function of temperature and pressure is presented in Fig. 9.2.

Fig. 9.2 Phase diagram of ^{3}He in the low millikelvin temperature and pressure region
9.2.1 ^{3}He: Normal Liquid Phase

Before presenting the theory of superfluidity in ^{3}He, we first briefly introduce a normal liquid phase of ^{3}He atoms. The ^{3}He atoms are charge neutral. Unlike the electrons in metals, these atoms are strongly interacting and highly correlated. According to the Fermi liquid theory, the low-lying excitations of the strongly interacting Fermi system can be described by a phenomenological model, in which the free energy of the system can be expanded in terms of low-energy excitation $\delta n_{\mathbf{p},\sigma}$

$$F = F_0 + \sum_{\mathbf{p},\sigma} (\epsilon_p - \mu)\delta n_{\mathbf{p},\sigma} + \frac{1}{2} \sum_{\mathbf{p},\sigma;\mathbf{p}',\sigma'} f_{\mathbf{p},\sigma;\mathbf{p}',\sigma'} \delta n_{\mathbf{p},\sigma} \delta n_{\mathbf{p}',\sigma'} + \dots . \quad (9.19)$$

The parameters in this expression can be deduced from experiments such as specific heat, compressibility, sound velocity, and spin susceptibility. Here the energy zero is defined as $-\mu$ at $p = 0$ such that $\epsilon_p = 0$ and $\epsilon_p = \frac{p^2}{2m^*}$ with the effective mass $m^* = 3m$, which is the three times of the bare mass of a ^{3}He atom. The spin dependence of the effective interaction is written as

$$f_{\mathbf{p},\sigma;\mathbf{p}',\sigma'} = f^{(s)}_{\mathbf{p},\mathbf{p}'} + \sigma \cdot \sigma' f^{(t)}_{\mathbf{p},\mathbf{p}'}. \quad (9.20)$$

For details the readers can refer to several excellent reviews of Fermi liquid theory such as Pine and Nozieres [8] and Leggett [9].

9.2.2 ^{3}He-B Phase

The theory of superconductivity for electrons in a spin triplet state was developed by Balian and Werthamer [10]; it successfully explains superfluidity in ^{3}He. In their theory, fermions form spin triplet pairs ($s = 1$) and the weak coupling between these pairs leads to condensation at low temperatures. The effective Hamiltonian for the quasi-particles has the form

$$H = \sum_{\mathbf{k},\sigma} (\epsilon_p - \mu)c^\dagger_{\mathbf{k},\sigma}c_{\mathbf{k},\sigma} + \frac{1}{2} \sum_{\mathbf{k},\sigma;\mathbf{k}',\sigma',\mathbf{q}} V(\mathbf{q})c^\dagger_{\mathbf{k}+\mathbf{q},\sigma}c^\dagger_{\mathbf{k}'-\mathbf{q},\sigma'}c_{\mathbf{k}',\sigma'}c_{\mathbf{k},\sigma}. \quad (9.21)$$

The interaction potential describes the scattering process of the momentum change of two vectors $\mathbf{k}_i$ and $\mathbf{k}_f = \mathbf{k}_i + \mathbf{q}$. It can be expanded in spherical harmonics, and the first two terms are

$$V(\mathbf{q}) = V_0 + V_1 \mathbf{k}_i \cdot \mathbf{k}_f + \dots . \quad (9.22)$$

The first term is a repulsive s-wave interaction, $V_0 > 0$, and cannot cause the bound states. The second term is for a p-wave interaction, $V_1 \mathbf{k}_i \cdot \mathbf{k}_f$, which leads to

p-wave pairing. Thus, we only keep the second term for the theory of superfluidity. The interaction terms contains four operators. In the BCS theory, the atoms tend to form Cooper pairs and the dominate interaction is reduced to the pair-pair interaction, $V(\mathbf{k}-\mathbf{k}')c^{\dagger}_{\mathbf{k},\sigma}c^{\dagger}_{-\mathbf{k},\sigma'}c_{-\mathbf{k}',\sigma'}c_{\mathbf{k}',\sigma}$. A mean-field approach is used to write the interaction term as two-operator term by introducing the order parameters for pairing,

$$
\begin{aligned}
H_{eff} = &\sum_{\mathbf{k},\sigma}(\epsilon_p - \mu)c^{\dagger}_{\mathbf{k},\sigma}c_{\mathbf{k},\sigma} \\
&+ \sum_{\mathbf{k}} \Delta_{+1}(\mathbf{k})c^{\dagger}_{k,\uparrow}c^{\dagger}_{-k,\uparrow} + \Delta^{*}_{+1}(\mathbf{k})c_{-k,\uparrow}c_{k,\uparrow} \\
&+ \sum_{\mathbf{k}} \Delta_0(\mathbf{k})c^{\dagger}_{k,\uparrow}c^{\dagger}_{-k,\downarrow} + \Delta^{*}_0(\mathbf{k})c_{-k,\downarrow}c_{k,\uparrow} \\
&+ \sum_{\mathbf{k}} \Delta_{-1}(\mathbf{k})c^{\dagger}_{k,\downarrow}c^{\dagger}_{-k,\downarrow} + \Delta^{*}_{-1}(\mathbf{k})c_{-k,\downarrow}c_{k,\downarrow},
\end{aligned}
\tag{9.23}
$$

where three types of pairing order parameters are introduced,

$$
\Delta_{+}(\mathbf{k}) = \sum_{\mathbf{k}'} V(\mathbf{k} - \mathbf{k}')\langle c_{-\mathbf{k}',\uparrow}c_{\mathbf{k}',\uparrow}\rangle,
\tag{9.24}
$$

$$
\Delta_0(\mathbf{k}) = \sum_{\mathbf{k}'} V(\mathbf{k} - \mathbf{k}')\langle c_{-\mathbf{k}',\uparrow}c_{\mathbf{k}',\downarrow}\rangle,
\tag{9.25}
$$

and

$$
\Delta_{-}(\mathbf{k}) = \sum_{\mathbf{k}'} V(\mathbf{k} - \mathbf{k}')\langle c_{-\mathbf{k}',\downarrow}c_{\mathbf{k}',\downarrow}\rangle,
\tag{9.26}
$$

and $\langle \cdots \rangle$ represents the thermodynamic average.

For a p-wave pairing, the order parameter $\Delta_m(\mathbf{k})$ is an odd function of momentum, $\Delta_m(-\mathbf{k}) = -\Delta_m(\mathbf{k})$. This condition can be derived from the definition,

$$
\Delta_{+}(-\mathbf{k}) = \sum_{\mathbf{k}'} V(-\mathbf{k} - \mathbf{k}')\langle c_{-\mathbf{k}',\uparrow}c_{\mathbf{k}',\uparrow}\rangle
\tag{9.27}
$$

$$
= -\sum_{\mathbf{k}'} V(-\mathbf{k} - \mathbf{k}')\langle c_{\mathbf{k}',\uparrow}c_{-\mathbf{k}',\uparrow}\rangle = -\Delta_{+}(\mathbf{k}),
\tag{9.28}
$$

where the extra minus sign comes from the permutation of two operators in $\langle c_{-\mathbf{k}',\uparrow}c_{\mathbf{k}',\uparrow}\rangle$, when the interaction potential is even for a p-wave. Thus, order parameters $\Delta_m(\mathbf{k})$ have p-wave symmetry, and is proportional to the spherical harmony, $Y_{1,-m}(\theta, \varphi)$,

$$
\Delta_{+1}(\mathbf{k}) = \Delta(-k_x + ik_y),
\tag{9.29}
$$

$$\Delta_0(\mathbf{k}) = \Delta k_z, \tag{9.30}$$

and

$$\Delta_{-1}(\mathbf{k}) = \Delta(k_x + ik_y). \tag{9.31}$$

In the lattice model, for example on a cubic lattice, they are modified to be fit the lattice symmetry,

$$\Delta_{+1}(\mathbf{k}) = \Delta(-\sin k_x + i \sin k_y), \tag{9.32}$$

$$\Delta_0(\mathbf{k}) = \Delta \sin k_z, \tag{9.33}$$

and

$$\Delta_{-1}(\mathbf{k}) = \Delta(\sin k_x + i \sin k_y). \tag{9.34}$$

The pairing potential can be written in a compact form $V + V^\dagger$,

$$V = \sum_k \left(c_{k,\uparrow}^\dagger, c_{k,\downarrow}^\dagger \right) \Xi(k) \begin{pmatrix} c_{-k,\downarrow}^\dagger \\ -c_{-k,\uparrow}^\dagger \end{pmatrix} \tag{9.35}$$

and

$$V^\dagger = \sum_k \left(c_{-k,\downarrow}, -c_{k,\uparrow} \right) \Xi^\dagger(k) \begin{pmatrix} c_{k,\uparrow} \\ c_{k,\downarrow} \end{pmatrix}, \tag{9.36}$$

where.

$$\begin{aligned}
\Xi(k) &= \begin{pmatrix} \Delta_0(k) & -\Delta_{+1}(k) \\ \Delta_{-1}(k) & -\Delta_0(k) \end{pmatrix} \\
&= \begin{pmatrix} \Delta k_z & \Delta(k_x - ik_y) \\ \Delta(k_x + ik_y) & -\Delta k_z \end{pmatrix} \\
&= \Delta(k_x \sigma_x + k_y \sigma_y + k_z \sigma_z).
\end{aligned} \tag{9.37}$$

We introduce the basis,

$$\psi_k^\dagger = \left(c_{k,\uparrow}^\dagger, c_{k,\downarrow}^\dagger, c_{-k,\downarrow}, -c_{-k,\uparrow} \right). \tag{9.38}$$

The effective Hamiltonian has the form:

$$H = \frac{1}{2} \sum_k \psi_k^\dagger H_{eff} \psi_k, \tag{9.39}$$

where

$$H_{eff} = \Delta \left(k_x \alpha_x + k_y \alpha_y + k_z \alpha_z \right) + \xi_k \beta \tag{9.40}$$

is identical to the modified Dirac equation.

As this Hamiltonian is identical to the one for a three-dimensional topological insulator, there exists a solution of the surface states near the boundary of the surface if it satisfies the condition for the topologically non-trivial phase. However, the bases of the fermion operators are quite different. In the ^{3}He-B phase, we have particle and hole excitations while we have the conduction bands and valence bands in topological insulators. Due to the particle-hole symmetry in the effective Hamiltonian, the particle and hole excitations always appear in pairs with energy, $\pm E$, which are connected by the particle-hole transformation,

$$\gamma(E, k) \to \gamma^\dagger(-E, -k). \tag{9.41}$$

Therefore, in the ^{3}He-B phase the surface state consists of only one half of a Dirac cone with a positive energy [11].

9.2.3 ^{3}He-A Phase: Equal Spin Pairing

When $\Delta_0 = 0$, there exists a state with equal spin pairing. In this case there is no relation between the orbital momenta of $\Delta_{+1}(k)$ and $\Delta_{-1}(k)$. Thus, the orbital motions of the spin-up and spin-down particles are arbitrary. We can write them as

$$\Delta_{+1} = \Delta(k_x + ik_y) \tag{9.42}$$

and

$$\Delta_{-1} = \Delta(k_x' + ik_y'). \tag{9.43}$$

For the particles with spin up, the effective Hamiltonian is

$$\begin{aligned}
H_\uparrow &= \frac{1}{2} \sum_k \left(c^\dagger_{k,\uparrow}, c_{-k,\uparrow} \right) \begin{pmatrix} \xi_k & \Delta(k_x + ik_y) \\ \Delta(k_x - ik_y) & -\xi_k \end{pmatrix} \begin{pmatrix} c_{k,\uparrow} \\ c^\dagger_{-k,\uparrow} \end{pmatrix} \\
&= \frac{1}{2} \sum_k \left(c^\dagger_{k,\uparrow}, c_{-k,\uparrow} \right) \left(\Delta k_x \sigma_x - \Delta k_y \sigma_y + \xi_k \sigma_z \right) \begin{pmatrix} c_{k,\uparrow} \\ c^\dagger_{-k,\uparrow} \end{pmatrix},
\end{aligned} \tag{9.44}$$

where

$$\xi_k = \frac{\hbar^2}{2m}(k_x^2 + k_y^2) - \left(\mu - \frac{\hbar^2 k_z^2}{2m} \right). \tag{9.45}$$

This is identical to the two-dimensional modified Dirac equation. For a layered system, the term $\frac{\hbar^2 k_z^2}{2m}$ may be suppressed. The spectrum of the quasi particle is

$$\varepsilon_k = \sqrt{|\Delta|^2 \, (k_x^2 + k_y^2) + \xi_k^2}. \tag{9.46}$$

The new feature of this model is that the effective chemical potential becomes k_z dependent, $\mu(k_z) = \mu - \frac{\hbar^2 k_z^2}{2m}$. The Chern number for a specific k_z is

$$n_c(k_z) = \begin{cases} 1 \; if \; \frac{\hbar^2 k_z^2}{2m} < \mu; \\ \frac{1}{2} \; if \; \frac{\hbar^2 k_z^2}{2m} = \mu; \\ 0 \; if \; \frac{\hbar^2 k_z^2}{2m} > \mu. \end{cases} \tag{9.47}$$

At $k_z^2 = 2m\mu/\hbar^2$, $\mu = 0$, and $\varepsilon_k = |\Delta_1| k_\parallel + O(k_\parallel^2)$, which is linear in the momentum for a small $k_\parallel$ ($k_\parallel^2 = k_x^2 + k_y^2$). It is a marginal phase between two topologically distinguishing phases. Thus, in the ^{3}He-A phase, there always exists a nodal point. Due to the non-zero Chern number, there exist chiral edge states around the boundary of the system.

There are several possible choices in the state of equal spin pairing.

The Anderson-Brinkman-Morel state [12]:

$$\Delta_{+1} = \Delta_\alpha(k)(k_x + ik_y), \tag{9.48}$$

$$\Delta_0 = 0, \tag{9.49}$$

and

$$\Delta_{-1} = \Delta_\alpha(k)(k_x + ik_y), \tag{9.50}$$

where $\Delta_\alpha(k)$ is an even function of k. In the case the two phases of spin up and spin down particles are identical, and possess the same Chern number if they are topologically non-trivial.

The two-dimensional planar state:

$$\Delta_{+1} = \Delta_\alpha(k)(k_x + ik_y), \tag{9.51}$$

$$\Delta_0 = 0, \tag{9.52}$$

and

$$\Delta_{-1} = \Delta_\alpha(k)(k_x - ik_y). \tag{9.53}$$

In the case the two phases of spin up and spin down particles possess opposite Chern numbers if they are topologically non-trivial.

The one-dimensional polar state:

$$\Delta_{+1} = 0, \tag{9.54}$$

$$\Delta_0 = \Delta_\alpha(k)k_z, \tag{9.55}$$

and

$$\Delta_{-1} = 0. \tag{9.56}$$

The effective Hamiltonian becomes

$$H_{eff} = \Delta_\alpha(k)k_z\alpha_z + \xi(k_\parallel, k_z)\beta, \tag{9.57}$$

where $\xi(k_\parallel, k_z) = \frac{\hbar^2}{2m}k_z^2 - (\mu - \frac{\hbar^2 k_\parallel^2}{2m})$. This equation can be deduced into two degenerated one-dimensional Dirac equation, as discussed in Chap. 2. There always exist two crossing points at $\frac{\hbar^2 k_\parallel^2}{2m} = \mu$ and $k_z = 0$.

9.3   Spin-Triplet Superconductor: Sr_2RuO_4

There are several classes of candidates of spin-triplet superconductors, such as heavy fermion superconductor UPt_3, organic superconductor $(TMTSF)_2X$ ($X = ClO_4$ and PF_6) and ruthenate superconductors Sr_2RuO_4. In this section we briefly introduce the unconventional properties of Sr_2RuO_4, which is thought to be a spin-triplet superconductor or even a topological superconductor, comparable with the odd-parity, pseudo-spin-triplet superconductor UPt_3.

Sr_2RuO_4 is an oxide superconductor in the same layered structure as high-Tc cuprates but with a low superconducting transition temperature of 1.5 K [13]. The availability of high quality single crystal and the relative simplicity of its fully-characterized Fermi surface lead to a large number of experimental and theoretical studies. Rice and Sigrist [14] proposed a similarity between the superconductivity of Sr_2RuO_4 and the spin-triplet superfluidity of ^{3}He soon after the discovery of the ruthenate superconductivity, which leads to the first direct experimental evidence of spin triplet pairing in Sr_2RuO_4 by the measurement of electron spin susceptibility with NMR.

At low temperatures, Sr_2RuO_4 maintains a tetragonal structure with the crystal point group symmetry D_{4h}. Neglecting the dispersion along the out-of-plane c direction, possible spin triplet states are limited to those for the two-dimensional square lattice with C_{4v} symmetry. One possible state in Sr_2RuO_4 is so called chiral pairing states, which possess two polarizations of the relative orbital angular momentum of

pairing quasi-particle: the left- and right-polarizations correspond to

$$\Delta_0 \propto \sin k_x \pm i \sin k_y, \qquad (9.58)$$

respectively. They are the states with the orbital angular momentum $L_z = +1$ and -1 and the Cooper pair spins lies in the plane, $S_z = 0$ whereas the total spin is $S = 1$.

The direct evidence of spin-triplet pairing in Sr_2RuO_4 is based on the electron spin susceptibility measurement by the NMR Knight shift of both ^{17}O and ^{99}Ru nuclei [15]. Combined with the observation of the internal magnetic field by μSR, it is believed that the superconducting state of Sr_2RuO_4 is a spin triplet chiral p-wave state, a two-dimensional analogue of the ^{3}He-A phase. The odd parity of the orbital part of the order parameter has been unambiguously demonstrated by phase sensitive measurements.

In the sector of $S = 1$ and $S_z = 0$, the superconducting state with $\Delta_0^{\pm} = \Delta(\sin k_x \pm i \sin k_y)$ is similar to a spinless $p + ip$ wave superconductor. The Chern number can be defined as we discussed in Sect. 9.1. The states with $\Delta_0^+ = \Delta(\sin k_x + i \sin k_y)$ and $\Delta_0^- = \Delta(\sin k_x - i \sin k_y)$ are degenerated, but may have opposite Chern number due to the sign difference in $\Delta_0^{\pm}$. According to the the bulk-edge correspondence, a non-zero Chern number will lead to the emergence of chiral edge states around the system boundary, which breaks the time reversal symmetry. The superconducting states of Δ_0^+ and Δ_0^- possess opposite propagating edge states, respectively. The superconducting state in Sr_2RuO_4 has broken the time reversal symmetry spontaneously, and one of the states of $\Delta_0^{\pm}$ will be selected to be the ground state.

The existence of edge states has been studied in an experiment using quasi-particle tunneling spectroscopy [16]. The measured conductance spectra has provided evidence of edge states. However, it is still under debate whether Sr_2RuO_4 is a topological superconductor. We expect more and conclusive experiments to settle the issue in the near future [17].

9.4 Superconductivity in Doped Topological Insulators

Doped topological insulator $Cu_xBi_2Se_3$ exhibits the signature of superconductivity at low temperatures [18, 19]. The undoped Bi_2Se_3 compound is a topological insulator with a single Dirac cone of the surface states. Copper atoms can add holes or electrons in the Bi_2Se_3 lattice. It was found that about 10% copper is needed to bring about superconductivity in bulk Bi_2Se_3 when the transition temperature of T_c is about 3.8 K; this was confirmed by the observation of the Meissner effect. The temperature dependence of specific heat suggests a fully gapped superconducting state. Experimental data even suggest the coexistence of superconductivity and surface states of protected by time reversal symmetry. However, superconductivity of a doped topological insulator does not mean that the superconducting phase is always topologically non-trivial.

For a time reversal invariant superconductor, the mean field Hamiltonian in Bogoliubov-de Gennes formalism preserves the additional particle-hole symmetry, $PH(k)P = -H(-k)$ with $P^2 = 1$. This particle-hole symmetry can define a Z_2 invariant as that for time reversal symmetry. Based on the calculation of the Z_2 invariant, Fu and Berg [20] and Saito [21] proposed that a time reversal-invariant centrosymmetric superconductor is a topological superconductor if (1) it has odd-parity pairing symmetry with a full superconducting gap and (2) its Fermi surface encloses an odd number of time reversal invariant momenta Γ_α (which satisfy $\Gamma_\alpha = -\Gamma_\alpha$ up to a reciprocal lattice vector) in the Brillouin zone.

It follows from the criteria that $Cu_x Bi_2 Se_3$ is a potential candidates as a topological superconductor, although further experiments to confirm this potential.

Chapter 10
Majorana Fermions in Topological Insulators

Abstract A Majorana fermion is a particle that is its own antiparticle. This type of particle can appear as an end state in a one-dimensional topological superconductor or as a bound state induced by a half quantized vortex in a two-dimensional topological superconductor.

In his interpretation of the Dirac equation, Dirac introduced the concept of antiparticles as part of the negative energy solution. While the positive energy solution is used to describe an electron with spin 1/2, the negative energy solution describes an anti-particle of an electron, i.e., a positron, which has a negative mass and a positive elementary charge [1]. Ettore Majorana found that the Dirac equation can be separated into a pair of real wave equations, in which the fields are real and an particle and its antiparticle have no distinction [2]. For massless and neutral particles, their own antiparticles might be themselves. Neutrinos and antineutrinos are expected to the same particles, but it has been confirmed experimentally that neutrinos do have tiny mass. Thus, Majorana fermions as elementary particles have never been realized in nature [3]. But now it is highly possible to realize Majorana fermions in solid as quasi-particles of the collective behavior of many-particle systems.

10.1 What Is a Majorana Fermion?

A Majorana fermion satisfies the rules

$$\gamma_i^\dagger = \gamma_i \tag{10.1}$$

and

$$\{\gamma_i, \gamma_j^\dagger\} = \gamma_i \gamma_j^\dagger + \gamma_j^\dagger \gamma_i = \delta_{ij}. \tag{10.2}$$

A fermion operator can be always written in terms of two Majorana fermions,

$$c_{12}^\dagger = \frac{1}{\sqrt{2}}(\gamma_1 + i\gamma_2) \tag{10.3}$$

and

$$c_{12} = \frac{1}{\sqrt{2}}(\gamma_1 - i\gamma_2), \tag{10.4}$$

with $\gamma_1^\dagger = \gamma_1$ and $\gamma_2^\dagger = \gamma_2$. Conversely,

$$\gamma_1 = \frac{1}{\sqrt{2}}(c_{12}^\dagger + c_{12}), \tag{10.5}$$

and

$$\gamma_2 = \frac{1}{i\sqrt{2}}(c_{12}^\dagger - c_{12}). \tag{10.6}$$

One γ_i toggles the fermion number between even and odd, which is called the fermion number parity. The fermion parity operator is

$$P = 1 - 2c_{12}^\dagger c_{12} = 2i\gamma_1\gamma_2, \tag{10.7}$$

which has an eigenvalue $+1$ if the state is empty, and -1 if the state is occupied.

10.2 Majorana Fermions in p-Wave Superconductors

10.2.1 Zero Energy Mode Around a Quantum Vortex

The quantum flux in a p-wave superconductor can induce a bound state of zero energy, which is a Majorana fermion. Consider a disk of size L with a hole of radius R in which a magnetic flux ϕ threads through. We require the wave function vanishes at $r = R$. In the presence of the magnetic flux, the wave function should satisfy the boundary condition

$$\phi(\theta + 2\pi) = e^{i2\pi\phi/\phi_0}\phi(\theta), \tag{10.8}$$

where the quantum flux $\phi_0 = h/e$ if we take a gauge that the vector potential is absent in the Hamiltonian,

$$H(\mathbf{p} - e\mathbf{A}) \to H(\mathbf{p}). \tag{10.9}$$

In a polar coordinate system the Hamiltonian becomes

$$H = \begin{pmatrix} -\frac{\hbar^2}{2m}(\partial_r^2 + \frac{1}{r}\partial_r + \frac{1}{r^2}\partial_\theta^2) - \mu & -i\Delta_0 e^{-i\theta}(\partial_r - \frac{i}{r}\partial_\theta) \\ -i\Delta_0 e^{+i\theta}(\partial_r + \frac{i}{r}\partial_\theta) & \frac{\hbar^2}{2m}(\partial_r^2 + \frac{1}{r}\partial_r + \frac{1}{r^2}\partial_\theta^2) + \mu \end{pmatrix}. \tag{10.10}$$

Solution of the wave function for the Schrödinger equation has the form,

$$\phi = \begin{pmatrix} f(r) \\ g(r)e^{i\theta} \end{pmatrix} e^{i\nu\theta}, \tag{10.11}$$

where $\nu = m + \phi/\phi_0$ and m an integer. In this way, this two-dimensional problem is reduced to a one-dimensional equation for radial part of the wave function,

$$\begin{pmatrix} -\frac{\hbar^2}{2m}(\partial_r^2 + \frac{\partial_r}{r} - \frac{\nu^2}{r^2}) - \mu & -i\Delta_0(\partial_r + \frac{\nu+1}{r}) \\ -i\Delta_0(\partial_r - \frac{\nu}{r}) & \frac{\hbar^2}{2m}(\partial_r^2 + \frac{\partial_r}{r} - \frac{(\nu+1)^2}{r^2}) + \mu \end{pmatrix} \begin{pmatrix} f \\ g \end{pmatrix} = E \begin{pmatrix} f \\ g \end{pmatrix}. \tag{10.12}$$

The solution of the equation has the form:

$$f = c_\nu K_\nu(G_+ r) + d_\nu K_\nu(G_- r), \tag{10.13}$$

and

$$g = c'_\nu K_{\nu+1}(G_+ r) + d'_\nu K_{\nu+1}(G_- r), \tag{10.14}$$

where $K_\nu(x)$ is the modified Bessel function, and the two coefficients are

$$G_\pm^2 = F \pm \sqrt{F^2 - \frac{4m^2}{\hbar^4}(\mu^2 - E^2)}, \tag{10.15}$$

where $F = 2m^2\Delta_0^2/\hbar^4 - 2m\mu/m\hbar^2)$. With the boundary condition $\phi(r = R) = 0$, one obtains

$$\frac{G_+^2 + 2m(E + \mu)/\hbar^2}{G_+} \frac{K_{\nu+1}(G_+ R)}{K_\nu(G_+ R)} = \frac{G_-^2 + 2m(E + \mu)/\hbar^2}{G_-} \frac{K_{\nu+1}(G_- R)}{K_\nu(G_- R)}. \tag{10.16}$$

Solving the set of (10.15) and (10.16), one may obtain the energy eigenvalues of the bound states around the hole. It is known that the equation becomes topologically non-trivial when $\mu > 0$. For $\mu < 0$ no bound state exist around the hole. For $\mu > 0$, there exist a series of bound states. For a half quantum flux $\phi/\phi_0 = \frac{1}{2}$, there always exists a zero energy mode that is independent of the radius of the hole, and robust against other interactions and even the geometry of the hole. For an integer quantum flux $\phi/\phi_0 = 1$ the bound states always exist in pairs of $\pm E$.

The robustness of the zero mode for a half quantum vortex can be demonstrated in the following way. When $\nu = -\frac{1}{2}$, (10.12) becomes

$$\left[-i\Delta_0(\partial_r + \frac{1}{2r})\sigma_x - \left[\frac{\hbar^2}{2m}\left(\partial_r^2 + \frac{\partial_r}{r} - \frac{1}{4r^2}\right) + \mu \right]\sigma_z \right]\begin{pmatrix} f \\ g \end{pmatrix} = E\begin{pmatrix} f \\ g \end{pmatrix}.$$
(10.17)

Furthermore, take a substitution,

$$\begin{pmatrix} f(r) \\ g(r) \end{pmatrix} = \frac{1}{\sqrt{r}}\phi(r),$$
(10.18)

then the equation for the radial part of the wave function is reduced to

$$\left[-i\Delta_0\partial_r\sigma_x - \left(\frac{\hbar^2}{2m}\partial_r^2 + \mu \right)\sigma_z \right]\phi(r) = E\phi(r),$$
(10.19)

which is identical to a one-dimensional modified Dirac equation in (2.33). r is between R and disk size L. The dispersions for several different angular momenta as a function of R are plotted in Fig. 10.1. There exists a zero energy mode, which is independent of radius R. One can find the bound state solution in Sect. 2.5. A zero mode always exists near $r = R$ and L if $\mu > 0$.

In the geometry of a disk with a finite radius, the solution of zero energy is split into two parts: one half is located around the vortex, the other half is distributed around the boundary. The zero energy modes appear simultaneously near the vortex and the system boundary. Thus, in this case, the Majorana fermions is non-local.

Ivanov [4] pointed out the equivalence between a half quantum vortex for spinful fermions and a single-quantum vortex for spinless fermions, and there exist an zero energy mode near a half quantum vortex.

Fig. 10.1 Energy eigenvalues of the bound states as a function of radius R of the hole in the presence of a half quantum vortex. The parameters for the numerical calculations are $\mu = \frac{1}{2m} = \Delta_0 = 1$ ($M = B = A = 1$)
10.2.2 Majorana Fermions in Kitaev's Toy Model

The Kitaev's toy model is a one-dimensional lattice chain of spinless p-wave super-conductor [5],

$$H = -\mu \sum_{x=1}^{N} c_x^\dagger c_x - \sum_{x=1}^{N-1} (t c_x^\dagger c_{x+1} + \Delta e^{i\phi} c_x c_{x+1} + h.c.), \qquad (10.20)$$

where μ, $t > 0$, and $\Delta e^{i\phi}$ denote the chemical potential, the tunneling strength, and the superconducting order parameters, respectively. It has the same form as the modified Dirac model on a one-dimensional lattice. In the special case, $\mu = 0$ and $t = \Delta$, the Hamiltonian can be factorized as

$$H = -t \sum_{x=1}^{N-1} (e^{i\phi/2} c_x + e^{-i\phi/2} c_x^\dagger)(e^{i\phi/2} c_{x+1} - e^{-i\phi/2} c_{x+1}^\dagger). \qquad (10.21)$$

We define

$$\gamma_{B,x} = \frac{1}{\sqrt{2}} (e^{i\phi/2} c_x + e^{-i\phi/2} c_x^\dagger) \qquad (10.22)$$

and

$$\gamma_{A,x} = \frac{1}{i\sqrt{2}} (e^{i\phi/2} c_x - e^{-i\phi/2} c_x^\dagger), \qquad (10.23)$$

which are Majorana fermions and obey

$$\gamma_{A,x} = \gamma_{A,x}^\dagger \qquad (10.24)$$

and

$$\gamma_{B,x} = \gamma_{B,x}^\dagger. \qquad (10.25)$$

In this way,

$$H = -2it \sum_{x=1}^{N-1} \gamma_{B,x} \gamma_{A,x+1}. \qquad (10.26)$$

Furthermore two Majorana fermions, $\gamma_{B,x}$ and $\gamma_{A,x+1}$, can be combined to form a new fermion operator $d_x = \frac{1}{\sqrt{2}} (\gamma_{A,x+1} + i\gamma_{B,x})$ and $i\gamma_{B,x}\gamma_{A,x+1} = \frac{1}{2} - d_x^\dagger d_x$. Notice that the new fermion operators are not the original c-operators in (10.20). The Hamiltonian has a diagonal form in term of d_x,

$$H = +2t \sum_{x=1}^{N-1} d_x^\dagger d_x - (N-1)t. \tag{10.27}$$

However, although all pairs of $(\gamma_{B,x}, \gamma_{A,x+1})$ for $x = 1, 2, \cdots, N-1$ form new fermions, $\gamma_{A,1}$ and $\gamma_{B,N}$ are absent from the Hamiltonian, i.e., $[\gamma_{A,1}, H] = [\gamma_{B,N}, H] = 0$. For $t > 0$, the lowest energy state is $|g\rangle$, in which $d_x |g\rangle = 0$ for all x, and

$$H |g\rangle = -(N-1)t |g\rangle. \tag{10.28}$$

As $[\gamma_{A,1}, H] = [\gamma_{B,N}, H] = 0$, we can construct two degenerated states $\gamma_{A,1} |g\rangle$ and $\gamma_{B,N} |g\rangle$, which are related to an ordinary zero-energy fermion $d = \frac{1}{\sqrt{2}}(\gamma_{A,1} + i\gamma_{B,N})$. As the γ operator changes the fermion parity, $\langle g| d |g\rangle = 0$. $\gamma_{A,1} |g\rangle$ and $\gamma_{B,N} |g\rangle$ have a relation:

$$\langle g| \gamma_{A,1}\gamma_{B,N} |g\rangle = \left\langle g \left| \frac{1 - 2d^\dagger d}{2i} \right| g \right\rangle = \begin{cases} +\frac{i}{2} \ for \ d^\dagger d = 1; \\ -\frac{i}{2} \ for \ d^\dagger d = 0. \end{cases} \tag{10.29}$$

This is determined by the number parity of $|g\rangle$. Thus, these two states are not independent. Therefore the ground states of the Kitaev model are doubly degenerate, i.e., $|g\rangle$ and $d |g\rangle$. The two states have different parities: one is even and the other is odd. The doubly degeneracy reveals that the Kitaev model is topologically nontrivial. The solution is illustrated in Fig. 10.2, which looks like the Aflack-Khomoto-Lieb-Tasaki state for a spin-one system.

As an example, we further present the solutions of a two-site problem. The Hamiltonian is

$$H = -t(c_1^\dagger c_2 + c_2^\dagger c_1 + c_1 c_2 + c_2^\dagger c_1^\dagger). \tag{10.30}$$

We have two eigenstates with even parity,

$$\Psi_{e,\pm} = \frac{1}{\sqrt{2}}(1 \pm c_2^\dagger c_1^\dagger) |0\rangle \tag{10.31}$$

with the eigenvalues $\epsilon_{e,\pm} = \mp t$, and two eigenstates with odd parity,

$$\Psi_{o,\pm} = \frac{1}{\sqrt{2}}(c_1^\dagger \pm c_2^\dagger) |0\rangle \tag{10.32}$$

with the eigenvalues $\epsilon_{e,\pm} = \mp t$. The states are doubly degenerate.
Fig. 10.2 Schematic of two end Majorana states in the Kitaev's toy model

In the language of the Majorana fermion operators,

$$H = -2it\gamma_{B,1}\gamma_{A,x+1} = +2td_x^\dagger d_x - t, \tag{10.33}$$

which commutes with $\gamma_{A,1}$ and $\gamma_{B,2}$. Multiplying the two Majorana operators on one of the ground states, one obtains

$$\gamma_{A,1}\Psi_{e,+} = \frac{i}{2}(c_1^\dagger + c_2^\dagger)\,|0\rangle = i\Psi_{o,+} \tag{10.34}$$

and

$$\gamma_{B,2}\Psi_{e,+} = \Psi_{o,+} = -i\gamma_{A,x}\Psi_{e,+}. \tag{10.35}$$

Thus, these two states are identical by differing a trivial phase factor.

10.2.3 Quasi-One-Dimensional Superconductors

The Kitaev model can also be realized in a quasi-one-dimensional system. Recently Potter and Lee [6] generalized the results to a quasi-one-dimensional system. They found that for a strip of a two-dimensional p-wave superconductor, when the width of the strip is narrow enough that the edge states at the two sides overlap in space, and open a finite energy gap as a consequence of finite size effect. The zero energy modes may exist at the two ends of the strip. The Majorana fermions of zero modes are quite robust against this disorder.

We consider a two-dimensional spinless p-wave superconductors on a square-lattice [7],

$$H = \sum_{j=1}^{L}\sum_{\alpha=1}^{n}\Big[-\mu c_{j,\alpha}^\dagger c_{j,\alpha} - \Big(tc_{j,\alpha}^\dagger c_{j,\alpha+1} + \Delta c_{j,\alpha}c_{j,\alpha+1} \tag{10.36}$$

$$+tc_{j,\alpha}^\dagger c_{j+1,\alpha} + i\Delta c_{j,\alpha}c_{j+1,\alpha} + h.c.\Big)\Big], \tag{10.37}$$

where $c_{j,\alpha}^\dagger$ creates an electron on site (j, α), t (> 0) is the hopping amplitude, μ is the chemical potential and Δ (for simplicity we take $\Delta > 0$) is the p-wave pairing amplitude. Here we consider a strip geometry in which the lattice site numbers are L along the x-axis direction and n along the y-axis direction (the sample width direction), thus, which total number of lattice sites is $N = nL$. First, we adopt a periodic boundary condition along the x-axis direction, i.e., $c_{L+1,\alpha}^\dagger = c_{1,\alpha}^\dagger$, and the Fourier transforms of the operator $c_{j,\alpha}^\dagger$

$$c_{j,\alpha}^\dagger = \frac{1}{\sqrt{L}}\sum_q c_\alpha^\dagger(q)\,e^{-iqj}, \tag{10.38}$$

where $q = q_x$ is the wave vector along the x-axis, and $-\pi \le q \le \pi$. In terms of the new creation and annihilation operators $c_\alpha^\dagger (q)$ and $c_\alpha (q)$, the Hamiltonian (10.37) can be rewritten as

$$H = \sum_q \sum_{\alpha=1}^{n} \{-(\mu + 2t \cos q) c_\alpha^\dagger (q) c_\alpha (q) \tag{10.39}$$

$$-\left[tc_\alpha^\dagger (q) c_{\alpha+1} (q) + |\Delta| c_\alpha (q) c_{\alpha+1} (-q) \right. \tag{10.40}$$

$$+i |\Delta| e^{-iq} c_\alpha (q) c_\alpha (-q) + h.c.] \} . \tag{10.41}$$

Then, we define a set of the operators $\gamma_{2\alpha-1} (q)$ and $\gamma_{2\alpha} (q)$ as,

$$\gamma_{2\alpha-1} (q) = i \left[c_\alpha^\dagger (-q) - c_\alpha (q) \right] \tag{10.42}$$

and

$$\gamma_{2\alpha} (q) = c_\alpha^\dagger (-q) + c_\alpha (q), \tag{10.43}$$

which satisfy the anticommutation relations $\left\{ \gamma_m^\dagger (q), \gamma_n (q') \right\} = 2\delta_{mn} \delta_{qq'}$ and $\gamma_m^\dagger (q) = \gamma_m (-q)$. In fact, $\gamma_m (0)$ is just a Majorana fermion operator due to $\gamma_m^\dagger (0) = \gamma_m (0)$. In the basis of the news operators $\gamma_{2\alpha-1} (q)$ and $\gamma_{2\alpha} (q)$, the Hamiltonian (10.41) has the following form

$$H = i\frac{1}{4} \sum_q \sum_{\eta,\kappa} \gamma_\eta (-q) B_{\eta,\kappa} (q) \gamma_\kappa (q), \tag{10.44}$$

where the elements of the $2n \times 2n$ matrix $B(q)$ are given as

$$B_{2\alpha,2\alpha} = -B_{2\alpha-1,2\alpha-1} = -2i |\Delta| \sin q, \tag{10.45}$$

$$B_{2\alpha,2\alpha-1} = -B_{2\alpha-1,2\alpha} = -\mu - 2t \cos q, \tag{10.46}$$

$$B_{2\alpha,2\alpha+1} = -B_{2\alpha+1,2\alpha} = -t - |\Delta|, \tag{10.47}$$

$$B_{2\alpha-1,2\alpha+2} = -B_{2\alpha+2,2\alpha-1} = t - |\Delta|, \tag{10.48}$$

and all other elements are zero.

Here we will give the phase diagrams of the presence of Majorana end modes in quasi-one-dimensional p-wave superconductors by using Kitaev's topological arguments [5]. To this end, we consider the $2n \times 2n$ matrix $B(q)$ in the Hamiltonian in (10.44). The matrix B is an antisymmetric matrix when q is equal to zero or π, such that we can calculate the Pfaffians $PfB(0)$ and $PfB(\pi)$. The topological property of the system described by the Hamiltonian in (10.44) is characterized by a Z_2 topological index (Majorana number) $\mathcal{M}$:

$$\mathcal{M} = sgn [Pf B(0)] sgn [Pf B(\pi)] = \pm 1, \tag{10.49}$$

where $+1$ means topologically trivial phases and -1 means topologically nontrivial states (i.e., the existence of zero mode Majorana end states).

For the simplest case, there is only one lattice site along the y-axis direction (i.e., $n = 1$). This case is just the one-dimensional Kitaev model. The two 2×2 antisymmetric matrices are

$$B_{n=1}(0/\pi) = \begin{pmatrix} 0 & \mu \pm 2t \\ -(\mu \pm 2t) & 0 \end{pmatrix}, \tag{10.50}$$

and $\mathrm{Pf}B_{n=1}(0/\pi) = \mu \pm 2t$, where $+$ and $-$ correspond to the cases of $q = 0$ and π, respectively. The Majorana number in the one-dimensional limit is

$$\mathcal{M}_{n=1} = sgn(\mu + 2t) \, sgn(\mu - 2t), \tag{10.51}$$

thus, we have the topologically nontrivial condition:

$$2|t| > |\mu| \tag{10.52}$$

with $(\Delta \neq 0)$. The (10.52) is consistent with the result given by Kitaev [5], who demonstrated that a long open chain (in the limit of $L \to \infty$) has zero energy Majorana end states located near the boundary under the same condition.

For the case of $n = 2$, the lattice site numbers along the y-axis direction are two. The two 4×4 antisymmetric matrices are

$$B_{n=2}(0/\pi) = \begin{pmatrix} 0 & \mu \pm 2t & 0 & t - \Delta \\ -(\mu \pm 2t) & 0 & -(t + \Delta) & 0 \\ 0 & t + \Delta & 0 & \mu \pm 2t \\ -(t - \Delta) & 0 & -(\mu \pm 2t) & 0 \end{pmatrix}. \tag{10.53}$$

The direct calculation yields the Pfaffians $\mathrm{Pf}B_{n=2}(0/\pi)$,

$$Pf B_{n=2}(0/\pi) = (\mu \pm 2t)^2 + \Delta^2 - t^2. \tag{10.54}$$

For the larger lattice site numbers $n \, (\geq 3)$, $\mathrm{Pf}B_n(0/\pi)$ can also be calculated analytically. A recursion relation gives

$$Pf B_n(0/\pi) = a_{\pm} Pf B_{n-1}(0/\pi) + b Pf B_{n-2}(0/\pi), \tag{10.55}$$

where $a_{\pm} = \mu \pm 2t$ and $b = |\Delta|^2 - t^2$. We further solve (10.55), and give an analytic formula for $\mathrm{Pf}B_n(0/\pi)$

$$Pf B_n(0/\pi) = \frac{(r_1^{n+1} - r_2^{n+1})}{\sqrt{a_{\pm}^2 + 4b}}, \tag{10.56}$$
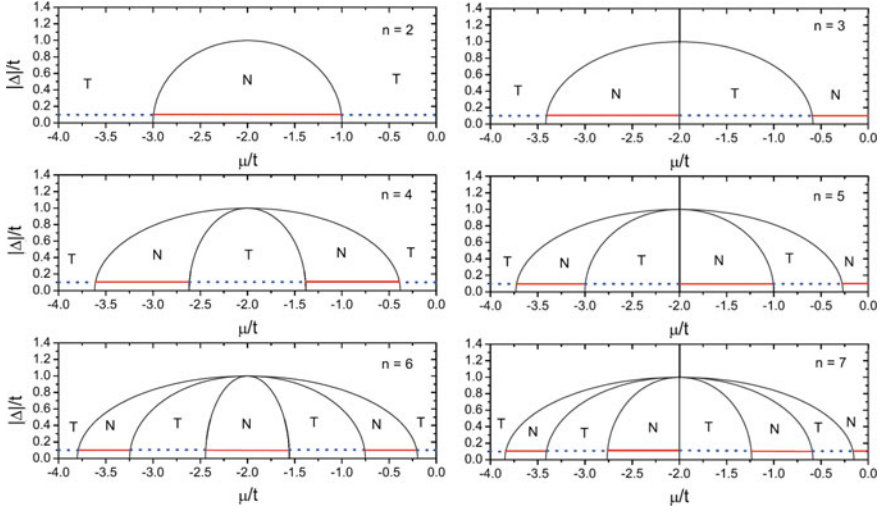

Fig. 10.3 Phase diagram for a quasi-1D p-wave superconductor model as a function of the p-wave pairing amplitude and chemical potential for lattice site numbers n along the y-axis direction. N denotes the topologically nontrivial region with zero-mode Majorana end states, and T denotes the topologically trivial region. When $|\Delta|/t = 0.1$, the *solid* (*red*) *lines* and *dotted* (*blue*) *lines* guide the values of μ/t, corresponding to the topologically nontrivial and trivial phases, respectively (Adapted from [7]) (color figure online)

where

$$r_1 = \frac{a_\pm + \sqrt{a_\pm^2 + 4b}}{2}, \ r_2 = \frac{a_\pm - \sqrt{a_\pm^2 + 4b}}{2}. \tag{10.57}$$

According to the Pfaffians PfB_n $(0/\pi)$ one can compute $\mathcal{M}$ as a function of the physical parameters, and then plot the phase diagram for the lattice site number n. Figure 10.3 presents the phase diagram for the lattice site number n along the y-axis direction. The phase diagrams of this tight binding model are symmetric for positive and negative μ, thus, here we only plot the part of negative μ values because the plot of positive μ values is a mirror image. However this $\mu \to \mu$ symmetry is not generic to models with say, next-nearest-neighbor hopping or next-nearest-neighbor pairing.

10.3 Majorana Fermions in Topological Insulators

Fu and Kane proposed that as a superconducting proximity effect the interface of the surface stets of a three-dimensional topological insulator and an s-wave superconductor resembles a spinless $p_x + ip_y$ superconductor, but does not break time

reversal symmetry [8]. The system supports Majorana bound states at vortices. Suppose that an *s*-wave superconductor is deposited on the surface of a topological insulator. Because of the proximity effect, Cooper pairs from superconductor can tunnel into the surface states of topological insulator, which is described by the pairing potential $V = \Delta c^\dagger_{\mathbf{k},\uparrow} c^\dagger_{\mathbf{k},\downarrow} + h.c.$ where $\Delta = \Delta_0 e^{i\phi}$. In the Nambu notation, $C^\dagger_{\mathbf{k}} = \{(c^\dagger_{\mathbf{k},\uparrow}, c^\dagger_{-\mathbf{k},\downarrow}), (c_{-\mathbf{k},\downarrow}, -c_{\mathbf{k},\uparrow})\}$, the surface states can then be described by

$$H = \frac{1}{2} \sum_{\mathbf{k}} C^\dagger_{\mathbf{k}} H_{eff}(\mathbf{k}) C_{\mathbf{k}}, \tag{10.58}$$

where

$$H_{eff} = -iv\tau_z \sigma \cdot \mathbf{k} - \mu\tau_z + \Delta_0(\tau_x \cos\phi + \tau_y \sin\phi), \tag{10.59}$$

where τ are the Pauli matrices that mix the c and $c^\dagger$ blocks of C. The Hamiltonian has the time reversal symmetry $\mathcal{T}$, $\Theta = i\sigma_y K$ (K is the complex conjugate operator), and the particle-hole symmetry $\mathcal{P}$, $\Xi = \sigma_y \tau_y K$. The energy spectra are

$$E_k = \pm\sqrt{(\pm vk - \mu)^2 + \Delta_0^2}. \tag{10.60}$$

For $\mu \gg \Delta_0$, the low energy spectrum resembles that of a spinless $p_x + ip_y$ superconductor. Define $d_k = (c_{k\uparrow} + e^{i\theta_k} c_{k\downarrow})$ for $\mathbf{k} = k(\cos\theta_k, \sin\theta_k)$ and $vk \sim \mu$. The projected Hamiltonian is then

$$H_{eff} = \sum_k (vk - \mu) d^\dagger_k d_k + \Delta_0(e^{i\theta_k} d^\dagger_k d^\dagger_{-k} + h.c.). \tag{10.61}$$

This is identical to the one for a p-wave pairing superconductor. Following the approach in a *p*-wave superconductor, a half quantum vortex in this system leads to a Majorana bound state.

Experimental realization of the proximity effect was reported in a superconducting topological insulator/superconductor heterostructure by growing Bi_2Se_3 thin films on superconductor niobium diselenide substrate. Using scanning tunneling microscopy and angle-resolved photoemission spectroscopy, the localized Majorana zero mode at the vortex core has been observed [9].

10.4   Sau–Lutchyn–Tewari–Das Sarma Model for Topological Superconductors

Sau et al. [10] proposed an idea to create Majorana fermions in a ferromagnetic insulator/semiconductor/s-wave superconductor hybrid system. They originally proved the existence of Majorana fermions in the setup by solving the vortex problem

in the Bogoliubov-de Gennes equation. Alicea [11] found that the model is connected to a spinless $p + ip$ superconductor. Here we prove that the system is actually equivalent to two spinless $p \pm ip$ superconductors, among which one is always topologically trivial, and the other is possibly topologically non-trivial.

Consider first an isolated zinc-blende semiconductor quantum well grown along the (100) direction in the presence of a perpendicular Zeeman field. Assume there is structural inversion asymmetry in the system, which generates Rashba spin-orbit coupling. The system can be modeled as a two-dimensional electron gas with Rashba spin-orbit coupling plus a perpendicular Zeeman field. The effective Hamiltonian reads

$$H_0 = \sum_{\mathbf{k},\sigma} c_{\mathbf{k},\sigma}^\dagger \left(\epsilon(k)\sigma_0 + \alpha(k_x\sigma_y - k_y\sigma_x) + V_Z\sigma_z \right)_{\sigma\sigma'} c_{\mathbf{k},\sigma'} \tag{10.62}$$

where $\epsilon(k) = \frac{k^2}{2m} - \mu$. μ is the chemical potential and $\alpha(>0)$ is the Rashba spin-orbit coupling strength. Furthermore consider the two-dimensional electron gas contacting an s-wave superconductor. Due to the proximity effect of superconductivity, an additional pairing potential is generated

$$V = \sum_{\mathbf{k}} \left(\Delta c_{\mathbf{k},\uparrow}^\dagger c_{-\mathbf{k},\downarrow}^\dagger + h.c. \right). \tag{10.63}$$

Thus, the total Hamiltonian for the electrons in quantum well becomes

$$H = H_0 + V. \tag{10.64}$$

To illustrate its connection to spinless p-wave superconductors, we first introduce a unitary transformation to diagonalize H_0,

$$\begin{pmatrix} c_{\mathbf{k},\uparrow} \\ c_{\mathbf{k},\downarrow} \end{pmatrix} = \begin{pmatrix} \cos\frac{\theta_{\mathbf{k}}}{2} & -e^{-i\varphi_{\mathbf{k}}}\sin\frac{\theta_{\mathbf{k}}}{2} \\ e^{i\varphi_{\mathbf{k}}}\sin\frac{\theta_{\mathbf{k}}}{2} & \cos\frac{\theta_{\mathbf{k}}}{2} \end{pmatrix} \begin{pmatrix} a_{\mathbf{k},+} \\ a_{\mathbf{k},-} \end{pmatrix}. \tag{10.65}$$

Consequently, H_0 is transformed to

$$H_0 = \sum_{\mathbf{k},\nu=\pm} (\epsilon(k) + \nu\Lambda_{\mathbf{k}})\, a_{\mathbf{k},\nu}^\dagger a_{\mathbf{k},\nu}. \tag{10.66}$$

where $\Lambda_{\mathbf{k}} = \sqrt{V_Z^2 + \alpha^2 k^2}$. The parameters are determined by $\cos\theta_{\mathbf{k}} = V_Z/\Lambda_{\mathbf{k}}$, $\sin\theta_{\mathbf{k}} = \alpha k/\Lambda_{\mathbf{k}}$ and $\tan\varphi_{\mathbf{k}} = -k_x/k_y$. After the transformation, the pairing potential V can be divided into two parts:

$$V = V_1 + V_2, \tag{10.67}$$

where

$$V_1 = \sum_{\mathbf{k}} \left(\Delta_{\mathbf{k},c} a_{\mathbf{k},+}^\dagger a_{-\mathbf{k},-}^\dagger + h.c. \right) \tag{10.68}$$

and

$$V_2 = -\frac{1}{2} \sum_{\mathbf{k},\circ} \left(\Delta_{\mathbf{k},\nu} a_{\mathbf{k},\nu}^\dagger a_{-\mathbf{k},\nu}^\dagger + h.c. \right). \tag{10.69}$$

Here $\Delta_{\mathbf{k},c} = \Delta \cos \theta_\mathbf{k}$ and $\Delta_{\mathbf{k},\pm} = \Delta e^{\mp i \varphi_\mathbf{k}} \sin \theta_\mathbf{k}$. Thus, $H_c = H_0 + V_1$ is equivalent to a s-wave superconductor with a "Zeeman" splitting, $\Lambda_\mathbf{k}$. We introduce the Bogoliubov transformation to diagonalize H_c:

$$\begin{pmatrix} a_{\mathbf{k},+} \\ a_{-\mathbf{k},-}^\dagger \end{pmatrix} = \begin{pmatrix} \cos \frac{\gamma_\mathbf{k}}{2} & -\sin \frac{\gamma_\mathbf{k}}{2} \\ \sin \frac{\gamma_\mathbf{k}}{2} & \cos \frac{\gamma_\mathbf{k}}{2} \end{pmatrix} \begin{pmatrix} b_{\mathbf{k},+} \\ b_{-\mathbf{k},-}^\dagger \end{pmatrix}, \tag{10.70}$$

where $\cos \gamma_\mathbf{k} = \epsilon(k)/\sqrt{\epsilon(k)^2 + \Delta_{\mathbf{k},c}^2}$ and $\sin \gamma_\mathbf{k} = \Delta_{\mathbf{k},c}/\sqrt{\epsilon(k)^2 + \Delta_{\mathbf{k},c}^2}$. As a result,

$$H_c = \sum_{\mathbf{k},\nu=\pm} \left(\sqrt{\epsilon(k)^2 + \Delta_{\mathbf{k},c}^2} + \nu \Lambda_\mathbf{k} \right) b_{\mathbf{k},\nu}^\dagger b_{\mathbf{k},\nu} \tag{10.71}$$

up to a constant. Meanwhile, the pairing potential V_2 has the form:

$$V_2 = -\frac{1}{2} \sum_{\mathbf{k},\circ} \left(\Delta_{\mathbf{k},\nu} b_{\mathbf{k},\nu}^\dagger b_{-\mathbf{k},\nu}^\dagger + h.c. \right). \tag{10.72}$$

In the language of $b_{\mathbf{k},\pm}^\dagger$ and $b_{\mathbf{k},\pm}$, the pairing potential V_2 consists of two pairing potentials between the same types of particles. The particles with $\nu = +$ and $\nu = -$ are decoupled completely. Therefore, the total Hamiltonian is reduced to

$$H = \sum_{\mathbf{k},\nu=\pm} \left[\left(\sqrt{\epsilon(k)^2 + \Delta_{\mathbf{k},c}^2} + \nu \Lambda_\mathbf{k} \right) b_{\mathbf{k},\nu}^\dagger b_{\mathbf{k},\nu} - \frac{1}{2} \left(\Delta_{\mathbf{k},\nu} b_{\mathbf{k},\nu}^\dagger b_{-\mathbf{k},\nu}^\dagger + h.c. \right) \right]. \tag{10.73}$$

The order parameters are

$$\Delta_{\mathbf{k},\nu} = \frac{\alpha \Delta}{\sqrt{V_Z^2 + \alpha^2 k^2}} \left(k_y + i\nu k_x \right), \tag{10.74}$$

which obey $p \pm ip$ symmetry. Thus, the effective model consists of two different types of spinless $p_x \pm i p_y$ wave pairing superconductors. By introducing a Nambu

spinor, $\psi^{\dagger}_{\mathbf{k},\nu} = \left(b^{\dagger}_{\mathbf{k},\nu}, b_{-\mathbf{k},\nu} \right)$, the total Hamiltonian has the form

$$H = \frac{1}{2} \sum_{\mathbf{k},\nu=\pm} \psi^{\dagger}_{\mathbf{k},\nu} \left[\left(\sqrt{\epsilon(k)^2 + \Delta^2_{\mathbf{k},c}} + \nu \Lambda_{\mathbf{k}} \right) \sigma_z - \frac{\alpha\Delta}{\Lambda_{\mathbf{k}}} \left(k_y \sigma_x - \nu k_x \sigma_y \right) \right] \psi_{\mathbf{k},°}.$$

$$(10.75)$$

The equation can be reduced to two modified Dirac equations near $k = 0$. In each type of superconductor, the factor $\alpha\Delta/V_Z$, which is equivalent to the velocity in the modified Dirac equation, plays a role in coupling the two bands. This fact illustrates that Rashba spin-orbit coupling, the pairing potential and the Zeeman field combine to form three indispensable ingredients to realize a topological superconductor. For the particles of $\nu = +$, the gap between the particle and hole bands is always positive, and never close if $\Delta \neq 0$. The Chern number is equal to zero. Thus, it is always topologically trivial. For the particles of $\nu = -$,

$$H \simeq \frac{1}{2} \sum_{\mathbf{k}} \psi^{\dagger}_{\mathbf{k},-} \left[\left(\sqrt{\mu^2 + \Delta^2} - |V_Z| \right) \sigma_z - \frac{\alpha\Delta}{|V_Z|} \left(k_y \sigma_x - \nu k_x \sigma_y \right) \right] \psi_{\mathbf{k},-}.$$

$$(10.76)$$

The gap closes at $|V_Z| = \sqrt{\mu^2 + \Delta^2}$. Thus, the sign change demonstrates that a topological quantum phase transition can occur near $|V_Z| = \sqrt{\mu^2 + \Delta^2}$. The Chern number can be calculated explicitly,

$$n_c = \frac{1}{2} \left[\mathrm{sgn} \left(\sqrt{\mu^2 + \Delta^2} - |V_Z| \right) - 1 \right].$$

$$(10.77)$$

It is topologically non-trivial if $\sqrt{\mu^2 + \Delta^2} < |V_Z|$. Therefore a large Zeeman term can induce a topological superconducting phase in this system.

Experimentally, it was reported that the bound, mid-gap states at zero bias voltage were observed in electric measurements on indium antimonide nanowires contacted with one normal (gold) and one superconducting electrode [12]. Several other groups also reported their experimental data to support existence of the Majorana fermions [13, 14].

10.5 4π-Josephson Effect

Consider two one-dimensional superconducting wires with Majorana end fermions connected at $x = 0$ to form a Josephson junction as shown in Fig. 10.4. The effective Hamiltonian of the junction can be written in terms of two Majorana fermions at the two ends

$$H_{junction} = 2i\,\Gamma(\phi)\gamma_{B,L}\gamma_{A,R} = \Gamma(\phi) \left(1 - 2d^{\dagger}_0 d_0 \right),$$

$$(10.78)$$

Fig. 10.4 *Top* Schematic of Josephson junction of Majorana fermions at two superconductors with the phase 0 and ϕ, respectively. *Bottom* The energies of two states with different parity as a function of the phase ϕ
where $\Gamma(\phi)$ is the coupling strength and is a function of the phase difference between the two superconductors, $\phi = \phi_R - \phi_L$. Suppose a gauge is chosen such that $\phi_L \rightarrow \phi_L + 2\pi$ and $\phi_R \rightarrow \phi_R$. In this gauge transformation, we have

$$\gamma_{B,L} \rightarrow -\gamma_{B,L} \tag{10.79}$$

and

$$\gamma_{A,R} \rightarrow \gamma_{A,R}. \tag{10.80}$$

As the Hamiltonian for the superconductor is invariant under the gauge transformation, we have a relation that $\Gamma(\phi) = -\Gamma(\phi + 2\pi)$. This condition shows that $\Gamma(\phi)$ is of period 4π and crosses zero at $\phi = \pm\pi$.

Equation (10.78) shows that $\Gamma(\phi)$ and $-\Gamma(\phi)$ are the eigenvalues of $H_{junction}$ and $|0\rangle$ and $d_0^+ |0\rangle$ are the corresponding eigenstates. If the fermion parity is conserved at the junction, this energy crossing is protected because $|0\rangle$ and $d_0^+ |0\rangle$ have different fermion parities and there is no transition from one state to the other when ϕ equals π. Since the energy eigenvalues $\pm\Gamma(\phi)$ are periodic of 4π and there are no transitions among the states with different fermion parities, the Josephson current, which is given by

$$I_{\pm} = \pm\frac{2e}{h}\partial_\phi\Gamma(\phi) \tag{10.81}$$

is also 4π periodic as shown in Fig. 10.4. The observation of this 4π periodic Josephson current is explicit evidence of Majorana fermions, and the sign of the current reveals the fermion parity of the junction.

10.6 Non-Abelion Statistics and Topological Quantum Computing

If the overall phase of the superconducting gap shifts by ϕ, it is equivalent to rotating the creation and annihilation operators of electron by $\phi/2$: $c \to e^{i\phi/2}c$ and $c^\dagger \to e^{-i\phi/2}c^\dagger$. The solution for the Majorana fermion $\gamma = uc^\dagger + u^*c \to ue^{-i\phi/2}c^\dagger + u^*e^{i\phi/2}c$. If the phase of the order parameter is changed by 2π, the Majorana fermion in the vortex changes its sign: $\gamma \to -\gamma$. Let us fix the initial positions of the vortices. Permutations of the vortices may form a braid group B_{2n}, which is generated by the elementary interchange T_i of neighboring vortices [4].

Under the action T_i,

$$\gamma_i \to \gamma_{i+1}, \tag{10.82}$$

$$\gamma_{i+1} \to -\gamma_i \tag{10.83}$$

and

$$\gamma_j \to \gamma_j \tag{10.84}$$

for $j \neq i$ and $j \neq i + 1$. This action obeys the commutation relations

$$T_i T_j = T_j T_i, \ for \ |i - j| > 1 \tag{10.85}$$

and

$$T_i T_j T_i = T_j T_i T_j, \ for \ |i - j| = 1 , \tag{10.86}$$

which describe for the braid group. The expression for this action is

$$\tau(T_i) = \exp\left(\frac{\pi}{2}\gamma_{i+1}\gamma_i\right) = \exp\left(-i\frac{\pi}{4}P\right) \tag{10.87}$$

$$= \cos\frac{\pi}{4} - i P \sin\frac{\pi}{4} = \frac{1}{\sqrt{2}}\left(1 + 2\gamma_{i+1}\gamma_i\right), \tag{10.88}$$

where P is the parity operator and $P^2 = P$. Thus, the Majorana fermions associated with a quantum vortex obey non-Abelion statistics.

In the case of four vortices the four Majorana fermions combine into two complex fermions $c_1 = \frac{1}{\sqrt{2}}(\gamma_1 + i\gamma_2)$ and $c_2 = \frac{1}{\sqrt{2}}(\gamma_3 + i\gamma_4)$. The ground state is four-fold degenerated and the three generators T_1, T_2 and T_3 of the braid group are represented by

$$\tau(T_1) = \exp\left(\frac{\pi}{2}\gamma_2\gamma_1\right), \tag{10.89}$$

$$\tau(T_2) = \exp\left(\frac{\pi}{2}\gamma_4\gamma_3\right)$$
(10.90)

and

$$\tau(T_3) = \exp\left(\frac{\pi}{2}\gamma_3\gamma_2\right).$$
(10.91)

One may write the operators in a matrix form in the basis $\{|0\rangle, c_1^\dagger |0\rangle, c_2^\dagger |0\rangle, c_1^\dagger c_2^\dagger |0\rangle\}$.

$$\tau(T_1) = \exp\left(\frac{\pi}{2}\gamma_2\gamma_1\right) = \begin{pmatrix} e^{-i\frac{\pi}{4}} & 0 & 0 & 0 \\ 0 & e^{+i\frac{\pi}{4}} & 0 & 0 \\ 0 & 0 & e^{-i\frac{\pi}{4}} & 0 \\ 0 & 0 & 0 & e^{+i\frac{\pi}{4}} \end{pmatrix},$$
(10.92)

$$\tau(T_2) = \exp\left(\frac{\pi}{2}\gamma_4\gamma_3\right) = \begin{pmatrix} e^{-i\frac{\pi}{4}} & 0 & 0 & 0 \\ 0 & e^{-i\frac{\pi}{4}} & 0 & 0 \\ 0 & 0 & e^{+i\frac{\pi}{4}} & 0 \\ 0 & 0 & 0 & e^{+i\frac{\pi}{4}} \end{pmatrix}$$
(10.93)

and

$$\tau(T_3) = \exp\left(\frac{\pi}{2}\gamma_3\gamma_2\right) = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 0 & 0 & -i \\ 0 & 1 & -i & 0 \\ 0 & -i & 1 & 0 \\ -i & 0 & 0 & 1 \end{pmatrix}.$$
(10.94)

A quantum computation consists of three steps.

1. Create: if a pair of i, j of vortices is created, they will be in the ground state $|0_{ij}\rangle$ with no extra quasi-particle excitations. Creating N pairs initialize the system.
2. Braid: Adiabatically rearranging the vortices modifies the state and performs a quantum computation.
3. Measure: Bringing vortices i and j back together allows the quantum state associated with each pair to be measured. $|0_{ij}\rangle$ will be distinguished by the presence or absence of extra fermionic quasi-particles associated with the pair.

Majorana fermions might provide the basic elements for a quantum computer. This is the motivation behind the search for Majorana fermions in condensed matter systems.

Chapter 11
Topological Dirac and Weyl Semimetals

Abstract A topological Dirac or Weyl semimetal is a topological phase of matter, in which the conduction and valence bands touch at a finite number of points, i.e., the Weyl nodes. Uniaxial rotation symmetries protect the nodes against gap formation. Topological Weyl semimetals host paired monopoles and antimonopoles of Berry curvature at the Weyl nodes and topologically protected Fermi arcs at certain surfaces. The chiral anomaly of the Weyl fermions, a pure quantum mechanical phenomenon, can be realized in solids, and is attributed to the exotic magneto-transport properties in Weyl and Dirac semimetals.

11.1 Weyl Equations and Weyl Fermions

11.1.1 Weyl Equations

In 1929, Weyl [1] found that the Dirac equation in (2.1) can be decoupled into two Weyl equations when the mass term vanishes, i.e., $m = 0$,

$$i \frac{\partial}{\partial t} \psi_\pm = \pm v \mathbf{p} \cdot \sigma \psi_\pm, \tag{11.1}$$

with $\psi_\pm = \psi_1 \pm \psi_2$. The subscripts $\pm$ in the Hamiltonians,

$$H_\pm = \pm v \mathbf{p} \cdot \sigma, \tag{11.2}$$

define two types of fermions with opposite chirality, the left- and right-handed particles. In a chiral particle, its quantum spin is tied to its momentum. The helicity is defined as $h = \mathbf{p} \cdot \sigma / p$ with two eigenvalues, ± 1, which is also the chirality for the gapless case.

Either H_+ or H_- has two eigenvalues, $E = \pm vp$. At $p = 0$ the two bands across at one point, i.e., the Weyl point. A Dirac point is usually regarded as consisting of two Weyl points of opposite chirality, i.e., fourfold degeneracy at the point. It is noted that in three dimensions, as there are only three Pauli matrices, any perturbation $\delta \cdot \sigma$ to $H_\pm = \pm v\mathbf{p} \cdot \sigma$ just shifts the crossing point from zero to $\mathbf{p} = \mp \delta/v$, and cannot gap out the crossing point. Thus, the crossing point is quite stable, and hence is dubbed the Weyl nodes. In two dimensions, say x–y plane, as only two Pauli matrices are used in the Hamiltonian $H = \pm v(p_x \sigma_x + p_y \sigma_y)$ as p_z is suppressed, addition of a mass term $mv^2 \sigma_3$ opens a gap at $p = 0$. Hence two-dimensional crossing point is not as robust as that in three dimensions except for some specific uniaxial rotation symmetries. For terminology, it is dubbed the Dirac points in two dimensions. The Dirac point can be stable if the system is protected by some specific rotation symmetries. For example graphene is a two-dimensional Dirac semimetal.

A more general form of the Hamiltonian for the Weyl fermions is

$$H = \sum_{i,i} v_{ij} \mathbf{p}_i \sigma_j, \tag{11.3}$$

where v_{ij} have dimension of velocity and form a 3×3 square matrix. The chirality number is defined as the sign of the determinant of the velocity matrix, $\chi = \mathrm{sgn}[\det(v_{ij})]$.

Helicity and chirality are two different concepts for massive Dirac fermions. The helicity is defined as

$$h = \frac{2\mathbf{J} \cdot \mathbf{p}}{|\mathbf{p}|} = \frac{\Sigma \cdot \mathbf{p}}{|\mathbf{p}|}, \tag{11.4}$$

where $\mathbf{J} = \mathbf{r} \times \mathbf{p} + \Sigma$ denotes the total angular momentum and $\Sigma = \sigma_0 \otimes \sigma$ denotes the spin matrix. Note that orbital angular momentum is normal to the momentum. The chirality operator is defined as

$$L = \frac{1}{2}(1 - \gamma_5); \; R = \frac{1}{2}(1 + \gamma_5). \tag{11.5}$$

For massive Dirac fermions the chirality operators do not commute with the Dirac Hamiltonian and the Dirac operator γ_5 (see Appendix C) does not commute with the mass term, unlike the helicity operator. For massless Dirac fermions both chirality and helicity are conserved.

11.1.2   A Single Node and Magnetic Monopole

Consider a single three-dimensional Weyl node, $H = v\hbar \mathbf{k} \cdot \sigma$. In spherical coordinate, the spinor wave function of the valence band can be found as

$$|u_+(k, \theta, \varphi)\rangle = \begin{pmatrix} \sin \frac{\theta}{2} \\ -\cos \frac{\theta}{2} e^{i\varphi} \end{pmatrix}, \tag{11.6}$$

where $\cos \theta \equiv k_z/k$ with $k = \sqrt{k_x^2 + k_y^2 + k_z^2}$. The Berry connection is defined as $\mathbf{A} \equiv i\langle u_+ | \nabla_{\mathbf{k}} | u_+\rangle$ with the gradient operator $\nabla_{\mathbf{k}} = (\partial_k, (1/k)\partial_\theta, (1/k\sin\theta)\partial_\varphi)$. One finds that

$$(A_k, A_\theta, A_\varphi) = \left(0, 0, -\frac{\cos^2 \frac{\theta}{2}}{k \sin\theta}\right). \tag{11.7}$$

The Berry curvature can be found as $\Omega \equiv \nabla \times \mathbf{A} = \frac{\mathbf{k}}{2k^3}$. The monopole charge is defined as the Berry curvature flux threading a sphere that encloses the origin,

$$\mathcal{N} = \frac{1}{2\pi} \int_\Sigma d\mathbf{S} \cdot \Omega = 1. \tag{11.8}$$

Using the Gauss's theorem, it is found that $\nabla \cdot \Omega = 2\pi\delta(\mathbf{k})$. In the Dirac cone of opposite chirality, the Hamiltonian can be written as $H = -v\hbar\mathbf{k} \cdot \sigma$, the wave function of the valence band $|u_-\rangle$ can be obtained by letting $\theta \to \pi/2 - \theta$ and $\varphi \to \pi + \varphi$ in $|u_+\rangle$, and $|u_-\rangle = (\cos\frac{\theta}{2}, \sin\frac{\theta}{2}e^{i\varphi})$. In the other Weyl node with opposite chirality, following the same procedure, the Berry curvature is $\Omega_k = -1/2k^2$, and the monopole charge is -1. Thus, they are called magnetic monopole and antimonopole in momentum space.

In 1981 Nielsen and Ninomiya proved a no-go theorem [2]: for a Hamiltonian H with translational invariance on a three-dimensional lattice, and its Fourier-transformation is a smooth function, the numbers of left-handed Weyl states are always equal to number of right-handed Weyl states. Equivalently, the theorem says that there are as many charges of monopoles as of anti-monopoles in a lattice.

11.2 Emergent Dirac and Weyl Semimetals

A three-dimensional Dirac or Weyl semimetal indicates a phase whose low energy excitations consists of degenerated quasiparticles with distinct chirality and linear energy dispersions. It may exist as a consequence of the band crossing in the systems with some uniaxial rotation symmetries.

11.2.1   Dirac Semimetal

Let us consider a system having both time reversal symmetry and inversion symmetry. In general the time reversal symmetry $\mathcal{T}$ requires that $E_{n,\uparrow}(\mathbf{k}) = E_{n,\downarrow}(-\mathbf{k})$, and the inversion symmetry P requires that $E_{n,\sigma}(\mathbf{k}) = E_{n,\sigma}(-\mathbf{k})$. Consequently the energy band is doubly degenerate for all $\mathbf{k}$, $E_{n,\uparrow}(\mathbf{k}) = E_{n,\downarrow}(\mathbf{k})$. Under the condition a three-dimensional Dirac point with fourfold degeneracy can be degenerated when an accidental band crossing occurs. Due to the strong repulsion between the degenerated bands, the accidental band crossing can be achieved at a time reversal invariant momentum only when the conduction and valence bands have opposite parities. In this case, a three-dimensional Dirac semimetal appears at the quantum critical point between a normal insulator and a topological insulator [3]. Usually this type of the Dirac semimetal is not stable when the system deviates from the critical transition point. It is found that some crystals with uniaxial rotational symmetry C_n as well as the time reversal symmetry and inversion symmetry may allow the Dirac semimetal to be stable.

The invariance of the system under the C_n rotation (the n-fold rotation about a principal axis) gives

$$C_n H(\mathbf{k}) C_n^{-1} = H(R_n \mathbf{k}), \tag{11.9}$$

where R_n is the 3×3 rotation matrix defining the $2\pi/n$ rotation in three dimensions with $n = 2, 3, 4, 6$. Combined with the time reversal symmetry and the inversion symmetry in space, a more rigorous classification of stable Dirac semimetals can be found in the paper by Yang and Nagaosa [4].

From the modified Dirac equation, when the band gap is closed, one has an effective Hamiltonian for massless Dirac fermions

$$H = v\mathbf{k} \cdot \alpha = vk_x \alpha_x + vk_y \alpha_y + vk_z \alpha_z, \tag{11.10}$$

where higher order terms are ignored. As α_i change their sign under time reversal, the Hamiltonian is time reversal invariant. In the Dirac representation, $\Theta = i\alpha_x \alpha_y K$. It is easy to find $\Theta H(k)\Theta^{-1} = H(-k)$. The crossing point is fourfold degenerated as shown in Fig. 11.1a.

$Bi_{1-x}Sb_x$ occurs a topological phase transition from a band insulator to a topological insulator at $x \approx 4\%$ as shown in Fig. 7.2. At the point the L_a and L_s bands cross, and massless Dirac fermions appear at the crossing point. Therefore $Bi_{1-x}Sb_x$ at the transition point is identified as a Dirac semimetal, in which the Dirac point is fourfold degenerated. It can be described in the three-dimensional modified Dirac equation by taking the gap parameter $M = 0$. Recent quantum transport measurement evidenced the properties of massless Dirac or Weyl fermions in $Bi_{1-x}Sb_x$ [5].

11.2.2 Topological Dirac Semimetal

One effective Hamiltonian for a topological Dirac semimetal is

$$H = A(k_x \alpha_x + k_y \alpha_y) + M(k)\beta. \tag{11.11}$$

For a time reversal invariant system, the coefficient before β has to be even in k under time reversal. One keeps the quadratic term by taking $M(k) = mv^2 - B_1 k_x^2 - B_1^2 k_y^2 - B_2 k_z^2$, and coefficients $B_{1,2}$ are introduced to describe the topological properties. One of α_i matrices, say α_z, is absent to guarantee the occurrence of the band crossing at $k_z \neq 0$. For m and B_2 with the same sign, the bands will cross at two points, $k_x = k_y = 0$ and $k_z = \pm k_w = \pm\sqrt{mv^2/B_2}$. As $M(k) \simeq B_1(k_w + k_z)(k_w - k_z)$ is linear in $k_z \pm k_w$ at the two points $k_z = \mp k_w$, hence the Hamiltonian describes a pair of Dirac points as shown in Fig. 11.1c. In this case the system still respects rotation symmetry around the z axis.

Under a unitary transformation, the Hamiltonian can be written as

$$H \rightarrow H = \begin{pmatrix} H(k) & 0 \\ 0 & H^*(-k) \end{pmatrix}, \tag{11.12}$$

where $H(\mathbf{k}) = A(k_x\sigma_x + k_y\sigma_y) + M(k)\sigma_z$ and $H^*(-\mathbf{k})$ is its time-reversal partner where the asterisk refers to a complex conjugate. The Dirac points are still fourfold degenerated. As there exists topological invariants for specific values of k_z between the two Dirac points, according to the bulk-boundary correspondence, there always exists an edge states for each Chern number, and a set of edge states for k_z between the two nodes. The dispersions of these edge states construct the Fermi arcs connecting the Dirac points near the Fermi surface, which is one of the key characteristics for topological Dirac semimetal.

Cd$_3$As$_2$ [6] and Na$_3$Bi [7] were predicted to be Dirac semimetals, and confirmed to be so by photoemission and transport experiments [8, 9].

11.2.3   Topological Weyl Semimetal

Furthermore if the inversion symmetry is broken, the fourfold degenerate Dirac points may be split in to two doubly degenerate points. In this case the two pairs of Dirac point in a topological Dirac semimetal can be split into two pairs of Weyl nodes, which means that the energy crossing point is only doubly degenerated. For example, the Dirac points in Dirac semimetal $(0, 0, \pm k_w)$ evolve into two pairs of Weyl nodes $(k_0, k_0, \pm k_w)$ and $(-k_0, -k_0, \pm k_w)$ as shown in Fig. 11.1d. Of course the time reversal symmetry breaking can also lift the degeneracy of the Dirac points. Thus, this class of materials is named topological Weyl semimetal. From the model in (11.12), one can have an effective Hamiltonian for a topological Weyl semimetal,

$$H \to H = \begin{pmatrix} H(k_x - k_0, k_y - k_0, k_z) & 0 \\ 0 & H^*(-k_x - k_0, -k_y - k_0, k_z) \end{pmatrix}. \quad (11.13)$$

TaAs [10, 11] is a stoichiometric, inversion breaking, single-crystal materials and confirmed to be a topological Weyl semimetal with the Fermi arc states on the surface. It is a representative of the transition metal monopnictide or TX family where T = Ta/Nb and X = As/P. There are twelves pairs of Weyl nodes near the Fermi surface. This material is confirmed as a topological Weyl semimetal by Xu et al. [12] and Lv et al. [13] using ARPES to detect the Fermi arcs on the sample surface.

11.3   Graphene: A Topological Dirac Semimetal

Graphene [14] is a monolayer of carbon atoms packing a hexagon lattice to host two pairs of two-dimensional Dirac fermions or four Dirac cones in the absence of or with negligible spin–orbit coupling. Each pair of Dirac fermions have two Dirac cones with opposite chirality [15], where the well-defined Berry phase π or $-\pi$ rest around the Dirac cones when an electron moves around the Dirac points adiabatically [16–18].
Fig. 11.2 a The lattice unit vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ in a unit cell of a hexagonal lattice of graphene. **b** The corresponding Brillouin zone, and the Dirac cones are located at the $\mathbf{K}$ and $\mathbf{K}'$ points. The *shadowed area* indicates the region with non-zero electric polarization

Since the spin–orbit coupling in graphene is tiny, only the spin degeneracy of electrons is assumed here. The energy dispersions of electrons in graphene have been investigated extensively [14, 19]. To diagonalize the tight-biding model for graphene, a basis of two-component "spinors" of Bloch states constructed on the two sublattices **A** and **B** is introduced. Let δ_1, δ_2 and δ_3 be the displacements from a B site to its three nearest-neighbor A sites as shown in Fig. 11.2a. The lattice vectors are chosen to be $\mathbf{a}_1 = \sqrt{3}a(\frac{\sqrt{3}}{2}, \frac{1}{2})$ and $\mathbf{a}_2 = \sqrt{3}a(\frac{\sqrt{3}}{2}, -\frac{1}{2})$. The corresponding reciprocal lattice vectors are $\mathbf{b}_1 = \frac{4\pi}{3a}(\frac{1}{2}, \frac{\sqrt{3}}{2})$ and $\mathbf{b}_2 = \frac{4\pi}{3a}(\frac{1}{2}, -\frac{\sqrt{3}}{2})$. In this representation the Hamiltonian becomes

$$H = -t \sum_{\mathbf{k}} \begin{pmatrix} 0 & \phi(\mathbf{k}) \\ \phi^*(\mathbf{k}) & 0 \end{pmatrix}, \tag{11.14}$$

where σ_i are the Pauli matrices and $\phi(\mathbf{k}) = \sum_{n=1}^{3} e^{i\mathbf{k}\cdot(\delta_n - \delta_1)}$. The energy band dispersions are obtained as,

$$E_s = -st\,|\phi(\mathbf{k})|, \tag{11.15}$$

where $s = \pm$. The two bands touch at the points of $\mathbf{K} = (\frac{2\pi}{3a}, \frac{2\pi}{3\sqrt{3}a}) = \frac{2}{3}\mathbf{b}_1 + \frac{1}{3}\mathbf{b}_2$ and $\mathbf{K}' = (\frac{2\pi}{3a}, -\frac{2\pi}{3\sqrt{3}a}) = \frac{1}{3}\mathbf{b}_1 + \frac{2}{3}\mathbf{b}_2$ in the Brillouin zone formed by the reciprocal lattice vectors $\mathbf{b}_1$ and $\mathbf{b}_2$ as shown in Fig. 11.2b, and the dispersions become linear in k approximately measured from the two points. Thus, two Dirac cones are formed around $\mathbf{K}$ and $\mathbf{K}'$. The density of states is linear in energy E near the two Dirac points, which is a key feature of a semimetal. The vector connecting $\mathbf{K}$ and $\mathbf{K}'$ is along $\delta\mathbf{K} = \mathbf{K} - \mathbf{K}' = \frac{1}{3}(\mathbf{b}_1 - \mathbf{b}_2)$. To explore the topological properties of the

two Dirac cones, we take $\mathbf{k} = k_1\mathbf{b}_1 + k_2\mathbf{b}_2$ and consider a specific direction by taking a specific value of k_1 (or k_2) as a constant, and the model is reduced to one-dimensional along the $\mathbf{b}_2$ (or $\mathbf{b}_1$) direction. When k_1 is away from the Dirac points, i.e., $k_1 \neq 1/3$ and $2/3$, the reduced one-dimensional system always possesses a finite band gap. This gap closes and re-opens when k_1 is sweeping over one Dirac point, which indicates that a topological phase transition may occur in the process.

Ryu and Hatsugai [20] first realized that zero energy modes in the zigzag ribbon of graphene are closely associated to a hidden chiral symmetry for a reduced one-dimensional Hamiltonian in a parameter space. Denote the eigenstates of H by $\left|\phi_s\left(k_x, k_y\right)\right\rangle = \frac{1}{\sqrt{2}}\left(1, s\phi(\mathbf{k})/|\phi(\mathbf{k})|\right)^T$ with the eigenvalue $E_s(\mathbf{k})$ in (11.15). In reduced one-dimensional momentum space, e.g., keeping k_1 constant, the electric polarization for the reduced one-dimensional band is defined as Sect. 4.4

$$P_s = -\frac{e\sqrt{3}a}{2\pi} \oint_C dk_2 \langle\phi_s(k_1, k_2)|\, (i\partial_{k_2})\, |\phi_s(k_1, k_2)\rangle . \qquad (11.16)$$

The electric polarization has its topological origin, and is quantized to be $P_s = e\nu_s\sqrt{3}a$, where the integer $\nu_s = 0$ or $1/2$ with modulo 1 appears as a topological invariant for quantum transport. It is found that $P_s = se\sqrt{3}a/2$ for $1/3 < k_1 < 2/3$, and $P_s = 0$ otherwise. Thus, the 1D system is topologically nontrivial when $1/3 \leq k_1 < 2/3$. Therefore a spinless graphene is a two-dimensional topological Dirac semimetal characterized by a topological invariant, which is very similar to the three-dimensional Weyl semimetal with k-dependent Chern numbers [21]. According to the bulk-boundary correspondence, there exists a pair of end modes near the two ends of an open and topological nontrivial chain, and the energy of the end states should be zero due to the chiral symmetry [20], just as the end modes in the Su–Schrieffer–Heeger model. Correspondingly, the open boundary parallel with the vector $\mathbf{b}_1$ (or $\mathbf{b}_2$) is the zigzag boundary of the lattice. Each k_1 in the shadow regime will have a pair of zero energy modes near two edges according to the the bulk-edge correspondence and the particle-hole symmetry. As the number of k_1 between the two Dirac points is finite, the same number of the zero energy of the end states form a flat band for a zigzag boundary of the graphene lattice. This demonstrates that the famous flat band of graphene with a zigzag boundary condition has its topological origin related to the non-zero electric polarization or topological invariant [22].

11.4   Two-Node Model

To explore the topological properties in topological Dirac and Weyl semimetals, one can start with an effective model which captures the key features of these systems. The results from this model can simply be generalized to the time reversal invariant systems.

11.4.1 Model

Under the time reversal symmetry breaking, a minimal model for a Weyl semimetal can be written as

$$H = A(k_x\sigma_x + k_y\sigma_y) + \mathcal{M}_{\mathbf{k}}\sigma_z, \tag{11.17}$$

where σ are the Pauli matrices, $\mathcal{M}_{\mathbf{k}} = M_0 - M(k_x^2 + k_y^2 + k_z^2)$, $\mathbf{k} = (k_x, k_y, k_z)$ is the wave vector, and A, M are model parameters. This minimal model gives a global description of a pair of Weyl nodes of opposite chirality. It has an identical structure as that for A-phase of ^{3}He superfluids as in (9.32). If $M_0 M > 0$, the two bands intersect at $(0, 0, \pm k_w)$ with $k_w \equiv \sqrt{M_0/M}$ (see Fig. 11.3), giving rise to the topological semimetal phase. Here we want to emphasize that if the quadratic terms of k_x and k_y are missed in $\mathcal{M}_{\mathbf{k}}$ the Hamiltonian can still describe two weyl nodes, but fails to describe the topological properties such as the Chern numbers and Fermi arc which will be discussed in the following subsection. In the topological semimetal phase, the model can also be written as

$$H = A(k_x\sigma_x + k_y\sigma_y) + M(k_w^2 - \mathbf{k}^2)\sigma_z, \tag{11.18}$$
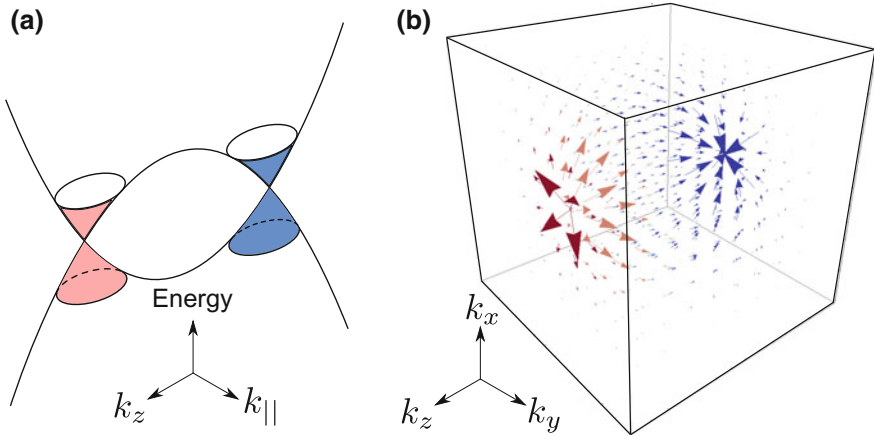

Fig. 11.3 Nontrivial band structure and Berry curvature of a topological semimetal. **a** A schematic of the energy spectrum of a topological semimetal. (k_x, k_y, k_z) is the wave vector. $k_{||}^2 = k_x^2 + k_y^2$. **b** The vector plot of the Berry curvature in momentum space. The conduction and valence bands of a topological semimetal touch at the Weyl nodes, at which a pair of monopoles are hosted. The *arrows* show that the flux of the Berry curvature flows from one monopole (*red*) to the other (*blue*), defining the nontrivial topological properties of a topological semimetal (Adapted from [25])

where A, M, k_w are model parameters. The dispersions of two energy bands are

$$E_\pm = \pm\sqrt{[M(k_w^2 - \mathbf{k}^2)]^2 + A^2(k_x^2 + k_y^2)}, \tag{11.19}$$

which reduce to $E_\pm = \pm M|k_w^2 - k_z^2|$ at $k_x = k_y = 0$. The two bands intersect at $(0, 0, \pm k_w)$ (see Fig. 11.3). Around the two nodes $(0, 0, \pm k_w)$, H reduces to two separate local models

$$H_\pm = \mathbf{M}_\pm \cdot \sigma, \tag{11.20}$$

with $\mathbf{M}_\pm = \left(A\widetilde{k}_x, A\widetilde{k}_y, \mp 2Mk_w\widetilde{k}_z\right)$ and $(\widetilde{k}_x, \widetilde{k}_y, \widetilde{k}_z)$ the effective wave vector measured from the Weyl nodes.

The topological properties in H can be seen from the Berry curvature [23], $\Omega(\mathbf{k})$ $= \nabla_\mathbf{k} \times \mathbf{A}(\mathbf{k})$, where the Berry connection is defined as $\mathbf{A}(\mathbf{k}) = i \langle u(\mathbf{k})| \nabla_\mathbf{k} |u(\mathbf{k})\rangle$. For example, for the energy eigenstates for the $+$ band $|u(\mathbf{k})\rangle = [\cos(\theta/2), \sin(\theta/2)e^{i\varphi}]$, where $\cos\theta \equiv \mathcal{M}_\mathbf{k}/E_+$ and $\tan\varphi \equiv k_y/k_x$. The three-dimensional Berry curvature for the two-node model can be expressed as

$$\mathbf{\Omega}(\mathbf{k}) = \frac{A^2 M}{E_+^3}\left[k_z k_x, k_z k_y, \frac{1}{2}\left(k_z^2 - k_w^2 - k_x^2 - k_y^2\right)\right]. \tag{11.21}$$

There exist a pair of singularities at $(0, 0, \pm k_w)$ as shown in Fig. 11.3. The chirality of a Weyl node can be found as an integral over the Fermi surface enclosing one Weyl node $(1/2\pi)\oint\Omega(\mathbf{k})\cdot d\mathbf{S}(\mathbf{k})$, which yields opposite topological charges $\mp\text{sgn}(M)$ at $\pm k_w$, corresponding to a pair of "magnetic monopole and antimonopole" in momentum space.

11.4.2 The Chern Number and Fermi Arc

For a given k_z, a Chern number is defined as

$$n_c(k_z) = -(1/2\pi)\int dk_x dk_y \Omega(k_x, k_y) \tag{11.22}$$

to characterize the topological property of the band in the sliced k_x-k_y plane,

$$n_c(k_z) = -\frac{1}{2}[\text{sgn}[M(k_w^2 - k_z^2)] + \text{sgn}(M)]. \tag{11.23}$$

The Chern number $n_c(k_z) = -\text{sgn}(M)$ for $-k_w < k_z < k_w$, and $n_c(k_z) = 0$ otherwise. One can say that a Chern number flux connects two Weyl notes. The ends of the flux are the magnetic monopole and antimonopole. The nonzero Chern number
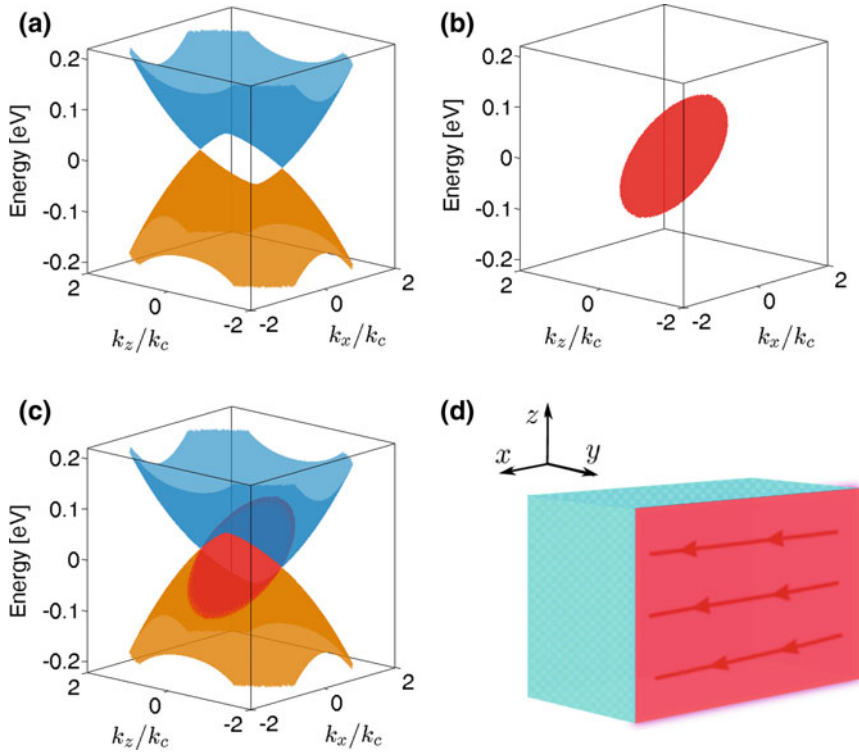

Fig. 11.4 The energy spectrum of the bulk states (**a**) and the surface states at the $y=0$ surface (**b**) of the topological Weyl semimetal. **c** Both the bulk and surface states. **d** The real-space schematic of the topological Weyl semimetal and its surface states. We assume that the $\hat{x}$ and $\hat{z}$ directions are infinitely long. The *lines with arrows* in the $y = 0$ (*red*) plane indicate that the chiral surface states travel along only one direction. In contrast, a topological Dirac semimetal hosts helical surface states that travel along both the $\hat{x}$ and $-\hat{x}$ directions. Parameters: $k_c = 0.1$/nm, $M = 5$ eV nm^2, and $A = 1$ eV nm (Adapted from [27])

corresponds to the k_z-dependent edge states (known as the Fermi arcs) according to the bulk-boundary correspondence [26].

To further demonstrate the topological properties of the two-node model, one can find the edge state solution and the Fermi arc in the k_z–k_x or k_z–k_y plane which is parallel with the z axis. Suppose a semi-infinite system in the half plane $y \leq 0$ with open boundary conditions and with translational symmetry along the x- and z-directions, as shown in Fig. 11.4d. In the case k_x and k_z are still good quantum numbers but k_y is replaced $k_y = -i\partial_y$ in (11.18). One can assume a trial wavefunction for each set of k_x, k_z as

$$\psi_\lambda = e^{ik_x x + ik_z z} \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix} e^{\lambda y}. \tag{11.24}$$

Substituting the trial wavefunction into the eigen equation

$$H(k_x, -i\partial_y, k_z)\psi_\lambda = E\psi_\lambda \tag{11.25}$$

after some algebra, one finds that the dispersion of the surface states is given by

$$E_{arc}(k_x, k_z) = \mathrm{sgn}(M)Ak_x. \tag{11.26}$$

The corresponding wavefunction is

$$\Psi^{arc}_{k_x, k_z}(\mathbf{r}) = Ce^{ik_x x + ik_z z}\begin{pmatrix} sgn(M) \\ 1 \end{pmatrix}(e^{\lambda_1 y} - e^{\lambda_2 y}), \tag{11.27}$$

where C is a normalization factor and $\lambda_{1,2} = A/2|M| \mp \sqrt{(A/2M)^2 - \Delta_k}$. The surface states are eigenstates of σ_x with a uniform effective velocity, $v_{eff} = sgn(M)A/\hbar$. Thus, they are chiral surface states around the surface parallel with the z axis. We require that $\lambda_1\lambda_2 > 0$ and henceforth $\Delta_k > 0$. Therefore the solution of Fermi surface states is restricted inside a circle defined by $k_x^2 + k_z^2 < k_c^2$, as shown by Fig. 11.4b, c. At zero Fermi energy, i.e., $k_x = 0$, the surface states exist for all $|k_z| < k_c$ which produces a Fermi arc connecting two Weyl nodes. For a non-zero Fermi energy, the ends of the Fermi arc are shifted away from the Weyl nodes until they vanish.

Thus, the two-node model in (11.18) provides a generic description for Weyl topological semimetals, including the band touching, opposite chirality, monopoles of Berry curvature, topological charges, and Fermi arcs.

11.4.3   Quantum Anomalous Hall Effect

In a magnetic field along the z direction, the energy spectrum is quantized into a set of one-dimensional Landau bands dispersing with k_z. Consider a magnetic field applied along the z direction, $\mathbf{B} = (0, 0, B)$, and choose the Landau gauge in which the vector potential is $\mathbf{A} = (-yB, 0, 0)$. Under the Pierls replacement, the wave vector in the Hamiltonian in (11.17) is replaced by the operator $\mathbf{k} = (k_x - \frac{eB_z}{\hbar}y, -i\partial_y, k_z)$, where k_x and k_z are still the good quantum numbers as introduction of the vector potential does not break the translational symmetry along the x and z direction. By using the the ladder operator in (7.32), then one can write the Hamiltonian in terms of the ladder operators,

$$H(\mathbf{k}) = \begin{bmatrix} M_k & Ak_- \\ Ak_+ & -M_k \end{bmatrix} \to \begin{bmatrix} M_a & \eta a \\ \eta a^\dagger & -M_a \end{bmatrix}, \tag{11.28}$$

where $\mathcal{M}_a = M_0 - M_1 k_z^2 - \omega(a^\dagger a + 1/2)$, $\omega = 2M_1/\ell_B^2$, and $\eta = \sqrt{2}A/\ell_B$. The eigen energies are

$$E_{k_z}^{\nu\pm} = \omega/2 \pm \sqrt{\mathcal{M}_\nu^2 + \nu\eta^2} \quad \nu \geq 1 \tag{11.29}$$

and

$$E_{k_z}^0 = \omega/2 - M_0 + M_1 k_z^2, \quad \nu = 0, \tag{11.30}$$

where $\mathcal{M}_\nu = M_0 - M_1 k_z^2 - \omega\nu$. The Landau energy bands (ν as band index) disperse with k_z. The corresponding eigen states for $\nu \geq 1$ are

$$|\nu, k_x, k_z, +\rangle = \begin{pmatrix} \cos\frac{\theta_{k_z}^\nu}{2}|\nu - 1\rangle \\ \sin\frac{\theta_{k_z}^\nu}{2}|\nu\rangle \end{pmatrix} |k_x, k_z\rangle \tag{11.31}$$

and

$$|\nu, k_x, k_z, -\rangle = \begin{pmatrix} \sin\frac{\theta_{k_z}^\nu}{2}|\nu - 1\rangle \\ -\cos\frac{\theta_{k_z}^\nu}{2}|\nu\rangle \end{pmatrix} |k_x, k_z\rangle, \tag{11.32}$$

where $\cos\theta_{k_z}^\nu = \mathcal{M}_\nu/\sqrt{\mathcal{M}_\nu^2 + \nu\eta^2}$, and the state for $\nu = 0$ is

$$|\nu = 0, k_x, k_z\rangle = \begin{pmatrix} 0 \\ |0\rangle \end{pmatrix} |k_x, k_z\rangle. \tag{11.33}$$

The wave functions $\psi_{\nu,k_z,k_x}(\mathbf{r}) = \langle\mathbf{r}|\nu, k_x, k_z\rangle$ are found to be

$$\psi_{\nu,k_z,k_x}(\mathbf{r}) = \frac{C_\nu}{\sqrt{L_x L_z \ell_B}} e^{ik_z z} e^{ik_x x} e^{-\frac{(y-y_0)^2}{2\ell_B^2}} \mathcal{H}_\nu\left(\frac{y - y_0}{\ell_B}\right), \tag{11.34}$$

where $C_\nu \equiv 1/\sqrt{\nu! 2^\nu \sqrt{\pi}}$, $L_x L_z$ is area of sample, the guiding center $y_0 = k_x \ell_B^2$, $\mathcal{H}_\nu$ are the Hermite polynomials. As the dispersions are not explicit functions of k_x, the number of different k_x represents the Landau degeneracy $N_L = 1/2\pi\ell_B^2 = eB/h$ in a unit area in the x–y plane.

Now it is ready to present a derivation for the Hall conductance. In the presence of an electric field E_y the correction to the model Hamiltonian comes from the electric potential, $\Delta V = -eE_y y$. Consider the Fermi level is located near the Weyl node, all the bands of $|\nu \geq 1, k_x, k_z, -\rangle$ are fully occupied. Only the band of $\nu = 0$ is partially occupied. Thus, one can focus on this band only. The energy dispersion of the band is corrected to $E_{k_z}^0 - eE_y \ell_B^2 k_x$ as $\langle y\rangle = l_B^2 k_x$ which is replaced by the guiding center of the Landau levels. This energy correction leads to a velocity shift along the x direction,

$$v_x \equiv \frac{1}{\hbar} \frac{\partial (E_{k_z}^0 - eE_y \ell_B^2 k_x)}{\partial k_x} = -\frac{eE_y \ell_B^2}{\hbar}. \tag{11.35}$$

For each k_z, the occupation of the band with the Landau degeneracy indicates to a quantized Hall conductance

$$\frac{j_x}{E_y} = -\frac{ev_x}{E_y} \times \frac{1}{2\pi \ell_B^2} = \frac{e^2}{h}. \tag{11.36}$$

The total Hall conductance is obtained by integrating over k_z up to the Fermi wave vector k_F^0, and $\sigma_{yx} = k_F^0 \frac{e^2}{\pi h}$. In particular, $k_F^0 = k_w + \pi n_0 h / eB$ for Weyl semimetals with a fixed carrier density n_0, and a Hall conductance is found as

$$\sigma_{yx} = \frac{en_0}{B} + \frac{e^2 k_w}{h\pi}. \tag{11.37}$$

The first term is attributed to the classical Hall effect, and the second term comes from the non-zero Chern number of the fully filled low energy bands of $-k_w < k_z < k_w$. When the Fermi level is located at the Weyl node, $n_0 = 0$, there is no free charge carriers. Hence the contribution from the Lorentz force vanishes.

Even in the absence of magnetic field the quantum anomalous Hall conductance still exists. This is one of the key features in the two-node model. The quantum anomalous Hall effect in this anisotropic three-dimensional system is attributed to the quantum transport of the surface electrons.

11.5 Tight-Binding Model and Topological Phase Transition

A tight-binding model can be established by using the replacement in (3.5) as done in Sect. 3.2. The Bloch Hamiltonian on a cubic lattice with lattice space $a = 1$ reads

$$H(k) = 2t_0 \sin k_x \sigma_x + 2t_0 \sin k_y \sigma_y + M(k)\sigma_z \tag{11.38}$$

with $M(k) = \Delta - 4t_1 \sin^2 \frac{k_z}{2} - 4t_2 \left(\sin^2 \frac{k_x}{2} + \sin^2 \frac{k_y}{2} \right)$. Here anisotropic coefficients t_1 and t_2 are introduced for the purpose of general discussion. The two bands are given by

$$E = \pm \sqrt{4t_0^2 \sin^2 k_x + 4t_0^2 \sin^2 k_y + M^2(k)}. \tag{11.39}$$

As a result the two bands touch only if $\sin k_x = \sin k_y = 0$ and $M(k) = 0$. The conditions require

$$\sin^2 \tfrac{k_z}{2} = \tfrac{\Delta}{4t_1} \text{ for } k_x = k_y = 0; \tag{11.40}$$

$$\sin^2 \tfrac{k_z}{2} = \tfrac{\Delta}{4t_1} - \tfrac{t_2}{t_1} \text{ for } k_x, k_y = 0, \pi; \tag{11.41}$$

$$\sin^2 \tfrac{k_z}{2} = \tfrac{\Delta}{4t_1} - \tfrac{2t_2}{t_1} \text{ for } k_x = k_y = \pi. \tag{11.42}$$

In the first case, if $0 < \Delta/4t_1 < 1$, $k_z = \pm k_w$ ($k_w = 2\arcsin\sqrt{\Delta/4t_1}$) gives two Weyl nodes. In the second case, the two Weyl nodes are located at $k_z = \pm 2\arcsin\sqrt{\frac{\Delta - 4t_2}{4t_1}}$ if $0 < \frac{\Delta - 4t_2}{4t_1} < 1$. In the third case, the two Weyl nodes are located at $k_z = \pm 2\arcsin\sqrt{\frac{\Delta - 8t_2}{4t_1}}$ if $0 < \frac{\Delta - 8t_2}{4t_1} < 1$.

Without loss of generality, we just focus on the first case in the following discussion. For a specific value of k_z, the model is equivalent to one for the quantum anomalous Hall effect as we discussed in Sect. 12.2. In the case of $0 < \Delta/4t_1 < 1$, there are two crossing points at $(0, 0, \pm k_w)$. If $k_z \neq \pm k_w$ there exists an energy gap. In the reduced two-dimensional momentum space, the Chern number is given by

$$n(k_z) = -\frac{sgn(t_1 t_2)}{2}\left[1 + sgn\left(\frac{\Delta}{4t_1} - \sin^2\frac{k_z}{2}\right)\right]. \tag{11.43}$$

The separation distance of two Weyl nodes is controlled by the ratio of $\Delta/4t_1$. Variation of the ratio leads to the annihilation of two monopoles at the Weyl nodes and generates topological quantum transitions in the system as shown in Fig. 11.5. Assume t_1 and t_2 have the same sign. The Chern numbers is $-sgn(\Delta t_2)$ when $-k_w < k_z < +k_w$. When $\Delta \to 0$, the pair of monopoles collide, and annihilate at $\Delta = 0$ due to their opposite signs. When the ratio of $\Delta/4t_1$ changes from positive to negative, the Weyl nodes disappear and the band gap opens. In the case the system changes from a Weyl semimetal into a normal insulator. Thus, the sign change of Δ can generate a topological quantum phase transition. On the other hand, when the ratio increases, the two monopoles move away in opposite direction. At $\Delta/4t_1 = 1$, $k_w = \pi$. The position of two nodes is separated by on one reciprocal lattice vector 2π. Due to the
Fig. 11.5 Annihilation of magnetic monopole and antimonopole and topological quantum phase transition. From **a**, **b**, **c**, a conventional insulator evolves into a topological Weyl semimetal, and further a topological Chern insulator while $\Delta/4t_1$ increases from a negative value to a positive one. Here assume $t_1 t_2 > 0$

periodicity of the Brillouin zone the two monopoles meet again and annihilate at the point. An energy gap opens as the ratio continues increasing. In this case the zone of non-zero Chern number extends into the whole space. Hence the system evolves into a topological Chern insulator from a topological Weyl semimetal. Similarly if t_1 and t_2 have the opposite signs, the system will evolve into a topological Chern insulator when the ratio of $\Delta/4t_1$ changes from positive to negative, and into a normal insulator when the ratio of $\Delta/4t_1$ becomes larger than 1.

The two-node model breaks time reversal symmetry. A minimal lattice model of topological Weyl semimetal respecting the time reversal symmetry should be a 4×4 square matrix. It can be constructed by using the continuous model as shown in (11.12). The topological invariants for the topological phases is the Z_2 index instead of the Chern number, and the surface states will appear in pairs with opposite velocities and spin or time reversal polarizations. In the case the system possesses quantum spin Hall effect.

11.6   Chiral Anomaly

Chiral anomaly is a quantum mechanical phenomenon for Weyl fermions dating back to 1960s. It is a surprising discovery that some exotic magnetotransport properties in Weyl semimetals is related to the chiral anomaly. Usually it is said to be a symmetry when in classical mechanics the Lagrangian $L(\{q_i, \dot{q}_i\})$ remains invariant under the transformation $q_i \rightarrow q_i + \delta q_i$ while in quantum mechanics the path integral must be invariant under the same transformation. However, symmetries in terms of classical variables may not be retained when expressed in terms of non-commuting quantum variables. Such a symmetry is said to have a symmetry anomaly. In the theory of a single massless fermion $L = \bar{\psi} i \gamma^\mu \partial_\mu \psi$. L is invariant under the transformation of $\psi \rightarrow e^{i\theta}\psi$ and $\psi \rightarrow e^{i\gamma^5\theta}\psi$, corresponding to the conserved vector current $J^\mu = \bar{\psi}\gamma^\mu\psi$ and the conserved axial current $J_5^\mu = \bar{\psi}\gamma^\mu\gamma^5\psi$. Consider the chirality operators in (11.5), $1 = R + L$ and $\gamma^5 = R - L$. J^μ and J_5^μ are the sum and difference of the right and left handed currents, respectively. Chiral anomaly here is related to the axial symmetry, in which the conservation of the axial current is violated due to the quantum fluctuation [29]. This anomaly for Weyl fermions was first proposed by Ader [30], and Bell and Jackiw [31]. It is Nielsen and Ninomiya who first realized that that the chiral anomaly could be detected in solid crystals [32].

In the presence of both electric field $\mathbf{E}$ and magnetic field $\mathbf{B}$, it is found that the chiral charges at each Weyl node ($\chi = \pm$) violate the continuity equation

$$\frac{\partial}{\partial t}\rho_\chi + \nabla \cdot \mathbf{J}_\chi = -\chi \frac{e^3}{4\pi^2\hbar^2}\mathbf{E} \cdot \mathbf{B}, \tag{11.44}$$

where ρ_χ is the charge density and $\mathbf{J}$ is the electric current near the Weyl node χ. As Weyl nodes always appear in pair of opposite chirality, the total charges is therefore

conserved. In quantum field theory this anomaly comes from two triangle Feynman diagrams associated with the decay of the π^0 particle. Here following Nielsen and Ninomiya, we present an intuitive derivation of chiral anomaly in condensed matter physics [32].

Consider a magnetic field **B** along the z direction. The energy dispersion of $\nu = 0$ is

$$E_{k_z}^0 = \frac{2M}{l_B^2} - M_0 + M_1 k_z^2 \tag{11.45}$$

which always crosses from the valence bands to conduction bands. The Landau bands disperse with k_z with the Landau degeneracy $N_L = eBL_xL_y/h$. When the Fermi level is located near the Weyl nodes at $k_z = \pm k_w$ only the zeroth Landau band is relevant to the low energy physics we are interested here. The system now looks like a one-dimensional conducting channel along the z direction or the magnetic field. If an electric field **E** is now applied, all electrons move along the magnetic field according to $\hbar \dot{k}_z = -e\mathbf{E} \cdot \mathbf{B}/B$. As the states in the zeroth Landau band move in one direction, electrons moving away at the Weyl node at $k_z = +k_w$ will appear at the other Weyl node at $k_z = -k_w$. In other words, the charges at each Weyl node are not conserved. The charge rate of charge at one Weyl node is given by

$$\frac{\partial Q_\chi^{1D}}{\partial t} = \chi \frac{e}{2\pi} L_z \dot{k}_z = -\chi e^2 L_z \frac{\mathbf{E} \cdot \mathbf{B}}{2\pi B \hbar}. \tag{11.46}$$

Consider the Landau degeneracy of the Landau bands. The three-dimensional charge density at Weyl node is $\rho_\chi = N_L Q_\chi^{1D}/L_xL_yL_z$, and the current at a single Weyl node is of divergence free $\nabla \cdot \mathbf{J}$ due to the translational invariance of the system. Hence one obtains the equation for the non-conservation of chiral charges in (11.44). Finally we need to pint out that although we only consider the zeroth Landau level in a strong field limit, the equations are valid for a general case when the Fermi level crosses even more Landau levels.

11.7   Exotic Magnetotransport

11.7.1   Three-Dimensional Weak Antilocalization

The Dirac fermions in the surface states of topological insulators give rise weak antilocalization as discussed in Sect. 7.4.2. The effective Hamiltonian for Weyl fermions in (11.2) respects the time reversal symmetry but breaks spin rotational symmetry. Hence it belongs to the symplectic class, and the weak antilocalization is expected. At low temperatures, when the mean free path is much shorter than the system size and phase coherence length, electrons suffer from scattering but can maintain their phase coherence. In this quantum diffusive regime, the quantum interference

between time reversal scattering loops is destructive, and can give rise to a positive correction to the conductivity. When a weak magnetic field is applied, the destructive interference can be destroyed, and the positive correction to the conductivity is suppressed, leading to a negative magnetoconductivity, or positive magnetoresistivity, as the signature for weak antilocalization. The weak antilocalization has been widely observed in three-dimensional Dirac and Weyl semimetals, including $Bi_{0.97}Sb_{0.03}$, $ZrTe_5$, Na_3Bi, Cd_3As_2, TaAs, etc. Three-dimensional weak antilocalization is one of the clear signatures for Dirac and Weyl semimetals.

A theoretical approach to calculate the magnetoconductivity is the linear response theory of conductivity by means of the Feynman diagram techniques. Both disorders and interaction have to be taken into account. The magnetoconductivity arising from the quantum interference $\delta\sigma^{qi}$ strongly depends on the phase coherence length l_ϕ and the magnetic length l_B. When $B \to 0$, $\delta\sigma^{qi}$ is proportional to $-\sqrt{B}$ for $l_\phi \gg l_B$ or at low temperatures, and $-B^2$ for $l_\phi \ll l_B$ or at high temperatures. l_B can be evaluated approximately as 12.8 nm/$\sqrt{B}$ with B in Tesla. Usually below the liquid helium temperature, l_ϕ can be as long as hundreds of nanometers to one micrometer, much longer than l_B which is tens of nanometers between 0.1 and 1 Tesla. Therefore, $-\sqrt{B}$ law of the magnetoconductivity at low temperatures and weak fields serves as a signature for the weak antilocalization of three-dimensional Weyl fermions.

Lu and Shen proposed a formula to fit the magnetoconductivity arising from the weak localization [34], which was applied in the experiment on TaAs [35]

$$\delta\sigma(B) = -C_W \left(\sqrt{B} \frac{B^2}{B^2 + B_c^2} + \gamma B^2 \frac{B_c^2}{B^2 + B_c^2} \right), \tag{11.47}$$

where the fitting parameters C_W and γ are positive and the critical field B_c is related to the phase coherence length ℓ_ϕ according to $B_c \sim \hbar/e\ell_\phi^2$. Empirically, the phase coherence length becomes longer with decreasing temperature and can be written as $\ell_\phi \sim T^{-p/2}$; then $B_c \sim T^p$, where p is positive and determined by decoherence mechanisms such as electron-electron interaction ($p = 3/2$) or electron-phonon interaction ($p = 3$). At high temperatures, $\ell_\phi \to 0$; thus, $B_c \to \infty$ and we have $\delta\sigma_{zz}^{qi} \propto B^2$. At low temperatures, $\ell_\phi \to \infty$; then $B_c = 0$ and we have $\delta\sigma_{zz}^{qi} \propto \sqrt{B}$. By fitting the magnetoconductivity, we find that $p \approx 1.5$. This indicates that the decoherence mechanism is dominated by the electron-electron interaction in TaAs.

11.7.2 Negative Magnetoresistance

Magnetoresistance is the tendency of a material to the value of its electric resistivity in an external magnetic field. In metals and semiconductors it is very common to have a positive magnetoresistance which is proportional to $1 + (\mu B_\perp)^2$ where μ is the electric mobility and $B_\perp$ is the perpendicular magnetic field to electric current because the charge carriers experience the Lorentz force when moving in a magnetic

Fig. 11.6 The electrons on the cone R are transferred to L due to the chiral anomaly as shown in the *arrow* at the *bottom*, and the exceeding electrons with higher energy in L are scattered back to L to form a steady state
field. However, negative magnetoresistance has been reported in a series of Dirac and Weyl semimetals. The measured negative magnetoresistance is quadratic in B, and sensitive to the directions of electric field to the magnetic field [36, 37], which is regarded as a consequence of chiral anomaly for Weyl fermions.

Consider a system with a pair of Weyl nodes. In the absence of external fields, without loss of generality, we assume that the chemical potentials near two Weyl nodes are equal, $\mu_+ = \mu_- = \mu > 0$. The linear dispersion gives the relations between the charge density of chiral electrons and the chemical potentials

$$\rho_\pm = -e\frac{\mu_\pm^3}{6\pi^2(v\hbar)^3}. \tag{11.48}$$

In the presence of both electric and magnetic fields, the chiral anomaly will force part of electrons move away at one node and reappear at the other node. However, the process will be balanced through the inter-node scattering between the left and right handed electrons as shown in Fig. 11.6. Denote the scattering time by τ_v. The equation for the chiral anomaly is changed to

$$\frac{d(\rho_+ - \rho_-)}{dt} = -\frac{e^3}{2\pi\hbar^2}\mathbf{E}\cdot\mathbf{B} - \frac{\rho_+ - \rho_-}{\tau_v}. \tag{11.49}$$

The solution of the equation in a steady state is given by

$$\rho_+ - \rho_- = -\frac{e^3}{2\pi^2\hbar^2}\mathbf{E}\cdot\mathbf{B}\tau_v. \tag{11.50}$$

The difference will lead to the chemical potentials deviating from μ, i.e., $\mu_\pm = \mu\pm\delta\mu/2$ (assume $\delta\mu \ll \mu$). Hence the chiral anomaly generates a chemical potential difference between the two Weyl nodes,

$$\delta\mu = -\frac{2\pi^2(v\hbar)^3}{e\mu^2}(\rho_+ - \rho_-). \tag{11.51}$$

Remember the total number of electrons should be conserved. The relation is valid for small $\delta\mu \ll \mu$. A finite chemical difference can produce a charge current from the general argument of energy conservation [32]. Since the Fermi levels are different, the transfer of electrons from one node to the other one costs energy is the product of the change rate and the energy difference, $\frac{e^2}{4\pi^2\hbar^2}\mathbf{B}\cdot\mathbf{E}\delta\mu$. The energy must be extracted from the electric field $\mathbf{E}$, i.e., the Joule's heating effect in the presence of a charge current $\mathbf{J}$. Thus, from the energy balance,

$$\mathbf{J}\cdot\mathbf{E} = \frac{e^2}{4\pi^2\hbar^2}\mathbf{B}\cdot\mathbf{E}\delta\mu. \tag{11.52}$$

As the electric field is continuous, the possible solution for the current is

$$\mathbf{J} = \frac{e^2}{4\pi^2\hbar^2}\delta\mu\mathbf{B} \tag{11.53}$$

which is proportional to the magnetic field. The magnetic field induced current is also called the chiral magnetic effect [38]. The Hall current is normal to the electric field and does not cost energy. So we do not include it here. Using the chemical difference produced by the chiral anomaly, one obtains

$$\mathbf{J} = \frac{e^2}{4\pi^2\hbar}\frac{e^2v^3}{\mu^2}\tau_v(\mathbf{E}\cdot\mathbf{B})\mathbf{B}. \tag{11.54}$$

Hence when $\mathbf{E}$ is parallel with $\mathbf{B}$, the conductivity caused by the chiral anomaly is given by

$$\sigma_{ca} = \frac{e^2}{2\pi h}\frac{e^2v^3B^2}{\mu^2}\tau_v. \tag{11.55}$$

This result is identical to the one by Son and Spivak by means of the semi-classical theory in terms of the Berry curvature [39]. Except for the chiral magnetic effect, the Ohmic current may also be magnetic field-dependent.

It is noted that the quadratic behavior of magnetoconductivity in B is based on the assumption that the inter-node scattering time is independent of B. However this may not be true at least in a quantum limit, or in a strong field case. Consider possible field dependence of the scattering time. The key feature of the chiral anomaly may not the quadratic B dependence of the magnetoconductance, but the electric current is along the direction of the magnetic field.

11.7.3 Linear Magnetoconductance Near the Weyl Nodes

When the Fermi level is located near the Weyl point at sufficiently low temperatures, i.e., $k_B T \ll \omega$ and in a strong magnetic field, the electronic transport can be effectively conducted by the 0th bands of Landau levels. When the electric and magnetic fields are in parallel with each other, the changing rate of density of charge carriers near one node is maximal according to the chiral anomaly. In this case, the semiclassical conductivity of the 0th Landau bands can be found with the help of the standard Green function formalism. It is found that the conductivity depends on the form of impurities potentials. Consider the random Gaussian potential

$$U(\mathbf{r}) = \sum_i \frac{u_i}{(d\sqrt{2\pi})^3} e^{-|\mathbf{r}-\mathbf{R}_i|^2/2d^2}, \tag{11.56}$$

where u_i measures the scattering strength of a randomly distributed impurity at $\mathbf{R}_i$, and d is a parameter that determines the range of the scattering potential. The Gaussian potential allows us to study the effect of the potential range in a controllable way. In the Born approximation, the conductivity is given by

$$\sigma_{zz}(B) = \sigma_0 \left(1 + 2\frac{d^2}{l_B^2}\right), \tag{11.57}$$

with $\sigma_0 = \frac{e^2}{h} \frac{4(Mk_c)^2}{V_{imp}} e^{4d^2 k_c^2}$, where $V_{imp} \equiv \sum_i u_i^2 / V$ measures the strength of the scattering and V is the volume of the system. This conductivity is generated by the inter-node scattering with a momentum transfer of $2k_c$. As the magnetic field goes to zero, the magnetic length diverges and $d/\ell_B \to 0$, and one has a minimum conductivity σ_0 even though the DOS vanishes at the Weyl nodes at zero magnetic field. The magnetoconductivity exists only for a finite potential range, i.e., $d > 0$. Using (11.57),

$$\Delta\sigma_{zz}(B) \equiv \frac{\sigma_{zz}(B) - \sigma_{zz}(0)}{\sigma_{zz}(0)} = \frac{B}{B_0}, \tag{11.58}$$

where $B_0 = \hbar/2ed^2$. This means that we have a positive linear z-direction magnetoconductivity for the Weyl semimetal. A small but finite carrier density n_0 can drive the system away from the Weyl nodes, then k_c in (11.57) is to be replaced by $k_F = k_c + \text{sgn}(M)2\pi^2 \ell_B^2 n_0$. The finite n_0 can vary the linear-B dependence, but a strong magnetic field can always squeeze the Fermi energy to k_c, and recover the linear magnetoconductivity.

11.7.4 High Mobility and Large Magnetoresistance

Ultrahigh mobility and extremely large magnetoresistance were measured in three-dimensional topological semimetals. According to the Einstein relation, the Drude conductivity is given as

$$\sigma = e^2 D N (E_F), \tag{11.59}$$

where $D = \frac{1}{3} v_F^2 \tau_{tr}$ is the diffusion coefficient, v_F is the Fermi velocity, τ_{tr} is the transport relaxation time and $N(E_F)$ is the density of states near the Fermi level. Alternatively, the Drude conductivity can be expressed in terms of mobility as

$$\sigma = ne\mu, \tag{11.60}$$

where μ is the mobility, and n is the carrier density. For three-dimensional Weyl and Dirac semimetals with linear dispersions $\varepsilon = \pm v_F \hbar k$, the corresponding zero-field mobility has the form

$$\mu = \frac{e v_F \tau_{\text{tr}}}{\hbar k_F}. \tag{11.61}$$

Thus, the large Fermi velocity and the long transport relaxation time leads to a high mobility. The typical value of Fermi velocity of Weyl and Dirac semimetals ranges from 10^5 to 10^6 ms^{-1}. It implies that high-quality Weyl semimetals and Dirac semimetals potentially have a relatively high mobility.

It was reported that an ultrahigh mobility, 9×10^6 cm^2 V^{-1} s^{-1} is measured at 5 K in single crystals of Dirac semimetal Cd_3As_2 [40]. The ratio between τ_{tr} and τ_{s} could reach value of 10^4, where the quantum lifetime τ_{s} is extracted from the Dingle temperature via Shubnikov–de Haas oscillation experiment. This high mobility in Dirac semimetal was attributed to strong suppression of backscattering processes through an unknown protection mechanism. Meanwhile, the transverse magnetoresistance ρ_{xx} of most samples shows a striking H-linear feature. There is a trend from H-linear to H^α with $\alpha = 2$–2.5 with increasing mobility. In fact, the H-linear profile of magnetoresistance here already exists at a very low magnetic field. Therefore, one can safely rule out the mechanism proposed by Abrikosov for Dirac electrons in the quantum limit. Furthermore, giant magnetoresistance was observed in all samples with a high mobility. It is also found that the H-linear feature remains almost unchanged even when the temperature is raised to 300 K, which calls for an unconventional mechanism.

The noncentrosymmetric Weyl semimetal NbP was also reported to exhibit an ultrahigh carrier mobility of 5×10^6 cm^2 V^{-1} s^{-1} and a giant non-saturating magnetoresistance of 850,000% in a magnetic field up to 9 T at about 2 K [41]. Unlike the Dirac semimetal Cd_3As_2, the band structure of NbP possesses an important feature that the Fermi surface crosses both the quadratic-type valence bands and the linear Dirac-type conduction bands. The ideal electron-hole compensation might account for the huge magnetoresistance in NbP.

Chapter 12
Topological Anderson Insulator

Abstract A topological Anderson insulator is a distinct type of topological insulator, which is induced by disorders. Unlike conventional topological insulators, its Fermi energy lies within a so-called mobility gap instead of in a real band gap. The robustness of the edge or surface states is protected by the mobility gap.

12.1 Band Structure and Edge States

We start with a two-dimensional ferromagnetic metal with strong spin-orbit coupling,

$$h(\mathbf{k}) = \epsilon(k) + \mathbf{d}(\mathbf{k}) \cdot \sigma, \tag{12.1}$$

where $\mathbf{d}(\mathbf{k}) = (Ak_x,\ Ak_y,\ M - Bk^2)$ and $\epsilon(k) = C - Dk^2$ with A, B, C and D being sample-specific parameters. This is a modified Dirac equation plus an additional term $\epsilon(k)$, which breaks the symmetry between the conduction and valence bands. In order to keep the band gap open, we require that $B^2 > D^2$. In this case, the Chern number for this model is given by

$$n_c = -\frac{1}{2}\left[sgn(M) + sgn(B)\right]. \tag{12.2}$$

For a positive B, the sign change of M signifies a topological quantum phase transition between a convention insulating phase ($M < 0$ and $n_c = 0$) and a topological quantum phase ($M > 0$ and $n_c = 1$). A non-zero Chern number indicates that the Hall conductance is quantized, $\sigma_H = n_c e^2/h$. Thus, the existence of the additional term $\epsilon(k)$ does not affect the Chern number once the band gap is open.

In an infinite-length strip with open lateral boundary conditions, the solution of the two-band model $\mathcal{H}\Psi = E\Psi$ is given by [1]:

$$\Psi(k_x, y) = (\mu_+ e^{\alpha y} + \mu_- e^{-\alpha y} + \nu_+ e^{\beta y} + \nu_- e^{-\beta y}), \tag{12.3}$$

$\mu_\pm$ and $\nu_\pm$ are two-component k_x-dependent coefficients, and α and β are determined self-consistently by the following set of equations,

$$\alpha^2 = k_x^2 + F - \sqrt{F^2 - \frac{M^2 - E^2}{B^2 - D^2}}, \tag{12.4}$$

$$\beta^2 = k_x^2 + F + \sqrt{F^2 - \frac{M^2 - E^2}{B^2 - D^2}}, \tag{12.5}$$

and

$$E_\alpha^2 \beta^2 + E_\beta^2 \alpha^2 - \gamma E_\alpha E_\beta \alpha \beta = k_x^2 (E_\alpha - E_\beta)^2. \tag{12.6}$$

Here, we have

$$F = \frac{A^2 - 2(MB + ED)}{2(B^2 - D^2)}, \tag{12.7}$$

$$E_\alpha = E - M + (B + D)(k_x^2 - \alpha^2), \tag{12.8}$$

$$E_\beta = E - M + (B + D)(k_x^2 - \beta^2), \tag{12.9}$$

$$\gamma = \frac{\tanh \frac{\alpha L_y}{2}}{\tanh \frac{\beta L_y}{2}} + \frac{\tanh \frac{\beta L_y}{2}}{\tanh \frac{\alpha L_y}{2}}, \tag{12.10}$$

and L_y is the width of the strip. We take the Dirichlet boundary condition at $y = \pm L_y/2$ to get

$$\Psi\left(k_x, y = \pm \frac{L_{2y}}{2}\right) = 0. \tag{12.11}$$

The solutions of this set of equations naturally contain both helical edge states ($\alpha^2 < 0$) and bulk states ($\alpha^2 > 0$), which are shown in Fig. 12.1 for the three cases $M < 0$, $M = 0$, and $M > 0$. The edge states (red lines in Fig. 12.1) are seen beyond the bulk gap for all cases, up to an M dependent maximum energy. When $M < 0$, the edge states cross the bulk gap producing a quantum Hall effect. At $M = 0$, the edge states exist only in conjunction with the lower band, terminating at the Dirac point. For $M > 0$, there are no edge states in the gap, producing a conventional insulator, but the edge states may co-exist with the valence band. The appearance of an edge state is a key feature of this model even for a normal band structure, although these states mix with the bulk states.
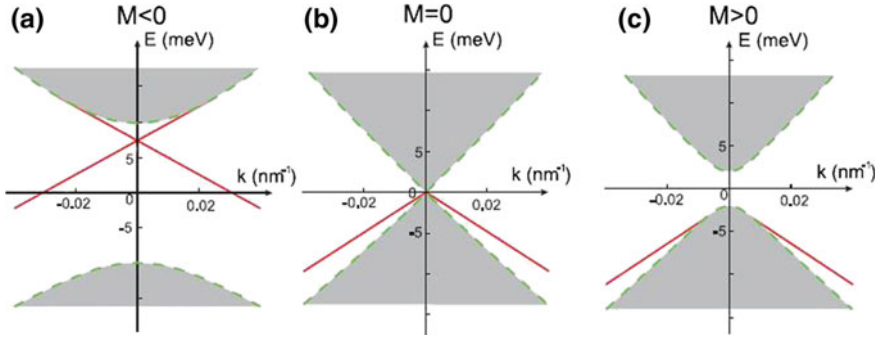

Fig. 12.1 Band structure of HgTe/CdTe quantum wells in a geometry of a stripe with a finite width. **a** The "inverted" band structure case with $M = -10$ meV. Edge states (*red lines*) cross the bulk band gap and merge into bulk states (*gray area*) at a maximum energy in the *upper band*. The *green dashed lines* mark the boundary of the bulk states. **b** The transition point between an inverted band structure and a "normal" band structure with $M = 0$ meV. **c** The normal band structure with $M = 2$ meV. In all the figures, the strip width L_y is set to $100\,\mu$m. The sample specific parameters are fixed to be $A = 364.5$ meV nm, $B = 686$ meV nm^2, $C = 0$, $D = 512$ meV nm^2 (Adapted from [2]) (color figure online)

12.2 Quantized Anomalous Hall Effect

For numerical simulation, we take the tight binding approximation on a square lattice, and the Hamiltonian has the form

$$\mathbf{d(k)} = \left(A \sin k_x, \ A \sin k_y, \ M - 4B \sin^2 \frac{k_x}{2} - 4B \sin^2 \frac{k_y}{2} \right) \qquad (12.12)$$

for the periodic boundary condition. In the lattice space, by performing the Fourier transformation we obtain a lattice model identical to the one as in Chap. 3, and then take specific open boundary conditions.

The most surprising aspect revealed by the numerical calculation is the appearance of quantized anomalous conductance at a large disorder when the clean system is a metal without a preexisting edge state. We study transport as a function of disorder, with the Fermi energy varying through all regions of the band structure. For this purpose, disorders are introduced through random on-site energy with a uniform distribution within $[-W/2, W/2]$. The conductance of the disordered strips with width L_y and length L_x was calculated in a two-terminal setup using the Landauer-Buttiker formalism [3, 4]. The conductance G as a function of disorder strength W is plotted in Fig. 12.2. Furthermore the conductance was scaled by the width of the strip. Figure 12.2 shows the calculated conductances of a strip as a function of its width L_y. In the region before the quantized anomalous conductance plateau is reached, the scaled conductance GL_x/L_y, or conductivity, is independent of width, as shown in the inset of Fig. 12.2, which implies bulk transport. Within the quantized plateau,
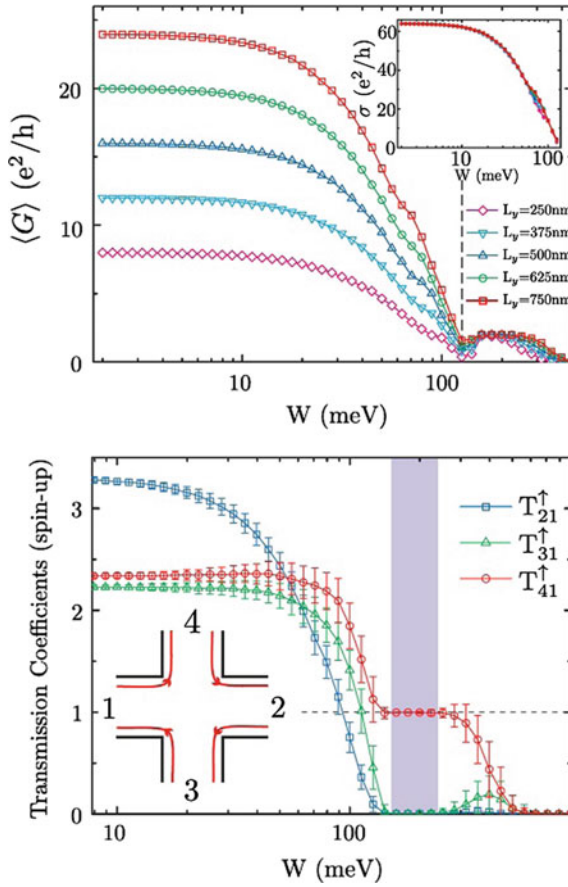

Fig. 12.2 (*Left*) Width-dependence of the conductance in disordered strips with several values of strip width L_y and a length $L_x = 2000$ nm. In the *inset*, the conductance traces prior to the quantum anomalous Hall phase (*left-hand-side of the dashed line*) are scaled with the width of the strips as $\sigma = GL_x/L_y$. The formation of the edge states is indicated by the presence of conductance quantization e^2/h. In this figure, $M = 2$ meV, and the Fermi energy $E_f = 20$ meV. (*Right*) Three independent spin-resolved transmission coefficients, $T_{21}^\uparrow$, $T_{31}^\uparrow$ and $T_{41}^\uparrow$, are plotted as functions of disorder strength W. Standard deviations of the transmission coefficients for 1000 samples are shown as the error bars. In the shadowed range of disorder strength, all bulk states are localized and only chiral edge states exist, which is schematically shown in the *inset* (for spin-up component only). The width of leads is 500 nm and $M = 1$ meV and $E_f = 20$ meV (Adapted from [2])

the absence of such scaling indicates a total suppression of the bulk conduction, thus, confirming the presence of conducting edge states in an otherwise localized system.

We further examine edge-state transport in a four-terminal cross-bar setup by calculating the spin resolved transmission coefficients T_{pq} between each ordered pair of leads p and q ($= 1, 2, 3, 4$). Three independent coefficients, T_{21}, T_{31} and T_{41}, are shown in Fig. 12.2 as a function of the disorder strength inside the cross region.

The shadowed area marks the appearance of a quantized plateau, where $\langle T_{41} \rangle = 1$, $\langle T_{21} \rangle = \langle T_{31} \rangle = 0$, and all of the transmission coefficients exhibit vanishingly small fluctuations. From symmetry, it follows that $\langle T_{41} \rangle = \langle T_{24} \rangle = \langle T_{32} \rangle = \langle T_{13} \rangle \to 1$, and all other coefficients are vanishing small. These facts are easily understood from the presence of a chiral edge state. Two consequences of this chiral edge state transport are a vanishing diagonal conductance $G_{xx} = (T_{21} - T_{12})e^2/h = 0$ and a quantized Hall conductance $G_{xy} = (T_{41} - T_{42})e^2/h = e^2/h$, which is analogous to Haldane's model for the integer quantum Hall effect with parity anomaly [5]. The quantized Hall conductance G_{xy} reveals that the topologically invariant Chern number of this state is equal to one. Thus, this is an disorder induced quantum anomalous Hall effect.

A noncommutative Chern number can be defined in a disordered system. Prodan [6] did a series of calculations for disordered systems, and found that the Chern number takes a quantized value of ± 1.

12.3 Topological Anderson Insulator

Now we are ready to consider a topological Anderson insulator, which does not break the time reversal symmetry. The effective Hamiltonian for a clean bulk HgTe/CdTe quantum well is given by [7]:

$$\mathcal{H}(k) = \begin{pmatrix} h(k) & 0 \\ 0 & h^*(-k) \end{pmatrix}, \tag{12.13}$$

where $h(k)$ has the form as the 2×2 Hamiltonian for a two-dimensional ferromagnet with spin-orbit coupling. This 4×4 model is a combination of $h(k)$ and $h^*(-k)$, which is the time reversal counterpart of $h(k)$. The model is equivalent to the two-dimensional modified Dirac model in (2.35) with an additional kinetic energy term $\epsilon(k)$. When $h(k)$ contributes a Hall conductance e^2/h its time reversal counterpart $h^*(-k)$ will also contribute a quantum Hall conductance, but with an opposite sign, $-e^2/h$. As a result the total Hall conductance in this system is always equal to zero. Both $h(k)$ and $h^*(-k)$ produce a chiral edge state: electrons in one of the edge states of $h(k)$ are moving in one direction, and electrons in the other edge state are moving in an opposite direction. The electron spins in the two states are connected by the time reversal operation and must be anti-parallel. Therefore this is a quantum spin Hall effect in $\mathcal{H}(k)$.

The calculated behavior confirms to the qualitative expectation for certain situations. For the Fermi level in the lower band, for both $M < 0$ and $M > 0$, an ordinary Anderson insulator results when the clean limit metal is disordered (green lines in Fig. 12.3a, d). The conductance in this case decays to zero at a disorder strength of around 100 meV, which is about five times that of the conventional hopping energy between nearest neighboring sites $t = -D/a^2 \approx 20.5$ meV, and much larger than the clean-limit bulk band gap $E_g = 2|M| = 20$ meV. Here $a = 5$ nm is the lattice spacing of the tight binding model. The topological insulator (red line in Fig. 12.3a)

The *upper panels* (**a**–**c**) show the results for a quantum well "inverted" with $M = -10$ meV, and the *lower panels* (**d**)–(**f**) show the results for a "normal" quantum well with $M = 1$ meV. **a** Conductance G as a function of disorder strength W at three values of Fermi energy. The *error bars* show the standard deviation of the conductance for 1000 samples. **b** Band structure calculated with the tight-binding model. Its vertical scale (energy) is the same as in **c** and the *horizontal lines* correspond to the values of Fermi energy considered in **a**. **c** Phase diagram showing the conductance G as a function of both disorder strength W and Fermi energy E_f. The panels **d**–**f** are the same as in **a**–**c**, but $M > 0$. The TAI phase regime is labeled. In all figures, the strip width L_y is set to 500 nm; the length L_x is 5000 nm in **a** and **d**, and 2000 nm in **c** and **f** (Adapted from [2])

is robust, and requires a strong disorder before it eventually yields to a localized state. This is the expected result of the absence of backscattering in a topological insulator when time reversal symmetry is preserved [8].

The most surprising aspect revealed by our calculations is the appearance of anomalous conductance plateaus at a large disorder for situations when the clean limit system is a metal without preexisting edge states. See, for example, the blue lines in Fig. 12.3a ($M < 0$) and Fig. 12.3d ($M > 0$). The anomalous plateau is formed after the usual metal-insulator transition in such a system. The conductance fluctuations (the error bar in Fig. 12.3a, d) are vanishingly small on the plateaus; at the same time, the Fano factor drops to nearly zero indicating the onset of dissipationless transport in this system, even though the disorder strength in this scenario can be as large as several hundred meV. This state is termed a topological Anderson insulator. The quantized conductance cannot be attributed to the relative robustness of edge states against disorder, because it occurs in the cases in which no edge states exist in the clean limit. The irrelevance of the clean-limit edge states to this physics is

further evidenced by the fact that no anomalous disorder-induced plateaus are seen for clean limit metals for which bulk and edge states coexist; these exhibit a direct transition into an ordinary Anderson insulator.

The nature of topological Anderson insulators is further clarified by the phase diagrams shown in Fig. 12.3c for $M < 0$ and in Fig. 12.3f for $M > 0$. For $M < 0$, the quantized conductance region (green area) of the topological Anderson insulator in the upper band is connected continuously with the quantized conductance area of the topological insulator phase of the clean-limit. One cannot distinguish between these two phases on the basis of the conductance value. When $M > 0$, however, a anomalous conductance plateau occurs in the highlighted green island labeled TAI (topological Anderson insulator), surrounded by an ordinary Anderson insulator. No plateau is seen for energies in the gap, where a trivial insulator is expected. The topology of the topological Anderson insulator as well as the absence of preexisting edge states in the clean limit demonstrate that the topological Anderson insulator owes its existence fundamentally to disorder.

The existence of topological Anderson insulators has been confirmed by several independent groups. As a new type of topological insulator, topological Anderson insulators exist even in three dimensions [9]. To confirm the genuine three-dimensional nature of the topological Anderson insulators, Guo et al. probed for the Witten effect in their three-dimensional model. According to Witten, a magnetic monopole in a media could bind electric charge $-e(n + \frac{1}{2})$ with an integer n. They found through numerical calculation that an half charge is bound to a monopole in a three-dimensional topological Anderson insulator.

12.4 Effective Medium Theory for Topological Anderson Insulator

Groth et al. [10] proposed an effective medium theory to explain the disorder induced transition from a conventional metal to a topological Anderson insulator. Consider a scalar short-ranged potential with for the disorder: $V(\mathbf{r}) = V_0 \sum_i (\mathbf{r} - \mathbf{R}_i)$ where V_0 is the strength of the disorder. The retarded Green function can be written as

$$G^R(k, E, \Sigma^R) = (E - h(k) - \Sigma^R)^{-1}. \tag{12.14}$$

Here the self energy Σ^R is defined by

$$(E_F - h(k) - \Sigma^R)^{-1} = \left\langle \frac{1}{E_F - h(k) - V(r)} \right\rangle \tag{12.15}$$

with $\langle \cdots \rangle$ the disorder average. The self energy can be expanded in terms of the Pauli matrices: $\Sigma^R = \sum_{i=0,x,y,z} \Sigma_i \sigma_i$. Thus, in the effective Hamiltonian, $H_{eff} = h(k) + \Sigma^R$, the renormalized parameters are given by

$$\tilde{M} = M + \lim_{k \to 0} Re \, \Sigma_z \tag{12.16}$$

and

$$\tilde{E}_F = E_F - \lim_{k \to 0} Re \, \Sigma_0. \tag{12.17}$$

The phase boundary of the topological Anderson insulator is at $\tilde{M} = 0$, while the Fermi level enters the negative band gap when $\tilde{E}_F = -\tilde{M}$. In the Born approximation, the self energy is given by the integral equation

$$\Sigma^R = \frac{1}{12} \left(\frac{a}{2\pi} \right)^2 V_0^2 \int_{Bz} \frac{d\mathbf{k}}{(2\pi)^2} G^R(k, E_F + i0^+, \Sigma^R), \tag{12.18}$$

where the integral runs over the first Brillouin zone.

   An approximate solution can be derived in a closed form,

$$\tilde{M} = M + \frac{U_0^2 a^2}{48\pi\hbar^2} \frac{B}{B^2 - D^2} \ln \left| \frac{B^2 - D^2}{E_F^2 - M^2} \left(\frac{\pi\hbar}{a} \right)^2 \right| \tag{12.19}$$

and

$$\tilde{E}_F = E_F + \frac{U_0^2 a^2}{48\pi\hbar^2} \frac{D}{B^2 - D^2} \ln \left| \frac{B^2 - D^2}{E_F^2 - M^2} \left(\frac{\pi\hbar}{a} \right)^2 \right|. \tag{12.20}$$

In the clean limit, if M and B have different signs, say $B > 0$ but $M < 0$, the system is a conventional metal. The modification of $\delta M = \tilde{M} - M$ is positive provided $B^2 > D^2$ which is the condition for the gap opening between the conduction and valence bands. This will change a negative M into a positive $\tilde{M}$, leading to a quantum phase transition.

   This theory describes very well the transition from a metal to a topological Anderson insulator in a weak disorder, but fails to predict the transition from a topological Anderson insulator to an Anderson insulator in an even stronger disorder.

12.5   Band Gap or Mobility Gap

The edge or surface states in a topological Anderson insulator are expected to be protected by the mobility gap instead of by the band gap as in a topological (band) insulator. In this section, a statistical analysis of the local density of states (DOS), a function of energy, makes it possible to identify which states are localized and which states are extended. The kernel polynomial method is a powerful method for evaluating spectrum properties [11–13].

There are two distinct average DOSs in a disordered calculation. The average DOS is defined as the algebraic average of the local DOS that is,

$$\rho_{av} = \langle \rho_i(E) \rangle \, ; \tag{12.21}$$

the typical DOS is defined as the geometric average of the local DOS that is

$$\rho_{typ} = \exp[\langle \ln(\rho_i(E)) \rangle]. \tag{12.22}$$

When the electrons states are extended, the DOS distribution is almost uniform in the space, and thus, there should be not much difference between the two definitions. However, when the electron states are localized, the DOS is high near some sites, but almost vanishes on the others. Thus, we expect a significant ratio between the two types of DOS [14].

We can take a lattice sample of the periodic boundary condition on both the x- and y-direction (i.e., a torus) and apply (12.21) and (12.22). The upper block of the Hamiltonian in (12.13) is used, and we take $A = B = 1, C = D = 0$ such that the electron-hole symmetry is recovered. $M = 0.2$ such that the system is initially a

Fig. 12.4 Averaged DOS ρ_{av} (*blue line*), typical DOS ρ_{typ} (*black line*) and the ratio between the two ρ_{typ}/ρ_{av} (*red line*) as a function of the Fermi level. From **a** to **e**, the disorder strength increases. **a** The band gap opens. **b** The band gap closes. **c** The mobility gap opens and the band gap disappears. **d** Either the band gap or the mobility gap closes. **e** The averaged DOS becomes flat in the strong disorder limit (color figure online)
trivial band insulator. The result is plotted in Fig. 12.4 with the increasing disorder strength shown in Fig. 12.4a–e.

The mass renormalization phenomenon proposed by Groth et al. [10] is confirmed in the weak disorder regime, where initially a band gap in Fig. 12.4a is clearly seen but is gradually closed in Fig. 12.4b as the disorder increases. As is seen from the ratio ρ_{typ}/ρ_{av}, at the strong disorder regime, we can observe two extended states at $E = \pm 1$ in Fig. 12.4c, which indicates that the system is topologically non-trivial. It is noted that no band gap opens again for a stronger disorder, but the mobility gap opens to separate the two extended states. As the disorder further increases, these two extended states move towards each other and finally collide and disappear in Fig. 12.4d. Finally, all of the the states become localized. This phenomenon can be identified as the Levitation and pair annihilation. Levitation and pair annihilation indicate that an extended state carryies topological numbers. Such states are stable against disorder until those with opposite topological numbers collide with each other and become trivial when the disorder strength is increased. In the disorder induced non-trivial Hamiltonian $h(k)$, these exist the gapless edge states between the two extended states, which is the origin of topological Anderson insulators.

12.6 Summary

Topological Anderson insulators are distinct from conventional topological insulator, and topological band insulators. We find that there exists a mobility gap instead of a band gap in the system. From the point of view of time reversal symmetry, both phases can be described by the Z_2 index, and belong to the same topological class. However, the disorder breaks the translational invariance. They are distinct provided whether or not electrons in the bulk are localized.

Chapter 13
Summary: Symmetries and Topological Classification

Abstract For non-interacting electron systems, symmetry classification has already exhausted all possible topological insulators and superconductors: each dimension has five possible topological phases.

13.1 Ten Symmetry Classes for Non-interacting Fermion Systems

Following Altland and Zirnbauer [1, 2], all of the possible symmetry classes of a random matrix, which can be interpreted as the Hamiltonian of some non-interacting fermionic systems, can be systematically enumerated: there are ten symmetry classes in total. All classes are sets of Hamiltonians with specific transformation properties under some discrete symmetries.

Consider a general system of non-interacting fermions, which is described by a second quantized Hamiltonian,

$$H = \sum_{A,B} \psi_A^\dagger H_{A,B} \psi_B, \tag{13.1}$$

where $\psi_A^\dagger$ and ψ_B are the creation and annihilation operators of fermions and satisfy the relation

$$\left\{ \psi_A^\dagger, \psi_B \right\} = \delta_{A,B}. \tag{13.2}$$

The subscripts A and B can be collective indices. For example, for a system of electrons on a lattice, $A = (i, \sigma)$, which represent the electrons with spin σ on the lattice site i. In this case, $H_{A,B}$ is a square matrix. The symmetries of the Hamiltonians means that Hamiltonian H is related to $-H$, its transpose H^T and its complex conjugation H^*. We demand that these transformations are implemented by unitary transformations and that their actions on the Hamiltonian square to one. Hence we consider the following transformations [3].

P symmetry: $H = -PHP^{-1}$, where $PP^\dagger = P^2 = 1$.
C symmetry: $H = \epsilon_c C H^T C^{-1}$, where $CC^\dagger = 1$ and $C^T = \eta_c C$ ($\epsilon_c = \pm 1$ and $\eta_c = \pm 1$).
K symmetry: $H = \epsilon_k K H^* K^{-1}$, where $KK^\dagger = 1$ and $K^T = \eta_k K$ ($\epsilon_k = \pm 1$ and $\eta_k = \pm 1$).

Type P symmetry is commonly referred to as chirality symmetry, C expresses as the particle-hole symmetry and K the time reversal symmetry. For Hermitian Hamiltonians, $H = H^\dagger = (H^*)^T$. Thus, $H^T = H^*$, and C and K are identical. We shall only talk about C symmetry, where $\epsilon_c = +1$ will be interpreted as time reversal symmetry and $\epsilon_c = -1$ will be referred to as particle-hole symmetry.

An ensemble of Hamiltonians without any constraints other than being Hermitian belong to the unitary symmetry class (A class). If a Hamiltonian possesses P symmetry, it belongs the chiral unitary classes (AIII class). For C symmetry, we have four classes of $\epsilon_c = \pm 1$ and $\eta_c = \pm 1$. If a Hamiltonian possesses both P and C symmetries, then it automatically has another C-type symmetry C':

$$H = \epsilon'_c C' H C'^{-1}, \tag{13.3}$$

where $C' = PC$ and $\epsilon'_c = -\epsilon_c$. As C' can be interpreted as a time reversal symmetry if $\epsilon_c = +1$ or a particle-hole symmetry if $\epsilon_c = +1$. the classes with P and C symmetries automatically have chirality, time reversal or particle-hole symmetry. As a result, we have ten symmetry classes related to P and C symmetries, as listed in Table 13.1.

Alternatively, the system can also be classified according to time reversal symmetry $\mathcal{T}$ and the particle-hole symmetry $\mathcal{P}$ [4]. $\mathcal{T}$ can be represented by an anti-unitary operator on a Hilbert space, which commutes with the Hamiltonian and is written as a product of the complex conjugate operator **K** and unitary operator **C**, $\mathcal{T} = \mathbf{KC}$,

$$\mathcal{T} H \mathcal{T}^{-1} = H, \tag{13.4}$$

or the system is invariant under time reversal symmetry if and only if the complex conjugation of the Hamiltonian is equal to itself up to a unitary operator:

Table 13.1 Ten symmetries classes following the random matrix ensembles

Symmetry classes				
A	$H = H^\dagger$			
AI		$\epsilon_c = +1$	$\eta_c = +1$	
AII		$\epsilon_c = +1$	$\eta_c = -1$	
C		$\epsilon_c = -1$	$\eta_c = -1$	
D		$\epsilon_c = -1$	$\eta_c = +1$	
AIII	$P^2 = 1$			
DI	$P^2 = 1$	$\epsilon_c = \pm 1$	$\eta_c = +1$	$PCP^T = C$
CII	$P^2 = 1$	$\epsilon_c = \pm 1$	$\eta_c = -1$	$PCP^T = C$
CI	$P^2 = 1$	$\epsilon_c = \pm 1$	$\eta_c = \pm 1$	$PCP^T = -C$
DIII	$P^2 = 1$	$\epsilon_c = \mp 1$	$\eta_c = \pm 1$	$PCP^T = -C$

$$\mathcal{T} : \mathbf{C}^\dagger H^*_{A,B} \mathbf{C} = +H_{A,B}. \tag{13.5}$$

Thus, for a time reversal symmetry $\mathcal{T}$, the Hamiltonian can be (i) not time reversal invariant, in which we take $T = 0$; (ii) time reversal invariant, but the square of the time reversal operator is $+1$, $\mathcal{T}^2 = 1$, in which case we take $T = 1$. For example, a spinless or integer spin system; (iii) time reversal invariant, but the square of the time reversal operator is equal to -1, $\mathcal{T}^2 = -1$, in which case we take $T = -1$ (for example, a half-odd-integer spin system). So there are three possible cases, $T = 0$, $+1$, and -1.

The particle-hole symmetry $\mathcal{P}$ is also an anti-unitary operator which anti-commutes with the Hamiltonian and can be expressed in terms of H:

$$\mathcal{P} H \mathcal{P}^{-1} = -H, \tag{13.6}$$

where $\mathcal{P} = \mathbf{KV}$ or the system is invariant under time reversal symmetry if and only if the complex conjugation of the Hamiltonian is equal to a minus itself up to a unitary operator $\mathbf{V}$:

$$\mathcal{P} : \mathbf{V}^\dagger H^*_{A,B} \mathbf{V} = -H_{A,B}. \tag{13.7}$$

Thus, for a particle-hole symmetry, the Hamiltonian can be (i) not particle-hole invariant, in which case we take $V = 0$; (ii) particle-hole invariant, but the square of the particle-hole operator is $+1$, $\mathcal{P}^2 = 1$, in which case we take $V = 1$; (iii) particle-hole invariant, but the square of the particle-hole operator is equal to -1, $\mathcal{P}^2 = -1$, in which case we take $V = -1$. So there are three possible cases, $V = 0$, $+1$, and -1.

Thus, there are at least 3×3 possible ways for a Hamiltonian to response the time reversal and particle-hole operations. In addition, the product of $\mathcal{T}$ and $\mathcal{P}$ gives $\mathcal{C} = \mathcal{T} \times \mathcal{P}$, often referred to as sublattice or chiral symmetry. $\mathcal{C}$ is an unitary operator which anti-commutes with the Hamiltonian. $\mathcal{C}$ is not independent of $\mathcal{T}$ and $\mathcal{P}$. The assignment $(T, V) = (1, 1)$ allows $\mathcal{C}$ to be present and $(T, V) = (1, 0)$ or $(T, V) = (0, 1)$ means $\mathcal{C}$ to be absent. However, if $(T, V) = (0, 0)$, then $\mathcal{C}$ to be either present $(C = 1)$ or absent $(C = 0)$. Therefore one obtains ten symmetry classes by combining time reversal symmetry and particle-hole symmetry together.

13.2 Physical Systems and the Symmetry Classes

13.2.1 Standard (Wigner–Dyson) Classes

Class A: The Hamiltonian that possesses neither the time reversal symmetry nor particle-hole symmetry belongs to the unitary symmetry class, i.e., class A. For example, a two-dimensional electron gas in an external magnetic field.

Class AI: The Hamiltonian of integer spin or spinless particles that possess time
reversal symmetry belongs to the orthogonal symmetry. In this case $\mathcal{T}^2 = +1$
and

$$H^T = H. \tag{13.8}$$

Class AII: The Hamiltonian of spin $\frac{1}{2}$ particles which possesses time reversal sym-
metry belongs to the symplectic symmetry. In this case $\mathcal{T}^2 = -1$. For example,
an electron system with spin-orbit coupling,

$$i\sigma_y H^T(-i\sigma_y) = H. \tag{13.9}$$

13.2.2 Chiral Classes

The symmetry classes of Hamiltonians possessing a P-type symmetry are convention-
ally called chiral symmetries. In complete analog with the standard (Wigner–Dyson)
classes, there are three types of chiral symmetries.

Class AIII: The ensemble of chiral Hamiltonians without any other constraint is
called a chiral unitary class.
Class CII: The ensemble of chiral Hamiltonians with time reversal symmetry and
$\mathcal{T}^2 = -1$ is called a chiral symplectic class.
Class DI: The ensemble of chiral Hamiltonians with time reversal symmetry and
$\mathcal{T}^2 = +1$ is called a chiral orthogonal class.

13.2.3 Bogoliubov-de Gennes (BdG) Classes

We consider a general form of a Bogoliubov-de Gennes Hamiltonian,

$$H = \frac{1}{2}(c^\dagger, c) \begin{pmatrix} \varXi & \Delta \\ -\Delta^* & -\varXi^T \end{pmatrix} \begin{pmatrix} c \\ c^\dagger \end{pmatrix}, \tag{13.10}$$

where $\varXi = \varXi^\dagger$ as required by the Hermiticity of the Hamiltonian $H^\dagger = H$ and $\Delta = -\Delta^T$ for Fermi statistics. c can be for either spinless fermions or spin$-\frac{1}{2}$ electron $c = (c_\uparrow, c_\downarrow)$.

BdG Hamiltonian can be classified into four subclasses: C and CI are primarily
relevant to spin singlet superconductors whereas D and DIII are primarily relevant
to spin triplet superconductors.

Class D: $t_x H^T t_x = -H$, for example, a $p \pm ip$ wave pairing superconductor:

$$H = \frac{1}{2} \sum_k (c_k^\dagger, c_{-k}) \begin{pmatrix} \epsilon_k - \mu & \Delta_0(k_x \pm ik_y) \\ \Delta_0(k_x \mp ik_y) & -\epsilon_k + \mu \end{pmatrix} \begin{pmatrix} c_k \\ c_{-k}^\dagger \end{pmatrix}. \tag{13.11}$$

Class DIII: $t_x H^T t_x = -H$ and $is_y H^T(-is_y) = H$, for example, a superposition of $p + ip$ and $p - ip$ wave pairing superconductor.

Class C: $r_y H^T r_y = -H$, for example, a $d \pm id$ wave pairing superconductor.

Class CI: $H^* = H$, for example, $d_{x^2-y^2}$ or d_{xy} wave pairing superconductor.

Note that t_α, s_α, and τ_α are all the Pauli matrices.

13.3 Characterization in the Bulk States

Following Schnyder et al. [4], we discuss the bulk characteristics of topological insulators based on the spectral projection operator. In the presence of translational invariance, the ground states of non-interacting fermion systems can be constructed as a filled Fermi sea in the first Brillouin zone. From the eigenvalue equation in the band theory,

$$H(k) |u_n(k)\rangle = E_n(k) |u_n(k)\rangle, \tag{13.12}$$

the projection operator onto the filled Bloch states at a fixed k is defined as

$$P(k) = \sum_{n \in filled} |u_n(k)\rangle \langle u_n(k)|. \tag{13.13}$$

Then it is convenient to define

$$Q(k) = 2P(k) - 1, \tag{13.14}$$

which satisfies the relations

$$Q^2 = 1, Q^\dagger = Q \tag{13.15}$$

and

$$Tr Q = m - n, \tag{13.16}$$

where m is the number of the filled states and n is the number of empty states. Depending on the symmetry class, an additional condition may be imposed on Q. Without any such further conditions, the projector takes values in the so-called Grassmanian $G_{m,m+n}(C)$: the set of eigenvectors as a unitary matrix, a member of $U(m + n)$. Once we consider a projection onto the filled Bloch states, we have a gauge symmetry $U(m)$. Similarly, we have $U(n)$ for the empty Bloch states. Thus, each projector is described by an element of the coset

$$U(m + n)/[U(m) \times U(n)] \simeq G_{m,m+n}(C) \simeq G_{n,m+n}. \tag{13.17}$$

As $Q(k)\, |u_n(k)\rangle = + |u_n(k)\rangle$ if n is filled, and $Q(k)\, |u_n(k)\rangle = - |u_n(k)\rangle$ if n is empty, an element of $G_{m,m+n}(C)$ can be written as

$$Q = U \Lambda U^{\dagger}, \ \Lambda = diag(1_m - 1_n) \tag{13.18}$$

and $U \in U(m + n)$. Imposing additional symmetry will prohibit certain type of maps from the Brillouin zone to the space of the projectors.

13.4   Five Types in Each Dimension

Possible topologically non-trivial phases with discrete symmetries are listed in Table 13.2. It gives possible values of topological invariants of such a symmetry in the dimension. An empty entry means that the system does not have a topological phase. In the case all gapped Hamiltonians with the symmetry in the dimension can be deformed into each other, without closing the bulk gap and without breaking any existing symmetry. Z means that the topological invariant is an integer number, $Q = 0, \pm 1, \pm 2, \ldots$ $2Z$ means that the topological invariant is an even integer, $Q = 0, \pm 2, \pm 4, \ldots$ Z_2 means that there are only two distinct topological phases, trivial or non-trivial with $Q = \pm 1$ (or $Q = 0, 1$, depending on convention).

A regular pattern appears in the Table 13.3 by reorganizing the ten classes into two categories, two complex classes and eight real classes.

For class A, Z at $d = 2$ means the Chern number or TKNN number, and such a system is quantum Hall effect. Z corresponds to the number of the edge states. In the case the topological invariant Z always appears in an even dimension, and does not exist in an odd dimension, which means that there is no quantum Hall effect in an odd

Table 13.2 Ten symmetry classes of single-particle Hamiltonians and possible topologically non-trivial ground states characterized by Z and Z_2 invariants. Z represents the group of an integer and Z_2 represents the group of $(0, 1)$ or $(-1, +1)$

Table 13.3 Periodic structure of the symmetry classes and possible topological phases

Class	$\mathcal{C}$	$\mathcal{P}$	$\mathcal{T}$	$d = 0$	1	2	3	4	5	6	7
A				Z		Z		Z		Z	
AIII	1				Z		Z		Z		Z
AI			1	Z				$2Z$		Z_2	Z_2
BDI	1	1	1	Z_2	Z				$2Z$		Z_2
D		1		Z_2	Z_2	Z				$2Z$	
DIII	1	1	-1		Z_2	Z_2	Z				$2Z$
AII			-1	$2Z$		Z_2	Z_2	Z			
CII	1	-1	-1		$2Z$		Z_2	Z_2	Z		
C		-1				$2Z$		Z_2	Z_2	Z	
CI	1	-1	1				$2Z$		Z_2	Z_2	Z

dimensions. For class AIII, an example of $d = 1$ is the Su–Schrieffer–Heeger model. Z represents the winding number. With increasing the dimension d, the topological phase interchanges from

$$A \rightarrow AIII \rightarrow A \rightarrow \cdots . \tag{13.19}$$

For the eight real classese from AI to CI, topological invariants also appear in a periodic structure with increasing dimension d, from Z to Z_2, and $2Z$,

$$AI \rightarrow EDI \rightarrow D \rightarrow DIII \rightarrow AII \rightarrow CII \rightarrow C \rightarrow CI \rightarrow AI. \tag{13.20}$$

This is called Bott periodicity.

In short, there are five possible topological phases in each dimension. Among them, there two topological phases with Z, one phase with $2Z$, and two phases with Z_2.

13.5   Conclusion

Topological classification has exhausted all of the possible topological insulators and superconductors. The topological phases exist from one dimension to three dimensions, and from insulators to superconductors. Some materials have been known for a long time, but their topological properties of some materials were only acknowledged in recent years. More and more new topological materials have been discoveried.

In conclusion, we can say that

Each topological insulator or superconductor is governed by one modified Dirac equation.

Appendix A
Derivation of Two Formulae

A.1 Quantization of the Hall Conductance

In this section we present a proof showing that the Hall conductance is quantized to be $\nu e^2/h$ (ν is an integer) in (4.54). For simplicity, we first drop the band index first. Given the definition of the Berry curvature, the Hall conductance is expressed as

$$\sigma_{xy} = \frac{e^2}{h}\frac{1}{2\pi}\int_0^{2\pi} dk_x \int_0^{2\pi} dk_y [\nabla_{\mathbf{k}} \times \mathbf{A}(k_x, k_y)]_z, \tag{A.1}$$

where the lattice constant is taken to be the unit. Therefore the conductance is determined by the Berry curvature integrated over the reduced Brillouin zone.

To evaluate the surface integral, the Stokes's theorem can be applied with the condition that the surface is simply connected. To this end, we illustrate the formation of the torus from a rectangle with the periodic boundary condition, as shown in Fig. A.1. In this way the surface integral can be reduced to a line integral around the first Brillouin zone:

$$\begin{aligned}
\sigma_{xy} &= \frac{e^2}{h}\frac{1}{2\pi}\int_0^{2\pi} dk_x \int_0^{2\pi} dk_y \left[\partial_{k_x}\mathbf{A}_y(k_x, k_y) - \partial_{k_y}\mathbf{A}_x(k_x, k_y)\right] \\
&= \frac{e^2}{h}\frac{1}{2\pi}\int_0^{2\pi} dk_y \left[\mathbf{A}_y(2\pi, k_y) - \mathbf{A}_y(0, k_y)\right] \\
&\quad - \frac{e^2}{h}\frac{1}{2\pi}\int_0^{2\pi} dk_x \left[\mathbf{A}_x(k_x, 2\pi) - \mathbf{A}_x(k_x, 0)\right].
\end{aligned} \tag{A.2}$$

Recalling that $|u(k_x, 0)\rangle$ and $|u(k_x, 2\pi)\rangle$ actually represent the same physical state due to the periodicity in the reciprocal vector space, which can only differ by a phase factor, $|u(k_x, 2\pi)\rangle = \exp[i\theta_x(k_x)]|u(k_x, 0)\rangle$, one has

$$\begin{aligned}
\mathbf{A}_x(k_x, 2\pi) &= \langle u(k_x, 2\pi)|i\partial_{k_x}|u(k_x, 2\pi)\rangle \\
&= -\partial_{k_x}\theta_x(k_x) + \mathbf{A}_x(k_x, 0).
\end{aligned} \tag{A.3}$$

Fig. A.1 Equivalence of the first Brillouin zone and a torus: **a** *rectangle* of the first Brillouin zone with periodic boundary conditions; **b** the *rectangle* is rolled into a tube along the k_y direction; **c** the tube is rolled into a torus along the k_x direction. The four corners of the *rectangle* are actually one point in the torus surface
Similarly, taking $|u(2\pi, k_y)\rangle = \exp[i\theta_y(k_y)]|u(0, k_y)\rangle$, one obtains

$$\mathbf{A}_y(2\pi, k_y) = -\partial_{k_y}\theta_y(k_y) + \mathbf{A}_y(0, k_y). \tag{A.4}$$

$\theta_x(k_x)$ and $\theta_y(k_y)$ are smooth functions. Using these two relations, the integral is reduced to

$$\sigma_{xy} = \frac{e^2}{h}\frac{1}{2\pi}\int_0^{2\pi} dk_y \left[-\partial_{k_y}\theta_y(k_y)\right] + \frac{e^2}{h}\frac{1}{2\pi}\int_0^{2\pi} dk_x \left[\partial_{k_x}\theta_x(k_x)\right]$$

$$= \frac{e^2}{h}\frac{1}{2\pi}\left[\theta_y(0) - \theta_y(2\pi) + \theta_x(2\pi) - \theta_x(0)\right]. \tag{A.5}$$

On the torus surface of the first Brillouin zone, the four wave states $|u(0, 0)\rangle$, $|u(0, 2\pi)\rangle$, $|u(2\pi, 0)\rangle$, and $|u(2\pi, 2\pi)\rangle$ actually represent the same states (see in Fig. A.1). Using the phase matching relations of these states,

$$e^{i\theta_x(0)}|u(0, 2\pi)\rangle = |u(0, 0)\rangle, \tag{A.6}$$

$$e^{i\theta_x(2\pi)}|u(2\pi, 2\pi)\rangle = |u(2\pi, 0)\rangle, \tag{A.7}$$

$$e^{i\theta_y(0)}|u(2\pi, 0)\rangle = |u(0, 0)\rangle, \tag{A.8}$$

$$e^{i\theta_y(2\pi)}|u(2\pi, 2\pi)\rangle = |u(0, 2\pi)\rangle, \tag{A.9}$$

one obtains

$$|u(0, 0)\rangle = e^{i[\theta_x(0)+\theta_y(2\pi)-\theta_x(2\pi)-\theta_y(0)]}|u(0, 0)\rangle. \tag{A.10}$$

The single-valuedness of $|u(0, 0)\rangle$ requires that the exponent must be an integer multiple of 2π, i.e.,

$$\theta_x(0) + \theta_y(2\pi) - \theta_x(2\pi) - \theta_y(0) = 2\nu\pi \tag{A.11}$$

with an integer ν (including 0). Therefore the Hall conductance must be quantized when the band is fully filled. This integer ν is called the Thouless-Kohmoto-Nightingale-Nijs (TKNN) number or the first Chern number, and it characterizes the topological structure of the Bloch states $|u(k_x, k_y)\rangle$ in the parameter space (k_x, k_y).

A.2 A Simple Formula for the Hall Conductance

A simple two-band model has a general form in terms of the Pauli matrices σ_α,

$$H(\mathbf{k}) = \epsilon(\mathbf{k}) + \sum_{\alpha=1,2,3} d_\alpha(\mathbf{k})\sigma_\alpha. \tag{A.12}$$

The energy spectra of the model are

$$E_\pm(\mathbf{k}) = \epsilon(\mathbf{k}) \pm d(\mathbf{k}) \tag{A.13}$$

with $d(\mathbf{k}) = \sqrt{\sum_{\alpha=1,2,3}|d_\alpha(\mathbf{k})|^2}$, and the corresponding eigenstates are

$$|\mathbf{k}, +\rangle = \begin{pmatrix} \cos\frac{\theta}{2}e^{-i\phi} \\ \sin\frac{\theta}{2} \end{pmatrix} \tag{A.14}$$

and

$$|\mathbf{k}, -\rangle = \begin{pmatrix} \sin\frac{\theta}{2}e^{-i\phi} \\ -\cos\frac{\theta}{2} \end{pmatrix}, \tag{A.15}$$

where $\theta = \arccos\frac{d_z(\mathbf{k})}{d(\mathbf{k})}$ and $\phi = \arctan\frac{d_x(\mathbf{k})}{d_y(\mathbf{k})}$.

In electric conduction, the conductivity $\sigma_{\alpha\beta}$ is defined as

$$J_\alpha(\mathbf{r}, t) = \sum_\beta \sigma_{\alpha\beta}(\mathbf{q}, \omega) \mathcal{E}_\beta \exp[i(\mathbf{q} \cdot \mathbf{r} - \omega t)], \tag{A.16}$$

where $J_\alpha(\mathbf{r}, t)$ is the electric current and $\mathcal{E}_\beta \exp[i(\mathbf{q} \cdot \mathbf{r} - \omega t)]$ is the electric field. In the linear response theory, the Kubo formula for the Hall conductance gives

$$\sigma_{xy}(\mathbf{q}, \omega) = +\frac{i}{\omega} \Pi_{xy}(\mathbf{q}, \omega) \tag{A.17}$$

with the retarded correlation function of the current operator $J_x(\mathbf{q}, t)$ and $J_y(\mathbf{q}, t')$

$$\Pi_{xy}(\mathbf{q}, \omega) = -\frac{i}{V} \int_{-\infty}^{+\infty} dt \theta(t - t') e^{i\omega(t-t')} \langle \psi | [J_x(\mathbf{q}, t), J_y(\mathbf{q}, t')] | \psi \rangle, \tag{A.18}$$

where V is the volume of the system. The dc conductivity is obtained by taking the limit $\mathbf{q} \to \mathbf{0}$ and then $\omega \to 0$,

$$\sigma_{xy} = \lim_{\omega \to 0} \lim_{q \to 0} \sigma_{xy}(\mathbf{q}, \omega). \tag{A.19}$$

Usually the retarded correlation function can be calculated in the Matsubara formalism

$$\Pi_{xy}^M(i\omega_\nu) = \frac{1}{V} \frac{1}{\beta} \sum_{k,\nu'} Tr \left\{ J_x(\mathbf{k}) G[\mathbf{k}, i(\omega_\nu + \omega_{\nu'})] J_y(k) G[\mathbf{k}, i\omega_{\nu'}] \right\} \tag{A.20}$$

with frequencies $\omega_\nu = 2\nu\pi/\beta$ and $\omega_{\nu'} = (2\nu' + 1)\pi/\beta$ ($\beta = k_B T$). The Matstubara-Green function is given by

$$G(\mathbf{k}, i\omega_\nu) = [i\omega_\nu - H(\mathbf{k})]^{-1}$$
$$\equiv \frac{P_+}{i\omega_\nu - E_+(\mathbf{k})} + \frac{P_-}{i\omega_\nu - E_-(\mathbf{k})} \tag{A.21}$$

with

$$P_\pm = \frac{1}{2} \left[1 \pm \sum_{\alpha=1,2,3} \frac{d_\alpha(\mathbf{k}) \sigma_\alpha}{d} \right]. \tag{A.22}$$

Using the frequency summation over $i\omega_{\nu'}$,

$$\frac{1}{\beta} \sum_{\nu'} \frac{1}{i(\omega_\nu + \omega_{\nu'}) - E_n} \frac{1}{i\omega_{\nu'} - E_m} = \frac{f_{\mathbf{k},m} - f_{\mathbf{k},n}}{i\omega_\nu + E_m(\mathbf{k}) - E_n(\mathbf{k})}, \tag{A.23}$$

where the Dirac–Fermi distribution function $f_{\mathbf{k},n} = 1/\{1 + \exp[\beta(E_n(\mathbf{k}) - \mu)]\}$, one obtains

$$\Pi_{xy}^{M}(\omega_\nu) = \frac{1}{V} \sum_{\mathbf{k},n,n'} \langle \mathbf{k},n| J_x(\mathbf{k}) |\mathbf{k},n'\rangle \langle \mathbf{k},n'| J_y(\mathbf{k}) |\mathbf{k},n\rangle \frac{f_{\mathbf{k},n} - f_{\mathbf{k},n'}}{i\omega_\nu + E_n(\mathbf{k}) - E_{n'}(\mathbf{k})}.$$

$$(A.24)$$

Its analytical continuation to the retarded function is realized by replacing $i\omega_n \to \hbar\omega + i\epsilon$,

$$\Pi_{xy}^{M}(\omega_\nu) \to \Pi_{xy}^{R}(\omega). \tag{A.25}$$

Using the L'Hospital's rule,

$$\lim_{\omega \to 0} \frac{\operatorname{Im}\left(\Pi_{xy}^{R}(\omega)\right)}{\omega} = \operatorname{Im}\left(\frac{d\Pi_{xy}^{R}(\omega)}{d\omega}\right)_{\omega=0} \tag{A.26}$$

and

$$\lim_{\omega \to 0} \frac{d}{\hbar d\omega} \left[\frac{1}{\hbar\omega + i\epsilon + E_n - E_{n'}}\right] = -\frac{1}{(E_n - E_{n'})(E_n - E_{n'} + i\epsilon)}, \tag{A.27}$$

the Kubo formula for the dc Hall conductivity can be written as

$$\sigma_{xy} = \frac{\hbar}{V} \lim_{\epsilon \to 0^+} \sum_{k,n \neq n'} \frac{(f_{\mathbf{k},n} - f_{\mathbf{k},n'})\operatorname{Im}\left(\langle \mathbf{k},n| J_x(\mathbf{k}) |\mathbf{k},n'\rangle \langle \mathbf{k},n'| J_y(\mathbf{k}) |\mathbf{k},n\rangle\right)}{(E_n(\mathbf{k}) - E_{n'}(\mathbf{k}))(E_n(\mathbf{k}) - E_{n'}(\mathbf{k}) + i\epsilon)}.$$

$$(A.28)$$

From the model in (A.12), the current operator $J_i(\mathbf{k}) = -ev_i(\mathbf{k})$ is given by

$$J_i(\mathbf{k}) = -\frac{e}{\hbar} \partial_{k_i} H(\mathbf{k}) = -\frac{e}{\hbar}\left(\partial_{k_i} \epsilon(\mathbf{k}) + \sum_{\alpha=1,2,3} \partial_{k_i} d_\alpha(\mathbf{k})\sigma_\alpha\right). \tag{A.29}$$

For $n \neq n'$, one has

$$\langle \mathbf{k},n| J_i(\mathbf{k}) |\mathbf{k},n'\rangle = -\frac{e}{\hbar} \sum_{\alpha=1,2,3} \partial_{k_i} d_\alpha(\mathbf{k}) \langle \mathbf{k},n| \sigma_\alpha |\mathbf{k},n'\rangle. \tag{A.30}$$

Furthermore,

$$\operatorname{Im}\left(\langle \mathbf{k},n| \sigma_\alpha |\mathbf{k},-n\rangle \langle \mathbf{k},-n| \sigma_\beta |\mathbf{k},n\rangle\right) = n\epsilon_{\alpha\beta\gamma} \frac{d_\gamma(\mathbf{k})}{d(\mathbf{k})}. \tag{A.31}$$

We limit our discussion in the case that two levels do not cross in the whole momentum space such that $\epsilon \to 0^+$ can be taken before the integral of $\mathbf{k}$. Thus, the conductance can be expressed as

$$\sigma_{xy} = \frac{1}{2\Omega}\frac{e^2}{\hbar}\sum_k \epsilon_{\alpha\beta\gamma}\frac{\left[\partial_{k_x}d_\alpha(\mathbf{k})\right]\left[\partial_{k_y}d_\beta(\mathbf{k})\right]d_\gamma(\mathbf{k})}{d^3(\mathbf{k})}(f_{\mathbf{k},+} - f_{\mathbf{k},-}). \qquad (A.32)$$

If there exists an energy gap between the upper and lower bands, and the lower band is fully filled, i.e., $E_{\mathbf{k},-} < \mu < E_{\mathbf{k},+}$, then $f_{\mathbf{k},+} = 0$ and $f_{\mathbf{k},-} = 1$ at zero temperature. The Hall conductance has the form

$$\sigma_{xy} = -\frac{e^2}{h}\frac{1}{4\pi}\int dk_x dk_y \frac{\left(\partial_{k_x}\mathbf{d}(\mathbf{k}) \times \partial_{k_y}\mathbf{d}(\mathbf{k})\right)\cdot \mathbf{d}(\mathbf{k})}{d^3(\mathbf{k})}. \qquad (A.33)$$

It is noted that the conductance may not be quantized in some continuous models in which the Brillouin zone is not finite. For example a massive Dirac model has a half-quantized conductance. This case does not occur in a lattice model.

Appendix B
Time Reversal Symmetry

The time reversal symmetry demonstrates the invariance of physical laws under time reversal transformation. The terminology was first introduced by E. Wigner in 1932.

B.1 Classical Case

Let us first consider a classic case: the motion of a particle subjected to a certain force. Its trajectory is given by the Newtonian equation of motion,

$$m\frac{d^2\mathbf{r}}{dt^2} = -\nabla V(r). \tag{B.1}$$

If $\mathbf{r}(t)$ is the solution of the equation, then $\mathbf{r}(-t)$ is also the solution of the equation. In other word, when we make the transformation $t \to -t$, the Newtonian equation of motion is unchanged. However, we should note any changes in the boundary condition or initial conditions of the problem.

Maxwell's equations and the Lorentz force $\mathbf{F} = -e(\mathbf{E} + \mathbf{v} \times \mathbf{B})$ are invariant under the time reversal provided that

$$\mathbf{v} \to -\mathbf{v}, \mathbf{j} \to -\mathbf{j}, \rho \to \rho \tag{B.2}$$

and

$$\mathbf{B} \to -\mathbf{B}, \mathbf{E} \to \mathbf{E}. \tag{B.3}$$

Maxwell's equations are

$$\nabla \cdot \mathbf{D} = \rho, \nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = 0, \tag{B.4}$$

$$\nabla \cdot \mathbf{B} = 0, \nabla \times \mathbf{H} - \frac{\partial \mathbf{D}}{\partial t} = I, \tag{B.5}$$

where $\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}$ and $\mathbf{H} = \mathbf{B}/\mu_0 - \mathbf{M}$. Therefore, the magnetic field changes its sign and the electric field remains unchanged under time reversal.

B.2 Quantum Case

In quantum mechanics, the Schrödinger equation is written as

$$i\hbar \frac{\partial \Psi(x, t)}{\partial t} = \left(-\frac{\hbar^2}{2m} \nabla^2 + V \right) \Psi(x, t), \tag{B.6}$$

in which the Hamiltonian in the right hand side is invariant under the time reversal. If $\Psi(x, t)$ is a solution of the equation, $\Psi(x, -t)$ is not a solution of the equation because of the first order time derivative and the imaginary sign of the left hand side. However, $\Psi^*(x, -t)$ is a solution. One can check it by using the solution of a free particle, $\Psi(x, t) = ce^{i(p \cdot x - Et)/\hbar}$. The $\Psi(x, -t) = ce^{i(p \cdot x + Et)/\hbar}$ is also a solution of the Schrödinger equation. However, the momentum is still p, NOT $-p$.

Definition: the transformation θ

$$|\alpha\rangle \rightarrow |\tilde{\alpha}\rangle = \theta |\alpha\rangle, \, |\beta\rangle \rightarrow \left|\tilde{\beta}\right\rangle = \theta |\beta\rangle \tag{B.7}$$

is said to be anti-unitary if

$$\left\langle \tilde{\beta} | \tilde{\alpha} \right\rangle = \langle \beta | \alpha \rangle^*; \tag{B.8}$$

$$\theta (c_1 |\alpha\rangle + c_2 |\beta\rangle) = c_1^* \theta |\alpha\rangle + c_2^* \theta |\beta\rangle. \tag{B.9}$$

In this case the operator θ is an anti-unitary operator. Usually, an anti-unitary operator can be written as

$$\theta = UK, \tag{B.10}$$

where U is a unitary operator and K is the complex conjugation operator, which is defined as

$$K\varphi = \varphi^* K.$$

Here, φ can be either a function or an operator.

B.3 Time Reversal Operator Θ

Let us denote the time reversal operator by Θ. Consider

$$|\alpha\rangle \rightarrow \Theta |\alpha\rangle, \tag{B.11}$$

where $\Theta \, |\alpha\rangle$ is the time reversed state. More appropriately, $\Theta \, |\alpha\rangle$ should be called the motion-reversed state. For a momentum eigenstate $|\mathbf{p}\rangle$, $\Theta \, |\mathbf{p}\rangle$ should be $|-\mathbf{p}\rangle$ up to a possible phase factor. Θ is an anti-unitary operator. We can see this property from the Schrödinger equation of a time reversal invariant system,

$$i\hbar \frac{\partial}{\partial t} \Psi(x, t) = H \Psi(x, t), \tag{B.12}$$

provided that $\Theta i \Theta^{-1} = -i$ and $\Theta \frac{\partial}{\partial t} \Theta^{-1} = \frac{\partial}{\partial(-t)}$. The transformed momentum operator $\mathbf{p}$, the position $\mathbf{x}$, and the angular momentum $\mathbf{J}$ are

$$\Theta \mathbf{p} \Theta^{-1} = -\mathbf{p}, \tag{B.13}$$

$$\Theta \mathbf{x} \Theta^{-1} = \mathbf{x}, \tag{B.14}$$

$$\Theta \mathbf{J} \Theta^{-1} = -\mathbf{J}. \tag{B.15}$$

Note that for $\mathbf{p} = -i\hbar \frac{d}{dx}$, $\Theta \mathbf{p} \Theta^{-1} = -\mathbf{p}$.

From the spherical harmonic $Y_l^m(\theta, \phi)$, one has

$$Y_l^m(\theta, \phi) \rightarrow \left(Y_l^m(\theta, \phi)\right)^* = (-1)^m Y_l^{-m}(\theta, \phi). \tag{B.16}$$

Therefore the eigenstate $|l, m\rangle$ of the orbital angular momentum and its z-component has the relation,

$$\Theta \, |l, m\rangle = (-1)^m \, |l, -m\rangle . \tag{B.17}$$

B.4   Time Reversal for a Spin $\frac{1}{2}$ System

Under the time reversal, $t \rightarrow -t$. Does applying the time reversal operation twice return us to the original states? Yes, but Θ^2 is not always equal to 1. For a spin $\frac{1}{2}$ system,

$$\Theta \sigma_\alpha \Theta^{-1} = -\sigma_\alpha, \tag{B.18}$$

where $\alpha = x, y, z$. Note that

$$\sigma_y \sigma_x \sigma_y = -\sigma_x, \tag{B.19}$$

$$\sigma_y \sigma_y \sigma_y = +\sigma_y, \tag{B.20}$$

$$\sigma_y \sigma_z \sigma_y = -\sigma_z. \tag{B.21}$$

By convention, σ_y is taken to be purely imaginary, as in (2.6), and σ_x and σ_z are real. We have $K\sigma_y = -\sigma_y K$ and $K\sigma_{x,z} = \sigma_{x,z} K$. Therefore the time reversal operator can be constructed by combining σ_y and the complex conjugation operator K,

$$\Theta = i\sigma_y K. \tag{B.22}$$

Its inverse matrix is

$$\Theta^{-1} = -\Theta = -i\sigma_y K. \tag{B.23}$$

One can check the relation,

$$\Theta^2 = -1. \tag{B.24}$$

Consider the eigenstate $|n, +\rangle$ of $\mathbf{S} \cdot \mathbf{n}$ with the eigenvalue $+\hbar/2$,

$$|n, +\rangle = e^{-iS_z\alpha/\hbar} e^{-iS_y\beta/\hbar} |+\rangle, \tag{B.25}$$

$$\Theta |n, +\rangle = \Theta e^{-iS_z\alpha/\hbar} e^{-iS_y\beta/\hbar} \Theta^{-1} \Theta |+\rangle. \tag{B.26}$$

As $\Theta S_\alpha \Theta^{-1} = -S_\alpha$ and $\Theta i \Theta^{-1} = -i$,

$$\Theta |n, +\rangle = e^{-iS_z\alpha/\hbar} e^{-iS_y\beta/\hbar} \Theta |+\rangle = e^{-iS_z\alpha/\hbar} e^{-iS_y\beta/\hbar} |-\rangle = |n, -\rangle. \tag{B.27}$$

where $\Theta |+\rangle = |-\rangle$ with an eigenvalue $-\frac{1}{2}$. On the other hand,

$$|n, -\rangle = e^{-iS_z\alpha/\hbar} e^{-iS_y(\pi+\beta)/\hbar} |+\rangle = e^{-iS_z\alpha/\hbar} e^{-iS_y\beta/\hbar} e^{-iS_y\pi/\hbar} |+\rangle. \tag{B.28}$$

Noting that K acting on $|+\rangle$ gives $|+\rangle$. We have

$$\Theta = e^{-i\pi S_y/\hbar} K = i\sigma_y K. \tag{B.29}$$

In general, for a system with the angular momentum operator of the eigenvalue j, the time reversal operator is

$$\Theta = i e^{-i\pi J_y} K, \tag{B.30}$$

where J_y is the y-component of orbital angular momentum operator. The operator satisfies the relation

$$\Theta^2 = (-1)^{2j}. \tag{B.31}$$

Kramers degeneracy: the energy states for an odd number of electrons in a time reversal invariant system has at least a double degeneracy.

This theorem is determined by the fact that the total spin of an odd number of electrons is always half of an odd number of $\hbar$. The time reversal operator has always the relation $\Theta^2 = -1$.

Appendix C
The Dirac Matrices and the Dirac Gamma Matrices

In the Dirac representation, the four Dirac matrices are

$$\alpha_x = \begin{pmatrix} 0 & \sigma_x \\ \sigma_x & 0 \end{pmatrix}, \ \alpha_y = \begin{pmatrix} 0 & \sigma_y \\ \sigma_y & 0 \end{pmatrix}, \ \alpha_z = \begin{pmatrix} 0 & \sigma_z \\ \sigma_z & 0 \end{pmatrix}, \ \beta = \begin{pmatrix} \sigma_0 & 0 \\ 0 & -\sigma_0 \end{pmatrix}. \quad \text{(C.1)}$$

The four Dirac Gamma matrices have the form

$$\gamma^1 = \begin{pmatrix} 0 & \sigma_x \\ -\sigma_x & 0 \end{pmatrix}, \ \gamma^2 = \begin{pmatrix} 0 & \sigma_y \\ -\sigma_y & 0 \end{pmatrix}, \ \gamma^3 = \begin{pmatrix} 0 & \sigma_z \\ -\sigma_z & 0 \end{pmatrix}, \ \gamma^0 = \begin{pmatrix} \sigma_0 & 0 \\ 0 & -\sigma_0 \end{pmatrix}. \quad \text{(C.2)}$$

The relation between the Dirac matrices and the Dirac Gamma matrices are

$$\gamma^i = \beta\alpha_i; \ \gamma^0 = \beta. \quad \text{(C.3)}$$

The gamma matrices satisfy the anticommutation relation,

$$\{\gamma^\mu, \gamma^\nu\} = \gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2\eta^{\mu\nu}I_4, \quad \text{(C.4)}$$

where $\eta^{\mu\nu}$ is the Minkowski metric with signature $(+, -, -, -)$ and I_4 is the identity matrix. The product of the four Gamma matrices defines

$$\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3 = \begin{pmatrix} 0 & \sigma_0 \\ \sigma_0 & 0 \end{pmatrix}. \quad \text{(C.5)}$$

γ^5 anticommutes with the four Gamma matrices, and is useful in discussion of quantum mechanical chirality. It is not one of the gamma matrices of $Cl_{1,3}(\mathbf{R})$. The number 5 is a relic of old notation in which γ^0 was called γ^4.

Under the time reversal symmetry $\Theta = i\alpha_x\alpha_z K$, the four Dirac matrices obey

$$\alpha_x \rightarrow -\alpha_x, \ \beta \rightarrow \beta. \quad \text{(C.6)}$$
